5) Gender and bandwidth detection: detection of gender and bandwidth is done using a Gaussian Mixture Model (GMM) for each of the 4 combinations of gender (male / female) and bandwidth (narrow/ wide band). Each cluster is labeled according to the characteristics of the GMM which maximizes likelihood over the features of the cluster.
6) GMM-based speaker clustering: a hierarchical agglomerative clustering is performed over the last diarization in order to obtain a one-to-one relationship between clusters and speakers.

Audio input files used in the executions of the system are in Wave format (16kHz / 16bit PCM mono). Output files show the properties of the analyzed segment, along with several frequency values related to each found cluster.

Figure 1 shows an example of output file in LIUM. It provides the instants in which every speaker change is recognized, the speech segment length in centi-seconds, the gender of the speaker and the speaker label.

2.2 SHoUT

SHoUT is a Dutch acronym for *Speech Recognition Research at the University of Twente*. It was completely developed by Marijn Huijbregts during his PhD research [18] at the University of Twente. It is also open source [6], and it is written in C++ in a Linux platform. SHoUT program follows next steps:

1) Speech activity detection: a silence-based segmentation strategy is employed based on silence and sound models training using HMM.
2) Segmentation and clustering: a new segmentation is performed merging multiple models throughout several iteration steps.
3) Automatic speech recognition: several features are extracted and normalized by means of cepstrum mean normalization and vocal tract length normalization. These features are decoded in order to obtain acoustic models dependent on speech clusters.
4) Acoustic model adaptation: the clustering information obtained during segmentation and clustering is used to create speaker dependent acoustic models.

The output file from SHoUT is shown in Figure 2. It is similar to the LIUM one previously explained, although the information length is provided using seconds as time unit.

3. Game modeling

A data fusion system has been designed according to a bimatrix game with the three main elements in every game: players, strategies and pay off.

```

Fig. 2: SHoUT output file

A. *Players*

We consider two players: A (LIUM) and B (SHoUT), which perform their strategies throughout the whole audio sample. Each played strategy corresponds to one second. Thus, the duration of the audio sample will determine the number of times the game is played, which is the same as the total number of performed strategies by each player.

B. *Strategies*

Each player can carry out three different strategies:

- *Strategy nº 1: No-change speaker*
  There is not a speaker change detection. The detected speaker in the current second is the same as the detected in the previous one.

- *Strategy nº 2: New speaker*
  A speaker change to an unknown speaker is detected, since the detected speaker in the current second is different to the detected one in the previous second. In addition, the current speaker is new, since he/she has not been previously detected in the audio sample.

- *Strategy nº 3: Former speaker*
  A speaker change is detected in the same way as in the previous strategy. However, the detected speaker in the current second has already been detected previously in the audio sample.

C. *Pay-off*

Initially, the pay-off matrixes have the same structure as a typical bimatrix game with two players and three strategies.

$$A = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{pmatrix} \; B = \begin{pmatrix} b_{11} & b_{12} & b_{13} \\ b_{21} & b_{22} & b_{23} \\ b_{31} & b_{32} & b_{33} \end{pmatrix} \tag{1}$$

The coefficients a_{ik} and b_{ik} stand for the pay-off received by player A (LIUM) and player B (SHoUT), respectively, if LIUM plays strategy i and SHoUT plays strategy k.

The fusion data system is designed according to a decider for this game. This decider performs the following steps. For each second:

1) Select LIUM and SHoUT strategy.
2) Compare both pay-offs, related to both strategies.
3) Choose the strategy which supposes highest pay-off for the corresponding player. The fusion system will adopt the selected strategy in current second.
4) Each player receives its pay-off.

Pay-off values have been decided according to the different observed behaviors in both diarization systems. The most reliable strategies have been assigned in line with the highest pay-off values. If a system is chosen by the decider, it receives a positive pay-off, whereas if the system has not been chosen, it receives the same pay-off value with negative sign. So far, a zero-sum game would be appropriate to model this behavior. However, there is another situation which must be taken into account: cases in which both systems perform the same strategy have been considered as the most reliable. In these cases, the decider certainly choose both systems. In addition, the selected strategy is provided with the maximum reliability since it is supported by two systems. Hence, these cases have been assigned to the highest pay-off values in both systems. Thus, a player receives a good pay-off if its strategy is chosen, but it receives an even better pay-off if both players are chosen. Consequently, the game is non-zero sum, and two pay-off matrixes are needed: therefore, the game is bimatrix. Moreover, several ideas that cause modifications in some pay-off values will be introduced subsequently.

To establish the required principles to set the pay-off values it is necessary to consider several properties related to both systems, which have been observed by means of several tests executed in both systems with different audio streams. The main goal of these considerations is to determine a direct relation between the reliability of each system and the pay-off values. On this way, the decider will select the most reliable strategy for each event, according to the pay-off values. The following properties have been implemented:

1) Initially, the pay-off related to different strategies for each player ($i \neq k$) are the same value with opposite

signs. Thus:

$$a_{ik} = -b_{ik} \qquad \forall i \neq k \tag{2}$$

2) If both systems execute the same strategy, the decider will certainly adopt it. Moreover, this strategy will be provided with the maximum reliability. Thus, in this case the pay-off values are the same and have the maximum value:

$$a_{ii} = b_{ii} \qquad \forall 1 \leq i \leq 3 \tag{3}$$
$$a_{ii} > a_{ik} \qquad \forall i \neq k \tag{4}$$
$$b_{ii} > b_{ik} \qquad \forall i \neq k \tag{5}$$

Note that these situations correspond to Nash equilibria [10], since they are maximum in both matrixes, i.e. they are optimum, and any other situation would suppose worse results. So, if both systems executed the same strategies all the time, the game would be constantly in an equilibrium point, reaching the maximum reliability.

3) Both systems perform silence, music and speech activity recognition with excellent results. In fact, the most remarkable found mistakes are related to errors in correct speaker identification. Specifically, both systems tend to consider former speakers as new speakers. Consequently, a detection of a former speaker (strategy nº3) is more reliable than a detection of a new speaker (strategy nº2). In addition, taking into account the negative pay-off values for non-chosen players, the final pay-off values fulfill the next properties:

$$a_{3i} > a_{21} > 0 \tag{6}$$
$$a_{i3} < a_{12} < 0 \tag{7}$$
$$b_{i3} > b_{12} > 0 \tag{8}$$
$$b_{3i} < b_{21} < 0 \tag{9}$$
$$\forall i < 3$$

Note that the pay-off values in entries below the main diagonal in A matrix are positive, since it supposes that the player A has been chosen. Same way in player B, but in this case the entries above the main diagonal are positive.

4) LIUM is more likely to detect erroneously new speakers than SHoUT. In fact, the final number of detected speakers by LIUM is commonly higher than the one by SHoUT. Therefore, a new speaker change detection in LIUM (strategy nº2) when SHoUT has not detected a change (strategy nº1) will be considered as less reliable than the opposite case:

$$a_{21} < b_{12} \tag{10}$$

4. Evaluations results

Several tests have been performed in order to evaluate the results of our fusion system. We have taken for the experiments audio segments with dialogues with different speakers from the movies *"Guess Who's Coming to Dinner"*, *"Marnie"*, *"Pride and Prejudice"*, *"Psycho"* and *"Sense and Sensibility"*. All the segments have been manually labeled to obtain the ground truth, creating a file with the same format as output files from LIUM and SHoUT programs. This reference file has the time slots from the audio sample associated to the proper speaker. To perform a numerical evaluation of the system, specific values have been assigned to A and B matrixes, according to the established properties on section 3.

$$A = \begin{pmatrix} 50 & -10 & -20 \\ 10 & 40 & -30 \\ 20 & 30 & 60 \end{pmatrix} \; B = \begin{pmatrix} 50 & 15 & 20 \\ -10 & 40 & 30 \\ -20 & -30 & 60 \end{pmatrix} \tag{11}$$

Therefore, numerical prizes have been settled to each player at the end of the execution of the fusion system. The prize values depend on the duration of each segment, since a different prize is obtained for each second. The obtained results are shown on Table 1, where it can be observed that SHoUT has *won the game* in every movie except in *"Psycho"*.

Table 1: Obtained prizes values.

Movie	LIUM	SHoUT	Duration (seconds)
Guess Who's Coming to Dinner	18190	18340	438
Marnie	23560	23620	603
Pride and Prejudice	19370	19555	463
Psycho	19500	19300	446
Sense and Sensibility	7120	7490	157

To evaluate the improvements introduced by our speaker diarization system, we have used the *Diarization Error Rate (DER)* value [20]. This parameter can be defined as the addition of the different possible errors of a speaker diarization system. In our experiment, *DER* has been defined as:

$$DER = FalseAlarmSpeech + MissedSpeech \tag{12}$$

False Alarm Speech is the number of times where a hypothesized speaker change is labeled as a non-change speaker in the reference. On the contrary, *Missed Speech* is the number of times where a hypothesized non-change speaker is labeled as a speaker change in the reference.

Silence activity detection can be also considered in a *DER* measure. Nevertheless, we have not taken it into account, since we have tested that the presented results by both systems in silence activity detection are much better than the results in speaker identification task, as it was explained

in section 3. Thus, only time slots related to detected speech have been considered.

The results obtained with LIUM, SHoUT, and our fusion system in terms of *DER*, are shown on Table 2, together with the added improvements (in %) by our system:

Table 2: *DER* and improvement values.

	DER			Improvements (%)	
Movie	LIUM	SHoUT	Fusion	LIUM	SHoUT
Guess Who's Coming to Dinner	22	19	4	82	79
Marnie	14	7	2	86	71
Pride and Prejudice	14	15	7	50	53
Psycho	12	11	3	75	73
Sense and Sensibility	5	10	4	20	60

On average, improvements of 63% and 67% on the *DER* parameter with respect to LIUM and SHoUT programs are reached with our fusion system. The less improvements correspond to those films, *"Pride and Prejudice"* and *"Sense and Sensibility"*, in which LIUM system performs lower *DER* than SHoUT. This can be translated into a possible unfairly performance of the fusion system, since the system which presents better results has *lost the game*. We are working to improve our system in these cases in order to reduce even more the *DER* parameter independently on the input stream.

In addition, the number of recognized speakers has been evaluated. As it has been previously explained, it is difficult to recognize properly former speakers, so the number of recognized speakers by speaker diarization systems is typically greater than the true value. However, our system reduces this number thanks to the fusion of strategies which allows clustering some speakers previously considered as different. The results are shown on Table 3. On average, we improve a 20% the number of detected speakers in comparison to the best output from LIUM and SHoUT systems working alone.

Table 3: Number of recognized speakers.

	Real speakers	Recognized			Improvements (%)	
Movie		LIUM	SHoUT	Fusion	LIUM	SHoUT
Guess Who's Coming to Dinner	4	19	8	6	68	25
Marnie	4	16	5	5	69	0
Pride and Prejudice	7	16	12	10	37	17
Psycho	5	8	9	6	25	33
Sense and Sensibility	3	6	7	4	33	43

5. Conclusions

In this paper we introduce a novel fusion algorithm based on game theory to improve the accuracy and reliability of two speaker diarization systems: LIUM and SHoUT. This algorithm is based on bimatrix game theory and performs a non-zero sum game. The establishment of the pay-off values has been carried out by means of different properties inferred by the analysis from both systems' behavior. The obtained tests show considerable advances of our fusion system in comparison to the results from LIUM and SHoUT programs working alone.

ACKNOWLEDGMENT

This paper is based on work performed in the framework of the Spanish national project BUSCAMEDIA (CEN-20091026), which is partially funded by the "CDTI-Ministerio de Economía y Competitividad".

An Automated Deduction of the Independence of the Orthomodular Law from Ortholattice Theory

Jack K. Horner
PO Box 266

email: jhorner@cybermesa.com

Abstract

The optimization of quantum computing circuitry and compilers at some level must be expressed in terms of quantum-mechanical behaviors and operations. In much the same way that the structure of conventional propositional logic is the logic of the description of the behavior of classical physical systems and is isomorphic to a Boolean lattice, so also the algebra, C(H), of closed linear subspaces of (equivalently, the system of linear operators on) a Hilbert space is a logic of the descriptions of the behavior of quantum mechanical systems and is a model of an ortholattice (OL). An OL can thus be thought of as a kind of "quantum logic" (QL). C(H) is also a model of an orthomodular lattice (OML), which is an OL conjoined with an orthomodularity axiom/law (OMA). The rationalization of the OMA as a claim proper to physics has proven problematic, motivating the question of whether the OMA is required in an adequate characterization of QL. Here, I use an automated deduction framework to show that the OMA is independent of the axioms of ortholattice theory. These results corroborate (and fix a minor defect in) previously published work characterizing the strength of the OMA, and demonstrate the utility of automated deduction in investigating quantum computing logic-optimization strategies.

Keywords: automated deduction, quantum computing, orthomodular lattice, Hilbert space

1.0 Introduction

The optimization of quantum computing circuitry and compilers at some level must be expressed in terms of the description of quantum-mechanical behaviors ([1], [17], [18], [20]). In much the same way that conventional propositional logic ([12]) is the logical structure of description of the behavior of classical physical systems (e.g. "measurements of the position and momentum of an electron are commutative") and is isomorphic to a Boolean lattice ([10], [11], [19]), so also the algebra, *C(H)*, of the closed linear subspaces of (equivalently, the system of linear operators on) a Hilbert space *H* ([1], [4], [6], [9], [13]) is *a* logic of the descriptions of the behavior of quantum mechanical systems (e.g., "the measurements of the position and momentum of an electron are *not* commutative ") and is a model ([10]) of an ortholattice (OL; [8]). An OL can thus be thought of as a kind of "quantum logic" (QL; [19]). *C(H)* is also a model of (i.e., isomorphic to a set of sentences which hold in) an orthomodular lattice (OML; [7], [8]), which is an OL conjoined with the orthomodularity axiom (OMA; see Figure 1).

The rationalization of the OMA as a claim proper to physics has proven problematic ([13], Section 5-6), motivating the question of whether the OMA is independent of the axioms of ortholattice theory.

Lattice axioms

```
x = c(c(x)).
x v y = y v x.
(x v y) v z = x v (y v z).
(x ^ y) ^ z = x ^ (y ^ z).
x v (x ^ y) = x.
x ^ (x v y) = x.
```

Ortholattice axioms

```
c(x) ^ x = 0.
c(x) v x = 1.
c(c(x)) = x.
x ^ y = c(c(x) v c(y)).
```

Orthomodularity law/axiom (OMA)

```
x v (c(x) ^ (x v y)) = x v y.
```

Definitions (useful, but not required)

```
i1(x,y) = c(x) v (x ^ y).
i2(x,y) = i1(c(y), c(x).
i3(x,y) = (c(x) ^ y) v (c(x) ^ c(y)) v i1(x,y).
i4(x,y) = i3(c(y), c(x)).
i5(x,y) = (x ^ y) v (c(x) ^ y) v (c(x) ^ c(y)).
le(x,y) = (x = (x ^ y)).
```

where

x, y are variables ranging over lattice nodes
^ is lattice meet
v is lattice join
c(x) is the orthocomplement of x
i1(x,y) means $x \rightarrow_1 y$ (Sasaki implication)
i2(x,y) means $x \rightarrow_2 y$ (Dishkant implication)
i3(x,y) means $x \rightarrow_3 y$ (Kalmbach implication)
i4(x,y) means $x \rightarrow_4 y$ (non-tollens implication)
i5(x,y) means $x \rightarrow_5 y$ (relevance implication)
le(x,y) means $x \leq y$
= is equivalence ([12])
1 is the maximum lattice element (= x v c(x))
0 is the minimum lattice element (= c(1))

Figure 1. Axioms (and some useful definitions) of lattices, ortholattices, orthomodularity.

The axioms for lattices, ortholattices, and orthomodularity, are shown in Figure 1.

In a QL, the distributive law

```
(x v (y ^ z) = (x v y)
     ^ (x ^ z))
```

does not hold, because the distributive law implies commutativity of

(measurement-) propositions, and in general, the (measurement-)propositions of QL are not commutative.
Roughly speaking, a QL can be thought of as a classical propositional logic (CL) in which the distribution law does not hold. Table 1 shows some further differences (and similarities) between classical propositional logic and quantum propositional logic.

Table 1. Quantum logic connective counterparts of classical logic connectives.

Classical logic connective	Quantum propositional logic connective "counterpart"
"x *or* y"	lattice join (x v y, or x $\cup$ y)
"x *and* y"	lattice meet(x ^ y, or x $\cap$ y)
"*not*-x"	orthocomplement (c(x), or $x^{\perp}$)
"*if* x, *then* y" (implication)	$x \rightarrow_i y$ (i = [1|2|3|4|5])

Note that there are five QL implications that satisfy the Birkhoff-von Neumann condition

$$(x \rightarrow_i y = 1) \leftrightarrow (x \leq y), \quad i = 1, 2, \ldots, 5 \qquad \text{(CBvN)}$$

In classical propositional logic, there is only one implication, sometimes denoted "$\rightarrow_0$", that satisfies CBvN.

2.0 Method

The ortholattice and OMA axiomatizations of Megill, Pavičić, and Horner ([5], [14], [15], [16], [21]) were implemented in a *mace4* ([2]) script ([3]) and then executed in that framework on a Dell Inspiron 545 with an Intel Core2 Quad CPU Q8200 (clocked @ 2.33 GHz) and 8.00 GB RAM, running under the *Windows Vista Home Premium /Cygwin* operating environment. More specifically, the script used in this work implements the derivation of a model (Figure 2) in which the ortholattice axioms conjoined with the *negation* of the OMA hold in at least one interpretation, demonstrating that the OMA is independent of the ortholattice axioms.

3.0 Results

Figure 2 shows a *mace4* "domain size 6" model which demonstrates "the OMA is independent of the ortholattice axioms".

```

Figure 2. A "domain size 6" *mace4* model in which the axioms of an ortholattice and the negation of the OMA hold (thus demonstrating that the OMA is independent of the ortholattice axioms). Each text line of values in the rightmost set of square brackets are assignments of values of integers to lattice positions. Such an assignment of values to nodes is said to *satisfy* or *be a model of* the indicated function/relation if the function/relation holds within the lattice under the assignment to those positions. Details of the *mace4* notation can be found in [2].

The time to produce the content of Figure 2 on the platform described in Section 2.0 was approximately 0.06 second.

4.0 Discussion

The results shown in Section 3.0 motivate at least three observations:

1. The OMA is independent of the ortholattice axioms.

2. The proof corrects a minor (right-associativity) defect in a previously published work ([21]) on the strength of the OMA.

3. A proof that the OMA is independent of the ortholattice axioms is implied by the proof in [22], which shows that the OMA is also independent of ortholattice axioms conjoined with the weak orthomodularity law.

Abstract - *Classical rationality as accepted by game theory assumes that a human chooser in a given moment has consistent preferences and beliefs and that actions result consistently from those preferences and beliefs, and moreover that these preferences, beliefs, and actions remain the same across equal choice moments. Since, as is widely found in prior experiments, subjects do not follow the predictions of classical rationality, behavioral game theorists have assumed consistent deviations from classical rationality by assigning to subjects certain dispositions—risk preference, cognitive abilities, social norms, etc. All of these theories are fundamentally cognitive theories, making claims about how individual human minds work when choosing. All of them are fundamentally wrong in assuming one kind of consistency or another. Or at least, all of the proposals for consistency in belief, preference, and action with which we are aware turn out to be wrong when tested experimentally.*

Keywords: Behavioral game theory, experiments, cognition, Trust, Dictator, Donation

1 Introduction

Game theoretic models are utilized for behavioral predictions across a variety of domains such as allocation of security forces [1], allocation of health care services [2], and the design of political, social and market institutions [3; for relevant surveys see: 4, 5, 6, 7]. Despite the widespread use of game theoretic models to explain human behavior, we often observe behavior, from voting, to the divergence of political parties platforms, to market bubbles and crashes that do not readily accord with the predictions derived from game theory [8].

To address the discrepancy between predicted and actual behavior, scholars have proposed four common patches: (1) cognitive biases or errors in how people make decisions [9, 10, 11, 12]; (2) a mismatch between the experimenter's defined payoffs and an individual's actual utility [13, 14]; (3) the effects of uncertainty, bounded search ability, limited time for learning and equilibration, or limits in the ability of thinking about others' likely behavior [15]; and (4) newer and more clever equilibrium refinements that capture the folk psychology of different game theorists [16, 17, 18, 19].

While it is common to report that experimental subjects do not make choices that comport with Nash equilibrium strategies (or even von Neumann-Morgenstern utility maximization), we should not infer that human reasoning is thus somehow flawed. It is perhaps the case that our existing, deductive, models of human reasoning are too limited. Humans are able to solve many tasks that are quite difficult [20, 21]. Like vision, taste and smell, human intelligence and behavior are varied and flexible, creating an enormous diversity of beliefs and choices, but the models that we use to predict behavior do not and cannot capture this diversity. To build a better theory of human behavior, we must start with an appreciation for how we actually reason. As cognitive science has shown, intuitive notions of how the mind works (vision, language, memory, etc.) may be very useful for humans to hold as scaffolding for consciousness, but they are comprehensively wrong and simplistic. Intuitive notions of how we reason are not a basis for science. How we reason must be discovered, not assumed, and certainly not borrowed from intuition

One of the principal problems stems from the core solution strategy for noncooperative games of Nash equilibrium. While it is mathematically elegant, it requires agents in the game to have correct and consistent beliefs [22]. To have "correct beliefs" we assume that the agents, or the players in a game, to regard all other players as being "Nash players" and to predict that they all follow Nash equilibrium (NE) strategies. It is also typically required that players have "common knowledge" that they are all Nash players, that is, that they know that other players know that they themselves are following Nash equilibrium strategies, and so on, ad infinitum. Others have pointed out that "Common Nash refinements have similar attributes. Although these refinements differ in what they allow players to know and believe, they continue to require that actors share identical conjectures of other players' strategies" [23, p. 106]. If players do not believe that other players will adopt NE strategies, however, it is

Prepared for the 2012 International Conference on Artificial Intelligence.

no longer true that players' best response to each other will be to follow a NE strategy. The natural, biological, or cognitive means by which this comes about are not specified, merely that, given enough time and effort, players can all learn what behaviors to adopt and when to adopt them, or, baring this eventuality, that societies will adopt rules, laws or norms to restrict and channel behavior to more efficient forms. Prior work on subjects' beliefs in experimental settings suggest that subjects possess non-equilibrium beliefs [24, 25] and that in at least some settings their behavior can be reasonable, given their beliefs [26].

In what follows, rather than trying to stitch together measurements from different experiments, with different protocols, run under different conditions and at different times, we use a within-subjects design, run over a single academic term, to investigate choices in a large battery of single-shot games. Within our battery of tasks we elicit subjects' beliefs about the other subject's actions, plus we elicit *recursive* beliefs about other subjects' *beliefs* in these games. We demonstrate that subjects' actions and beliefs are consistently inconsistent, deviating from one person to another and for each person from one task to another. A given subject is often not consistent in action across nearly identical choice moments at different times in the same within-subject battery of tasks and a given subject is often not consistent even at the same time in their beliefs, preferences and actions. We also see great variation across subjects for a given task. For our specific battery, this refutes not only Nash equilibrium but also the patches that have been designed to explain deviation from it.

2 Experimental Design

We report on a number of tasks here related to the well-known Trust Game [27]. In our experiments, subjects know that their choices are always private and anonymous, even to the experimenters at the time of the experiment (i.e., double blind). Subjects receive no feedback during the course of the experiment about the consequences of their choices, except for quizzes related to the given tasks (subjects may, for some of our tasks, be able to infer the consequences of their choices). For each task, subjects are randomly matched to another subject. Thus, to the extent possible, every task is a single shot, separate from the prior and future choices. Subjects are divided into two rooms, in groups of ten in each room. We ensure that no subject knows anyone else in either of the two rooms of the experiment. As much as possible, then, this environment creates a situation in which subjects derive their utility solely from the payoffs in the experimental tasks and not from concerns about reputation, signaling for future games, experimenter demand, or other actions that are not related to the immediate monetary payoffs we present.

The Trust Game (sometimes called the investment game) involves two players. Each player begins with a $5 endowment. The first player (Player 1 or the "Investor" [27]) chooses how many dollars, if any, to pass to an anonymous second player (Player 2 or "Trustee" [27]). In our experimental protocols, we use no labels other than "the other person(s)" (to avoid a gaming frame). To avoid suggesting an investment or reciprocity frame we label each action as a "transfer." The first player keeps any money he does not pass. As in [27], the money that is passed is tripled in value and the second player receives the tripled amount. The second player at that point has the original endowment of $5 plus three times the amount the first player passed, and decides how much, if any, of that total amount to return (i.e., transfer) to the first player. The second player at the moment of choice in the Trust Game is in a role that is equivalent to the role of Dictator in the classic Dictator Game [see 8]. As in the Dictator Game, the dominant strategy equilibrium, which is trivially the subgame perfect Nash equilibrium (SPNE), is that Player 2 will return $0. By backward induction, then Player 1 in the Trust Game will send $0. This is also a dominant strategy. As such, any amount sent by Player 1 to Player 2 should be viewed by Player 1 as a donation, and we label the first half of the Trust Game as what we call a Donation Game.

These equilibrium strategies derive from the assumption is that all players maximize their monetary payoff and that they believe that all other players do the same. In the Trust Game, a Player 1 with these beliefs would conclude that Player 2 will return nothing and so, as a maximizer, Player 1 sends nothing. The beliefs that players hold about other players lead to the belief at every level of recursion that all players will send $0, and that they will guess that others will send $0, and they will guess that others will predict that everyone will send $0, and so on, ad infinitum.

But what happens if a subject with these NE beliefs finds himself off the equilibrium path? In the Trust Game, only Player 2 could make a choice after finding himself or herself presented with an off-the-equilibrium-path choice. If Player 2 is gifted with anything more than his or her $5 endowment, the subgame perfect Nash equilibrium strategy is still to send $0 back.

Every subject makes decisions first as Player 1. They are then randomly paired with someone from the other room and they make choices as Player 2. So everyone gets to be Player 1 first, then Player 2, about 90 minutes later. To limit learning, even if it is just learning about the actions of a randomly assigned partner in another room, we defer the choices for all subjects as Player 2 to the end of the experiment. They thus play Trust twice, but in different roles. Player 1 never learns the consequences of any of his or her choices in the Trust Game. Player 2 can of course infer the consequences of his or her own choices.

We add elements to the basic Trust Game to tap into subjects' beliefs. Our belief elicitation mechanism borrows

from the idea of a prediction market [28], which in experimental settings such as those described here have been referred to as "scoring rules" [29, 30, and for a brief survey see 8]. We do not ask subjects to report their expectations, as some experimenters have done, in order to prod strategic thinking, rather, we ask them to "guess" other subjects' choices, or to guess other subjects' "predictions." As with all of our protocols, we try to provide little or no framing of the experimental tasks offered to our subjects. Only after Player 1 makes his choice about how much to transfer, do we ask him to guess how much Player 2 will return. We then elicit Player 1's recursive beliefs about Player 2. So, we next ask Player 1 to guess what Player 2 will later predict how much Player 1 is transferring. We further ask Player 1 to guess Player 2's prediction of Player 1's guess of how much Player 2 will return. We also elicit each subject's recursive beliefs when they are in the role of Player 2. Before Player 2 learns Player 1's choice, and thus before Player 2 knows how much they have available to them, we ask Player 2 to guess how much money Player 1 transferred. We also ask Player 2 to guess how much Player 1 predicted that Player 2 would guess that Player 1 transferred. After Player 2 learns Player 1's transfer, we ask Player 2 to guess how much Player 1 predicted she would return. All subjects know that all subjects earn $3 for each correct guess and earn nothing for a guess that is wrong. All subjects in our experiments know this. We also allowed subjects to, in essence, "double-down," on each guess, adding a second "bet" equal to $3 if they are correct in their guess and $0 otherwise. We also always quizzed our subjects with respect to the instructions, paying them for correct answers.

In calibrating these prediction questions prior to the launch of our experiments we learned two things: (1) that there does not exist an easy language for eliciting recursive beliefs, so we made use of generic cartoon "heads" to represent what subjects are predicting and "$" sign and arrow icons to represent actions and the object of their current attention; and (2) subjects laughed and failed to answer our queries, even when diagrammed in cartoon form, with written explanations. These two preliminary findings suggested to us that people really do not have the recursive beliefs required by NE.

The questions we ask vary slightly for each task, but as an example, here is the exact question we ask Player 2: "How much money do you guess the other person transferred to you? If you guess correctly, you will earn $3. If not, you will neither earn nor lose money." We add similar incentivized prediction tasks to various experimental tasks. Players do not learn whether their predictions were right or wrong and subjects never have any information about other subjects' guesses.

Subjects also make decisions in a variety of other games, including the already mentioned Dictator Game and what we call the Donation Game. In both these games, each subject is randomly paired with yet other subjects in the other room. In the Dictator Game, The Dictator (Player 1) and the Receiver (Player 2) have endowments identical to those the subjects had when they were in the role of Player 2 and Player 1 in Trust (although they have been randomly rematched and they known they've been randomly rematched). Accordingly, the Dictator Game was identical right down to the specific endowments to the second half of the Trust Game. In effect, each subject replayed the second half of the Trust Game, but now without the reciprocity frame. The SPNE is for the Dictator to send $0 to the Receiver. The Donation Game is identical, except that each player begins with a $5 endowment and the amount Player 1 chooses to send is quadrupled before it is given to Player 2 (making it roughly similar but not identical to the choice faced by Player 1 in the Trust Game, without the possibility of reciprocity). The dominant strategy and SPNE is again for the Donor to send $0.

The subjects in our experiment completed the tasks using pen and paper in a controlled classroom environment. Subjects were recruited using flyers and email and text messages distributed across a large public California university and were not compelled to participate in the experiment, although they were given $5 in cash when they showed up and signed in. A total of 180 subjects participated in this experiment. The experiment lasted approximately two hours, and subjects received on average $41 in cash. The experiment was followed sometime later with a questionnaire, for which subjects were also paid.

3 Result: Subjects' Beliefs in the Trust Game

Common patches to help explain the commonly observed departures to NE strategies (other-regarding preferences, cognitive constraints, decision-making biases, or equilibrium refinements) usually continue to maintain the assumption that players deviate from game-theoretic expectations in consistent ways. For example, if players prefer to reduce inequality, that preference should be stable across all manner of economic games [10]. Or, if players cannot perform backward deletion of dominated sub-games, as game theory requires, then this handicap should operate in all game environments of equal difficulty [17, 18, 19]. In this section we focus both on whether subjects have beliefs that are consistent with SPNE and whether their beliefs are consistent across tasks (regardless of alignment with SPNE). To date, there has been little focus on identifying the extent to which players have consistent beliefs or behavior across games.

Cognitive science gives us considerable reason to doubt that players will behave identically across different

environments, because changes in environment lead to changes in mental activation, which affects beliefs and behavior. As Sherrington famously wrote, the state of the brain is always shifting, "a dissolving pattern, always a meaningful pattern, though never an abiding one" [32]. If the particular tasks, and order of those tasks, induce different mental activations, then belief and behavior should vary accordingly. Our experiment is designed to shed light on whether subjects have consistent beliefs and make consistent choices.

In many of our tasks, we ask subjects to make guesses about other players' actions and predictions. Do subjects believe what game theory assumes they believe? The answer is that there is huge variance across what subjects believe in a single game and also huge variance within subjects from one task to another.

The SPNE in the Trust Game is that neither Player 1 nor Player 2 will send any money to the other. All should believe that all others will predict that no one will send money, and all such beliefs should be infinitely recursive, so that Player A believes Player B believes Player A believes Player B will send no money, and so on for any number of steps and for any subject in any role A or B.

But we see quite the contrary in our experiments: only 68 of 180 subjects as Player 2 believe that Player 1 will send nothing. In other words, 62% of subjects have "incorrect" beliefs, that is, beliefs contrary to those that support SPNE strategies.

Next we examine the guesses made by Player 1 of the amount Player 2 will return. In what follows, we include even the Player 1s who sent nothing. (Since Player 2 begins with a $5 endowment, Player 2 can transfer money even if Player 1 sent nothing.) Ninety-two of the 180 subjects guess that Player 2 will return $0, but 88, or 49%, believe that Player 2 will return some money. This means that 49% of these subjects have "incorrect" beliefs. Their beliefs diverge broadly from SPNE, across a large span of possible returns.

We can compare subjects' beliefs about others in one part of the Trust Game with their choices in that same part of the Trust Game. For example, we can examine the difference between what a subject choose to do as Player 1 in the Trust Game, and what they believe as Player 2 that Player 1 will do (and recall, when they are Player 2, they've already made choices as Player 1). The modal category is subjects believe that other subjects will play like them: 109 of the 180 subjects guess that the choice of the Player 1 with whom they are randomly matched will be the same as their own choice when they were Player 1. For these subjects, theory of mind might equal theory of self, or this may simply represent the "false consensus" effect in which people think others are more like them than they actually are [31], or it might be akin to the curse of knowledge, but we can't really tell. Perhaps most surprising, there is a large variance, with 71 subjects (39%) making guesses that differ from their own choices.

We can also examine the number of subjects who have beliefs consistent with NE across tasks. In the Trust Game, subjects make predictions as Player 1 about the behavior of Player 2 and as Player 2 about the behavior of Player 1. We already demonstrated that in either single task, a great many subjects do not have SPNE beliefs. If Player 1 has NE beliefs, it means that this subject guessed that Player 2 would return nothing. If Player 2 has NE beliefs, it means that the subject guessed that Player 1 would send nothing. Overall, out of 180 subjects in our analysis, only 63 subjects made guesses as both Player 1 and 2 that were consistent with NE beliefs. In other words, only 35% of our subjects have consistently "NE beliefs" *even inside this one game*.

There were 83 subjects who lacked NE beliefs in both part of the Trust Game, 29 subjects who possessed "NE beliefs" as Player 1 but not as Player 2, and only 5 subjects who possessed "NE beliefs" as Player 2 but not as Player 1. Our experiment does not allow us to identify why players' beliefs diverge from the NE beliefs, but it is clear that most subjects deviate from NE beliefs during at least one of the experimental tasks.

There were 60 subjects who were "fully Nash actors" in the Trust Game, that is, the subjects whose actions as both Player 1 and 2 were consistent with SPNE strategy. We examine whether these 60 subjects have beliefs that are "fully Nash" in the Trust Game. The answer is no. First, let us consider these 60 subjects in the role of Player 1 in Trust. Of these 60 subjects, 56 guessed as Player 1 that Player 2 would return nothing, which is consistent with SPNE. Only 40 of the 60 "fully Nash" Trust players (66%) guessed that Player 2 predicted that they would transfer $0. The other 20 of the 60 "fully Nash" Trust players (1/3rd) lacked that SPNE belief. 49 of the 60 also guessed Player 2's prediction of Player 1's guess of what Player 2 will return to be $0. These results show that even the 60 "fully Nash" Trust subjects hold beliefs whose degree of consistency with SPNE principles varies question by question even when we look at only those questions asked of them when they are in the role of Player 1. Beliefs show flexibility.

We next turn to the beliefs of those 60 "fully Nash" Trust subjects when they are in the role of Player 2 in Trust. Of the 60, 44 guess that Player 1 will transfer nothing; that is, 16 of 60 (27%) lack SPNE beliefs. Of the 60, 35 guess that Player 1 predicts that they will return nothing; that is, for this question, 42% of these 60 "fully Nash" Trust subjects have beliefs that are inconsistent with SPNE. Overall, non-SPNE beliefs are quite common even among the 60 "fully Nash" actors in the Trust Game. Beliefs show flexibility and refute the assumed beliefs of Nash equilibrium and the four patches often applied to NE.

4 Result: Inconsistency of Behavior in Trust, Donation, and Dictator

We turn next to examine the actions of subjects across a number of similar tasks to see if individual subjects behave consistently. In particular, we look at a set of tasks, all of which involve choosing how much money to transfer to another person and in some tasks the decision is not contingent on the other player. In the Trust Game, subjects play the role of Player 1 and 2 during the course of the experiment.

One way to investigate consistency of behavior is to examine the choices of subjects who as Player 2 in Trust received money from Player 1. Of the 100 subjects who received money as Player 2 in Trust, only 62 returned any of the money to Player 1. Additionally, of those 62, only 40 sent money in the Dictator Game, which is identical to the percentage of subjects who sent nothing in other "double blind" versions of the Dictator Game [13]. This shows that many subjects do not behave consistently in these two identical choice situations, in which their actions could reduce inequality. Further, of the 40 who sent money in Dictator, only 29 also send money in the Donation Game. This means that of the 100 subjects who received money as Player 2 in Trust, only 29 sent money to the other player in all three related tasks. This shows that the same subjects do not behave consistently even in their violations of SPNE.

Another example of apparently inconsistent behavior comes from examining the subjects who passed \$0 out of \$5 in the Donation Game, suggesting they are not concerned with others' earnings. Of the 87 subjects who passed \$0 in the Donation Game, 63 of them also passed nothing as Player 1 in the Trust Game, both behaviors of which are consistent with standard game theoretic behavior. However, the other 24 subjects passed \$0 in the Donation Game and some amount greater than \$0 in the Trust Game. What model predicts this behavior? Why would a player who passes nothing in the Donation Game pass money in the Trust Game? One possibility is that the player believes that passing money in Trust will result in greater earnings, because Player 2 will return enough money to make the choice to pass money financially beneficial. However, among these 24 subjects some guess they will earn money in the Trust Game and others guess they will lose money. The lack of consistency in these two very similar settings is further evidence that assumptions of consistent behavior are at odds with much human action.

Subjects deviate remarkably from NE strategies. We have reported how subjects' beliefs deviate from those necessary to support equilibrium strategies. We have also shown that these deviations are not consistent. Accordingly, it is doubtful that proposals to explain deviation from NE strategies will succeed if they presume a consistent mental or behavioral signature.

Now, we ask whether actions are minimally rational, that is, do subjects' actions accord with their beliefs? To begin, we investigate whether action and belief accord in the Trust Game. In our experiment, over one-half of subjects in the role of Player 1 (100 out of 180) pass a nonzero amount of money to Player 2 (this differs from [27]), which is inconsistent with a SPNE strategy, and on average subjects pass \$1.44 (which is not significantly different than the findings in [27]). Of the 100 subjects who receive money as Player 2, 62 of them return some money to Player 1. On net, Player 1 loses money (our results here are almost identical to those by [27]).

To look at the relationship between beliefs and actions we examine the difference between the amount Player 1 sends to Player 2 and the amount Player 1 guesses Player 2 will return. Recall that any money sent by Player 1 is tripled before it is sent to Player 2 and added to Player 2's initial \$5, (e.g., if Player 1 sends all \$5, then Player 2 has \$20, and if Player 2 splits that money, then Player 1 and Player 2 end with \$10 each, and we would say that each has "earned" \$5 through their actions). Overall, there are only a few players who guess that they will lose money by sending money to the other player. Mostly, players expect to break even or benefit slightly from their decision. The beliefs held by these players imply not only that they do not expect others to play consistently with SPNE strategies, but also that they expect, on average, to profit from their non-SPNE strategy to send money. But again, beliefs are not consistent across subjects.

There are 100 subjects who as Player 1 in Trust chose to send a positive amount to Player 2, and 20 of those players guess they will not receive anything in return. These 20 players guess that Player 2 will follow a SPNE strategy. These 20 subjects cannot simultaneously be maximizing their payoffs and hold the belief that Player 2 will follow a SPNE strategy of returning \$0 so it is hard to see how their choices accord with their own beliefs. We must either conclude that they are not payoff maximizers or relax the assumption that subjects act according to beliefs. One possible response is to give up the assumption that believing, preferring, deciding, and acting are coordinated mental events. Perhaps subjects act without fully activating their decisions, or believe without activating the consequences of those beliefs for action, or act without activating beliefs, and so on.

These results make it clear that we may not be able to simply observe behavior and then make correct inferences about the underlying beliefs that generated the behavior. When we observe a Player 1 in the Trust Game pass money what beliefs do we presume preceded that behavior? Is this a subject who is motivated by other-regarding preferences who does not expect to benefit financially? Or, is this a player who sincerely believes that

the 2nd player in the Trust Game will return enough money to make the initial decision profitable?

There were 60 subjects who were "fully Nash actors" throughout the game; that is, they chose SPNE strategies (i.e., $0) as both Player 1 and Player 2., We ask whether these 60 "fully-Nash" actors in Trust are "fully Nash" in the related Donation and Dictator Games. Of these 60 subjects, 57 pass $0 in the Dictator Game and 50 of the 60 pass $0 in the Donation Game. If we focus on those 57 subjects who are "fully Nash actors" as both Player 1 and Player 2 in Trust and also as Dictator in the Dictator Game, we find that 48 of the 57 pass nothing in the Donation Game. Therefore, across our entire subject pool, only 48 (27%) have consistent NE behavior in three related games of Trust, Donation, and Dictator.

Although deviations in a single game have been widely recognized, research has not focused on how behavior across games is related. We have shown in a variety of ways that NE-consistent behavior in one task does not guarantee similar behavior in another setting. Therefore, even accurately predicting a subjects' action in one setting is no guarantee that it is possible to predict accurately the subjects' action in another setting. We demonstrate thisusing game theoretic environments that are exceedingly similar, which would seem to stack the deck in favor of finding consistent behavior across games. However, the results from our battery of experimental tasks demonstrate that subjects regularly deviate from SPNE in both their beliefs and behavior, that the deviations are themselves inconsistent, and that there is variation in the degree to which behavior accords with belief. These deviations are so pervasive and the variation so large, even among subjects taking actions in similar or identical strategic settings, that is seems unwarranted to refer to them as "deviations." On the contrary, even though our subject pool is derived from subjects with very high math SATs, who were on the whole in the top 2% of high school graduates, consistent "NE behavior and beliefs" appear to be remarkable deviations from human cognitive patterns and human behavior.

5 Discussion

Games are defined by seven characteristics: players, actions, information, strategies, payoffs, outcomes, and equilibria, including equilibrium refinement [33]. Equilibria must be mutually consistent, indeed, "[T]he Nash equilibrium (NE) concept . . . entails the assumption that all players think in a very similar manner when assessing one another's strategies. In a NE, all players in a game base their strategies not only on knowledge of the game's structure but also on *identical conjectures about what all other players will do.* The NE criterion pertains to whether each player is choosing a strategy that is a best response to a shared conjecture about the strategies of all players. A set of strategies satisfies the criterion when all player strategies are best responses to the shared conjecture. In many widely used refinements of the NE concept, such as subgame perfection and perfect Bayesian, the inferential criteria also require players to have shared, or at least very similar, conjectures" [23: 103-104]. NE is, at its core, a cognitive theory.

In cognitive science, "theory of mind" refers to our amazing disposition to attribute mindedness to other human beings. Classical economics takes theory of mind for granted, and extends it to the view that all of those minds are driven by consistent preferences and beliefs to consistent actions. Behavioral game theory applies patches to come up with a conception of individual minds as consistently deviant from classical rationality. Hence the phrase "predictably irrational." The difference between classical rationality and behavioral game theory is not about consistency: classical rationality assumes that everyone is consistent in the same way, while behavioral game theory assumes that each person is consistent in a certain "deviant" way. While classical rationality and behavioral game theory are often taken to be opposed, we seem them as uniformly based on an assumption of consistency that does not stand with experimental test.

Some scholars justify consistency as a mathematical shortcut that is meant to represent the result of some unspecified learning, evolutionary adjustment process, or the adoption of social norms, laws or institutions [34]. These processes, however, are rarely defined. This line of reasoning also implies that beliefs and choices will not be consistent if players do not have time to learn or evolve.

As in many related experiments [for a survey see 8], subjects in our experiments do indeed deviate from SPNE predictions, both in their actions and in their beliefs. We also demonstrate that subjects' recursive beliefs (beliefs about the beliefs of other players) are often inconsistent with NE predictions, a result that has not been widely appreciated. We show further that the variance in actions and beliefs is very large.

Even the common patches of behavioral game theory do not predict the tremendous diversity that we observed for *individual subjects* and the variance across subjects' beliefs and behavior. Subjects' reported beliefs and their behavior are regularly incongruent – subjects who play consistently with NE prediction do not always possess the assumed game theoretic beliefs. Furthermore, subjects' beliefs differ across settings even when there are no changes in the cognitive complexity of the setting. Taken together these results suggest that game theoretic models and common modifications employed to make them explain the deviations from straightforward NE, do not accurately predict the variations in behaviors we observe in a laboratory setting. Therefore, research into decision-making should turn to discovering the cognitive patterns of decision-making.

An Automated Deduction of the Independence of the Axioms of the Megill-Pavičić Formulation of Ortholattice Theory

Abstract

The optimization of quantum computing circuitry and compilers at some level must be expressed in terms of quantum-mechanical behaviors and operations. In much the same way that the structure of conventional propositional logic is the logic of the description of the behavior of classical physical systems and is isomorphic to a Boolean lattice, so also the algebra, C(H), of closed linear subspaces of (equivalently, the system of linear operators on) a Hilbert space is a logic of the descriptions of the behavior of quantum mechanical systems and is a model of an ortholattice (OL). An OL can thus be thought of as a kind of "quantum logic" (QL). In order to delimit the axiomatic basis of the derivation of a proposition in a formal system, it is helpful to formulate a theory so that none of its axioms depend on any others in that theory. Here, I use an automated deduction framework to show that the axioms of the Megill-Pavičić formulation of ortholattice theory are independent. In addition, these results illustrate the utility of automated deduction in investigating the foundations of quantum computing.

Keywords: automated deduction, lattice theory

1.0 Introduction

The optimization of quantum computing circuitry and compilers at some level must be expressed in terms of the description of quantum-mechanical behaviors ([1], [17], [18], [20]). In much the same way that conventional propositional logic ([12]) is the logical structure of description of the behavior of classical physical systems (e.g. "measurements of the position and momentum of an electron are commutative") and is isomorphic to a Boolean lattice ([10], [11], [19]), so also the algebra, *C(H)*, of the closed linear subspaces of (equivalently, the system of linear operators on) a Hilbert space *H* ([1], [4], [6], [9], [13]) is *a* logic of the descriptions of the behavior of quantum mechanical systems (e.g., "the measurements of the position and momentum of an electron are *not* commutative ") and is a model ([10]) of an ortholattice (OL; [8]). An OL can thus be thought of as a kind of "quantum logic" (QL; [19]).

The Megill-Pavičić formulation of ortholattice theory ([11]) is shown in Figure 1.

```
% Definitions
le(x,y)  <->  (x v y = y)    # label("Df of le").
1 = x v c(x)                 # label("Df of 1").
0 = x ^ c(x)                 # label("Df of 0").

% Axioms
x = c(c(x))                                          # label"(MP_L1").
le(x, x v y)  &  le(y, x v y) & le(y, x v c(x))      # label("MP_L2").
(le(x,y) & le(y, x)) -> (x = y)                      # label("MP_L3a").
le(x,y) -> le(c(y), c(x))                            # label("MP_L4").
(le(x,y) & le(y,z)) -> le(x,z)                       # label("MP_L5").
(le(x,z)  &  le(y,z))  -> le(x v y, z)               # label("MP_L6").

where
       x, y are variables ranging over lattice nodes
       ^ is lattice meet
       v is lattice join
       c(x) is the orthocomplement of x
       =  is equivalence
       1 is the maximum lattice element (= x v c(x))
       0 is the minimum lattice element (= c(1))
```

Figure 1. The Megill-Pavičić formulation of ortholattice theory ([11]).

2.0 Method

The ortholattice axiomatization of [11] was implemented in *mace4* ([2]) scripts ([3]), then executed in that framework on a Dell Inspiron 545 with an Intel Core2 Quad CPU Q8200 (clocked @ 2.33 GHz) and 8.00 GB RAM, running under the *Windows Vista Home Premium /Cygwin* ([5]) operating environment. The script implements the derivation of models (Figure 2) in which all of those axioms, minus one, conjoined with the *negation* of the excluded axiom, hold in at least one interpretation, demonstrating that the axiom which has been negated is independent of the remaining lattice axioms ([10]).

3.0 Results

The six proofs Figure 2 show the independence of the ortholattice axioms of [11] from each other.

Figure 2. *mace4* models showing, in turn, the independence of each of the axioms of the ortholattice theory formulation in [11] from each other Each text line of values in the rightmost set of square brackets are assignments of values of integers to lattice positions. The number of nodes in such a lattice is N, where N is the first parameter in the "interpretation" line in the model. For example, in the model showing the independence of MP_L6, the "interpretation" line begins with "interpretation (4, ...", so N = 4. Such an assignment of values to nodes is said to *satisfy* or *be a model of* the indicated function/relation if the function/relation holds within the lattice under the assignment to those positions. Details of the *mace4* notation can be found in [1].

The time to produce the content of Figure 2 on the platform described in Section 2.0 was approximately 0.5 second.

4.0 Discussion

The results shown in Section 3.0 motivate at least two observations:

1. Each ortholattice theory axiom of [11] is independent of the other axioms in that formulation.

2. All the models in Figure 2 are distinct.

ABSTRACT

The HP software teams have built an enterprise social platform for over 40,000 employees distributed across the globe to share knowledge, learn from each others' experiences, and search for content relevant to the Hewlett Packard Application Services business. Given the unstructured nature of the content inside the platform, a key issue for the participants is to search for and retrieve content. To address this challenge, social platforms typically allow their participants to tag and thematize content. The platform then uses the tags and themes to facilitate content search and retrieval. However, platform participants do not always tag and themetize their content, and when they do, the tags and themes can often be incomplete or misleading.

A robust and accurate tagging and themetization system that will support the search and retrieval capabilities is critical to the platform. We provide a keyword and key phrase extraction technique based on term co-occurrences that performs better than traditional tfidf-based techniques. The extracted keywords and key phrases are used to construct a semantics graph. We further provide a content thematization system that discovers the major themes within the content based on the constructed semantics graph.

1. INTRODUCTION

The Industrialized Delivery System (IDS) Square is an enterprise social platform built by Hewlett Packard to help create a globally-connected community of 40,000+ employees. The sharing, search and retrieval of content in social platforms often rely on manually-assigned tags to content; however, participants often do not tag their content, and when they do, the tags can be incomplete and misleading. In collaboration with the software teams at Hewlett Packard, we have built a system that automatically tags content, clusters the sections of content into themes, and deduces the semantics of the search phrases input by the participants. The system relies on novel pattern recognition, data mining and graph clustering techniques developed by our teams. Our system is currently being integrated into the IDS Square platform.

The HP software teams have built an enterprise social platform for over 40,000 employees distributed across the globe to share knowledge, learn from each others' experiences, and search for content relevant to the Hewlett Packard Application Services business. The platform is called the Industrialized Delivery System (IDS) Square, announced by the Application Services leadership team to their employees in late August, 2011. The 40,000+ IDS Square participants will contribute to the network through a range of activities such as posting services-related entries, linking their entries to HP's internal and external sites, and commenting and voting on each others' posts.

Given the unstructured nature of the content inside the IDS Square platform, a key issue for the participants is to search for and retrieve content. To address this challenge, social platforms typically allow their participants to tag and thematize content. The platform then uses the tags and themes to facilitate content search and retrieval. However, platform participants do not always tag and themetize their content, and when they do, the tags and themes can often be incomplete or misleading. A robust and accurate tagging and themetization system that will support the search and retrieval capabilities is critical to the IDS Square platform.

In collaboration with the Hewlett Packard software team, we have built a system that automatically tags and themetizes services-related content with the intent of providing search and retrieval capability within the IDS Square. The system is currently being integrated into the IDS Square platform.

Our system automatically builds a repository of services-related tags and generates a semantic graph of their relationships. The repository is used to automatically assign tags to any enterprise services-related content. The relationships between the assigned tags - provided by the semantic graph - are used to cluster the sections of the content (e.g., paragraphs of text) into themes. Fig. 1 illustrates the system components and their dependencies. The system consists of the following components:

- Corpus Builder - We have available to us a small number of seed websites for each HP enterprise service line. A seed site can be viewed as a main webpage for the corresponding service line; it describes the corresponding service line with links to related sites. Starting from the seed sites, our crawlers retrieve HP's internal and external sites (as well as Sharepoint sites). The retrieved content constitutes the corpus.

- Tag Extractor - Tag extraction is the discovery of the words and phrases (i.e., two or more words) relevant to the domain of interest, which, in our case, is the HP Enterprise Services. The tags are automatically extracted from the HP Enterprise Services content retrieved by the corpus builder.

  Typically, tag extraction algorithms rely on the TF/IDF technique, which discovers words and phrases that occur frequently in the corpus and rarely outside the cor-

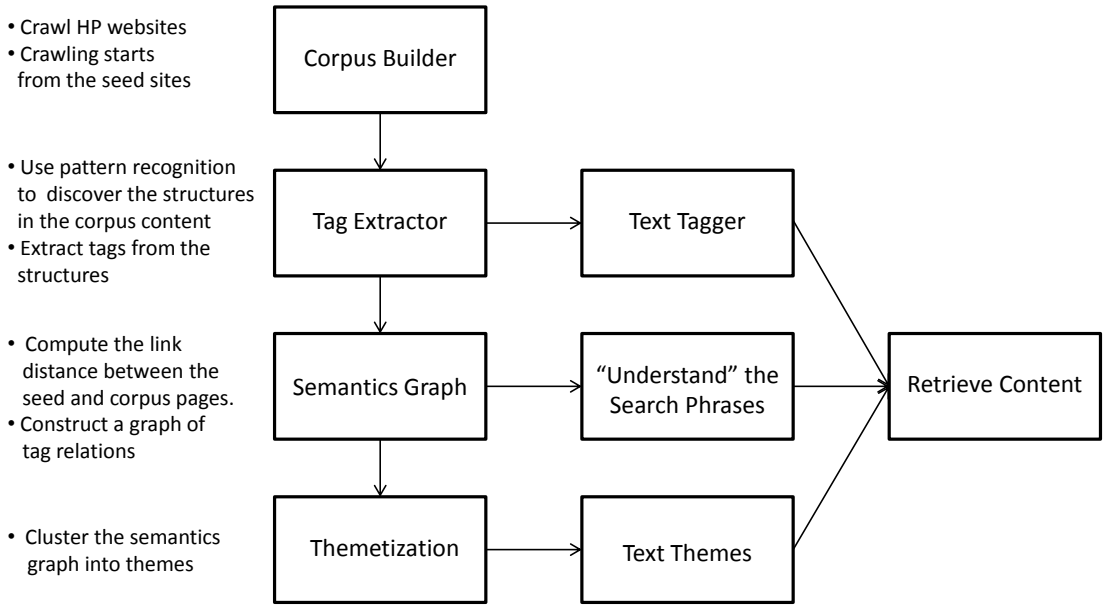

Figure 1: The architecture of the tags extraction, semantics graph building and thematization systems for search and retrieval in the enterprise service platform designed for HP's application services business

pus. However, in our context, the higher frequency of occurrence of a phrase does not necessarily indicate that the phrase is more relevant, or vice versa. For instance, the phrase "new opportunities" occurs more frequently than the phrase "application rationalization" in our corpus, although application rationalization is an actual service offering by the Application Services business. Instead of applying the TF/IDF-based techniques, we perform tag extraction through pattern recognition. Our starting assumption is that the critical words and phrases are more likely to occur inside structures such as the titles, sub-titles, lists, tables and link descriptors. Following this assumption, we design pattern recognition algorithms that automatically discover and extract the members of the structures from the corpus content.

We further apply pattern recognition techniques to discover which section(s) of a given content, are more likely to represent the content topics. For instance, if the content is an HTML page, we seek to differentiate the main sections from the side-bars, as the side-bars are less likely to be of relevance.

Once the members of titles, sub-titles, lists, tables and link descriptors are identified, we use co-occurrence based techniques [1] to extract the tags in the corpus.

- Semantics Graph Builder - The semantics graph is the graph of relations between the tags. The nodes of the graph are the tags, while the edges connecting the nodes have weights, representing the distances between the tags. A small distance between two tags indicates that the two tags are highly related to each other.

  If the phrases u and v relate to similar services lines or if they frequently appear in the same titles, lists and tables, then we force the semantic distance between u and v to be small. Towards this end, we compute the minimum number of web links to reach from each seed page to each corpus page on which the phrase u appears. From this, we deduce to which service lines u is most related. We repeat the procedure for the phrase v, and discover whether u and v relate to similar service lines.

- Thematization - The tagging by itself does not provide sufficient insight about the content. We take one step further and thematize the content, i.e., we summarize each section of the content with a theme. In order to progress from tags to themes, we cluster the semantic graph into themes. To cluster the graph, we first coarsen it by iteratively finding a matching of the graph [2], and collapsing each set of matched nodes into one node. We then partition the coarsened graph by computing a small edge-cut bisection [2] of the coarse graph such that each part contains roughly

half of the edge weights of the original graph. Finally, we project the partitioned graph back to the original graph.

- Tags, Themes and Search - The content in the IDS Square (e.g., plain text, HTML page, e-mail message, Sharepoint document) are assigned tags by matching the n-tuples in the texts by the tags discovered in the Tag Extractor stage. The content are then themetized by finding the graph clusters in which the assigned tags appear most often.

  When a participant enters a search phrase in a search box in IDS Square, our system understands the semantic of the input phrase through the semantics graph, and has the ability to retrieve the relevant content.

Our system is currently being integrated into the IDS Square platform to be used by the over 40,000 employees that support the Application Services business. The system addresses the issue of understanding the meaning of tags in their accepted meaning within HP. For instance, as Fig. 2 illustrates, our system relates "managed messaging" to concepts such as "workplace services" and "enterprise e-mail", while Wikipedia (http://www.wikipedia.org) relates it to the "fairness test", "chamber of commerce" and "rehabilitation services".

Social platforms often rely on manual tagging by the participants to support search and retrieval. Our system automatically assigns tags and themes to content without any manual step. More importantly, the system is designed specifically for the HP services domain through building a corpus of services content with crawling that starts from a set of seed services pages. Thus, the extracted tags and themes are highly relevant to HP's services business, the employees of whom will be the participants the IDS Square platform.

2. KEYWORD EXTRACTION

Keyword extraction techniques are often based on the tfidf method. The tfidf method compares the word frequencies in the repository with the word frequencies in the sample text; if the frequency of a word in the sample text is high while its frequency in the repository is low, the word is extracted as a keyword.

While the tfidf-based techniques are known to perform well in many text mining applications, they have a major shortcoming in the context of mining threads in an enterprise social platform. An enterprise social thread typically contains only few sentences and words, making it difficult to obtain reliable statistics based on word frequencies. Many relevant words appear only once in the thread, making it difficult to distinguish them from the other, less relevant words of the thread.

An alternative approach would be to form a vector of keywords in the repository of forum threads, and, generate a binary features vector for each thread. If the i^{th} repository keyword appears in the thread, the i^{th} element of the thread's feature vector is 1, and if the keyword does not appear in the thread, the i^{th} element of the thread's feature vector is 0.

The question with this simple alternative approach is then that of generating keywords in a given repository. We apply three different techniques:

- Remove only stop-words: We only filter out stop words (e.g., if, and, we, etc.) from the repository, and let the vector of keywords be the set of all remaining distinct repository words.
- The tfidf method: We apply the tfidf method on the entire repository by comparing the word frequencies in the repository with word frequencies in the English language. If the frequency of a word is high in the repository and low in the English language, we take the word as a keyword.
- Term co-occurrence: The term co-occurrence method extracts keywords from the repository without comparing the repository frequencies with the English language frequencies. This method is explained next [9].

2.1 Term Co-occurrence

Let N denote the number of all distinct words in the repository of forum threads. We construct a $N \times M$ co-occurrence matrix, where M is pre-selected integer with $M < N$. We typically take M to be 500. We index all distinct words by n, i.e., $1 \leq n \leq N$. We index the most frequently observed M words in the repository by m such that $1 \leq m \leq M$.

The $(n.m)$ element (i.e. ,n^{th} row and the m^{th} column) of the $N \times M$ co-occurrence matrix counts the number of times the word n and the word m occur together. Consider the word ẅirelesswith index n and the word c̈onnectionẅith index m, and that ẅirelessänd c̈onnectionöccur together 218 times in the repository. Then, the $(n.m)$ element of the co-occurence matrix is 218.

If the word n appears independently from the words $1 \leq m \leq M$ (the frequent words), the number of times the word n co-occurs with the frequent words is similar to the unconditional distribution of occurrence of the frequent words.

On the other hand, if the word n has a semantic relation to a particular set of frequent words, then the co-occurrence of the word n with the frequent words is greater than the unconditional distribution of occurrence the frequent words.

We denote the unconditional probability of a frequent word m as the ex- pected probability p_m and the total number of co-occurrences of the word n and fre- quent terms as c_n. Frequency of co-occurrence of the word n and the word m is written as $freq(n, m)$. The statistical value of χ^2 is defined as

$$\chi^2(n) = \sum_{1 \leq m \leq M} \frac{freq(n,m) - N_n p_m}{n_m p_m}. \quad (1)$$

2.2 Clustering of Frequent Terms

We cluster two or more frequent terms together in either of the following two conditions:

- The frequent words m_1 and m_2 co-occur frequently with each other.
- The frequent words m_1 and m_2 have a similar distribution of co-occurrence with other words.

To quantify the first condition of m_1 and m_2 co-occurring frequently, we use the mutual information between the occurrence probability of m_1 and that of m_2.

To quantify the second condition of m_1 and m_2 having a similar distribution of co-occurrence with other words, we

use the Kullback-Leibler divergence between the occurrence probability of m_1 and that of m_2.

3. ALGORITHM

We design a statistical clustering algorithm to minimize (in the Lloyd-optimal sense) the error probability given in (2) under the cluster entropy constraints. Gaussian mixture models have been used extensively in the literature to design generative algorithms for data clustering. Such algorithms are often based on the EM algorithm [5]; however, there also exists alternative training approaches such as Gauss mixture vector quantization (GMVQ) [8, 11, 12, 13, 16]. The EM algorithm assumes that the underlying data follows a Gaussian mixture distribution and tries to fit a Gaussian mixture model to the data, while the GMVQ is a Lloyd clustering algorithm and it does not make any assumptions about the statistics of the underlying data.

We use the GMVQ to design a hierarchical clustering algorithm. Our choice of GMVQ (over the EM) is motivated by the intractability of the EM solution in minimizing (2) through a hierarchical clustering scheme. We first extend the GMVQ to design a hierarchical (tree-structured) clustering algorithm.

In section 3.1, we provide an overview of the GMVQ and include the iterative solution for the GMVQ. In section 3.2, we extend the GMVQ to design a tree-structured clustering algorithm.

3.1 Gauss mixture vector quantization (GMVQ)

Consider the training set $\{z_i, 1 \leq i \leq N\}$ with its (not necessarily Gaussian) underlying distribution f in the form $f(Z) = \sum_k p_k f_k(Z)$. The goal of GMVQ is to find the Gaussian mixture distribution, g, that minimizes the distance between f and g. It has been shown in [8] that the Gaussian mixture distribution g that minimizes this distance (i.e., minimizes in the Lloyd-optimal sense) can be obtained iteratively with the following two updates at each iteration:

i. Given μ_k, Σ_k and p_k for each cluster k, assign each z_i to the cluster k that minimizes

$$\frac{1}{2}\log(|\Sigma_k|) + \frac{1}{2}(z_i - \mu_k)^T \Sigma_k^{-1}(z_i - \mu_k) - \log p_k, \quad (2)$$

where $|\Sigma_k|$ is the determinant of Σ_k. We note that (5) is also known as the QDA distortion.

ii. Given the cluster assignments, set μ_k, Σ_k and p_k as

$$\mu_k = \frac{1}{\|S_k\|} \sum_{z_i \in S_k} z_i, \quad (3)$$

$$\Sigma_k = \frac{1}{\|S_k\|} \sum_i (z_i - \mu_k)(z_i - \mu_k)^T, \quad (4)$$

and

$$p_k = \frac{\|S_k\|}{N}, \quad (5)$$

where S_k is the set of training vectors z_i assigned to cluster k, and $\|S_k\|$ is the cardinality of the set.

3.2 Tree-structured Gauss Mixture Vector Quantization

We use the BFOS algorithm to design a hierarchical (i.e., tree-structured) extension of GMVQ [13]. The BFOS algorithm requires each node of a tree to have two linear functionals such that one of them is monotonically increasing and the other is monotonically decreasing. Toward this end, we view the QDA distortion (5) of any subtree, T, of a tree as a sum of two functionals, u_1 and u_2, such that

$$u_1(T) = \frac{1}{2}\sum_{k \in T} l_k \log(|\Sigma_k|) + \frac{1}{N}\sum_{k \in T}\sum_{z_i \in S_k} \frac{1}{2}(z_i - \mu_k)^T \Sigma_k^{-1}(z_i - \mu_k), \quad (6)$$

and

$$u_2(T) = -\sum_{k \in T} p_k \log p_k \quad (7)$$

where $k \in T$ denotes the set of clusters (i.e., tree leaves) of the subtree T, and μ_k, Σ_k, p_k and the set S_k are as defined in section 3.1.

The magnitude of u_2/u_1 increases at each iteration. This is a key point of the design as, then, pruning is terminated when the magnitude of u_2/u_1 reaches λ, resulting in the subtree minimizing $u_1 + \lambda u_2$.

4. EXPERIMENTS

We've tested our approach using HP's internal enterprise services content including websites and SharePoint sites. We compared the hierarchical tree-based clustering approach to 3 other clustering techniques (EM, GMVQ and agglomerative hierarchical clustering) under 3 different feature vector constructions, and under 2 different keyword extraction schemes. The comparisons are performed on a subset of 6000 webpages of content. In each comparison, we measured the misclassification error, which is the probability of a customer query being assigned to a cluster of a product problem different from the problem expressed in the query. The ground truth for the threads, problems and queries have been established by HP's internal website owners, independently of the author of this paper.

4.1 Feature vectors

The i^{th} thread has two feature vectors, the page title and metadata $x_{i,1}$ and the page content $x_{i,2}$. Each feature vector is a W-length binary (0 or 1) vector, where W is the total number of unique words used across all pages. Each word is indexed by w, where $1 \leq w \leq W$.

The w^{th} element of $x_{i,1}$ is 1 if and only if the word w occurs in the title of the i^{th} page. Similarly, the w^{th} element of $x_{i,2}$ is 1 if and only if the word w occurs in the content of the i^{th} page. We exclude the stop-words (e.g., and, if, such, etc.) from the feature vectors.

4.2 Comparisons

We've compared the hierarchical TS-GMVQ algorihm to the EM algorithm, standard GMVQ algorithm and agglomerative clustering. In each comparison, we've tested three different feature vector constructions for the EM, GMVQ, TS-GMVQ and agglomerative clustering: the feature vector is $x_{i,1}$, the feature vector is $x_{i,2}$, and the feature vector

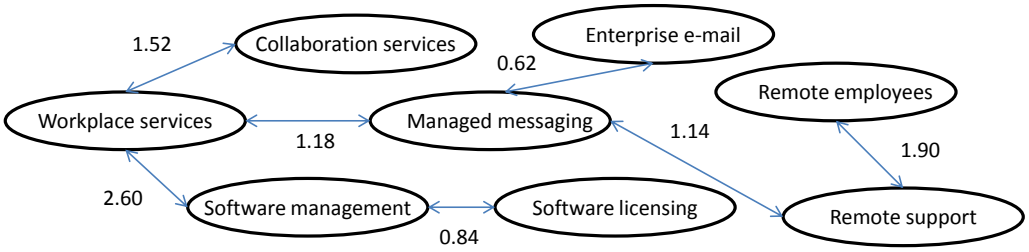

Figure 2: A section of the semantics graph with key phrases and associated pairwise weights.

is $[x_{i,1}\ x_{i,2}]$. The number of clusters established as ground truth is 54.

4.2.1 Feature vector constructions

Denoting the feature vector of the training samples by y_i, we consider three feature vector constructions:

i. $y_i = x_{i,1}$. The clustering algorithm takes only the meta data and page titles into account. The remaining content are ignored.

ii. $y_i = x_{i,2}$. The clustering algorithm takes only the content other than meta data and page titles.

iii. $y_i = [x_{i,1}\ x_{i,2}]$. The clustering algorithm takes into account both the page titles and meta data and the remaining page content.

We compare the hierarchical TS-GMVQ approach with the EM, GMVQ, and agglomerative clustering under each of these three feature vector construction settings.

4.2.2 Compared algorithms

i. EM: We use the standard EM algorithm. At each iteration, the E-step updates the membership probabilities, $v_{i,k}$, for each cluster k and sample i, while the M-step updates the mean, covariance and the probability of occurrence for each cluster k as

ii. GMVQ: The standard GMVQ algorithm updates are as given in (5)-(8) in section 4.1.

iii. TS-GMVQ: The TS-GMVQ is grown and pruned by the BFOS algorithm using (9) and (10) as described in section 4.2.

iv. Agglomerative hierarchical clustering: We start with N clusters, where N is the number of threads in the training set, and apply agglomerative clustering with the distance criterion given in (5). At each iteration, we merge the two clusters, whose closest feature vectors are closest. In other words, at each iteration, for each pair of clusters, c_k and c_m, we compute the distances between the feature vectors of c_k and the feature vectors of c_m, and denote the closest distance by $d_{k,m}$. We merge the two clusters with the minimum $d_{k,m}$.

Fig. 1 shows the classification error as a function of the number of clusters for the threads in the notebook PC set. The tfidf method is used for extracting keywords. In each plot, the classification error rate of the TS-GMVQ approach (red solid line) is compared to that of the GMVQ (blue dashed line), EM (black dash-dot line) and agglomerative hierarchical clustering (green dot-plus line). The top plot shows the setting, where the training vector for GMVQ, EM, TS-GMVQ and agglomerative hierarchical clustering are the page title and meta data feature vectors, i.e., $y_i = x_{i,1}$. In this setting, the TS-GMVQ approach outperforms the other three algorithms.

The middle plot in Fig. 1 shows the setting where the training vectors for the four approaches are the page content feature vectors, i.e., $y_i = x_{i,2}$. Similar to the setting with $y_i = x_{i,1}$, the TS-GMVQ approach leads to the minimum classification error.

The bottom plot in Fig. 1 shows the classification errors for the setting where both the page titles and meta data and page content are included as feature vectors, i.e., $y_i = [x_{i,1}\ x_{i,2}]$. The performance of the four algorithms (GMVQ, EM, TS-GMVQ and agglomerative hierarchical clustering) all improve compared to the settings shown in the top and middle plots.

5. CONCLUDING REMARKS

The HP software teams have built an enterprise social platform for over 40,000 employees distributed across the globe to share knowledge, learn from each others' experiences, and search for content relevant to the Hewlett Packard Application Services business. The platform is called the Industrialized Delivery System (IDS) Square, announced by the Application Services leadership team to their employees in late August, 2011. The 40,000+ IDS Square participants will contribute to the network through a range of activities such as posting services-related entries, linking their entries to HP's internal and external sites, and commenting and voting on each others' posts.

Given the unstructured nature of the content inside the IDS Square platform, a key issue for the participants is to search for and retrieve content. To address this challenge, social platforms typically allow their participants to tag and thematize content. The platform then uses the tags and themes to facilitate content search and retrieval. However, platform participants do not always tag and themetize their content, and when they do, the tags and themes can often

be incomplete or misleading. A robust and accurate tagging and themetization system that will support the search and retrieval capabilities is critical to the IDS Square platform.

In collaboration with the Hewlett Packard software team, we have built a system that automatically tags and themetizes services-related content with the intent of providing search and retrieval capability within the IDS Square. The system is currently being integrated into the IDS Square platform.

Stochastic Search and Planning for Maximization of Resource Production in RTS Games

Thiago F. Naves and Carlos R. Lopes
Faculty of Computing, Federal University of Uberlândia, Uberlândia, Minas Gerais, Brasil

Abstract— *RTS games are an important field of research in Artificial Intelligence Planning. In these games we have to deal with features that represent challenges for Planning such as time constraints, numerical effects and actions with a large number of preconditions. RTS games are characterized by two important phases. The first one has to do with gathering resources and developing an army. In the second phase the resources produced in the first phase are used in battles against enemies. Thus, the first phase is vital for success in the game and the power of the army developed directly reflects in the chances of victory. Our research is focused on the first phase. In order to maximize resource production we developed algorithms based on Simulated Annealing and classical planning. As a result we have obtained a signification improvement of the strength of the army.*

Keywords: Real-Time Strategy Games, Resources, Actions, Goal, Search, Planning.

1. Introduction

Real-time strategy (RTS) games are one of the most popular categories of computer games. Titles like "Starcraft 2" and "World of Warcraft" are two representative examples of this category. These games have different character classes and resources, which are employed in battles. Battles can be waged by a human player or a computer.

It is possible to identify two phases in a RTS game. First, there is an initial period in which each player starts the game with some units and/or buildings and develops his army via resource production. In the next phase military campaigns take place. In this phase the resources gathered earlier are employed for offense and defense. Therefore, the stage of resource production is vital to succeed in this game.

The resources in RTS games are all kinds of raw materials, basic construction, military units and civilization. For obtaining a desired set of resources is necessary to carry out actions. In general we have three sorts of actions related to resources: actions that produce resources, actions that consume resources and actions that collect resources.

Once we conceive a sequence of actions (a plan) that produces a desired set of resources (a goal), we carry out this plan to take the game from an initial state of resources to another final state in which the desired set of resources is achieved. To identify what resources to be achieved (a goal) is an important step to elaborate a plan of action. The choice of an adequate goal has a direct impact on the strength of the army, which is important in the development phase. Thus, in the specification of a goal it is necessary to maximize the amount of resources to be achieved in order to raise the strength of the army. In this paper we describe our approach to achieve goals that maximize production of resources.

The domain used for this work is StarCraft, which is considered the game with the highest number of constraints on planning tasks [1]. In our approach we have to generate an initial plan of action to achieve an arbitrary amount of resources. In order to do this, we developed an sequential planner based on the STRIPS language [2]. The initial plan is the basis for exploring new plans in order to find the one that has largest amount of resources.

In this paper, we focus on the task of finding the goal that maximizes resource production based on an initial plan of action, as we stated earlier. Once we have an initial plan, we use Simulated Annealing [3] (SA) to maximize the amount of resources to be achieved. However, SA is not only used for goal specification. In the process of figuring out a goal specification, SA is also used to produce a plan to achieve that goal. Our work is motivated by the results obtained in [4] and by gaps in the approaches of [5] and [6] with respect to the choice of goals to be achieved during the production of resources. For the correct functioning of SA, techniques were introduced to adjust its parameters and validate the plans generated during the search. The results obtained are encouraging and show the efficiency of the method to find good solutions.

We understand that this research is interesting for the AI planning field because it deals with a number of challenging problems such as concurrent activities and real-time constraints. Most work in RTS games do not consider the choice of goals within the game. Usually goals for resource production have a random amount of resources to be achieved. Thus, this research can go toward a new approach to resource production, and can be extended to other applications.

The remainder of this paper is organized as follows. Section 2 lists the characteristics of the problem. In section 3 related work is presented and discussed. Section **??** explains about the domain of production resources. Section 4 describes techniques and algorithms for adjusting the parameters of SA in RTS games. Section 5 presents the

consistency checker that works with SA. Section 6 discusses the results of the experiments. In section 7 we make final considerations about our approach.

2. Characterization of the problem

The planning problem in RTS games is to find a sequence of actions that leads the game to a goal state that achieves a certain amount of resources. This process must be efficient. In general, the search for efficiency is related to the time that was spent in the execution of the plan of actions (makespan). However, in our approach we seek for actions that increase the amount of resources that raise the army power of a player. This is achieved by introducing changes into a given plan of action in order to increase the resources to be produced, especially the military units, without violating the preconditions between the actions that will be used to build these resources.

To execute any action you must ensure that its predecessor resources are available. The predecessor word can be understood as a precondition to perform an action and the creation of the resource as a effect of its execution. In this paper actions and resources have the same name. To tell them apart we use the prefix *act* to indicate actions and the prefix *rsc* when referring to resources. Resources can be labeled in one of the following categories: $Require$, $Borrow$, $Produce$ and $Consume$. Figure 1 shows the precedence relationship among some of the main resources of the domain. These resources are based on StarCraft, which has three different character classes: Zerg, Protoss and Terran. This work focuses on the resources of the class Terran.

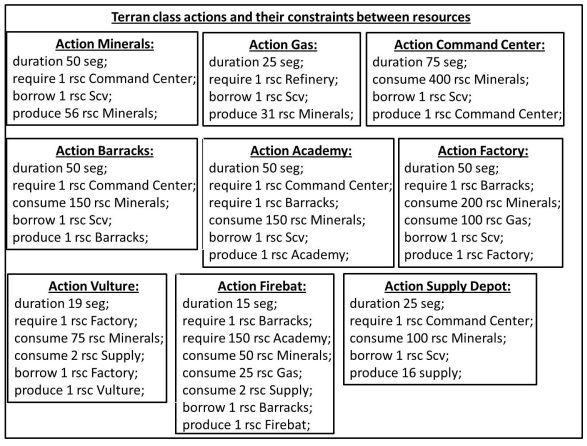

Fig. 1: Some resources of the class Terran and their dependencies.

For example, according to Figure 1 to execute an action that produces a $Firebat$ resource you must have a $Barracks$ and $Academy$ available, a certain amount of $Minerals$ and Gas is also required. The Firebat is a military resource. Thus, the action $Firebat$: $Require$ *(1 rsc Academy, 1 rsc Barracks)*, $borrow$ *(1 rsc Barracks)*, $consume$ *(50 rsc Minerals, 25 rsc Gas)* and $produces$ *(1 rsc Firebat)*. The $Barracks$ will be $borrow$, i.e, it is not possible to perform another action until *act firebat* is finished. The time to build a $Firebat$ is 15 seconds. This situation describes the challenges that surround the planning of actions.

In our approach each plan of action has a time limit, army points, feasible and unfeasible actions. The time limit constrains the maximum value of makespan of the plan of action. The army points are used to evaluate the strength of the plan in relation to its military power. Each resource has a value that defines its ability to fight the opponent. Feasible actions in a plan are those actions that can be carried out, i.e, they have all their preconditions satisfied within the current planning. Unfeasible actions are those that can not be performed in the plan and are waiting for their preconditions to be satisfied at some stage of planning. Unfeasible actions do not consume resources of planning and do not contribute for the evaluation of the army points of the plan.

Returning to the example of the $Firebat$, suppose that a goal with a time limit of 700 seconds is *(1 rsc Firebat, 1 rsc Marine)*. A plan for this goal can be achieved by the following actions: *(10 act Minerals, 1 act Gas, 1 act Refinery, 1 act Barrack, 1 act Academy, 1 act Firebat, 1 act Marine)*. In a plan every action produces a resource with its respective name, i.e, *10 act Minerals* correspond to ten individual executions of action *Minerals*. The plan contains 28 army points and a makespan of 680 seconds. Among the possible operations that can be made in this plan, consider replacing an action $Minerals$ by a new action $Firebat$. In this case the action $Minerals$ contributes to make available the resource $Barracks$. In this way $Barracks$ becomes unfeasible within the plan due to lack of $Minerals$ and consequently the other resources such as $Academy$, $Firebat$ and $Marine$ will also be because $Barracks$ is a precondition for those resources.

With all the actions that became unfeasible the plan now has 0 army points. Now, suppose if instead of removing $Minerals$ it was requested to include a $Marine$ action in place of a *Gas* action. This exchange is feasible, because $Marine$ has just as preconditions *(1 rsc Minerals, 1 rsc Barracks)* and these are already available at the time. The action $Firebat$ becomes unfeasible and the duration of the plan (makespan) drops to 670 sec. If in the next operation an action Gas is inserted into the plan the action $Firebat$ action would become feasible. In this way a plan is established with 40 army points and 695 sec of makespan. The plan that is found is better than the initial one. Reducing the makespan of the goal is not one of the objectives of this work. However,due to the characteristics of changes in the plan this might happen.

Results, as the example presented above, are motivators for this research.

3. Related Work

There is little research in maximizing goals of resources production in RTS games. One of the reasons is the complexity involved in searching and managing the state space, which makes difficult to attend the real-time constraints.

The work developed by [4] remains our approach in a certain sense. He also uses Simulated Annealing to explore the state space of the StrarCraft in order to balance the different classes in the game by checking the similarity of plans in each class. In our work Simulated Annealing is used to determine a goal to be achieved that maximizes resources production, given the current state of resources in the game and a time limit for completion of actions.

[7] developed a linear planner to generate a plan of action given an initial state and a goal for production of resources, which is defined without the use of any explicit criterion. The generated plan is scheduled in order to reduce the makespan. Our work also makes use of a sequential planner. However, our approach deals with dynamic goals for resources production. This is necessary in order to find out a goal that maximizes the strength of the army. To the contrary, [7] works with a goal with fixed and unchangeable resources to be achieved.

Work developed by [6] has the same objective as the one pursued by [7]. These approaches differ on use of the planning and scheduling algorithms. [6] developed their approach using Partial Order Planning and SLA* for scheduling. [6] also works with a goal with fixed and unchangeable resources to be achieved and not can be adapted to our problem.

We also surveyed some existent planners that could be applied. [8] and [9] were considered for our problem at hand, but both have a different approach and would have to be modified to adapt to our goal. In short, most of the approaches surveyed have different focus and the techniques used are not efficient for the domain that we are exploring.

4. The use of Simulated Annealing to Maximize Resource Production

Simulated Annealing is a meta-heuristic which belongs to the class of local search algorithms [3]. SA was chosen due to the robustness and possibility to be combined with other techniques. it was also the algorithm that achieved the best results among those used during the experiments. SA takes as input a possible solution of the problem, in our case a plan of action developed by a sequential planner. The mechanism that generates neighbors will perform operations of exchange and replacement of actions in the plan. It should be noted that these operations generate new plans of action.

In SA a possible solution is evaluated through the use of an objective function. In our approach the objective function is responsible for counting the army points existent in each plan of action. In this way it is possible to find out which states have the highest attack strength. A state that is better evaluated that the current state becomes the current state. Even if the new plan generated is not chosen as the current solution there is still a probability of its acceptance. Algorithm 1 shows the pseudocode of the Simulated Annealing algorithm.

Algorithm 1 SA($G_{initial}$, P, M, α)

```
1:  G_current ← G_initial
2:  T_0 ← InitialTemp()
3:  while T_0 > 0 do
4:    i ← 1
5:    nSuccess ← 0
6:    while i < M do
7:      G_neighbor ← NewNeighbor(G_current)
8:      Δr ← Evaluation(G_current) - Evaluation(G_neighbor)
9:      if Δr < 0 or Random() < PrAcceptance()
        then
10:       G_current ← G_neighbor
11:       nSuccess ← nSuccess + 1
12:     end if
13:     i ← i + 1
14:   end while
15:   if nSuccess ≥ P then
16:     T_0 ← α * T_0
17:   end if
18: end while
19: return G_current
```

The parameters of SA were adjusted to the domain of RTS games. In the next subsections we describe in details the algorithm, techniques were developed and parameters used.

4.1 Initial Solution

The algorithm takes as input a initial solution (plan of action) and performs operations on its actions. The initial solution $G_{initial}$ is generated by the sequential planner (it will be briefly explained in the next subsection) and it is a plan with the actions ordered by their starting time. The resources that should be achieved in the initial plan are chosen randomly and the makespan is constrained to the time limit established for the goal. Time limits vary from 3 to 5 minutes. The idea is to make SA work with varied plans, which avoids that the algorithm becomes biased to a specific value of the objective function.

4.2 Sequential Planner

The planning algorithm takes a goal to be achieved a list of resources available , which contains all the resources available to the player as the amount of minerals or units, and a time limit for the execution of the plan to be generated The planning algorithm was built upon STRIPS[2]. In this

way, based on the input data, a linear plan of actions is generated to achieve a goal.

Depending on the available time, given by the time limit parameter, the planner may be called more than once, each time with a random goal. The algorithm takes only one resource as a goal at a time because the idea is to build an initial plan of action without setting a fixed amount of resources. In each iteration a plan of action is achieved and appended to a previous plan obtained in early iterations. This is done until the time limit is reached by the resulting plan. The algorithm takes this behavior because it is necessary to build a plan of action without exceeding the time limit.

While a resource is being planned is possible to check whether the plan under development is not exceeding this time. If an action exceeds the time limit, the planning is stopped and the plan built so far is considered a valid plan and returned. Generate a plan based on a time limit is a way to build the plan based on the behavior of a human player, which does not specify an amount of resources to their goal, but builds as many resources as he can in a interval of time.

As an example suppose that it is necessary to produce a plan to achieve the resource *Marine* with time limit of 150 sec. based on the following available resources: (*(4 Scv, 50 Minerals)*. Our planner is capable of producing the following plan: (*(3 act Minerals, 1 act Barracks, 1 act Marine)*. Therefore, in order to produce *Marine*, it is necessary to execute three actions *Minerals*, one action *Barracks* and one action *Marine*.

4.3 The Cooling Scheme

The initial temperature T_0 ($InitialTemp()$, line 2) is achieved based on the average number of actions in the plan of action, which is given as input to the algorithm. With the time limit is possible to generate plans with a small number of actions. Our objective is to reproduce a typical behavior of a human player. This is achieved by establishing an initial temperature of about five times the quantity of actions in the plan. This is a appropriate value for the domain.

For cooling, a value close to a few tenths of a percent of the initial temperature is good. A logarithmic function can make the algorithm become very slow, which is an inappropriate behavior for an RTS game environment.

We developed an adaptive method of reduction, where the temperature T_{i+1} drops by a factor α (line 19) if for a given number of iterations P the new plans are always accepted. The alpha value is low and close to 1. For instance, 0.97 is a good value to be defined by alpha. P must be large enough to explore the possibilities of operations on the plans. Based on experiments we found that values between 15 and 20 represent a good choice for P.

$$T_{i+1} = \begin{cases} T_i & \text{if the number of plans accepted } < P. \\ \alpha.T_i & \text{if the number of plans accepted } = P. \end{cases}$$

The probability of a new plan to be accepted if it is not better evaluated than the current plan is given by the equation 1.

$$1 - 0.5 \tanh [2\Delta r(v_i - v_{i+1}T_{i+1}] \quad (1)$$

Where v_i is the feasible number of actions that the plan has in the corresponding iteration. The variable Δr is a factor derivation and is obtained from the difference between the values of the objective function (army points) of the current plan and new plan generated (line 11 Algorithm 1). Finally this value is divided by temperature. Thus, the algorithm can behave differently depending on the temperature value.

The function responsible for calculating the probability is $PrAcceptance()$ (line 9). Its value must be greater than the value generated by the function $Random()$ (line 9), which produces a random value between 0 and 1. The parameter M determines how many neighbors will be generated before the temperature decreasing (line 6). Its value should enable a good search in the space of states given the temperature of the algorithm.

4.4 The mechanism that generates neighbors

There are several ways to generate a new neighbor plan $G_{neighbor}$ from the current solution $G_{current}$ in Simulated Annealing. This generation is the essential for the SA get a good conversion, which is the way the plan is modified to be compatible with the characteristics of RTS games. Next we describe four possible mechanisms for acomplishing this task.

- *A.* Two actions are randomly selected in the plane and switched places, one assuming the position of other.
- *B.* An action of the plan is randomly chosen and replaced by a new action that is that is randomly chosen among all available actions in the game.
- *C.* One of the following moves is randomly chosen: Randomly select two actions within the plan and switch their positions, or replace a action chosen randomly within the plan by a new action randomly selected among all available actions in the game.
- *D.* The same mechanism as above, but the new action that will replace the other will be randomly chosen among the available actions in the plan.

The mechanism A is useful when the actions of the plan are known. Thus, the initial plan must be developed with a high value in its objective function to get good permutations. This makes the algorithm with an tendentious implementation, a situation we want to avoid in this work. The mechanism B can return satisfactory results, due to the insertion of new actions in the plan, exploring well the possibility of new resources. But C is the mechanism that returns the best results through a combination of two exploration strategies. The mechanism D has the same

problem as A. It needs quality guarantee in the initial plan to achieve good results.

When a neighbor plan is generated with function $NewNeighbor(G)$ (line 8), the consistency checker is used to manage and evaluate the changes made in the goal. The algorithm for checking consistency will be further discussed in the following sections.

5. Consistency Checker

In planning when changes are made in a plan of action it is necessary to see how these changes affect it, especially when the dependency relationship is as strong as in the case of StarCraft. A simple insertion of an action may result in the inviability of many others. However, this makes the plan suitable for the introduction of new actions. This relationship is given by the loss and addition of resources and needs to be checked effectively to not harm the planning. Therefore, we developed a checker capable of dealing with changes in a plan, verifying its consistency, ordering and managing the resources.

The consistency checker is used when SA calls the mechanism for generating neighbors. Algorithm 2 shows the pseudo-code of the checker. The algorithm takes the plan of action $Actions$, a list $NewActions$ with the new action to be inserted or two actions that will be switched, and the list of resources available R_{avaib}. Initially is checked whether any action becomes unfeasible due the operation to be carried out in the plan, either to replace one action or exchange actions of place. This checking is performed by function $checkPlan(Actions)$.

Unfeasible Actions are placed in the list $actionsUnf$. When at least one action is inserted into the $actionsUnf$, the algorithm can find the others which will also become unfeasible. This is done by going through the graph of precedence of the actions of the plan. If any of these has a resource marked as unfeasible in the predecessor list, it will become unfeasible as well.

The method $Update(Action, R_{avaib})$ (line 8 of algorithm 2) is used for check what resources will no longer exist and which will be available in the plan to be used by other actions, when the list of actions unfeasible insert some action. This means that if a resource *ScienceFacility* becomes unfeasible it does the same with *CovertOps* and *NuclearSilo*, but in return it releases 88 seconds and provides 250 *Minerals* and 300 *Gas*. These resources enable the introduction of new actions or make others that were unfeasible in the plan become feasible again.

The amount of resources that are released do not always covers the loss of actions that become unfeasible in the plan because these actions may be contributing directly to maximizing the objective function. To help the algorithm to make a decision a variable penalty is used. For each action that becomes unfeasible in the plan a μ value is added to it. Thus, the more unfeasible actions appear greater will be

Algorithm 2 Consistency($Actions$, $NewActions$, R_{avaib})

```
1:  actionsUnf ← checkPlan(NewActions)
2:  for all Action Inf ∈ actionsUnf do
3:    for all Action Act ∈ Actions do
4:      if Act.Predecessors = Inf then
5:        Act.feasible ← false
6:        actionsUnf.push(Act)
7:        penalty += μ
8:        Update(Act, R_avaib)
9:      end if
10:   end for
11: end for
12: adaptPlan(NewActions, R_avaib)
13: continue ← true
14: Actions Act
15: while continue = true do
16:   if Act ← checkPred(actionsUnf, R_avaib) then
17:     Act.feasible ← true
18:     actionsUnf.erase(Act)
19:     penalty -= μ
20:     Update(Act, R_avaib)
21:   else
22:     continue ← false
23:   end if
24: end while
25: return Actions
```

the penalty on the plan when it is evaluated. The value of μ should be small and its value is based on the formula:

$$\mu = 0.1 \text{ - } n/2 \tag{2}$$

where n is the number of actions in the plan.

With unfeasible actions already established and available resources defined, the function $adaptPlan(NewActions, R_{avaib})$ (line 2) is called. This function is responsible for changing the current plan, either by insertion or switch of actions. This function also rearranges the scheduling of actions in the plan, due to the changes made by the operation performed.

In the last stage the consistency checker verifies that after the changes in the plan some unfeasible action can become feasible again. The algorithm goes through the list of unfeasible actions and for each one checks whether its predecessors are available. This is done by function $checkPred(Act, actionsUnf, R_{avaib})$ (line 16). When an action becomes feasible again it is removed from the list of unfeasible actions, the value of the penalty is decreased and the function $Update$ (line 20) is again used to update the resources available. If the function $checkPred$ is called and no action is feasible then the algorithm exits the loop. However, if the opposite happens the algorithm is repeated because an action that is now feasible can make others to become feasible.

Finally, the algorithm returns the new plan for SA that evaluates the objective function and decides whether it will be the new solution. The following is an application example of the consistency checker.

5.1 Example of application

To illustrate the behavior of the checker suppose we have a initial plan of action that achieve the resource *Firebat* as depicted in Figure 2. The initial state of the plan is (13, 0, 42, 6, 6, 16, 565). These plan values correspond to the number of actions, number of actions unfeasible, amount of minerals available, amount of gas available, supply used, army points and the makespan of the plan. The time limit is 600 sec.

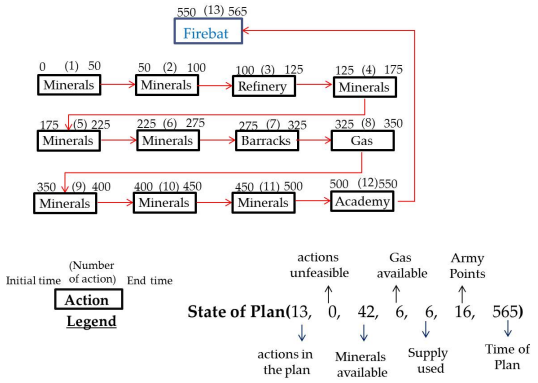

Fig. 2: An plan of action to achieve the resource Firebat.

For instance, suppose that in the first run of SA an action *Marine* substitutes the *Minerals* of number 10. Thus, the *act Minerals* is placed on the list of unfeasible actions and this action is the predecessor of *act Academy*, this also becomes unfeasible and with it the *act Firebat*. At this point the plan state is (13, 2, 186, 31, 4, 0, 465). The algorithm now inserts the new action and updates the resources it will consume. It is feasible based on available resources and the state of the plan is changed to (13, 2, 136, 31, 6, 12, 480). The algorithm cannot enable either of the two unfeasible actions, as the *act Marine* that entered does not contribute for these actions. Although there is enough *rsc Gas* and *rsc Minerals* for *act Firebat*, it may not be feasible as the *act Academy*, its predecessor continues unfeasible. The plan is then returned to SA that can opt for it, although it has fewer army points than the previous.

With the plan accepted suppose that SA indicates replacement of the action *Gas* of number 8 by another action *Marine*. *Gas* is the predecessor of *act Firebat*, but since this is already unfeasible the removal of *Gas* does not affect the plan. Now the plan state is (13, 3, 136, 0, 6, 12, 455). Although the *act Minerals* predecessor of *act Marine* are in the plan, it is in a forward position, i.e, the *act Marine* is being done prior to its predecessor. The new action goes unfeasible into the plan. No action becomes feasible in the next review and the final state of this plan is the same.

Now in SA suppose that occurs an switch of positions between the actions *Minerals* of number 11 and *Marine* of number 8. In this operation the actions remain feasible, not being necessary to check whether any action will be unfeasible. After the switching of actions the algorithm detects that *act Marine* has all its predecessors being executed before it and becomes feasible. The plan is now status (13, 2, 86, 0, 8, 24, 505) with 24 points army. The goal found is better than the original and the makespan is also reduced from 565 to 505. Although, reducing the makespan is not a goal yet explored in this work.

6. Experiments and Discussion of Results

The experiments were conducted on a computer intel core i7 1.6 GHz CPU with 4 GB of ram running on a windows operating system. The API Bwapi [10] allows to control Starcraft units and get information such as number of cycles and time of the game. It was used as an interface for the experiments with a human player and for performance evaluation of SA.

Table 1 contains comparison results. In the tests, we worked with different time limits for the makespan of the plans. We consider the planner as real-time because it can have smaller runtime (CPU time) than the makespan of the goals that it finds. In fact, this strategy was successfully used in the experiments, where the SA was able to find and maximize a future goal while the current goal was being executed in the game. The values that appear under the SA and the human player are the army points in the final plan of action obtained by both.

Table 1: Results of the test between SA and a human player

Time limit	Human player	SA	Makespan of SA	Runtime of SA
200 sec.	12	12	196	35 sec.
400 sec.	31	**34**	392	80 sec.
600 sec.	**52**	47	586	205 sec.
800 sec.	102	**109**	800	386 sec.
1000 sec.	141	**146**	990	555 sec.
1200 sec.	**204**	199	1189	696 sec.
1400 sec.	**241**	236	1388	812 sec.

Regarding the results SA proved to be able to compete with a human player, in some cases surpassing him. The most promising results were in the goals with medium time limit, where game tactics are not yet a determining factor for success in a direct confrontation, and production of more military resource can be crucial to the victory. The time limit imposed for the tests is high because the plans do not have their actions parallelized. This will be implemented in further work.

Table 2 shows the performance of SA. For goals with time limit medium the results are good, with 60% over 95% of

Table 2: Results of performance tests of SA

Time Limit	450 sec.	750 sec.	1050 sec.
Optimum value for army points	41	92	156
Number of runs over 95% of optimum	60%	40%	50%
Number of runs over 90% of optimum	30%	40%	40%
Average value	34	79	144
Number of Runs	10	10	10

optimal value. The best solution for plans with medium limit of time is known because many players share their rankings on the Internet informing these valuesâĂŃâĂŃ. For larger goals the results are encouraging. Although, with higher time limits (1050 sec.) the average of the results was better than with shorter (750 sec.). This happens because in larger plans is easier to validate actions due to the presence of more resources available.

The algorithm returns good results, but not always the optimal solution. This happens because in our approach, the SA was adapted to return a solution compatible with characteristics of real-time performance. StarCraft has a search space of exponential order, and SA running without the techniques that we have built could take hours to return the optimal solution.

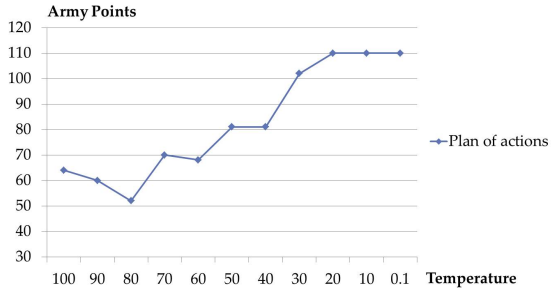

Fig. 3: Convergence of Simulated Annealing.

Figure 4 shows the convergence of the SA in a execution with time limit of 900 sec. At lower temperatures it accepts few new plans and keep those with the highest army points, a desired behavior for the SA. For this implementation the action plan given as input to the SA had 0 army points, demonstrating that even with bad entries the algorithm achieved good convergence.

7. Conclusion and Future Work

In this paper we propose the use of Simulated Annealing to maximize resource production in an RTS game. Research in this area is recent and the proposed approach is little explored by existing work. Our research is divided into two parts: The use of a sequential planner to generate one plan of action without fixed resources with time limit; and use of Simulated Annealing to maximize the resources of that plan of action by increasing the strength of its army.

Analyzing the results, the goals achieved always have an army points greater than the initial plan of action, which shows the convergence of the algorithm. The techniques developed to manage the planning contributed effectively in the quality of the results, and can be used in any domain of real-time games.

As future work we intend to explore interesting scheduling algorithms in order to reduce the makespan of the plans and achieve results with more quality. Also, We are investigating other features of StarCraft that can be used in the objective function evaluation. Based on our experience with Simulated Annealing, we also understand that other techniques such as bio-inspired algorithms may be explored.

Abstract— **The Strength Pareto Gravitational Search Algorithm (SPGSA) to solve Economic Load Dispatch (ELD) is presents this paper with various generator constraints in power systems. The ELD problem in a power system is to determine the optimal combination of power outputs for all generating units which will minimize the total fuel cost while satisfying all practical constraints. For practical generator operation, many nonlinear constraints of the generator, such as ramp rate limits, prohibited operating zone, generation limits, transmission line loss and non-smooth cost functions are all considered using the proposed technique. The proposed algorithm applied on different test standard power system. The effectiveness of the proposed method is compared with other heuristic algorithm. Results showed the efficiency of the proposed algorithm.**

Keywords: SPGSA, Economic Load Dispatch, Valve Point.

I. INTRODUCTION

The efficient and optimum economic operation of electric power systems has always occupied an important position in electric power industry. In recent decades, it is becoming very important for utilities to run their power systems with minimum cost while satisfying their customer demand all the time and trying to make profit. With limited availability of generating units and the large increase in power demand, fuel cost and supply limitation, the committed units should serve the expected load demand with the changes in fuel cost and the uncertainties in the load demand forecast in all the different time intervals in an optimal manner.

The basic objective of ELD of electric power generation is to schedule the committed generating unit outputs, so as to meet the load demand at minimum operating cost while satisfying all unit and system equality and inequality constraints [1]. The ELD problem has been tackled by many researchers in the past [2]. ELD problem involves different problems. The first is Unit Commitment or pre-dispatch problem where in it is required to select optimally out of the available generating sources to operate to meet the expected load and provide a specified margin of operating reserve over a specified period of time. The second aspect of ELD is on-line economic dispatch where in it is required to distribute the load among the generating units actually parallel with the system in such a manner as to minimize the total cost of supplying power. In case of ELD, The generations are not fixed but they are allowed to take values again within certain limits so as to meet a particular load demand with minimum fuel consumption.

The ELD problem is inherently a large-scale, nonlinear, non-convex, non continuous optimization problem. Many techniques are applied to deal with ELD problem both conventional optimization approaches [3-4] such as Linear Programming (LP) or Quadratic Programming (QP) and Artificial Intelligence (AI)-based optimization techniques such as Simulated Annealing (SA) [5], Tabu Search (TS) [6], Genetic Algorithm (GA) [7-8], hybrid TS/SA [9], Evolutionary Programming (EP) [9], and Improved Evolutionary Programming (IEP) [11] etc. Gravitational Search Algorithm (GSA), a new optimization algorithm is applied to solve the above problem. Algorithm, as mentioned earlier is a new search algorithm that has been proven efficient in solving many problems. In the case of ELD, the main use of GSA would be to obtain a solution close to the global optimum in a short period of time.

II. ELD PROBLEM

The problem of ELD has been introduced in 1960s as an extension of conventional economic dispatch to determine the optimal set of control variables while subject to various equality and inequality constraints. In conventional power flow the values of control variables are pre-specified unlike an ELD value of some control variables need to be found to optimize an objective function [2]. Hence, the ELD is one of the most important optimization strategies for power system managing and nonlinear programming problem. The ELD planning performs the optimal generation dispatch among the operating units to satisfy different constraints that change from problem to problem [12, 14]. In this paper, the ramp rate limits and prohibited operating zone are considered as practical operation constraints of generators for 6 and 15 unit systems and valve-point loading effects without transmission loss is tested to 40 unit system.

Actually, the adjustments of the power output are instantaneous that is one of the unpractical assumptions. Accordingly, generators are constrained because of ramp rate limits where, generation may increase or decrease with corresponding upper and downward ramp rate limits [12]. Therefore, the operating range of all online units is restricted by their ramp rate limits which are defines as:

- Power generation increasing

$P_i - P_i^0 \le UR_i$

- Power generation decreasing

$P_i^0 - P_i \le DR_i$

Where,
P_i: The current is output power of ith unit
P_i^0: previous output power
UR_i: The up ramp limit of the ith generator
DR_i: The down ramp limit of the ith generator

According to this fact that, the prohibited operating zones in the input/output curve of generator are due to vibration in a shaft bearing/steam valve operation it should be noted that, finding the actual prohibited zone by actual performance testing /operating records is really difficult. That leads to getting the best economy by avoiding operation in areas [12]. Therefore, adjustment of the generation output of a unit must avoid operation in the prohibited zones. For this purpose, the feasible operating zones of generators are described as:

$$A_{ai} = \begin{vmatrix} P_i^{\min} \le P_i \le P_{i,1}^l \\ P_{i,j-1}^u \le P_i \le P_{i,j}^l,\ j = 2,3,...,n_i,\ i = 1,...,m \\ P_{i,ni}^u \le P_i \le P_i^{\max} \end{vmatrix} \quad (1)$$

Where, A_{ai}= Feasible operating zones of i^{th} unit

Due to minimizing fuel cost is the primary concern of operation planning; the objective of ELD problem in this study is to minimizing total generator fuel cost. That can be expressed as:

$$F_t = \sum_{i=1}^{m} F_i(P_i) \quad (2)$$

Where, $F_i(P_i) = \sum_{i=1}^{m} (a_i P_i^2 + b_i P_i + c_i), i = 1,...,m$

For the mentioned equation, the F_t is the total generation cost and F_i is the cost function of the i^{th} generator. a_i, bi and c_i present the cost coefficients in i^{th} generator. Also the electrical output of the i^{th} generator is shown by P_i and m is the number of generators committed to the operating system. This constrained ELD problem is subjected to a variety of constraints depending upon assumptions and practical implications [12, 14]. These constraints are discussed as follows. Constrained conditions are:

A. Power Balance

This constraint is based on the principle of equilibrium between total system generation ($\sum_{i=1}^{m} P_i$) and total system loads (P_D) and losses (P_L) that is

$$\sum_{i=1}^{m} P_i = P_D + P_L, i = 1,...,m \quad (3)$$

P_L: Obtained using B-coefficients, given by:

$$P_L = \sum_{i=1}^{m}\sum_{j=1}^{m} P_i B_{ij} P_j + \sum_{i=1}^{m} B_{0i} P_i + B_{00} \quad (4)$$

B. Generator Operation Constraints

$$P_i^{\min} \le P_i \le P_i^{\max} \max(P_i^{\min}, P_i^0 - DR_i) \le P_i \le \min(P_i^{\max}, P_i^0 + UR_i) P_i \in A_{ai} \quad (5)$$

Where, P_i^{min} and P_i^{max} are lower and upper bounds for power outputs of the i_{th} generating unit.

C. Line Flow Constraints

$$\left|P_{Lf,k}\right| \le P_{Lf,k}^{\max}, k = 1,...,L \quad (6)$$

Where, $P_{Lf,k}$ is the real power flow of line k; $P_{Lf,k}^{max}$ is the power flow up limit of line k and L is the number of transmission lines.

III. GRAVITATIONAL SEARCH ALGORITHM

A. GSA Review

The Gravitational Search Algorithm (GSA) is constructed based on the law of gravity and the notion of mass interactions. GSA is one of the newest heuristic algorithms which have been inspired by the Newtonian laws of gravity and motion. In GSA a set of agents called masses are introduced to find the optimum solution by simulation of Newtonian laws of gravity and motion [15].

Also, each mass agent has four specifications: position, inertia mass, active gravitational mass, and passive gravitational mass. The position of the mass corresponds to a solution of the problem, and its gravitational and inertial masses are determined using a fitness function. In other words, each mass presents a solution, and the algorithm is navigated by properly adjusting the gravitational and inertia masses. By lapse of time, we expect that masses be attracted by the heaviest mass. This mass will present an optimum solution in the search space [16].

The GSA could be considered as an isolated system of masses. It is like a small artificial world of masses obeying the Newtonian laws of gravitation and motion. More precisely, masses obey the following laws:

- Law of gravity: Each particle attracts every other particle and the gravitational force between two particles is directly proportional to the product of their masses and inversely proportional to the distance between them, R.
- Law of motion: The current velocity of any mass is equal to the sum of the fraction of its previous velocity and the variation in the velocity. Variation in the velocity or acceleration of any mass is equal to the force acted on the system divided by mass of inertia.

To describe the GSA consider a system with s masses in which position of the ith mass is defined as:

$$X_i = (x_i^1, ..., x_i^d, ..., x_i^n), i = 1,2,..., s \quad (7)$$

Where, x_i^d is position of the ith mass in the dth dimension and n is the dimension of the search space. According to [19] mass of each agent is computed after calculating current population's fitness as:

$$M_i(t) = \frac{q_i(t)}{\sum_{j=1}^{s} q_i(t)} \quad (8)$$

Where, Mi(t) is the mass value of the agent i at t.

$$q_i(t) = \frac{fit_i(t) - worst(t)}{best(t) - worst(t)} \quad (9)$$

Where, $fit_i(t)$ is the fitness value of the agent i at t, and worst (t) and best (t) are defined as follows for the minimization problem:

$$best(t) = \underset{j\in\{1,...,s\}}{Min}\ fit_i(t), \quad worst(t) = \underset{j\in\{1,...,s\}}{Max}\ fit_i(t)$$

To compute acceleration of an agent, total forces from a set of heavier masses that apply on it should be considered based on the law of gravity, which is followed by calculation of agent acceleration using the law of motion. Afterwards, next velocity of an agent is calculated as a fraction of its current velocity added to its acceleration. Then, its next position can be calculated using:

$$F_i^d(t) = \sum_{j\in kbest,\, j\neq i} rand_i G(t) \frac{M_j(t) M_i(t)}{R_{ij}(t) + \varepsilon} (x_j^d(t) - x_i^d(t))$$

$$a_i^d(t) = \frac{F_i^d(t)}{M_i(t)} = \sum_{j\in kbest,\, j\neq i} rand_j G(t) \frac{M_j(t)}{R_{ij}(t) + \varepsilon} (x_j^d(t) - x_i^d(t))$$

$$V_i^d(t+1) = rand_i \times v_i^d(t) + a_i^d(t) \quad (10)$$

$$x_i^d(t+1) = x_i^d(t) + v_i^d(t+1)$$

Where, $rand_i$ and $rand_j$ are two uniformly distributed random numbers in the interval [0, 1], ε is a small value, $R_{ij}(t)$ is the Euclidean distance between two agents i and j, defined as $R_{ij}(t)=\|X_i(t), X_j(t)\|_2$, kbest is the set of first K agents with the best fitness value and biggest mass, which is a function of time, initialized to K_0 at the beginning and decreasing with time. Here K_0 is set to s (total number of agents) and is decreased linearly to 1.

In GSA, the gravitational constant, G, will take an initial value, G_0, and it will be reduced with time:

$$G(t) = G(G_0, t) \quad (11)$$

Also some differences and advantages of this technique are consisting of [16]:

- In GSA, the agent direction is calculated based on the overall force obtained by all other agents.
- In GSA the force is proportional to fitness value and so agents see the search space around themselves in the influence of force.
- GSA is memory-less and only current position of the agents plays a role in the updating procedure.
- In GSA the force is inversely proportional to the distance between solutions.

Fig. 1 shows the flowchart of the proposed intelligent algorithm.

B. SPGSA

If we plot the objective values f1 and f2 of these optimal solutions against each other in one plot. A multi-objective optimization algorithm tries to approximate

these solutions but uses a different approach to obtain these solutions. The supposed algorithm sorts the population based on non-dominated fronts. The first front found is ranked the highest and the last one the lowest. This ranking is used in the mating flight selection process. In addition to, for assure diversity in a population (honey bee) employed crowding distance measure.

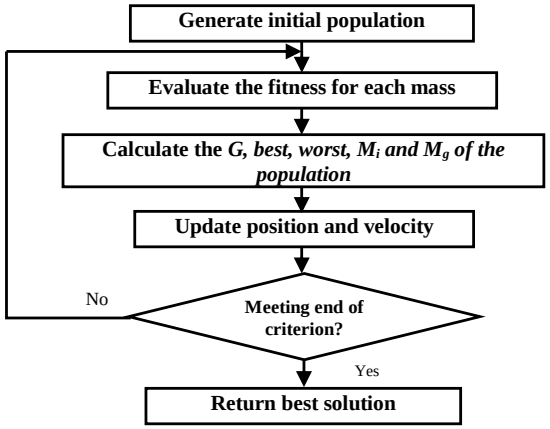

Figure 1. Flowchart of GSA

The main steps of the SPO algorithm are explained in more detail as follows:

C. Non-Dominated sort

This set of non-dominated solutions is called a Pareto front. A multi-objective algorithm selects and improves solutions based on this domination principle to approximate the real trade-off curve. Non-domination occurs when a candidate cannot be improved any further in one objective while degrading in another objective. Figure 2 explains this in more detail. The figure shows that crowding distance for solution y(x4) is calculated relative to the solutions from the same front which are all colored blue. The distance is the sum of the length and width of a cubical that can be drawn through these two closest neighbours.

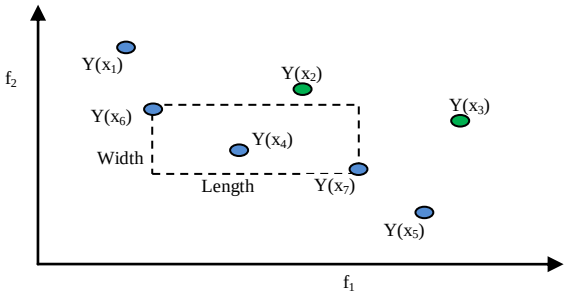

Figure 2. Crowding distance measure

D. Crowding Distance

The population density around a particular solution i is estimated by the average distance of the two solutions at either side of i along each of the objectives. Crowding distance is assigned front wise and comparing the crowding distance between two individuals in different front is meaningless.

IV. Simulation and Results

The different methods discussed earlier are applied to two cases to find out the minimum cost for any demand. In this part the three test systems as: IEEE 6-generator 30-bus, IEEE 14-generator 118-bus IEEE with transmission loss, 15 unit system with prohibited operating zones and ramp rate limits and 40 unit system is tested with valve-point loading effects without transmission loss.

A. Case I. IEEE 30-bus system

In the first case study, the IEEE 30-bus system with six generators and forty one lines is used. The system configuration of the proposed case study is shown in Fig. 3 and the system data can be found in [6,15].

The values of the fuel and emission coefficients of the IEEE 30-bus system are illustrated in Table 1. The line data and bus data of the system are referenced in [1]. The load of the IEEE 30-bus system was set to 2.834 pu on a 100MVA base. In order to demonstrate the effectiveness of the proposed approach on the IEEE 6-generator 30-bus test system. All constraints about emission, fuel cost and system loss are considered. For show efficiency and ability of supposed algorithm in EED problem, used index mismatch power as follows:

$$\text{mismatch power} = \sum_{i=1}^{N_g} P_i(G_i) - P_d$$

Where, P(G) is the power output and Pd is the total power demand.

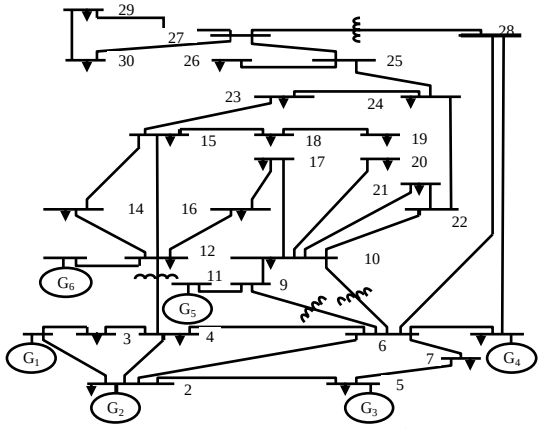

Figure 3. The IEEE 30-bus system configuration.

Results of proposed SPGSA algorithm are compared with the MOPSO [17] and MODE [14], which have been implemented and applied to the EED problem with impressive success. The results of simulation are given in Table 2. The distribution of the non-dominated solutions in Pareto optimal front using the proposed SPGSA is

represented in Fig. 4, which clearly shows the relationships among fuel cost, emission, and transmission loss.

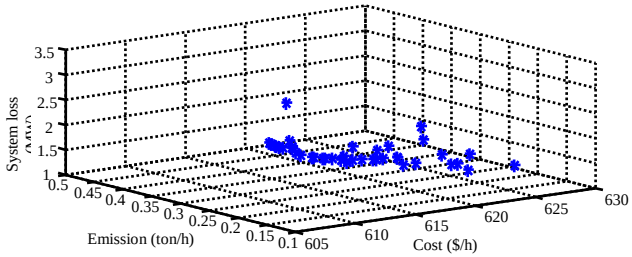

Figure 4. Three-dimensional Pareto front of SPGSA algorithm for IEEE 30-bus system

A. Case II. 15 Unit Systems

The information of 15 unit system is presented in [18]. The load demand of the system is 2630 MW. The loss coefficients matrix is shown in [19]. Also Table 3, shows the numerical results of this case study in comparison with other techniques.

B. Case II. 15 Unit Systems

The information of 15 unit system is presented in [20]. The load demand of the system is 2630 MW. The loss coefficients matrix is shown in [19]. The feasibility of the proposed method has been compared in terms of solution quality and computation efficiency with PSO [20], Hybrid GAPSO [13], IPSO [20], SOH-PSO [12]. Also convergence characteristic for this case study is shown in Fig.5.

V. CONCLUSION

The ELD problems are the important problems in the electric power system operation. In this paper, the ELD problem has been solved considering transmission losses, valve point effects and environmental pollution. The problem has been formulated by the modified form of constraint method. The ELD problem is converted into an optimization problem which is solved by the SPGSA technique with competing objectives of fuel cost, environmental pollution (emission) and loss transmission. Numerical results for some test system have been presented to demonstrate the performance, found to converge to optimum in a faster rate and applicability of the proposed method. The proposed algorithm applied to three standard IEEE systems to show advantages of proposed algorithm in EED problem, 30-bus 6-generator IEEE test system, 15 units system and 40 units system with valve point effects. The convergence speed of this algorithm is higher than other heuristics algorithms such as NSGA, MODE, MOPSO, etc and thus the high precision and efficiency are achieved.

BIOGRAPHIES

Heidarali Shayanfar received the B.S. and M.S.E. degrees in Electrical Engineering in 1973 and 1979, respectively. He received his Ph. D. degree in Electrical Engineering from Michigan State University, U.S.A., in 1981. Currently, he is a Full Professor in Electrical Engineering Department of Iran University of Science and Technology, Tehran, Iran. His research interests are in the Application of Artificial Intelligence to Power System Control Design, Dynamic Load Modeling, Power System Observability Studies, Voltage Collapse, Congestion Management in a Restructured Power System, Reliability Improvement in Distribution Systems and Reactive Pricing in Deregulated Power Systems. He has published more than 405 technical papers in the International Journals and Conferences proceedings. He is a member of Iranian Association of Electrical and Electronic Engineers and IEEE.

Ali Ghasemi received the B.Sc. and M.Sc. (Honors with first class) degree in Electrical Engineering from Isfahan University of Technology (IUT), Esfahan, Iran in 2009 and Technical Eng. Department of the University of Mohaghegh Ardabili (UMA), Ardabil, Iran in 2011. His Areas of interest in Research are power system control and operation, adaptive and robust control of power systems, operation and Planning and Power System Restructuring and applications of heuristic techniques in power systems.

Nima Amjady (SM'10) was born in Tehran, Iran, on February 24, 1971. He received the B.Sc., M.Sc., and Ph.D. degrees in electrical engineering from Sharif University of Technology, Tehran, Iran, in 1992, 1994, and 1997, respectively. At present, he is a Professor with the Electrical Engineering Department, Semnan University, Semnan, Iran. He is also a Consultant with the National Dispatching Department of Iran. His research interests include security assessment of power systems, reliability of power networks, load and price forecasting, and artificial intelligence and its applications to the problems of power systems.

Oveis Abedinia received the B.S. and M.Sc. degrees in Electrical Engineering from Azad University, Ardabil and Science and Technology Research Branch, Tehran, Iran in 2005 and 2009, respectively. Currently, he is a Ph. D. student in Electrical Eng. Department, Semnan University, Semnan, Iran. His areas of interest in research are Application of Artificial Intelligence to Power System and Control Design, Load and Price Forecasting, Distribution Generation, Restructuring in Power Systems, Congestion Management, Optimization.

The Exploration of Greedy Hill-climbing Search in Markov Equivalence Class Space

Abstract - *The greedy Hill-climbing search in the Markov Equivalence Class space (E-space) can overcome the drawback of falling into local maximum in Directed Acyclic Graph space (DAG space) caused by the score equivalent property of Bayesian scoring function, and one representative algorithm is Greedy Equivalence Search algorithm (GES algorithm) which is inclusion optimal in the large sample size, but not parameter optimal. In fact GES algorithm does not comply with the inclusion boundary condition which is a guarantee of gaining the highest score, but the unrestricted form of GES algorithm (UGES algorithm) complies with the inclusion boundary condition approximately. However, the greedy Hill-climbing search both in the DAG space and in the E-space has the drawback of time-consuming. The idea of confining the search using the constraint-based method is a good solution for the time-consuming drawback. This paper conducts experiments to compare the effects of greedy Hill-climbing search algorithm in DAG space (GS algorithm), GES algorithm and UGES algorithm both without the restriction of the parents and children sets and with the restriction of parents and children sets, and finds that GS/GES/UGES with the restriction have achieved improvement in time-efficiency and structure difference, with a little reduction in Bayesian scoring function.*

Keywords: Inclusion Boundary Condition, GES algorithm, UGES algorithm, MMHC algorithm, local discovery algorithms

1 Introduction

In the field of Bayesian network (BN), BN structure learning is a research hotspot. There are two main categories of BN structure learning algorithms, namely the constraint-based method and the search-and-score method. The constraint-based method[1][2] firstly uses the conditional independence (CI) test to determine the skeleton of the BN structure, and then directs the skeleton using the directional rules. The CI test has several forms, like Pearson's chi2 test, G2 likelihood ratio test, and mutual information.

The search-and-score method includes two typical algorithms, namely K2 algorithm[3] and greedy Hill-climbing algorithm. The K2 algorithm finds parent nodes for each node from the nodes before the node according to the initial node sequence, and builds the Bayesian network structure gradually. The initial node sequence can be determined by the method mentioned in paper [4], namely building the maximum weight spanning tree (MWST) using mutual information, and then using the topological order of the oriented MWST as the initial node sequence.

The greedy Hill-climbing algorithm in the DAG space (GS algorithm) takes an initial graph, defines a neighborhood, computes a score for every graph in this neighborhood, and chooses the one which maximizes the score for the next iteration, until the scoring function between two consecutive iterations does not improve. And the neighborhood is defined as the set of graphs that differ only with one insertion, one reversion, and one deletion from our current graph. The initial graph can be chosen as the oriented MWST. The GS algorithm has several drawbacks. Firstly, according to the score equivalent property of Bayesian scoring function, the directed acyclic graphs in the same equivalence class have the same score value. So if the two adjacent iterations are within the same equivalence class, the GS algorithm will fall into local maximum. Secondly, if we use random selection to break ties when we encounter more than one graph owning the highest score in the neighborhood, the finally learnt BN structures are more fluctuating when the GS algorithm runs multiple times. Thirdly, the GS algorithm is much more time-consuming, as the number of variables grows.

The greedy Hill-climbing search in the Markov Equivalence Class space can overcome the drawback of falling into local maximum caused by the score equivalent property of Bayesian scoring function, and can improve the volatility of the finally learnt BN structures. One state of the art algorithm of the greedy Hill-climbing search in the E-space is the GES algorithm[5]. GES algorithm starts from the empty graph, firstly adds edges until the scoring value reaches a local maximum, then deletes edges until the scoring value reaches another local maximum, and finally returns that equivalence class as the solution. In paper [6], it has been proved that in the limit of large sample sizes, the GES algorithm identifies an inclusion-optimal equivalence class of DAG models. However, GES may not be able to identify a parameter-optimal model even in the limit of large sample size, namely the parameters of the finally identified model are not the fewest among all the BNs that include the distribution. Then according to the consistent property of Bayesian scoring function, the score of the finally identified equivalence class in the GES algorithm is not the highest.

The paper [7] defines the Inclusion Boundary Condition based on the Inclusion Order provided by Meek's conjecture, and the paper [8] proves that the

hill-climbing algorithm using the penalized score function and a traversal operator satisfying the Inclusion Boundary Condition always finds the faithful model which has the highest score. In fact, the GES algorithm does not comply with the Inclusion Boundary Condition and does not get the guarantee of gaining the highest score. The UGES algorithm considers both the edge addition and the edge deletion at each step, and complies with the Inclusion Boundary Condition approximately. It is an unrestricted form of the GES algorithm and may get higher score than the GES algorithm. Both the GES algorithm and the UGES algorithm have the drawback of time-consuming.

About the drawback of time-consuming, some algorithms improve this drawback by restricting the maximum number of parents allowed for every node in the network, like the Sparse Candidate algorithm[9][10]. But it is not a sound solution. Firstly it is hard to set the value of the maximum number of parents, and secondly this parameter imposes a uniform constraint for each node in the network. If we use the constraint-based method to find the set of parents and children for each node, and restrict the greedy search within the parents and children set of each node, it will not encounter such two problems. The Max-Min Hill-climbing algorithm (MMHC algorithm)[11] is one such BN structure learning algorithm. It firstly uses the Max-Min Parents and Children algorithm (MMPC algorithm)[12] to find the set of parents and children for each node, and then applies the GS algorithm within the parents and children set of each node. It is shown that the MMHC algorithm results in computational savings and performs better than many existing algorithms.

This paper intends to conduct experiments to compare the GES algorithm and the UGES algorithm from the aspects of Bayesian score, Structural Hamming Distance (SHD)[11] and number of calls to scoring function, with the GS algorithm as a reference. Besides, we intend to use the parents and children sets learnt by the MMPC algorithm to restrict the GES algorithm and the UGES algorithm to improve the time-efficiency of these two algorithms, and conduct experiments to compare the performances of the GES algorithm and the UGES algorithm under the restriction of parents and children sets, with the MMHC algorithm (MMPC+GS) as a reference. We use the data sampled from the Alarm network[13] to conduct experiments. We implement the experiments in Matlab environment with the Bayes Net toolbox[14], the BNT Structure Learning package[15], and the Causal Explorer package[16].

This paper is structured as follows. Section 2 analyzes the GES algorithm and the UGES algorithm using the knowledge of E-space, scoring function, and Inclusion Boundary Condition. Then Section 3 introduces the local discovery algorithm MMPC and the combination of MMPC with GES algorithm and UGES algorithm. Experimental results and analysis are showed in Section 4. Finally, Section 5 presents some conclusions.

2 The greedy Hill-climbing search in the Markov Equivalence Class space

2.1. The Markov Equivalence Class space and the scoring function

The Markov Equivalence Class space (E-space) is divided into Markov equivalence classes. The DAGs in the same Markov equivalence class are equivalent.

Theorem 1 Two DAGs are equivalent if and only if they have the same skeletons and the same v-structures[17].

The skeleton of any DAG is the undirected graph resulting from ignoring the directionality of every edge. A v-structure in DAG G is an ordered triple of nodes (X, Y, Z) such that (1) G contains the edges X->Y and Z->Y, and (2) X and Z are not adjacent in G.

The equivalence classes of DAGs are represented with completed partially DAGs (CPDAGs). The CPDAG is a graph that contains both directed and undirected edges. The directed edges represent the compelled edges and the undirected edges represent the reversible edges. The compelled edge is the edge that has the same orientation for every member of the equivalence class. The reversible edge is the edge that is not compelled.

In a CPDAG or PDAG, a pair of nodes is neighbor if they are connected by an undirected edge, and they are adjacent if they are connected by either an undirected edge or a directed edge.

The DAGs in the same equivalence class gain the same score if the scoring function owns the property of score equivalence. In fact, the scoring function may own three properties:

Property 1 The scoring function is decomposable if it can be written as a sum of measures, each of which is a function only of one node and its parents.

Property 2 The scoring function is score equivalent if the DAGs in the same equivalence class gain the same score.

Property 3 The scoring function is consistent if in the large sample size, the following conditions hold: (1) If H contains the distribution and G does not contain the distribution, then the score of H is larger than the score of G; (2) If H and G both contain the distribution, and H contains fewer parameters than G, then the score of H is larger than the score of G.

Bayesian Dirichlet (BD) scoring function is one of the commonly used scoring functions. BDe scoring function is the BD scoring function which satisfies the score equivalent property. And the BDeu scoring function is the BDe scoring function whose parameter prior has uniform mean. The form of the BDeu scoring function is as follows:

$$p(G,D|\xi)=\log p(G|\xi)\cdot\prod_{i=1}^{n}\prod_{j=1}^{q_i}\frac{\Gamma(N_{ij}^{'})}{\Gamma(N_{ij}^{'}+N_{ij})}\cdot\prod_{k=1}^{r_i}\frac{\Gamma(N_{ijk}^{'}+N_{ijk})}{\Gamma(N_{ijk}^{'})} \quad (1)$$

Where $N_{ijk}^{'}=\frac{N^{'}}{r_i\cdot q_i}$, q_i denotes the number of configurations of the parent set $\pi(x_i)$, r_i denotes the

number of states of variable x_i, N_{ijk} is the number of records in dataset D for which $x_i=k$ and $\pi(x_i)$ is in the j^{th} configuration, and $N_{ij}=\Sigma_k N_{ijk}$. $\Gamma(\cdot)$ is the *Gamma* function, which satisfies $\Gamma(y+1)=y\Gamma(y)$ and $\Gamma(1)=1$.

The components N'_{ijk} and $p(G|\xi)$ specify the prior knowledge. In BDeu scoring function, the parameter prior $N'_{ijk}=\frac{N'}{r_i \cdot q_i}$ is set as uniform joint distribution, N' is the equivalent sample size, and N' is usually set to ten in most experiments. $p(G|\xi)$ is the network structure prior, the assessment of $p(G|\xi)$ is discussed in paper [18] in detail, and we set the network structure prior $p(G|\xi)$ as one in this paper. From Eq. (1), we can find that the BDeu scoring function is decomposable. Besides, the paper [18] shows that the BDeu scoring function is score equivalent, and the paper [5] shows that it is consistent. So the BDeu scoring function satisfies the three properties of the scoring function mentioned above.

2.2. Greedy Equivalent Search algorithm

The Greedy Equivalent Search algorithm (GES algorithm) starts from the empty graph, firstly adds edges until the scoring value reaches a local maximum, then deletes edges until the scoring value reaches another local maximum, and finally returns that equivalence class as the solution. The GES algorithm searches through the E-space and the equivalence classes in the E-space are represented with CPDAGs. The paper [5] proves Meek's conjecture, and shows that the local maximum reached in the first phase of the algorithm contains the generative distribution and the final equivalence class that results from the GES algorithm is asymptotically a perfect map of the generative distribution.

There are two kinds of operators which are used to construct the neighborhood in GES algorithm, namely the Insert operator in the first phase and the Delete operator in the second phase. In order to compute the scores of the PDAGs in the neighborhood after applying the operators, it needs to convert the PDAG to DAG, and the paper [19] gives a simple implementation of the algorithm PDAG-To-DAG. Besides, the GES algorithm needs the algorithm DAG-To-CPDAG[20] to convert the finally chosen DAG to CPDAG to make the greedy search continue. The two kinds of operators are listed as follows.

Definition 1 $Insert(X,Y,\mathrm{T})$ [5]

For non-adjacent nodes X and Y in the CPDAG P^c, and for any subset T of the neighbors of Y that are not adjacent to X, the $Insert(X,Y,\mathrm{T})$ operator modifies P^c by (1) inserting the directed edge $X \to Y$, and (2) for each $T \in \mathrm{T}$, directing the previously undirected edge between T and Y as $T \to Y$.

Definition 2 $Delete(X, Y, \mathrm{H})$ [5]

For adjacent nodes X and Y in the CPDAG P^c connected either as $X-Y$ or $X \to Y$, and for any subset H of the neighbors of Y that are adjacent to X, the $Delete(X, Y, \mathrm{H})$ operator modifies P^c by deleting the edge between X and Y, and for each $H \in \mathrm{H}$, (1) directing the previously undirected edge between Y and H as $Y \to H$ and (2) directing any previously undirected edge between X and H as $X \to H$.

These two operators need to satisfy the validity conditions, so that the PDAG P^{c^*} resulting from applying the operators will admit a consistent extension. If a DAG G has the same skeleton and the same set of v-structures as a PDAG P and if every directed edge in P has the same orientation in G, we say that G is a consistent extension of P. If there is at least one consistent extension of a PDAG P, we say that P admits a consistent extension. If the PDAG P^{c^*} resulting from applying the operators admits a consistent extension, it will be converted to a DAG by the algorithm PDAG-To-DAG. Otherwise, the algorithm PDAG-To-DAG will give an error during the conversion of the PDAG P^{c^*}.

The validity conditions all include the problem of judging clique. A clique in a DAG or a PDAG is a set of nodes for which every pair of nodes is adjacent. And directing the edges of the clique will not create new v-structure. About the implementation of judging clique, there are two methods. One is firstly finding all the maximal cliques of the graph, and then checking that whether the node set is a subset of any maximal clique found in the first phase. However, the general problem of finding optimal triangulations for undirected graphs in the process of finding all the maximal cliques of the graph is NP-hard[21], so heuristic algorithms[22][23] are developed, which are time-consuming. The other method of judging clique is a direct form used in the algorithm PDAG-To-DAG which is more time-efficient. For every vertex y, adjacent to x, with (x, y) undirected, if y is adjacent to all the other vertices which are adjacent to x, then x and all the vertices adjacent to x form a clique. This paper takes the second method of judging clique.

From the Profile file of the GES algorithm, we find that the GES algorithm is a time-consuming algorithm, and most of the running time is consumed in the calculation of the scores of the neighborhood and the conversion from PDAG to DAG. Since the size of the neighborhood is exponential in the number of adjacencies for a node, one paper [25] proposes changing exhaustive search by greedy search which is linear, to improve the time-efficiency of the GES algorithm. This paper intends to improve the time-efficiency of the GES algorithm by finding the parents and children set for each node using the constraint-based method and confining the GES within the parents and children set of each node.

The paper [6] proves that in the limit of large sample sizes, the GES algorithm identifies an inclusion-optimal equivalence class of DAG models, but GES may not be able to identify a parameter-optimal model. The parameter-optimal model is the model which includes the distribution with the fewest parameters. So the parameters of the final model identified by the GES algorithm may be not the fewest among all the BNs that include the distribution. Then according to the consistent property of the BDeu scoring function, the score of the finally identified equivalence class in the GES algorithm

is not the highest. This paper investigates the conditions of recovering the right structure, and intends to combine the conditions with the GES algorithm to improve the score of the GES algorithm.

2.3. Inclusion Boundary Condition

Inclusion Boundary Condition is one of the conditions that will guarantee the achievement of the highest score of the hill-climbing algorithm. It is based on the theory of Inclusion Order.

A graphical Markov model (GMM) $M(G)$ is the family of probability distributions that are Markov over G. A probability distribution P is Markov over a graph G if and only if every CI restriction encoded in G is satisfied by P. The intuition behind the Inclusion Order is that one GMM $M(G)$ precedes another GMM $M(G')$ if and only if all the CI restrictions encoded in G are also encoded in G'. Meek has provided an Inclusion Order in Meek's conjecture and Chickering has proved Meek's conjecture.

Conjecture 1 Meek's conjecture[24]

Let $D(G)$ and $D(G')$ be two Bayesian Networks determined by two DAGs G and G'. The conditional independence model induced by $D(G)$ is included in the one induced by $D(G')$, *i.e.* $D^I(G) \subseteq D^I(G')$, if and only if there exists a sequence of DAGs $L_1,\ldots,L_n$ such that $G=L_1$, $G'=L_n$ and the DAG L_{i+1} is obtained from L_i by applying either the operation of covered arc reversal or the operation of arc removal for $i=1,\ldots,n$.

The paper [7] defines the Inclusion Boundary $IB(G)$, and intuitively, the Inclusion Boundary of a given GMM $M(G)$ consists of those GMMs $M(G_i)$ that induce a set of CI restrictions $M^I(G_i)$ which immediately follow or precede $M^I(G)$ under the Inclusion Order. Then based on the definition of Inclusion Boundary, the paper [7] gives the definition of Inclusion Boundary Condition and the paper [8] gives the theorem which proves the correctness of the hill-climbing algorithm under the faithfulness and unbounded data assumptions.

Definition 3 Inclusion Boundary Condition[7]

A learning algorithm for GMMs satisfies the Inclusion Boundary Condition if for every GMM determined by a graph G, the traversal operator creates neighborhood $N(G)$ such that $N(G) \supseteq IB(G)$.

Theorem 2 The hill-climbing algorithm using the scoring function and a traversal operator satisfying the Inclusion Boundary Condition always finds the faithful model which has the highest score[8].

Based on the Inclusion Order defined by Meek's conjecture, the neighborhood created by the operators of one arc addition or one arc removal in the E-space, namely the ENR neighborhood, satisfies the Inclusion Boundary Condition. And the neighborhood created by the operators of one arc addition, one arc removal or one arc reversal in the DAG space does not satisfy the Inclusion Boundary Condition, which is the neighborhood formed in the GS algorithm.

The paper [8] gives an approximation neighborhood of the ENR neighborhood in the DAG space. But when we use the CPDAG to represent the equivalence class in the E-space, we can implement the operators of producing the ENR neighborhood directly on the CPDAG. However, in the GES algorithm, the neighborhoods formed both in the first phase and in the second phase do not contain the Inclusion Boundary defined by Meek's conjecture. So the GES algorithm does not satisfy the Inclusion Boundary Condition, the score of the BN structure identified by the GES algorithm is not the highest, and the final score of the GES algorithm still has room for improvement. This is consistent with the conclusion that the BN structure identified by the GES algorithm may be not parameter-optimal.

2.4. Unrestricted GES algorithm

GES algorithm uses the operator $Insert(X,Y,T)$ to produce the neighborhoods in the first phase and uses the operator $Delete(X,Y,H)$ to produce the neighborhoods in the second phase. The unrestricted GES algorithm (UGES algorithm) uses both the operator $Insert(X,Y,T)$ and the operator $Delete(X,Y,H)$ to produce the neighborhoods in each iteration. The neighborhood formed in the UGES algorithm asymptotically satisfies the Inclusion Boundary Condition. Therefore, we can predict that the score of the BN structure identified by the UGES algorithm is higher than the score of the BN structure identified by the GES algorithm. But the size of the neighborhood in the UGES algorithm is larger than that in the GES algorithm, so the UGES algorithm may be more time-consuming than the GES algorithm. In this paper, we conduct experiments to compare the UGES algorithm with the GES algorithm from both the aspect of algorithm time-efficiency and the aspect of structure identification quality.

3 Algorithm Improvement

Both the GES algorithm and the UGES algorithm have the drawback of time-consuming. Most of the running time is spent in the conversion from PDAG to DAG and the computation of the scoring function. This part of time has relation with the size of the neighborhood formed in the GES algorithm and the UGES algorithm. We can find the parents and children set for each node using the constraint-based method, and confine the GES algorithm and the UGES algorithm within the parents and children set of each node to reduce the size of the neighborhood and thus improve the time-consuming drawback of the GES algorithm and the UGES algorithm.

3.1. Max-Min Parents and Children algorithm

The Max-Min Parents and Children algorithm (MMPC algorithm) is the first local learning algorithm for discovering the parents and children sets of nodes. The MMPC algorithm discovers the parents and children set using a two-phase scheme. In phase I, the forward phase, variables enter sequentially a candidate parents and children set, by use of a heuristic function. In phase II, the backward phase, it removes all false positives that

entered in the first phase. In the end, the candidate parents and children set is the parents and children set.

In the backward phase, the MMPC algorithm relies on the result of the CI test to remove the false positive. The kind of CI test that the MMPC algorithm uses in the backward phase is G2 likelihood ratio test. In the forward phase, the MMPC algorithm needs to measure the strength of association between a pair of variables. The MMPC algorithm uses the negative $p-$ value returned by the G2 likelihood ratio test as the measure of association.

3.2. The combination of the GES/UGES algorithm with the MMPC algorithm

There are already papers describing the combination of the MMPC algorithm with the GS algorithm, namely the Max-Min Hill-climbing algorithm (MMHC algorithm), and the experiments show that the MMHC algorithm is a promising new algorithm that outperforms all other comparison algorithms, like the GS algorithm, the GES algorithm and the BNPC algorithm[2], in the aspects of running time, number of statistical calls, Bayesian score and Structural Hamming Distance (SHD).

This paper intends to combine the GES algorithm with the MMPC algorithm (MMPC-GES algorithm) and combine the UGES algorithm with the MMPC algorithm (MMPC-UGES algorithm). The specific implementation of the combination of the GES/UGES algorithm with the MMPC algorithm is that when the GES/UGES algorithm uses the operator $Insert(X,Y,\mathrm{T})$ to produce the neighborhood, X should be in the parents and children set of Y. We conduct experiments to compare the MMPC-GES algorithm and the MMPC-UGES algorithm with the GS/GES/UGES algorithm without the restriction of the parents and children sets, as well as the MMHC algorithm, and find some useful conclusions.

4 Experimental results and analysis

This paper uses the datasets sampled from the ALARM network[13] to conduct comparison experiments. The ALARM network stands for a medical diagnostic system of patient monitoring. It contains 37 variables and 46 edges. Each variable has two to four possible values. The max indegree is four and the max outdegree is five. The max and min of the size of the parents and children set is six and one. We randomly sampled 10 training datasets for each of the three different sample sizes 500, 1000, and 5000. Each reported statistic is the average over the 10 runs of an algorithm on the 10 different datasets of certain sample size.

This paper chooses three metrics to measure the quality of structure identification and the time-efficiency of the algorithms, namely Bayesian score, Structural Hamming Distance (SHD), and number of calls to the scoring function.

We use the BDeu scoring function to calculate the score, with the equivalent sample size of ten and the network structure prior of one. The BDeu score is the bigger the better. SHD is the sum of missing edges, extra edges, and reversed edges including edges that are undirected in one graph and directed in the other, between two PDAGs. SHD does not penalize for structural differences that cannot be statistically distinguished, so it is defined on PDAGs instead of DAGs. The SHD is the smaller the better.

Since the running time has relation with the configuration of computer, the usage of CPU and so on, this paper does not use this metric to measure the time-efficiency of the algorithms and uses number of calls to scoring function during the greedy search to measure the time-efficiency of the algorithms which is in proportion to the running time.

4.1. BDeu score results

We randomly sample one testing dataset containing 5000 cases for each of the training dataset. And the BDeu score is the average over the 10 runs of an algorithm on the 10 different testing datasets of certain sample size. Besides, we calculate the score of the true ALARM network by the same way. The results of the average BDeu score of three different sample sizes are in Table 1.

From Table 1, we can find several useful rules. Firstly, with the increase of the sample size, the BDeu score of the identified BN becomes higher. Secondly, the GES algorithm and the UGES algorithm in the E-space, achieve higher BDeu score than the GS algorithm in the DAG space, since the greedy search in the E-space improves the drawback of falling into local maximum caused by the score equivalent property of BDeu scoring function in the DAG space. Thirdly, the UGES algorithm achieves slightly higher BDeu score than the GES algorithm, since the UGES algorithm satisfies the Inclusion Boundary Condition asymptotically but the GES algorithm does not satisfy the Inclusion Boundary Condition. Fourthly, when the GS/GES/UGES algorithms are restricted by the parents and children sets produced by the MMPC algorithm, however the MMPC-GES algorithm performs the worst in BDeu score among the three algorithms MMHC, MMPC-GES and MMPC-UGES. Maybe the performance of MMPC-GES is reduced greatly by its strict two-phase search strategy. The MMPC-UGES algorithm in E-space still outperforms the MMHC algorithm in DAG space in BDeu score.

Fifthly, in all, GS/GES/UGES with the restriction of MMPC achieve lower BDeu score than GS/GES/UGES without the restriction, namely the BDeu score of GS/GES/UGES is reduced by the restriction of parents and children sets. Especially we find that the BDeu score of the MMHC algorithm is lower than that of the GS algorithm, and the BDeu score of the GS algorithm doesn't outperform the BDeu score of the true ALARM network, which doesn't show signs of overfitting. We need to remember that the parents and children sets identified by the MMPC algorithm may be not the exact parents and children sets of the true network and have relation with the quality of dataset.

Table 1: Average BDeu Score Results.

Sample size	True Alarm	GS	GES	UGES	MMHC	MMPC-GES	MMPC-UGES
500	-47892.85	-48742.44	-48425.9	-48422.26	-49538.36	-50381.35	-49002.71
1000	-47953.66	-48490.64	-48338.42	-48318.08	-49486.32	-50159.25	-48816.94
5000	-47536.78	-47941.26	-47865.43	-47835.32	-48994.44	-49008.54	-48765.58

Table 2: Average SHD Results. In the format A(B, C, D), A is the SHD, B is the number of extra edges, C is the number of missing edges, and D is the number of reversal edges.

Sample size	GS	GES	UGES	MMHC	MMPC-GES	MMPC-UGES
500	71.3(46.3, 3.4, 21.6)	59.2(43.9, 2.6, 12.7)	60.0(44.8, 2.5, 12.7)	30.8(7.6, 3.7, 19.5)	30.3(3.0, 8.5, 18.8)	29.6(8.2, 3.8, 17.6)
1000	64.6(39.2, 1.8, 23.6)	56.7(39.3, 1.7, 15.7)	55.3(38.7, 1.7, 14.9)	27.8(5.7, 2.3, 19.7)	24.5(1.5, 6.4, 16.6)	24.3(5.7, 2.3, 16.3)
5000	57.4(27.4, 0.9, 29.1)	43.7(23.4, 1.1, 19.2)	44.0(24.0, 0.8, 19.2)	23.4(4.3, 0.3, 18.8)	20.8(0.7, 0.1, 20.0)	25.9(5.1, 0.0, 20.8)

Table 3: Average Number of Calls to BDeu Scoring Function Results.

Sample size	GS	GES	UGES	MMHC	MMPC-GES	MMPC-UGES
500	105265.9	111524.5	118216.1	6073.1	1662	4379.4
1000	101082.2	114311.9	120510.4	5709.7	1527.7	3909.7
5000	94832.8	108326.8	118639.2	6117.1	2013.6	4322.4

4.2. SHD results

This paper has calculated the SHD which is the average over the 10 runs of an algorithm on the 10 different training datasets of certain sample size, as well as the three components of SHD, namely number of extra edges, number of missing edges and number of reversal edges including edges that are undirected in one graph and directed in the other. The results of the average SHD of three different sample sizes are in Table 2.

From Table 2, we can find that with the increase of the sample size, the SHD of the identified BN becomes smaller, as well as the number of extra edges and the number of missing edges, but the number of reversal edges doesn't show this feature. The GES algorithm and the UGES algorithm perform better than the GS algorithm in SHD, but the gap between the GES algorithm and the UGES algorithm in SHD is not obvious. Besides, the gaps among MMHC, MMPC-GES and MMPC-UGES in SHD are not obvious too.

In all, the SHD of GS/GES/UGES with the restriction of MMPC is lower than that of GS/GES/UGES without the restriction, namely the SHD of GS/GES/UGES is improved by the restriction of parents and children sets, especially number of extra edges.

4.3. Number of calls to BDeu scoring function results

We use number of calls to BDeu scoring function to measure the time-efficiency of algorithms. We need to know that each call to the BDeu scoring function in the E-space corresponds to one conversion from PDAG to DAG, and the time cost of one conversion is nearly the same as that of one call to the BDeu scoring function. The results of the average number of calls to BDeu scoring function of three different sample sizes are in Table 3.

From Table 3, we can find that the GES/UGES algorithms calculate about ten percent more BDeu scoring function than the GS algorithm, but the GES/UGES algorithms in E-space need extra conversions between PDAG and DAG, so we can expect that the running time of GES/UGES is much longer than that of GS. The UGES algorithm calculates about seven percent more BDeu scoring function than the GES algorithm, so we can expect that the running time of UGES is slightly longer than that of GES. Besides, the number of calls to BDeu scoring function in the MMPC-UGES algorithm is more than twice that in MMPC-GES algorithm, so the running time of MMPC-UGES is expected to be about twice that of MMPC-GES. The MMHC algorithm calculates about 40% more BDeu scoring function than the MMPC-UGES algorithm, considering the extra time cost of conversions between PDAG and DAG in MMPC-UGES, so we can expect that the running time of MMHC and MMPC-UGES should be almost the same.

In all, the number of calls to BDeu scoring function in GS/GES/UGES with the restriction of MMPC is lower than that in GS/GES/UGES without the restriction, namely the amount of calculation in GS/GES/UGES is reduced by the restriction of parents and children sets. The number of calls to BDeu scoring function in the MMPC-GES algorithm reduces the most, which also causes the worst performance of MMPC-GES in BDeu score, comparing with MMHC and MMPC-UGES.

5 Conclusions

In this paper, we use the Inclusion Boundary Condition to analyze the GES algorithm and the GS algorithm. We point out that the unrestricted form of GES algorithm which implements both the Insert operator and the Delete operator to produce the neighborhood asymptotically satisfies the Inclusion Boundary Condition. Still, the combinations of the GES/UGES algorithms with the local discovery algorithm MMPC, namely the MMPC-GES algorithm and the MMPC-UGES algorithm, are proposed. We compare GS/GES/UGES/MMHC/MMPC-GES/MMPC-UGES on the datasets sampled from the ALARM network. The experiments show that MMHC/MMPC-GES/MMPC-UGES compute less number of calls to BDeu scoring function and achieve better SHD than

GS/GES/UGES without the restriction of the parents and children sets, while the BDeu score is reduced by the restriction of the parents and children sets. Considering the huge improvement on time-efficiency and SHD, MMHC/MMPC-GES/MMPC-UGES are still compelling. And among the three algorithms MMHC/ MMPC-GES/MMPC-UGES, MMPC-GES performs the worst in BDeu score, and MMPC-UGES performs the best in BDeu score.

Finally, the combination of constraint-based method, Bayesian search-and-score method and Markov Equivalence Class space is a promising combination. The problem of confining the greedy search can also be seen as the problem of directing the skeleton identified. Many constraint-based methods usually firstly identify the skeleton and then direct the skeleton using direction rules. In some of my initial experiments with the constraint-based algorithms, the effect of skeleton identification is good, but the effect of direction on skeleton is not good, like the BNPC algorithm. If we use the search-and-score method to direct the skeleton identified by the constraint-based method, it will improve the final BN structure identified by the constraint-based method.

Abstract— **In this paper, the parameters of PID controller are tuned by Gravitational Search Algorithm (GSA). The key idea of the proposed method is to use a new design PID controller of Hydro-turbine governing. The result of simulation are shown effectiveness of the proposed method and GSA algorithm for solve Hydro-turbine governing problem in different load condition of power system. The achieved result of GSA algorithm compare with CEP, FEP, MFEP and DCMEP algorithm, the table and figure shown transcendent GSA algorithm for optimizations problem.**

Keywords- Hydro-turbine governing, GSA, robust PID controller.

I. INTRODUCTION

Energy is the basic need for economic development; every sector of country's economy (industry, agricultural, transport, commercial and domestic) needs input of energy. The Hydro-turbine governing systems contain many parts, high dimension complex systems, time-variant and multi-parameters. With attention to increases demand, the generating of energy is near to demand of energy, so need a best controller to guarantee systems for different condition. In most study used ideal PID controller for model of Hydro-turbine governing but in industrial production of ideal PID controller is not possible, so in this paper used a robust PID (RPID) controller for control Hydro turbine governing system with disturbance. PID controller is a best controller for us decide, and use many artificial algorithm for getting best answer for PID controllers (K_P, K_I, K_D) to guarantee system in best condition of working, hitherto used Genetic Algorithm (GA) [1], Simulated annealing (SA) algorithm [2], Evolutionary Programming (EP) [3], Conventional Evolutionary Programming (CEP) [4], Fast Evolutionary Programming (FEP) [4,5], Deterministic Chaotic Mutation Evolutionary Programming (DCMEP) [4,6], but the above algorithms cannot best solution for optimization of Hydro-turbine governing, so this paper a new optimization algorithm based on the law of gravity, namely Gravitational Search Algorithm (GSA) for problem solving is proposed [8]. This algorithm is based on the Newtonian gravity: ‘‘every particle in the universe attracts every other particle with a force that is directly proportional to the product of their masses and inversely proportional to the square of the distance between them”. In Sect. II, the proposed GSA algorithm is described, in Sect. IV experiments and results are presented.

Nomenclature:

N: population size
T_a: inertial time constant of generator
T_w: current inertial time constant
T_S: adjust time in seconds
Δ: overshoot level
T_y: Engagers relay time constant
e_y: hydro-turbine torque vine opening level transfer coefficient
e_h: hydro-turbine torque pressure transfer coefficient
e_{qy}: hydro-turbine hydraulic flux vine opening level transfer coefficient
e_{qh}: hydro-turbine hydraulic flux pressure transfer coefficient
K_P: proportional adjustment coefficient
K_I: integral adjustment coefficient
K_D: deferential adjustment coefficient
e_n: generator's self adjustment coefficient

II. GRAVITATIONAL SEARCH ALGORITHM (GSA)

The gravitational search algorithm is constructed based on the law of gravity and the notion of mass interactions. The GSA algorithm uses the theory of Newtonian physics and its searcher agents are the collection of masses. In GSA, we have an isolated system of masses. Using the gravitational force, every mass in the system can see the situation of other masses. The gravitational force is therefore a way of transferring information between different masses. GSA was introduced by E. Rashedi et all, 2009, In GSA, agents are considered as objects and their performance is measured by their masses. All these objects attract each other by the gravity force, and this force causes a global movement of all objects towards the objects with heavier masses. Hence, masses cooperate using a direct form of communication, through gravitational force. The heavy masses - which correspond to good solutions - move more slowly than lighter ones, this guarantees the exploitation step of the algorithm [7,8]. In GSA, each mass (agent) has four specifications: position, inertial mass, active gravitational mass, and passive gravitational mass. The position of the mass corresponds to a solution of the problem, and its gravitational and inertial masses are determined using a fitness function. In other words, each mass presents a solution, and the algorithm is navigated by properly adjusting the gravitational and inertia masses. By lapse of time, we expect that masses be attracted by the heaviest mass. This mass will present an optimum solution in the search space. The GSA could be considered as an isolated system of masses. It is like a small artificial world of masses obeying the Newtonian laws of gravitation and motion. More precisely, masses obey the following laws: Law of gravity: each particle attracts every other particle and the gravitational force between two particles is directly proportional to the product of their masses and inversely proportional to the distance between them, R. Law of motion: the current velocity of any mass is equal to the sum of the fraction of its previous velocity and the variation in the velocity. Variation in the velocity or acceleration of any mass is equal to the force acted on the system divided by mass of inertia [8, 9].

In the GSA algorithm particle researcher, is sum of all mass. We define the position of the i_{th} agent by:

$$X_i = (x_i^1 \ldots x_i^d \ldots x_i^N) \text{ for } i = 1, 2, 3 \ldots N \quad (1)$$

In the Eqs.1 x_i^d is the position of ith agent in the dth dimension. N is total of agent. At a particular time (t), we have define the force acting on mass (i) from mass (j) as pursuing:

$$F_{ij}^d(t) = G(t)\,(M_{pi}(t) - M_{aj}(t))/(R_{ij}(t)+\varepsilon)\times(X_j^d(t) - X_i^d(t)$$

$M_{aj}(t)$ is the active gravitational mass related to agent j, M_{pi} is the passive gravitational mass related to agent i, G (t) is gravitational constant at time t, ε is a small constant, and $R_{ij}(t)$ is the Euclidian distance between two agents i and j:

$$R_{ij} = \left\| X_i(t), X_j(t) \right\|_2 \quad (2)$$

To give a chromatic characteristic to GSA algorithm, suppose that the total force that acts on agent i in a dimension d be a randomly weighted sum of dth components of the forces exerted from other agents:

$$F_i^d(t) = \sum_{j=1, j\neq i}^{N} rand_j F_{ij}^d(t) \quad (3)$$

Where $rand_j$ is generate random in the interval [0, 1]. by the law of motion, the acceleration of the agent i at time t, and in direction dth, $a_i^d(t)$, give from equation 5 is equal:

$$a_i^d(t) = \frac{F_i^d(t)}{M_{ii}(t)} \quad (4)$$

In the equation (4) M_{ii} is the inertial mass of ith agent. Velocity for next step will update from equation 5 it is similar to PSO algorithm, because any particle get a new vector of velocity for generate new population. After update velocity vector for agents the position of any agent get from equation 6. The equation for give new velocity and new position following:

$$v_i^d(t+1) = rand_i \times v_i^d(t) + a_i^d(t) \quad (5)$$

$$x_i^d(t+1) = x_i^d(t) + v_i^d(t+1) \quad (6)$$

With attention to Eqs.5, the next velocity of an agent is considered as a fraction of its current velocity added to its acceleration. $rand_i$ is a uniform random variable in the interval [0, 1]. For give a randomized characteristic to the search used this random number.

The gravitational constant, G, is initialized at the beginning and will be reduced with time to control the search accuracy. In other words, G is a function of the initial value (G0) and time (t):

$$G(t) = G(G0, t) \quad (7)$$

Gravitational and inertia masses are simply calculated by the fitness evaluation. A heavier mass means a more efficient agent. This means that better agents have higher attractions and walk more slowly. Assuming the equality of the gravitational and inertia mass, the values of masses are calculated using the map of fitness. We update the gravitational and inertial masses by the following Eqs.8-10:

$$M_{ai} = M_{pi} = M_{ii} = M_i, i = 1, 2, \ldots, N \quad (8)$$

$$m_i(t) = \frac{fit_i(t) - worst(t)}{best(t) - worst(t)} \quad (9)$$

$$M_i(t) = \frac{m_i(t)}{\sum_{j=1}^{N} m_i(t)} \quad (10)$$

Fitness value of the agent i at time t show with fit_i (t) and, worst (t) and best (t) are defined as follows (for a minimization problem):

$$best(t) = \min_{j\in\{1,2,...,N\}} fit_j(t) \quad (11)$$

$$worst(t) = \max_{j\in\{1,2,...,N\}} fit_j(t) \quad (12)$$

It is to be noted that for a maximization problem, Eqs. (11) and (12) are changed to Eqs. (13) and (14), respectively:

$$best(t) = \max_{j\in\{1,2,...,N\}} fit_j(t) \quad (13)$$

$$worst(t) = \min_{j\in\{1,2,...,N\}} fit_j(t) \quad (14)$$

For getting best performed with desirable compromise between exploration and exploitation, one way is to reduce the number of agents with lapse of time in Eq. (3). For getting that target, suggest set an agent with bigger mass apply their force to the other. However, we should be careful of using this policy because it may reduce the exploration power and increase the exploitation capability. We remind that in order to avoid trapping in a local optimum the algorithm must use the exploration at beginning.

By lapse of iterations, exploration must fade out and exploitation must fade in. To improve the performance of GSA by controlling exploration and exploitation only the K_{best} agents will attract the others. K_{best} is a function of time, with the initial value K0 at the beginning and decreasing with time. In such a way, at the beginning, all agents apply the force, and as time passes, K_{best} is decreased linearly and at the end there will be just one agent applying force to the others. Therefore, Eq. (3) could be modified as:

$$F_i^d(t) = \sum_{j\in K_{best}, j\neq i}^{N} rand_j F_{ij}^d(t) \quad (15)$$

Where K_{best} is the set of first K agents with the best fitness value and biggest mass. The principle of GSA is shown in flowchart of Fig. 1. The flowcharts show how the proposed algorithm is efficient some remarks are noted:

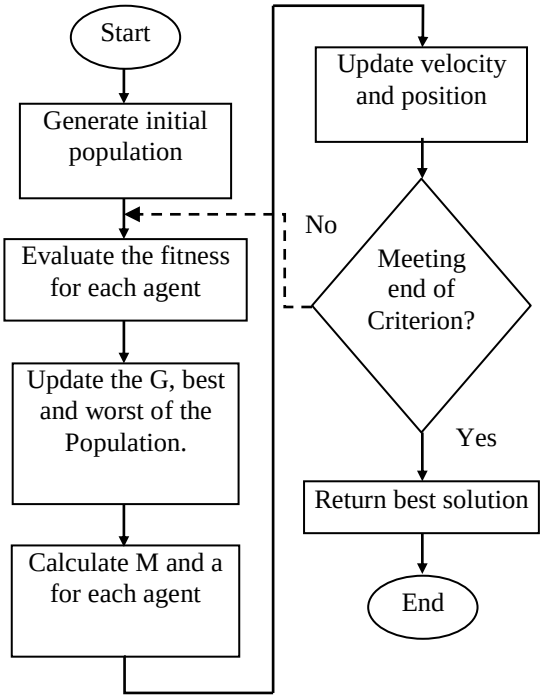

Figure 1. Flochart of GSA.

III. MODEL FOR PID CONTEROLLER IN SYSTEM STUDY

The system structure based on the GSA algorithm shown in Fig. 2 is targeted for optimizing the on line RPID parameters in the hydro-turbine governing system. The gains of the RPID controller are tuned online in terms of the knowledge base and GSA inference, and then, the RPID controller generates the control signal.

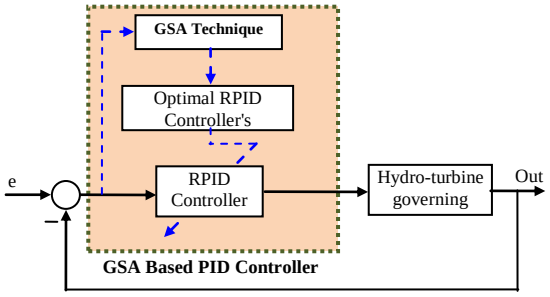

Figure 2. The proposed RPID controller design problem

The system consists of the PID governing system, the GSA algorithm parameter optimization, the hydraulic pressure servo system, the hydro-turbine system and the generator and load system In Fig. 3, y is the turbine rotating speed, r is a given signal, e = r _ y is the error signal, u is the output, Mg is the disturbance or load, Ta is the inertial time constant, Tw is the current inertial time constant and other parameters are defined in Ref. in Classical PID (CPID) controller equation is:

$$PID = k_p + \frac{K_I}{S} + k_D S \tag{16}$$

But in design industrial or robust PID controller use a low filter for delete the noise of high frequents, so this paper the function of derive represent Eqs.18:

$$\frac{k_D S}{1+T_d S}, T_d >> k_D \tag{17}$$

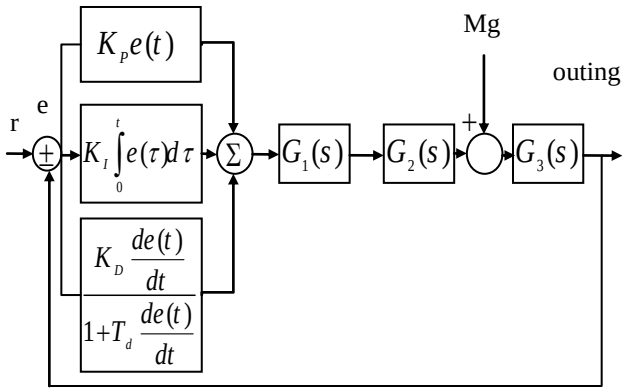

Figure 3. The system structure of Hydro-turbine governing system

The transfer function of the hydraulic pressure servo system is:

$$G_1(S) = \frac{1}{1+T_y S} \tag{18}$$

The transfer function of the hydro-turbine system is

$$G_2(S) = \frac{e_y - (e_{qy} e_y - e_{qh} ey) T_w S}{1+e_{qh} T_w S} \tag{19}$$

The transfer function of the generator and load is

$$G_3(S) = \frac{1}{T_a S + e_n} \tag{20}$$

The transfer function of the PID governing system is

$$G_g(Z) = K_p + \frac{K_1}{1-Z^{-1}} + K_D(1-Z^{-1}) \tag{21}$$

Its incremental expression is

$$\begin{aligned} \Delta U(k) &= K_p(e(k) - e(k-1)) + K_I e(k) \\ &+ K_D(e(k) - 2e(k-1) + e(k-2)) \end{aligned} \tag{22}$$

where U(k) is the governor output and e(k) is the frequency error of the kth sampling. The GSA algorithm optimizes the three PID parameters to improve the static and dynamic performances of the governed object.

IV. RESULT OF RPID DESIGN USING GSA ALGORITHM

The proposed method was applied for RPID design for hydropower station in two scenarios pursues and any scenarios contain two cases. For show proficiency of GSA algorithm in solve intricate problem with many parameters, compare the result of GSA algorithm with CEP, FEP, MFEP and DCEMP [4,5]. The object function for optimization is:

$$\text{Min } J = eTe \tag{23}$$

s. t.

$$K_{P,min} \le K_P \le K_{P,max}$$

$$K_{I,min} \le K_I \le K_{I,max}$$

$$K_{D,min} \le K_D \le K_{D,,max}$$

$$\min j = e^T e$$

Where $K_{P,min}$, $K_{I,min}$, $K_{D,min}$ and $K_{P,max}$, $K_{I,max}$, $K_{D,max}$ are the upper and lower bounds of K_P, K_I,K_D, respectively.

Scenario1: the model of Hydro-turbine is HL638-WJ-60, winding speed n=1000 r/min, power P_T = 1612 kW, pipeline length L = 1956m, cross area 4.22 m^2, inertial time constant T_a = 3.9 s, current inertial time constant T_w = 0.365 s. The result simulation from GSA, DCEMP, FEP, MFEP and CEP of scenario 1 is presented in Table 1.

Case 1: for vane opening level = 60%, the transfer coefficients are:

e_x = -0.728, e_y = 1.28 , e_h = 0.95 , e_{qx} = -0.075 , e_{qy} = 0.956 , e_{qh} = 0.618

Case 2: for vane opening level = 80%, the transfer coefficients are:

e_x = -0.860, e_y = 0.948 , e_h = 1.31 , e_{qx} = -0.029 , e_{qy} = 0.868, e_{qh} = 0.830

V. CONCLUSIONS

Actually, conventional PID control has been largely applied to hydro-turbine governors and has achieved valuable results. The main reason is due to their simplicity of operation, inexpensive maintenance and low cost. But many researches were shown that classical PID control was unable to perform optimally over the full

range of operating conditions and disturbance, due to the highly complex, non-linear characteristic of hydro-turbine governing system. So to solve this problem in recent years the methods intelligence algorithms such as the (CEP, FEP, MFEP and DCMEP) is used. This paper employed GSA algorithms for optimization of RPID parameters to hydro turbine governors. The results from the two simulation cases show that the proposed method is practical and efficient in achieve optimal PID parameters for the hydro-turbine governing system. also the results of simulation cases show that the presented control strategy has enhanced response speed and robustness and achieves good performance when applied to the hydro-turbine governing system and over shoot and setting time is less than other algorithm Presented in this article.

BIOGRAPHIES

Ali Yousefi received the B.S. degree in Electrical Engineering from Islamic Azad University, Ardabil,Iran in 2009 and M.S.E. degree in Technical Eng. Department of the University of Mohaghegh Ardabili, Ardabil, Iran, 2011. His research interests are in the Artificial Intelligence to Power System Control Design, power system operation and control, power market analysis and expansion planning for Electric power system.

Ali Ghasemi received the B.Sc. and M.Sc. (Honors with first class) degree in Electrical Engineering from Isfahan University of Technology (IUT), Esfahan, Iran in 2009 and Technical Eng. Department of the University of Mohaghegh Ardabili (UMA), Ardabil, Iran in 2011. His Areas of interest in Research are power system control and operation, adaptive and robust control of power systems, operation and Planning and Power System Restructuring and applications of heuristic techniques in power systems.

Reza Bazyar was born in Tabriz, Iran in 1984. He received the B.S. degree in electrical engineering from Azarbaijan Higher Education & Research Complex (AHERC), Tabriz, Iran, in 2008 and the M.S. degrees in electrical engineering from Department of Engineering, ECE Group, Mohaghegh Ardebili University, Ardebil, Iran, in 2011. He is currently an Engineer of the East Azarbayjan Power Generation Management Company, Iran. His research interests include Economic dispatch, O&M Gas power plant, hybrid energy system, Power system control and operation.

Heidarali Shayanfar received the B.S. and M.S.E. degrees in Electrical Engineering in 1973 and 1979, respectively. He received his Ph. D. degree in Electrical Engineering from Michigan State University, U.S.A., in 1981. Currently, he is a Full Professor in Electrical Engineering Department of Iran University of Science and Technology, Tehran, Iran. His research interests are in the Application of Artificial Intelligence to Power System Control Design, Dynamic Load Modeling, Power System Observability Studies, Voltage Collapse, Congestion Management in a Restructured Power System, Reliability Improvement in Distribution Systems and Reactive Pricing in Deregulated Power Systems. He has published more than 405 technical papers in the International Journals and Conferences proceedings. He is a member of Iranian Association of Electrical and Electronic Engineers and IEEE.

Oveis Abedinia received the B.S. and M.Sc. degrees in Electrical Engineering from Azad University, Ardabil and Science and Technology Research Branch, Tehran, Iran in 2005 and 2009, respectively. Currently, he is a Ph. D. student in Electrical Eng. Department, Semnan University, Semnan, Iran. His areas of interest in research are Application of Artificial Intelligence to Power System and Control Design, Load and Price Forecasting, Distribution Generation, Restructuring in Power Systems, Congestion Management, Optimization.

Hossein Gholamalitabar Firoozjaee was born in Babol, Mazandaran, Iran, in 1988. He received the B.S. degree in electrical engineering from the University of Nooshirvanibabol, mazandaran, iran, in 2010. He is currently M.S. degree student in electrical engineering group from Mohaghegh Ardebili University, Ardebil, Iran. His current research interests are in power market, renewable energy and optimization with artificial algorithms.

ABSTRACT

Users frustrated with corporate helpdesks are utilizing internet searches and social media sites for support purposes. There is a wealth of support-related content available publicly; supplier's web sites, blogs, product forums are just some examples. HP is in an optimal position to deliver a platform that utilizes the publicly available content to automatically answer corporate users' support questions.

We identify three primary technical challenges on the design of an automated platform that uses social media to answer support questions: understanding the context in which the question is asked, finding and retrieving the resources in the social media where the question has been discussed, and organizing the content retrieved from the social media resources in a user-friendly way. We apply novel statistical clustering and data mining techniques to address these challenges on the design of an automated platform that answers support questions based on content from social media.

1. INTRODUCTION

As the number of Generation Y and millennial employees increases within the corporate environment, so does the trend toward consumerization and self-help. Many employees now find it natural to use social networking sites to resolve issues they encounter with home computers, appliances, and automobiles. So, it is only natural the same employees would follow a similar process when a problem or issue arises at the office.

Users frustrated with corporate helpdesks are utilizing internet searches and social media sites for support purposes. There is a wealth of support-related content available publicly; supplier's web sites, blogs, product forums are just some examples. HP is in an optimal position, given our unique combination of client technologies and Intellectual Property (think Watercooler), and continuing RD, to deliver an automated platform that uses social media content to answer IT support questions. Yet, there are various technical challenges on the design of such an automated IT support platform:

"Understanding" the context in which the question is asked: An RD engineer at HP is unlikely to have the same hardware and software requirements and needs as, for example, a human resources manager at Walmart. The platform should have knowledge of the IT assets of each user, and leverage this knowledge to better understand the context in which the user asks their question.

Finding the resources in the social media where the question has been discussed: There are billions of websites on the world-wide web, it will be an unfruitful effort to blindly crawl and retrieve every piece of content. The crawlers that will retrieve content from the social platforms should be designed such that they "know" where to look for information on each social platform.

Organizing the content retrieved from the social media resources in a user-friendly way: Presenting the user with large amounts of redundant data in an unorganized form will be of little or no use to the user; the data needs needs to be presented to the user in an organized, easy-to-navigate way.

We apply novel statistical clustering and data mining techniques to address the challenges on the design of an automated platform that answers support questions based on content from social media.

For each corporate customer, we have available to us a set of seed URLs of the customer's main corporate IT support sites. We are further provided with each user's organization, job function, and the devices and business applications used for work. The empirical data will be available from sources such as Active Directory, IT Asset Management systems, or desktop management systems.

We crawl the customer's IT sites, starting from this set of seed URLs. The crawler is directed, i.e., it focuses on the hardware and software the user uses or is likely to use in his/her work. Our directed crawlers retrieve content from the customer's IT support sites (as well as any IT Sharepoint sites) that are likely to be of relevance to the user's environment. The retrieved content constitutes the user-centric corpus.

Then concepts are extracted from the corpus using co-occurrence based techniques [1]. The concepts include single words as well as n-tuples, where n>1. A semantics graph is then constructed that reflects the relations between the extracted concepts. The nodes of the graph are the concepts, while the edges connecting the nodes have weights, representing the distances between the concepts. A small distance between two tags indicates that the two tags are highly related to each other. In computing the distances, we take into account how frequently two concepts appear in the same paragraphs, on the same pages, and on the pages that have links between them. If two tags appear frequently, then their distance is set to be small.

Our approach to extracting concepts and their relations is critical for our platform to understand the concept in which a user asks an IT support question. Through directed crawling, we focus our corpus to the customer's IT support pages that are most relevant to the individual user. This helps us extract concepts and concept relations specific to the user's

context and environment.

We first identify the platforms in the social media that may be of relevance to IT technical support. Then, for each platform, we design a crawler that retrieves content to our repository from the platform. Since the crawler is designed for specifically for the platform, it "knows" which parts of the site to focus on, e.g., which links are more likely to contain the technical support discussions. Organizing the retrieved content

The content retrieved from the social media resources often includes too much redundant information, since the question being asked is likely to have been discussed in multiple social platforms. Presenting the user with large amounts of redundant data in an unorganized form will be of little or no use to the user; such an approach will likely require more effort on the part of the user than if the user had gathered the content through a Google search.

Statistical clustering techniques are applied to organize the content into clusters. Further, we propose a hierarchical clustering approach which organizes the content in a tree structure - so that the user can navigate easily between the clusters. For instance, the user can initially select the expected number of entries in each cluster; if the user then decides to increase the number of entries, s/he can navigate to the parent nodes, or if s/he decides to reduce the number of entries, s/he can navigate to the children nodes without having to reconstruct the clustering tree.

We note that the retrieved content from a social platform has multiple views. For instance, if the content is being retrieved from a forum, there are at least two views: the thread title and the thread content. The thread title (often consisting of just a few words) has a very different characteristic than the thread content (often consisting of at least several sentences), making it infeasible to combine the two into a (feature) vector to feed into a single clustering algorithm.

To address the issue that the retrieved content has multiple views, we design a set of clustering techniques called multi-view clustering techniques [2]. In multi-view clustering, each view has its own clustering algorithm, yet the algorithms are dependent on each other. In particular, we design a clustering tree based for each view, and each clustering tree is grown and pruned with feedback from the other clustering trees. For instance, in the case of two views, thread titles and thread content, we introduce a common penalty function, and the two trees are trained to minimize the common penalty function. In this case, the common penalty function is selected to be the clustering disagreement probability between the two trees with constraints on the entropy (size or depth) of the trees.

Our solution has been used to build an engine that accepts enterprise support desk questions as input, and outputs the questions/answers that best match the inputted IT question.

For the questions/answers, we used our crawlers to build a repository that consists of the 75,000 questions that we downloaded from an enterprise IT discussion forum called serverfault.com.

Our engine has multiple sub-engines. One sub-engine accepts the IT question from the user as input, and finds the concepts from the semantics graph that best reflect the question. A second sub-engine analyzes each question/answer in the 75,000 question/answer repository, and for each question/answer pair, it finds the concepts that reflect the pair. Finally, a third sub-engine matches the input question with the question/answer pairs in the repository based on the the concepts and the graph.

As an example, in response to the user input (see the figure on the left) "I have a problem with configuring nginx. I want the nginx to make requests to the HTTP server to upload files. In the past, the HTTP server was responsible for the uploads and the requests," our system extracted "nginx", "HTTP server" and "upload" as concepts, and related the "HTTP server" to another concept "Apache". Then, it retrieved the following question (with its answer) from the repository (see the figure on the right): "I recently put nginx in front of apache to act as a reverse proxy. Up until now Apache handled directly the requests and file uploads. Now, I need to configure nginx so that it sends file upload requests to apache". We note that this was in fact the closest question to the user input.

There are many platforms that aggregate and present content from social media for different purposes. However, to the best of our knowledge, our solution is unique in at least two ways: First, we build a content corpus specifically designed for the individual user taking into account the user's IT environment; the user-specific content corpus is then used to build a concept graph customized for the user's context.

This provides us with the ability to understand the context in which the user has asked their question. Second, we organize the retrieved content by multi-view clustering. Thus, the amount of redundant information the user is presented minimized; rather the user is presented with content grouped into clusters that can be easily navigated.

2. KEYWORD EXTRACTION

Keyword extraction techniques are often based on the tfidf method. The tfidf method compares the word frequencies in the repository with the word frequencies in the sample text; if the frequency of a word in the sample text is high while its frequency in the repository is low, the word is extracted as a keyword.

While the tfidf-based techniques are known to perform well in many text mining applications, they have a major shortcoming in the context of mining customer forum threads. A customer forum thread typically contains only few sentences and words, making it difficult to obtain reliable statistics based on word frequencies. Many relevant words appear only once in the thread, making it difficult to distinguish them from the other, less relevant words of the thread.

An alternative approach would be to form a vector of keywords in the repository of forum threads, and, generate a binary features vector for each thread. If the i^{th} repository keyword appears in the thread, the i^{th} element of the thread's feature vector is 1, and if the keyword does not appear in the thread, the i^{th} element of the thread's feature vector is 0.

The question with this simple alternative approach is then that of generating keywords in a given repository. We apply three different techniques:

- Remove only stop-words: We only filter out stop words (e.g., if, and, we, etc.) from the repository, and let the vector of keywords be the set of all remaining distinct repository words.
- The tfidf method: We apply the tfidf method on the entire repository by comparing the word frequencies

in the repository with word frequencies in the English language. If the frequency of a word is high in the repository and low in the English language, we take the word as a keyword.

- Term co-occurrence: The term co-occurrence method extracts keywords from the repository without comparing the repository frequencies with the English language frequencies. This method is explained next [9].

2.1 Term Co-occurrence

Let N denote the number of all distinct words in the repository of forum threads. We construct a $N \times M$ co-occurrence matrix, where M is pre-selected integer with $M < N$. We typically take M to be 500. We index all distinct words by n, i.e., $1 \leq n \leq N$. We index the most frequently observed M words in the repository by m such that $1 \leq m \leq M$.

The $(n.m)$ element (i.e. ,n^{th} row and the m^{th} column) of the $N \times M$ co-occurrence matrix counts the number of times the word n and the word m occur together. Consider the word ẅirelesswith index n and the word c̈onnectionẅith index m, and that ẅirelessänd c̈onnectionöccur together 218 times in the repository. Then, the $(n.m)$ element of the co-occurence matrix is 218.

If the word n appears independently from the words $1 \leq m \leq M$ (the frequent words), the number of times the word n co-occurs with the frequent words is similar to the unconditional distribution of occurrence of the frequent words.

On the other hand, if the word n has a semantic relation to a particular set of frequent words, then the co-occurrence of the word n with the frequent words is greater than the unconditional distribution of occurrence the frequent words.

We denote the unconditional probability of a frequent word m as the ex- pected probability p_m and the total number of co-occurrences of the word n and fre- quent terms as c_n. Frequency of co-occurrence of the word n and the word m is written as $freq(n, m)$. The statistical value of χ^2 is defined as

$$\chi^2(n) = \sum_{1 \leq m \leq M} \frac{freq(n,m) - N_n p_m}{n_m p_m}. \quad (1)$$

2.2 Clustering of Frequent Terms

We cluster two or more frequent terms together in either of the following two conditions:

- The frequent words m_1 and m_2 co-occur frequently with each other.
- The frequent words m_1 and m_2 have a similar distribution of co-occurrence with other words.

To quantify the first condition of m_1 and m_2 co-occurring frequently, we use the mutual information between the occurrence probability of m_1 and that of m_2.

To quantify the second condition of m_1 and m_2 having a similar distribution of co-occurrence with other words, we use the Kullback-Leibler divergence between the occurrence probability of m_1 and that of m_2.

3. ALGORITHM

We design a statistical clustering algorithm to minimize (in the Lloyd-optimal sense) the error probability given in (2) under the cluster entropy constraints. Gaussian mixture models have been used extensively in the literature to design generative algorithms for data clustering. Such algorithms are often based on the EM algorithm [5]; however, there also exists alternative training approaches such as Gauss mixture vector quantization (GMVQ) [8, 11, 12, 13, 16]. The EM algorithm assumes that the underlying data follows a Gaussian mixture distribution and tries to fit a Gaussian mixture model to the data, while the GMVQ is a Lloyd clustering algorithm and it does not make any assumptions about the statistics of the underlying data.

We use the GMVQ to design a multi-view hierarchical clustering algorithm. Our choice of GMVQ (over the EM) is motivated by the intractability of the EM solution in minimizing (2) through a hierarchical clustering scheme. We first extend the GMVQ to design a hierarchical (tree-structured) clustering algorithm. We then extend it further to the multi-view setting, where the goal is to minimize the disagreement between two different views of the training data as expressed in (2). The two views in our setting are the thread titles and the thread content.

In section 4.1, we provide an overview of the GMVQ and include the iterative solution for the GMVQ. In section 4.2, we extend the GMVQ to design a tree-structured clustering algorithm. Finally, in section 4.3, we extend it further to the multi-view setting to minimize (2).

3.1 Gauss mixture vector quantization (GMVQ)

Consider the training set $\{z_i, 1 \leq i \leq N\}$ with its (not necessarily Gaussian) underlying distribution f in the form $f(Z) = \sum_k p_k f_k(Z)$. The goal of GMVQ is to find the Gaussian mixture distribution, g, that minimizes the distance between f and g. It has been shown in [8] that the Gaussian mixture distribution g that minimizes this distance (i.e., minimizes in the Lloyd-optimal sense) can be obtained iteratively with the following two updates at each iteration:

i. Given μ_k, Σ_k and p_k for each cluster k, assign each z_i to the cluster k that minimizes

$$\frac{1}{2}\log(|\Sigma_k|) + \frac{1}{2}(z_i - \mu_k)^T \Sigma_k^{-1}(z_i - \mu_k) - \log p_k, \quad (2)$$

where $|\Sigma_k|$ is the determinant of Σ_k. We note that (5) is also known as the QDA distortion.

ii. Given the cluster assignments, set μ_k, Σ_k and p_k as

$$\mu_k = \frac{1}{\|S_k\|} \sum_{z_i \in S_k} z_i, \quad (3)$$

$$\Sigma_k = \frac{1}{\|S_k\|} \sum_i (z_i - \mu_k)(z_i - \mu_k)^T, \quad (4)$$

and

$$p_k = \frac{\|S_k\|}{N}, \quad (5)$$

where S_k is the set of training vectors z_i assigned to cluster k, and $\|S_k\|$ is the cardinality of the set.

3.2 Tree-structured Gauss Mixture Vector Quantization

We use the BFOS algorithm to design a hierarchical (i.e., tree-structured) extension of GMVQ [13]. The BFOS algorithm requires each node of a tree to have two linear functionals such that one of them is monotonically increasing and the other is monotonically decreasing. Toward this end, we view the QDA distortion (5) of any subtree, T, of a tree as a sum of two functionals, u_1 and u_2, such that

$$u_1(T) = \frac{1}{2}\sum_{k\in T} l_k \log(|\Sigma_k|) + \frac{1}{N}\sum_{k\in T}\sum_{z_i\in S_k}\frac{1}{2}(z_i-\mu_k)^T\Sigma_k^{-1}(z_i-\mu_k), \quad (6)$$

and

$$u_2(T) = -\sum_{k\in T} p_k \log p_k \quad (7)$$

where $k \in T$ denotes the set of clusters (i.e., tree leaves) of the subtree T, and μ_k, Σ_k, p_k and the set S_k are as defined in section 4.1.

The magnitude of u_2/u_1 increases at each iteration. This is a key point of the design as, then, pruning is terminated when the magnitude of u_2/u_1 reaches λ, resulting in the subtree minimizing $u_1 + \lambda u_2$.

3.3 Iterative and multi-view TS-GMVQ

We iteratively design two clustering trees, one using the thread title feature vectors, $X_{i,1}$, and the other using the thread content feature vectors, $X_{i,2}$. At each iteration, the two trees are designed (includes tree growing and tree pruning) jointly to minimize (2), the disagreement probability with constraints on the entropy of clusters.

At each iteration, the tree growing starts with a single node tree out of which two child nodes are grown. The Lloyd updates, i.e., (5)-(8), are applied to these two child nodes, minimizing (5), i.e., assigning each training vector to one of the two nodes. Then, one of the two nodes is selected to be split into a pair of new nodes. The selected node is the one, among all the existing nodes, that minimizes (2) after the split. The Lloyd updates, (5)-(8) are then applied to each pair of new nodes, minimizing (10). This procedure of growing a pair of child nodes out of one of the existing nodes, and running the Lloyd updates within the new pair of nodes is repeated until a fully-grown tree is obtained.

We denote the title feature tree by T_1 and the content feature tree by T_2. The trees, T_1 and T_2, are designed using the BFOS algorithm to minimize (2). This implies that, at iteration m, the subtree functionals for T_1 are

$$u_1^m(T) = \sum_{k\in T_1^m}\sum_{x_i\in S_k} P(\alpha_1^m(x_{i,1}) \neq \alpha_2^{m-1}(x_{i,2})), \quad (8)$$

and

$$u_2^m(T) = -\sum_{k\in T_1^m} p_k \log p_k. \quad (9)$$

The u_1 and u_2 functionals for T_2 are analogous.

We observe, by comparing (3) and (12), that

$$\sum_{T_1} u_2^m(T) = R_v \quad (10)$$

and, by comparing (1) and (11), that

$$\sum_{T_1} u_1^m(T) = P(\alpha_1^m(X_1) \neq \alpha_2^{m-1}(X_2)). \quad (11)$$

The u_2^m functional in (12) is identical to the u_2 functional in section 4.2. As for the u_1^m functional, we use (9) for growing the tree and (11) during the pruning. This is possible since (11) is also a linear and monotonically decreasing functional.

Based on the discussion in this section, the multi-view algorithm consists of the following steps (we omit the initialization steps):

i. Grow a TS-GMVQ T_1 tree for the training set $X_{i,1}$, using u_1 and u_2 as given in (9) and (10), respectively.

ii. Grow a TS-GMVQ tree T_2 for the training set $X_{i,2}$, analogously to (i).

iii. Given the tree T_2, prune the fully-grown T_1, using the BFOS algorithm with u_1 and u_2 as given in (11) and (9), respectively.

iv. Given the tree T_1, prune the fully-grown T_2, analogously to (iii).

v. Stop if the change in the cost function, given in (2), from one iteration to the next is less than some ϵ (We set ϵ such that the algorithm stops if the change in (2) is less than 1 percent from one iteration to the next). Else go back to step (i).

4. EXPERIMENTS

We've tested the hierarchical multi-view approach on the customer threads included in the forums over the web. The forum is intended to help IT customers (both the enterprise customers and the consumers) with troubleshooting their product-related problems. Each thread includes a post by a customer, explaining a problem, followed by replies by others. Each thread has a a title, in addition to thread content.

We've compared the hierarchical multi-view clustering approach to 4 other clustering techniques (EM, GMVQ, TS-GMVQ and agglomerative hierarchical clustering) under 3 different feature vector constructions. The comparisons are performed on a set of 75,000 threads in 30 clusters for the product line. In each comparison, we measured the misclassification error, which is the probability of a customer query being assigned to a cluster of a product problem different from the problem expressed in the query. The ground truth for the threads, problems and queries have been established by the website owners, independently of the author of this paper.

4.1 Feature vectors

The i^{th} thread has two feature vectors, the thread title $x_{i,1}$ and the thread content $x_{i,2}$. Each feature vector is a W-length binary (0 or 1) vector, where W is the total number of unique words used across all threads. Each word is indexed by w, where $1 \leq w \leq W$.

The w^{th} element of $x_{i,1}$ is 1 if and only if the word w occurs in the title of the i^{th} thread. Similarly, the w^{th} element of $x_{i,2}$ is 1 if and only if the word w occurs in the content of the i^{th} thread. We exclude the stop-words (e.g., and, if, such, etc.) from the feature vectors.

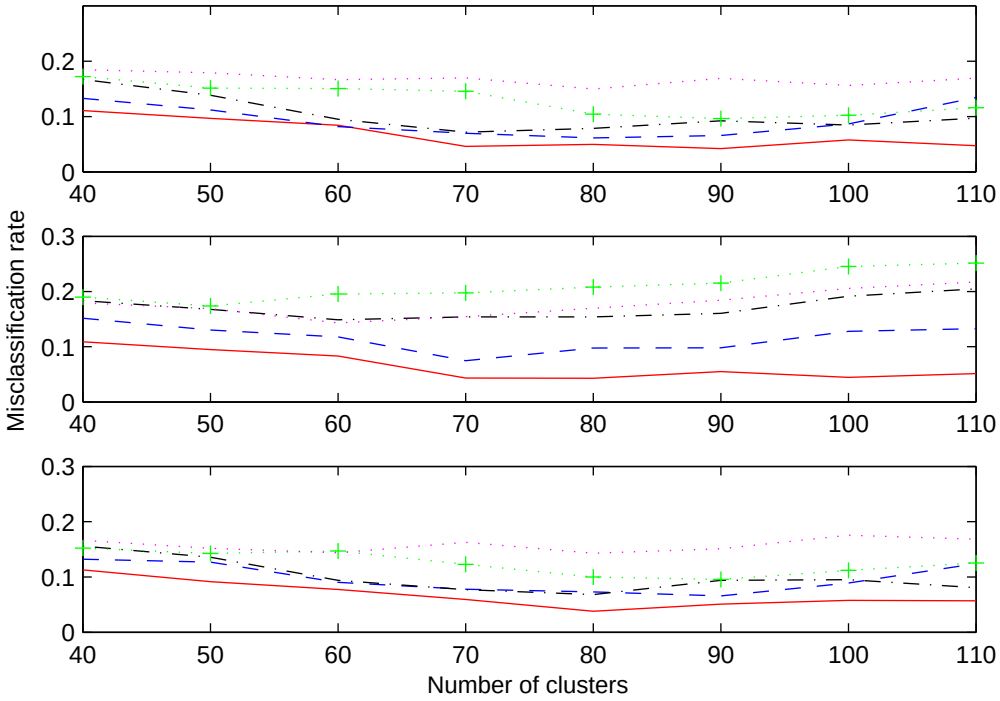

Figure 1: The classification error rate as a function of the number of clusters for the notebook computer thread. The tfidf keyword extraction. The multi-view approach (red solid line) is compared to the GMVQ (blue dashed line), EM (black dash-dot line), TS-GMVQ (magenta dotted line) and agglomerative hierarchical clustering (green dot-plus line). The top plot shows the setting with $y_i = x_{i,1}$, the middle plot shows the setting with $y_i = x_{i,2}$ and the bottom plot shows the setting with $y_i = [x_{i,1}\ x_{i,2}]$.

4.2 Comparisons

We've compared the hierarchical multi-view clustering approach to the EM algorithm, standard GMVQ algorithm, TS-GMVQ algorihm and agglomerative clustering. In each comparison, we've tested three different feature vector constructions for the EM, GMVQ, TS-GMVQ and agglomerative clustering: the feature vector is $x_{i,1}$, the feature vector is $x_{i,2}$, and the feature vector is $[x_{i,1}\ x_{i,2}]$.

4.2.1 Feature vector constructions

Denoting the feature vector of the training samples by y_i, we consider three feature vector constructions:

i. $y_i = x_{i,1}$. The clustering algorithm takes only the thread titles into account. The thread content are ignored.

ii. $y_i = x_{i,2}$. The clustering algorithm takes only the thread content into account. The thread titles are ignored.

iii. $y_i = [x_{i,1}\ x_{i,2}]$. The clustering algorithm takes into account both the thread titles and the thread content.

We compare the hierarchical multi-view approach with the EM, GMVQ, TS-GMVQ and agglomerative clustering under each of these three feature vector construction settings. To avoid any confusion, we emphasize that, the three different feature vector constructions apply only to the EM, GMVQ, TS-GMVQ and agglomerative clustering. The hierarchical multi-view algorithm, on the other hand, always makes use of both $x_{i,1}$ and $x_{i,2}$ in our experiments.

4.2.2 Compared algorithms

i. EM: We use the standard EM algorithm. At each iteration, the E-step updates the membership probabilities, $v_{i,k}$, for each cluster k and sample i, while the M-step updates the mean, covariance and the probability of occurrence for each cluster k as

ii. GMVQ: The standard GMVQ algorithm updates are as given in (5)-(8) in section 4.1.

iii. TS-GMVQ: The TS-GMVQ is grown and pruned by the BFOS algorithm using (9) and (10) as described in section 4.2.

iv. Agglomerative hierarchical clustering: We start with N clusters, where N is the number of threads in the training set, and apply agglomerative clustering with the distance criterion given in (5). At each iteration, we merge the two clusters, whose closest feature vectors are closest. In other words, at each iteration, for each pair of clusters, c_k and c_m, we compute the distances between the feature vectors of c_k and the feature vectors of c_m, and denote the closest distance by $d_{k,m}$. We merge the two clusters with the minimum $d_{k,m}$.

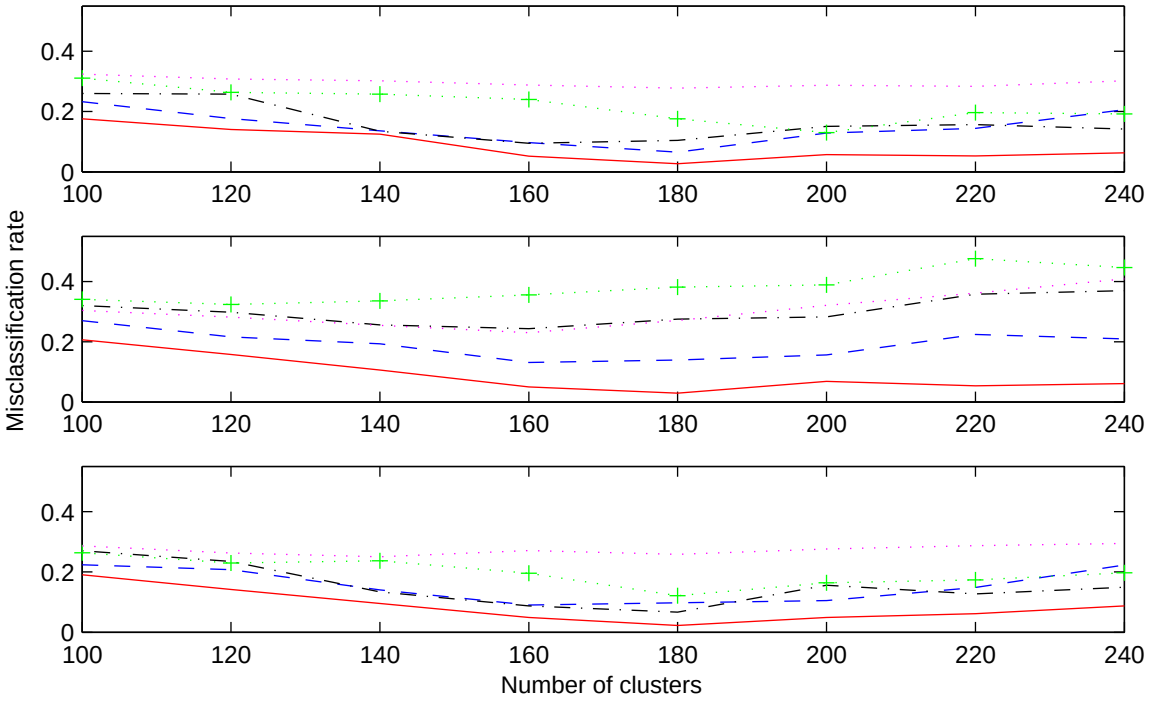

Figure 2: The classification error rate as a function of the number of clusters for the notebook computer thread. The term co-occurrence keyword extraction. The multi-view approach (red solid line) is compared to the GMVQ (blue dashed line), EM (black dash-dot line), TS-GMVQ (magenta dotted line) and agglomerative hierarchical clustering (green dot-plus line). The top plot shows the setting with $y_i = x_{i,1}$, the middle plot shows the setting with $y_i = x_{i,2}$ and the bottom plot shows the setting with $y_i = [x_{i,1}\ x_{i,2}]$.

4.3 Discussion of Results

Fig. 1 shows the classification error as a function of the number of clusters for the threads in the notebook PC set. The tfidf method is used for extracting keywords. In each plot, the classification error rate of the multi-view approach (red solid line) is compared to that of the GMVQ (blue dashed line), EM (black dash-dot line), TS-GMVQ (magenta dotted line) and agglomerative hierarchical clustering (green dot-plus line). The top plot shows the setting, where the training vector for GMVQ, EM, TS-GMVQ and agglomerative hierarchical clustering are the thread title feature vectors, i.e., $y_i = x_{i,1}$. In this setting, the multi-view approach outperforms the other four algorithms, implying that the inclusion of the thread content to the training process improves the classification.

The middle plot in Fig. 1 shows the setting where the training vectors for the four approaches are the thread content feature vectors, i.e., $y_i = x_{i,2}$. Similar to the setting with $y_i = x_{i,1}$, the multi-view approach leads to the minimum classification error, implying that the thread title should be included in the training to improve the classification accuracy.

The bottom plot in Fig. 1 shows the classification errors for the setting where both the thread titles and thread content are included as feature vectors, i.e., $y_i = [x_{i,1}\ x_{i,2}]$. The performance of the four algorithms (GMVQ, EM, TS-GMVQ and agglomerative hierarchical clustering) all improve compared to the settings shown in the top and middle plots. Once again, this implies that both thread titles and thread content should be included in the feature vectors. However, more importantly, the multi-view approach still outperforms the four algorithms.

It is not surprising for the multi-view approach to outperform the other four approaches in the setting with $y_i = [x_{i,1}\ x_{i,2}]$, because customer queries are more similar to thread titles (short, a few words) than to thread content. Thus, a clustering of thread titles, trained with guidance from the thread content, lead to a more accurate retrieval than a clustering of combined thread titles and thread content.

In Fig. 2, we show the classification error rates. The difference is that here the term co-occurrences are used for extracting the keywords. A comparison with Fig. 1 indicates that, for each clustering strategy, the term co-occurrence keyword extraction leads to a more accurate classification (i.e., lower classification error rates) than the tfidf keyword extraction.

5. CONCLUDING REMARKS

Customers discuss product malfunctions, errors and problems through the threads they post on business-supported online forums. It is not feasible to use web search algorithms such as PageRank for retrieving the relevant threads in response to a search query in the forum since the threads lack recommendation links. We provided a keyword extrac-

tion technique based on term co-occurrences that performs better than traditional tfidf-based techniques. Further, we provided statistical, iterative and multi-view approach to searching and retrieving the customer threads in such forums. The hierarhical clustering of the threads makes it possible to present the retrieved threads in a rank-ordered fashion to the customer.

Keywords Clustering, Data Mining, Algorithms

Abstract In this paper we give a new clustering algorithm based on statistics trees called CLUSTRE (CLUstering on Statistics Trees). The input data is first loaded into a statistics trees and then level by level the identified dense units are merged and expanded so that a minimum number of dense regions are formed. CLUSTRE is robust, interactive, fast and scalable. Experiments show the effectiveness of the new clustering method.

1. INTRODUCTION

As an important data mining task, data clustering is to find clusters or dense objects embedded in database. The data objects are more similar while inter-cluster similarity is lower. Clustering researches have focused on designing scalable and high quality classifiers on large relational databases or multidimensional data warehouses. The challenges include the scalability issue, construction interaction with users and integration with other data mining algorithms [1].

In this paper we give a new clustering algorithm based on statistics trees [5] called CLUSTRE (CLUstering on Statistics Trees). The input data is first loaded into a statistics trees and then level by level the identified dense units are merged and expanded so that a minimum number of dense regions are formed.

Most clustering algorithms handle only numerical attributes. For example, k-MEANS seeks full-dimensional clusters by selecting a set of relevant attributes and assigning weights [2]. Mihael Ankerst et al developed OPTICS algorithm through the creation of an augmented cluster-ordering of database objects [3]. The problems are that input parameters are hard to determine and results are sensitive to them. In addition, it is infeasible to several million of high-dimensional objects. CLARANS [6] is a random searching and hill-climbing clustering algorithm based on graph and a data structures called R*-trees [7].

In [4], PROCLUS (Papered CLUStering) is based on dimensions as well as points, as a generalization of feature selection and medoid techniques using locality analysis. The algorithm has three phases: 1) initialization: reduce set to do climbing, 2) iteration: find best set of medoids using hill-climbing (like CLARANS, gradually improving medoids) on corresponding dimensions. It uses Manhattan segment distance to assign points to medoids, and 3) cluster refinement. This is an interesting algorithm but may generate many overlaps of reported dense units called partitions.

DBSCAN [8] is a famous density based clustering algorithm that can cluster different shapes. It also suffers the scalability problem. BIRCH [9] is a very popular and classic clustering algorithm that can handle noisy data. It is incremental and dynamic. More noticeably, it is scalable. As in DBSCAN, CURE [10] can also cluster different shapes and sizes. It uses multiple representatives and compression to eliminate outliers.

Our work is most closely related to CLIQUE [11] in the sense that both use regions DNF (Disjunctive Normal Form), easy to interpret and both can cluster sub-spaces. CLIQUE uses a bottom-up, self adjoining, and MDL pruning approach. By using a graph DFS traversal and a greedy strategy to find minimum covers of the dense regions. However, it needs multiple passes and is largely overlapping as well. It is not interactive.

CLUSTRE has the following features:

1. robust: not sensitive to individual tuple noise
2. interactive: User specify the parameters such as the collapsed dimensions and minSupport.
4. precise: instead of algorithms based on sampling and reducing dimensions
5. numerical and nominal attributes are OK.
6. not overlapping
7. fast: optimal 1-pass when the tree fits into memory
8. scalable with the size of the database due to the increase of the number of records.

The rest of the paper is given as follows. Next section will briefly review the statistics tree structure and how to load it. Section 3 will detail CLUSTRE itself especially through a 3-D example to visualize and illustrate the clustering process. Some experiments are given in section 4. Section 5 concludes the paper.

2. STATISTICS TREE

Statistics Tree [5] is a multi-dimensional array data structure for dealing with multiple dimensions at the same time. Its internal nodes are used for forming branches to arrive in leaves, which contain aggregates. The aggregates can be any operators, such as SUM, AVG, MIN, MAX and so on. The attribute A_0, A_1, …, A_{k-1}, (with cardinalities d_0, d_1,…,d_{k-1}) corresponds to both dimensions of a relational table R and the levels of the statistics tree. The node at each level contains (index, pointer) pairs. The indexes represent the domain values of the corresponding dimensions (current level where the node is located). The pointers extend query paths to corresponding nodes at the next level. A feature index value called *star value*, denoted by * and located in the right most position following cardinality, represents the ALL value of dimension where the star is; the corresponding *star pointer* extends the path to the next level for a query that has no constraints for dimension where the star pointer starts. In the bottom level are leaves, which are marked by "v" in Figure 1. They only store the aggregation values of the corresponding input record tuple represented by the root-to-leaf paths, rather than records or pointers to records.

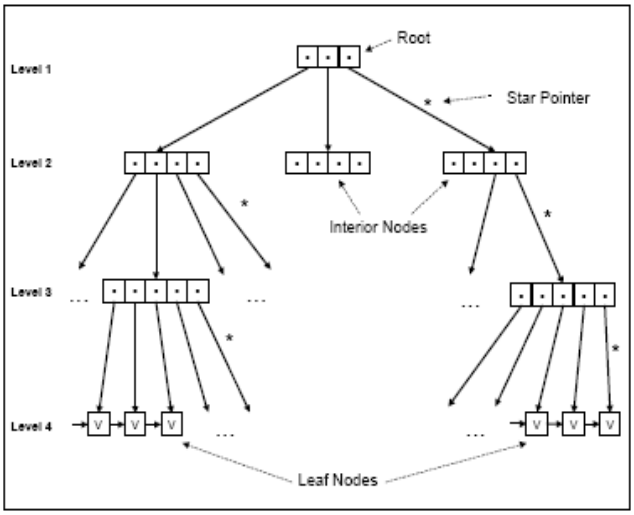

Figure 1: Statistics tree for data set with 3 dimensions.

The count values are initially zero in the leaf nodes. Next, we load the relational data set one record by one record, using the attribute values to update the aggregates and number of star in the leaves. The attribute value is component x_i of the input record $x=(x_0, x_1, \ldots x_{i,\ldots}, x_k)$, where i indicates the current level and k indicates it is a k dimensional relational data set. The update procedure starts at the root (level 0) with record component x_i, and star, then follow the $(x_i+1)^{th}$ pointer and the star pointer to the two nodes at next lower level. All pointed star nodes follow their star pointers arriving at their child star nodes. When reaching the leaves in the bottom level, increment the count values and the star number according to the number of star contained in the corresponding root-to-leaf path. Repeat above steps for each input record until all records have been loaded in this fashion.

Let us use the following 3-D case as an example. We mark the entry 1 in a 3-D cube space, if the case cell is non-empty. For example (0, 1, 3), (0, 1, 4), (0, 1, 5), (0, 1, 6) are marked as 1 in the second row of level 0. Now we create a table according to this example as the input of setting up a statistics tree. The above non-empty cells will be turned in to these four tuples (0, 1, 3; 1), (0,1, 4; 1), (0,1, 5; 1), (0, 1, 6; 1). The right most value is the measure value. In our example, we implement count operation.

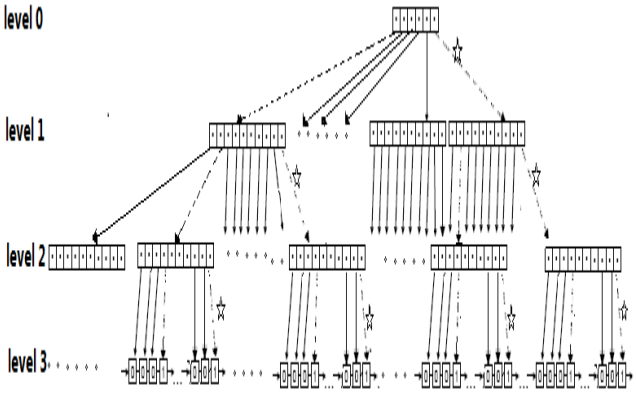

Figure2 : Statistics tree after processing input record (0,1,3).

Let us take three dimensional record tuple (0, 1, 3) as an input example to illustrate the record loading procedure. There are three dimensions A_0, A_1, A_2 with cardinalities d_0=5, d_1=10, and d_2=10, respectively. Figure 2 shows the statistics tree after (0, 1. 3) is loaded into an empty tree and dashed lines indicate its update paths of (0, 1, 3).

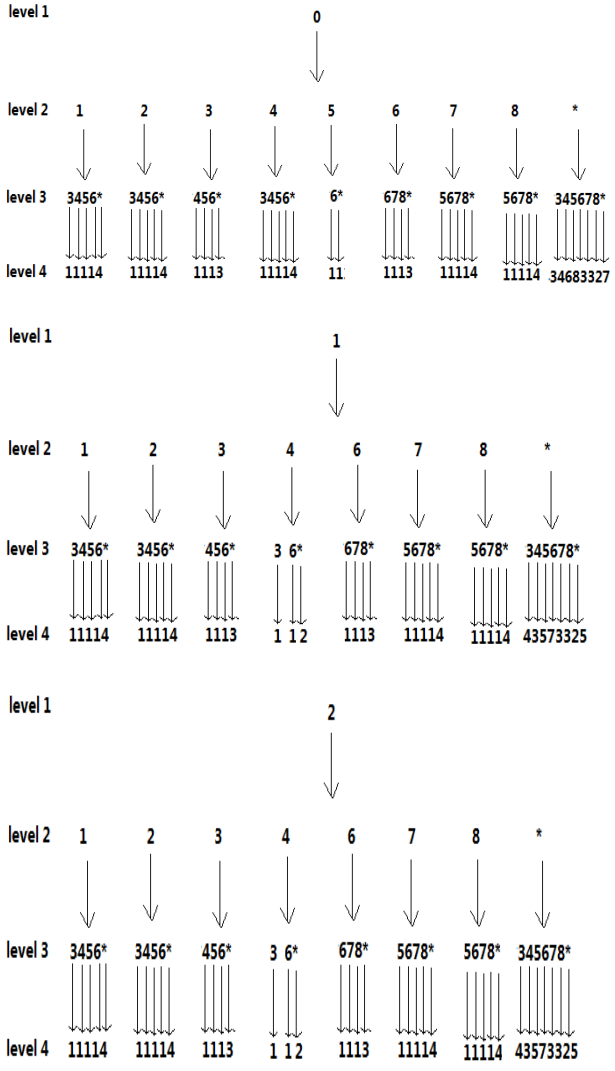
3.THE INTERACTIVE CLUSTERING ALGORITHM BASED ON STATISTICS TREES

3.1 Identifying Dense Units According to User's Input Parameters

After we set up a statistics tree and loaded a set of input data records. We need to identify dense unites according to user's input parameters. From the introduction of section 2, we know each leaf stores the aggregation of each root-to-leaf path which represents an input record

tuple. Users will be asked to input a threshold which is called MiniSupport. The leaves/paths/records, whose aggregation is no smaller than the threshold, will be identified as dense units. In other words, only the leaves whose aggregation is no smaller than the MiniSupport will participate the following cluster programs.

Continue above example, the values of threshold could be integers from 1 to 102 based on the loaded statistics tree in Figure 3. If a user inputs 5 as the threshold, only the aggregation of root-to-leaf paths, which represents input records, are no smaller than 5 will be identified as dense units and selected to carry on the following cluster. However, 5 is not an appropriate threshold in this case, because no duplicated record is inputted. No aggregation in the leaf expect leaves of star nodes is bigger than 1. Hence in this case we will set 1 as the threshold to implement the following cluster. Therefore, the selection of threshold for MiniSupport should accord to the feature and real situation of input data set.



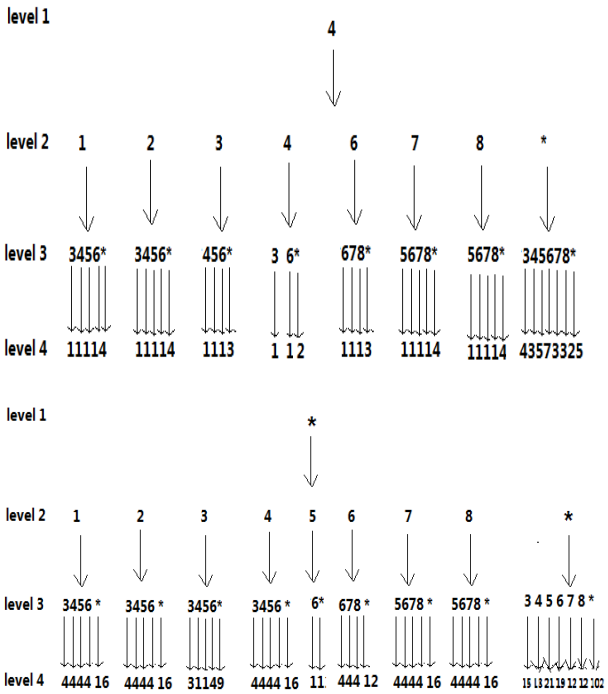


Figure 3 Statistics tree after loading the whole set of above record

3.2 Cover Dense Units with Minimal Number of Regions

When the statistic tree has been set up, clustering works on the tree structure created above. The basic idea is that we form multi-dimensional dense regions and cover them using minimal number of regions. Let us first introduce several terminologies.

Definition 1, **Range [l, h]** represents consecutive values, starting with integer **l** and ending with integer **h minus one** respectively. The volume of the range is **h-l**.

Definition 2, If l1>= l2 and h1<= h2, the boundary values are included, range r_1 [l_1, h_1] is **included** in range r_2 [l_1, h_2]. If r_1 is included in r_2 and l1= l2 or h1= h2, We say range r_1 is **on the end** of range r_2.

Definition 3, A **region** is defined as the Cartesian product of ranges. The volume of a region is the product of the volume of the ranges.

A region can be formed by different ranges, figure 4 shows region R_1 = $range_1$* $range_2$* $range_3$.

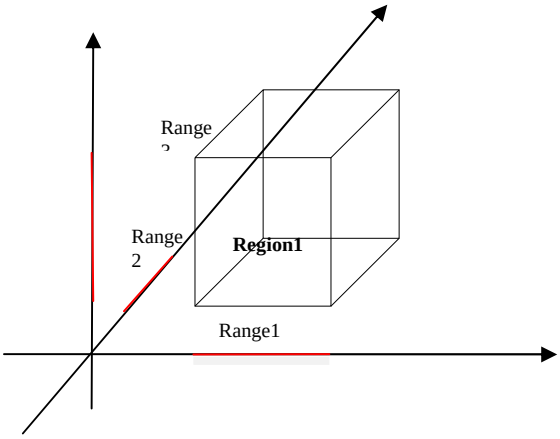

Figure 4 $Region_1 = Range_1 * Range_2 * Range_3$

A region is can be expanded from another region. Region $R_{2=}$ [l, h]*[l^{i1}, h^{i1}]*[l^{i1}, h^{i2}]*...*[l^{is}, h^{is}] , where [l, h] is a range r and [l^{i1}, h^{i1}]*[l^{i2}, h^{i2}]*...*[l^{is}, h^{is}] is region R_3 Figure 5 shows region R_2= [l, h] * R_3 = [l, h] * [l^{31}, h^{31}] * [l^{32}, h^{32}]. The bottom face is region R_3 and the cube is R_2.

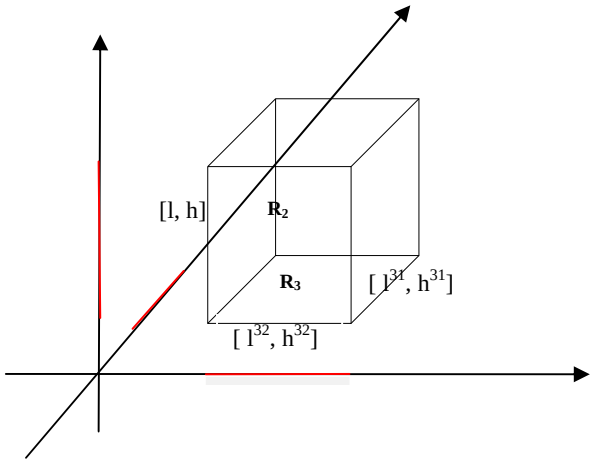

Figure 5 R_2= [l, h] * R_3 = [l, h]*[l^{31}, h^{31}] * [l^{32}, h^{32}].

Definition 4, Region R1 **is included** in region R2 for all the dimensions, each range of R1 is included in the corresponding range of R2. Region R1 = region R2, where all the corresponding ranges are exactly the same. Region R1 is on the end of region R2: if R1 is included in R2 and except that one dimension of which range end of R_2, all other corresponding ranges are exactly the same.

Definition 5, Cut the end region R1 from region R2: if R1 is on the end of R2 and the possible unequal pair of ranges are [l1, h1] and [l2, h2] respectively, [l2, h2]is changed to

[h1, h2], if l1= l2;
[l2, l1], if h1= h2.

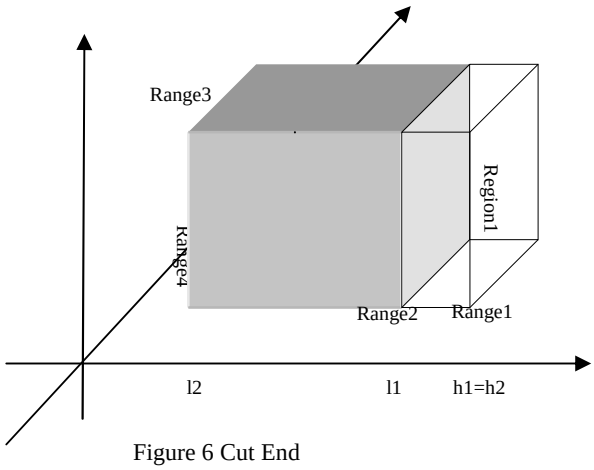

Figure 6 Cut End

For instance, in figure 6, $Range_1$[l1, h1] and $Range_2$ [l2, h2] are the only one pair of ranges that are not equal in the same dimension, where [l1, h1] is included in range [l2, h2], and other ranges of $region_1$ and $region_2$ are equal. So $Region_1$ is included $Region_2$, and $Region_1$ is the end of $Region_2$. We cut $Region_1$, the empty part, from Region2, to change [l2, h2] to [l2, l1] according to definition 5. We then get a shadow part, which is the new $Region_2$.

Region list: a linked list of regions

[l^{11}, h^{11}] * [l^{12}, h^{12}] * …*[l^{1n}, h^{1n}]: $measure_{1;}$ ($region_1$)

[l^{21}, h^{21}] * [l^{22}, h^{22}] * …*[l^{2m}, h^{2m}]: $measure_{2;}$

.....

.....

.....

[l^{i1}, h^{i1}] * [l^{i2}, h^{i2}] * …*[l^{is}, h^{is}]: $measure_{i;}$

In the linked list of regions, [l^{i1}, h^{i1}]*[l^{i2}, h^{i2}]* …*[l^{is}, h^{is}]:$measure_{i;}$ respects region i, and i is a positive integer and it indicates the size of the list m, n∈ {1,2…..k} in a k dimensional cube space. Measure is the aggregation of each region.

Cut a region r from the region list L: if there is a region R of which r is on the end, then cut r out of R (if the volume of R's remains is 0, remove it from list) and return true; else return false.

To cluster the loaded input data records on the statistic tree, the first step is to take care of the base case where we merge consecutive nodes on one level above leaves,

and return a linked list of dense units in a form of indexed region lists.

Algorithm merger:
Input: a node N in the ST at level "level";
Output: a region list that is the dense units in the sub-tree rooted at N;
RegionList clustre(N) { // base case
IF level = k-1; // When it is the bottom node level of statistic tree
THEN
Find the region list in which each region is a consecutive range;
The last region is a special region (-1,-1) (assign vol =1 to it, for the star node);
Return the region list;
// Recursively clustering its children and itself
level ← level+1; // when it starts from the first level,
FOR i = 0 TO (d_{level}-1), DO: listA[i]=clustre(i_th child of N);
outList = expand (listA);
Append to outList the regions expanded by range (-1,-1) and regions
in the region list clustre(star node child of N;
Return outList;
}

From the first node in this level, all nodes will be scanned one by one, and a set of consecutive nodes which are pointed by the same parent node will generate a range (*l*, *h*). The first node of the consecutive nodes is the lower bound *l* of a new range, and the node after the last consecutive node is the higher bound *h*. Merger ends until all of the consecutive nodes are merged. In other words, for one set of nodes which have the same parent node, whenever it is not consecutive to its previous node, a new range starts at this node and ends at the one after its last consecutive node. Notice that the last node of each set of nodes is Star node. We use range (-1,-1) to represent it specially.

Continuing the motivating example, we illustrate this algorithm with the nodes at level 2. ListA[i] is a Linked List of indexed region lists, where i indicates different region. Refer to the statistic tree in figure 3, we get List A as below. In the list, each tuple represents a region, where the first number represents domain value in first dimension, second value represents domain value in second dimension, and rightmost range is what previous algorithm merged in the third dimension.

After merging consecutive nodes in the second lowest level, we generate higher dimension dense unites by an expansion algorithm. The input is an array of region lists (list A) we get from the previous algorithm, and the output is a list of higher dimensional regions which is called OutList. We start from the minimal volume range (from one dimension to two dimensions) or minimal region (from two dimensions to multiple dimensions), and grow it both to the above and to the below of the minimal volume range/region along higher dimension, so that a range grows to a rectangle in a geometry space; a minimal region grows to a cuboid and go forth in this fashion.

Algorithm expansion:
RegionList expand (listA) { // listA is an array of "size" number of region lists initially
WHILE listA has non-empty list DO
Compute the region m_i with minimal volumes for the listA[i], i=(0,1,2,…size-1)
Compute k m_k = min { m_0 , m_1, m_2,…};
FOR low= k To 0, DO: IF (cutting m_k from listA[low] return false) BREAK;
// expand below
FOR high= k+1 To (size-1), DO: IF (cutting m_k from listA[high] return false) BREAK;
// expand above
Expand m_k with range [low,high] to higher dimensional region Mk and append to outList;
Remove m_k from region list listA[k];
}

Among all regions we search for the minimal region m_k,. It may be a part of a region or entire of a region in listA. If we found it in a region listA[k], next we check upwards if m_k is in the end of region listA[k-1]. If yes, cut it out of region listA[k-1]. Then continue to check if it is end of region listA[k-2]. If so, cut it out, too. Keep checking upwards one region by one region in this fashion and stop until the first region which does not contain m_k, as an end. Store the higher dimensional index of uppermost region that contains m_k as an end to be "low", which represents the lower bound for m_k expanding along the higher dimension. Then check if m_k is an end of region listA[k+1]. If yes, cut it out of region listA[k+1]. Then continue to check if it is an end of region listA[k+2]. Repeat check and cut steps for other regions downwards one by one in listA. Stop cutting until the first region which does not contain m_k, as an end. Store the higher dimensional index of nethermost region that includes m_k as an end plus one to be "high", which represents higher bound for m_k expanding along the higher dimension. Then expand m_k with range [low, high] to higher dimensional region M_k= m_{k*}[low,high], and append M_k to OutList. Remove m_k from region list listA[K].Repeat above steps for regions in listA until all regions in listA are moved in this fashion.

Continuing above example, refer to listA being generated by the previous algorithm, scanning the region lists, 0*5*(6,7); will be the first minimal region m_k to be found out. We first expand above. Check if this minimal region is an end of its above regions one by one. Then we found it is an end of following regions 0*4 * (3,7),

0*3*(4, 7), 0*2*(3, 7) and 0*1*(3, 7). Hence, we cut it out of these regions consecutively and store the index, 1, as "low" to be the lower bound in higher dimensional, because 0*1*(3,7) is the uppermost region that includes

$$m_i = \min_{r \in listA[i]}\{ vol_r \};$$

(6,7) as an end. Then the region 0*5*(6,7) becomes empty, and need to be moved out of listA. We continue to expand below. We found minimal region 0*5*(6,7) is only the end of regions, 0*6*(6, 9). Cut (6,7) out of this region. And store index, 7, as "high" to be the higher bound for minimal region expanding along higher dimension. In this way, m_k is expanded by range [low, high] to higher dimensional region M_k = 0*(1,7)* (6,7), which will be append to OutList.

The whole of cluster algorithm consists of merger part and expansion part, and it stars from merger algorithm. However, the merger algorithm stars at the bottom node level of the statistics tree, so we design a recursive part for the cluster algorithm to scan statistics tree from top to bottom to look for the level that meets the condition of starting base case of algorithm merger. After implement the solved case at the lowest *node* level of the statistics tree, algorithm expansion can be executed on the work of algorithm merger.

4 EXPERIMENTS

In this section we will discuss the efficiency of algorithm in terms of different volumes of input records, and different numbers of dimensions. We will use a data generation program to produce several sets of random records to compare. Firstly, we compare three sets of input data with the same number of dimensions and cardinalities, but different number of records. We set all of them have 3 dimensions with the same cardinalities 10, 10, 10. However, numbers of records are set to 100, 10000, 1000000 respectively. The running results as follows, (some output regions are omitted to improve readability)

```
setting up DST from file ...
setting finished. Spend time: 0

### FINAL ANS: ###

-- list: ---
(2,7)*(4,5)*(4,5)*:10
(3,4)*(3,7)*(4,5)*:4
(4,5)*(2,6)*(4,5)*:4
(4,6)*(3,5)*(5,6)*:8
(3,5)*(4,5)*(2,4)*:12
(4,5)*(3,5)*(6,7)*:7
(5,6)*(3,6)*(4,5)*:9
(4,5)*(5,6)*(2,6)*:10
(5,6)*(4,5)*(3,7)*:12
list length = 9

Cluster run time of DST = 0
```

Result 1: records volume=100 , dimension=3, cardinality=10, 10, 10.

```
setting up DST from file ...
setting finished. Spend time: 234

### FINAL ANS: ###

-- list: ---
(1,7)*(4,5)*(2,3)*:6
(2,8)*(5,6)*(3,4)*:6
(2,8)*(6,7)*(4,5)*:6
(1,9)*(4,5)*(4,5)*:8
(1,8)*(3,4)*(4,5)*:7
...
...
...
list length = 34

Cluster run time of DST = 0
```

Result2: records volume=10000, dimension=3,cardinality=10,10,10.

```
setting up DST from file ...
setting finished. Spend time: 19453

### FINAL ANS: ###

-- list: ---
(0,8)*(3,7)*(4,5)*:32
(1,9)*(4,5)*(6,7)*:40
(0,8)*(4,6)*(5,6)*:48
(7,8)*(1,7)*(2,3)*:6
(2,8)*(2,8)*(3,4)*:36
(2,3)*(0,8)*(5,6)*:8
...
...
...

list length = 47

Cluster run time of DST = 0
```

Result3: records volume=1000000, dimension=3,cardinality=10,10,10.

We find, for different volumes of input data with same dimensions and cardinalities, the Statistics tree setting and loading time goes up with the volume increasing, but the cluster run time does not change. They should not be zero but just the time is so small due to the size of tree is small.

Then, we compare three sets of input data the same volume and cardinalities, but different dimensions. We set all of them have 10000 input records and each cardinality is 10. However, each of record set has 3, 4 and 5 dimensions respectively. The running results as follows, (some output regions are omitted to improve readability)

```
setting up DST from file ...
setting finished. Spend time: 234

### FINAL ANS: ###

-- list: ---
(1,7)*(4,5)*(2,3)*:6
(2,8)*(5,6)*(3,4)*:6

(1,3)*(4,5)*(5,6)*(2,3)*:2
(1,2)*(5,6)*(4,5)*(2,3)*:1
(3,4)*(1,2)*(6,7)*(4,5)*:1
(4,5)*(1,2)*(4,5)*(7,8)*:1
(4,5)*(2,3)*(7,8)*(5,6)*:1
(4,5)*(6,7)*(0,1)*(4,5)*:1
(4,5)*(6,7)*(5,6)*(7,8)*:1
...
...
...
list length = 108

Cluster run time of DST = 16
```

Result4: records volume=10000, dimension=4,cardinality=10,10,10,10.

```
setting up DST from file ...
setting finished. Spend time: 624

### FINAL ANS: ###

-- list: ---
(1,6)*(2,3)*(3,4)*(4,5)*(4,5)*:5
(1,2)*(2,3)*(5,6)*(3,4)*(4,5)*:1
(1,2)*(3,4)*(3,4)*(3,4)*(4,5)*:1
(1,2)*(4,5)*(0,1)*(4,5)*(4,5)*:1
(1,6)*(5,6)*(4,5)*(4,5)*(3,4)*:5
(2,3)*(2,3)*(1,2)*(3,4)*(4,5)*:1
(2,3)*(2,3)*(4,5)*(6,7)*(4,5)*:1
...
...
...
list length = 329

Cluster run time of DST = 31
```

Result5: records volume=10000, dimension=5,cardinality= 10,10,10,10,10.

We find, for different volumes of input data with the same volume and cardinalities, when number of dimensions increases, it takes longer time to set up the statistics tree. Similarly, the cluster algorithm run time goes up with the number of dimensions increasing.

5 CONCLUSION

In this paper we propose a new clustering algorithm based on Statistics Tree data structure. The structure of the statistics tree is determined by the number of dimensions and their cardinalities. Other than the loading phase, the number of records is irrelevant in the clustering phase, thus rendering the new clustering algorithm a competitive edge. The clustering algorithm merges and expands the dense regions level by level recursively. We only implement the clustering algorithm based on dense statistics trees where the attribute values are contiguous. In future work, we may develop similar clustering algorithms based on sparse trees [12] which may accommodate much larger cardinality dimensions.

Abstract - *Data mining, a part of the Knowledge Discovery in Databases process (KDD), is the process of extracting patterns from large data sets by combining methods from statistics and artificial intelligence with database management. Analyses of biomedical data have evolved towards genome-wide and high-throughput approaches, thus generating great amounts of data for which data mining is essential. Therefore, a novel approach based on genetic programming with the aim of weighting the importance of the different variables contained in the data generated in the biomedical field is presented. This approach was applied to SNP data from Galician schizophrenia patients, showing the possibilities it offers.*

Keywords: genetic programming, evolutionary computation, variable analysis, data mining, schizophrenia

1 Introduction

Data mining, a part of the Knowledge Discovery in Databases process (KDD), is the process of extracting patterns from large data sets by combining methods from statistics and artificial intelligence with database management. Analyses of biomedical data have evolved towards genome-wide and high-throughput approaches, thus generating great amounts of data for which data mining is essential.

During recent years, the advances in data collection have enabled scientists to store a huge amount of data. However, traditional data analysis techniques cannot usually address this increase of data, so new approaches, as data mining, were promoted. Some of the specific challenges that motivated the development of data mining techniques were precisely the scalability and the chance to work with highly dimensional data or the lack of traditional methods to work with heterogeneous and complex data. This situation is especially relevant in biomedical fields.

However, traditional data mining techniques present many drawbacks and, often, lack of the necessary flexibility. Evolutionary algorithms have a global search feature which makes them especially adequate for solving problems found along the different stages of a knowledge discovery process. For this reason, in this work, a technique based on evolutionary computation is presented. This technique was applied to biomedical data with the objective of obtaining a list of prioritized variables extracted from the data.

The fact of weighting the importance of the variables has become relevant, since, as mentioned previously, not only more biomedical data is being generated, but also the number of variables present in this data is so high that their influence and importance is of very difficult interpretation. Therefore, the technique herewith presented, apart from analyzing the data, will give useful information to the researcher and make the task of interpretation easier.

2 State of the art

2.1 Genetic Programming (GP)

Genetic programming (GP) is an evolutionary technique used to create computer programs that represent approximate or exact solutions to a problem [1]. GP works based on the evolution of a given population. In this population, every individual represents a solution for the problem that is intended to be solved. GP looks for the best solution by means of a process based on the Theory of Evolution [2], in which, from an initial population with randomly generated individuals, after subsequent generations, new individuals are produced from old ones by means of crossover, selection and mutation operations, based on natural selection. This way, the good individual will have more chances of survival to become part of the

next generation. Thus, after successive generations, the best-so-far individual is obtained, corresponding to the final solution of the problem. The GP encoding for the solutions is tree-shaped, so the user must specify which are the terminals (leaves of the tree) and the functions (nodes capable of having descendants) to be used by the evolutionary algorithm in order to build complex expressions. Additionally, a fitness function that is used for measuring the appropriateness of the individuals in the population has to be defined in GP. This is the most critic point in the design of a GP system.

The wide application of GP to various environments and its success are due to its capability of adaptation to numerous different problems. Although one of the most common applications of GP is the generation of mathematical expressions [3], it has also been used in other fields such as rule generation [4], filter design [5], classification [6], etc.

2.2 Variable analysis

Subsequently, the latest and most related papers regarding variable analysis applied to biomedical data, especially those were SNPs are used, are described.

Chen et al. [7] review four variations of LR, namely Logic Feature Selection, Monte Carlo Logic Regression, Genetic Programming for Association Studies, and Modified Logic Regression-Gene Expression Programming, and investigate the performance of each method using simulated and real genotype data. They also contrast these with another tree-like approach, namely Random Forests, and a Bayesian logistic regression with stochastic search variable selection.

Kulkarni et al. [8] compare class prediction accuracy of two different classifiers, genetic programming and genetically evolved decision trees, using microarray data. The dataset used for the tests contained the best 10 and best 20 genes ranked by the t-statistic and mutual information. In their work, they conclude that genetic programming together with mutual information-based feature selection is the most efficient alternative to the existing colon cancer prediction techniques.

Zhang et al. [9] present a framework to evolve optimized feature extractors that transform an input pattern space into a decision space in which maximal class separability is obtained. The authors applied this method to real world datasets from the UCI Machine Learning and StatLog databases to verify their approach and compare their proposed method with other reported results.

Archetti et al. [10] present a genetic programming-based framework for predicting anticancer therapeutic response. They used the NCI-60 microarray dataset and they looked for a relationship between gene expressions and responses to oncology drugs Fluorouracil, Fludarabine, Floxuridine and Cytarabine.

Nunkesser et al. [11] present a procedure based on genetic programming and multi-valued logic that enables the identification of high-order interactions of categorical variables such as SNPs. This method, called GPAS, cannot only be used for feature selection, but can also be employed for discrimination. They applied their method to the genotype data from the GENICA study, an association study concerned with sporadic breast cancer, finding that GPAS was able to identify high-order interactions of SNPs leading to a considerably increased breast cancer risk for different subsets of patients that are not found by other feature selection methods. GPAS can also be employed to analyze whole-genome data, as demonstrated in its application to a subset of the HapMap data.

Nandi et al. [12] adapted GP and applied it to a dataset of 57 breast mass mammographic images, each with 22 features computed. The extracted features relate to edge-sharpness, shape, and texture. To refine the pool of features available to the GP classifier, the authors used five feature-selection methods, including three statistical measures - Student's t-test, Kolmogorov-Smirnov Test, and Kullback-Leibler Divergence.

3 Method

With the aim of analyzing a database, genetic programming can be used in order to generate expressions that allow characterizing which variables are important and how they influence the output. For this purpose, a novel approach based on genetic programming is presented in this paper. Therefore, in this case, the set of terminals is composed of the variables involved in the analysis and a series of random constants, and the set of functions is composed of arithmetic operators. This is described in more depth in the “GP configuration” below.

This way, it is possible that genetic programming may generate a great amount of expressions very hard to interpret. In this work, GP is not used to interpret these expressions, but to analyze them with the objective of discovering the importance of each variable.

Hence, the following is done: the proposed system is executed a very large number of times and, for each execution, the best individual obtained is considered. Thus, after all the executions have finished, there will be a set of expressions that characterize, with high precision, the variable of interest, that is, the class variable. Given the stochastic character of GP, the expressions contained in this set will be, in general, different, but all of them will have the highest precision value obtained in their corresponding evolutionary process.

Once this set of expressions has been obtained, each of these expressions is analyzed to calculate the density of apparition of each variable in the whole set. Thus, the relative importance of each variable can be quantified, depending on if this variable appears in a greater or lower number of expressions.

As a second analysis technique, this process has been performed analyzing each pair of variables, instead of taking only each of them separately, observing when they appear together in the expressions obtained.

3.1 GP configuration

Before applying genetic programming to solve a real-world problem, several types of parameters need to be defined in advance.

3.1.1 The function set and the terminal set

Although there are many different functions which can be used in GP, normally only a small sub-set of those is used simultaneously, because the size of the search space increases exponentially with the size of the function set. The function set employed in this work is listed in Table I. Since the functions need to satisfy the closure property in GP, the division operator is implemented in a protected way. Protected-division works identically to ordinary division except that it outputs the value of nominator when its denominator is zero.

TABLE I. THE FUNCTION SET

Name	Number of arguments	Operation
+	2	Arithmetic add
-	2	Arithmetic subtract
*	2	Arithmetic multiply
%	2	Protected division

Referring to the terminal set of this work, it includes 48 variables and random constants in the interval [-1, 1].

3.1.2 The control parameters

These parameters are used to control the GP run. There exist many possibilities of combination with different control parameters.

For solving the given problems, several different combinations of parameters have been tried. The parameters that returned the best results are shown in Table II.

TABLE II. CONTROL PARAMETERS IN GP

Initial population generation	Ramped half-and-half method
Maximum tree depth	9
Population size	1,000
Crossover probability	95%
Mutation probability	4%

3.1.3 The termination criteria

The GP execution is terminated when the following condition is fulfilled: the generated individuals changed less than a threshold (0.000001) in a maximum number of generations (10,000).

4 Experimentation and results

The objective of this work is to analyze data taking into account a certain number of variables in order to choose those that have more influence in relation to a specific characteristic. In this case, the technique was applied to data related to schizophrenia.

4.1 Description of the problem

Association studies are those in which DNA from patients that have not developed the disease is compared to DNA from affected patients in order to find relationships between mutations in the DNA and the disease studied. Usually, mutations such as SNPs (Single Nucleotide Polymorphisms) [13] are studied. A SNP is a single nucleotide site where two (of four) different nucleotides occur in a high percentage of the population, that is, at least in 1% of the population. Since there exist 14 million of SNPs in human beings then a huge amount of data obtained from DNA genotyping needs to be dealt with, thus many variables have to be taken into account.

These studies can be done on complex diseases [14]. In these diseases, apart from the influence of genetic predisposition, environmental factors also affect, in such a way that a person could be genetically predisposed but never develop the disease. Due to the nature of these diseases, it is hard to establish a relationship between a gene and the disease since, in general, this type of disease is caused by combination of effects of several sets of SNPs which, separately, have a low effect. There is a high prevalence and impact of complex diseases like cancer, mental disorders and cardiovascular diseases.

In this work, schizophrenia data from Galician patients [15] were used. This data contained 48 SNPs at the DRD3 and HTR2A genes [16], genes which are

associated to schizophrenia. These SNPs were encoded taking different values:

- 0 if homozygous (both copies of a given gene have the same allele) for the first allele (one of a number of alternative forms of the same gene occupying a given position on a chromosome),
- 1 if heterozygous (the patient has two different alleles of a given gene),
- 2 if homozygous for the second allele or
- 3 if unknown.

The original dataset contained 260 positive subjects (genetically predisposed to schizophrenia) and 354 negative subjects (not predisposed), a total of 614 patients. The equivalence between the variable number and the SNP real name is shown in Table III.

TABLE III. EQUIVALENCE BETWEEN VARIABLE# AND REAL SNP NAME

Variable #	SNP	Variable #	SNP
SNP1	rs4682148	SNP25	rs1058576

4.2 Results

Table IV shows a list of variables, ordered by the density of apparition in 134 parallel executions of the method described. As a result, an average classification accuracy of 77.38% was obtained.

This table shows the relative importance of each of these SNPs, measured as the density of apparition. As it can be seen, the SNP with the highest density is SNP48, appearing in 94.03% of the expressions obtained by the method. This SNP was also obtained as that one with the highest density of apparition by another method based on evolutionary computation [17, 18] also designed for feature selection.

TABLE IV. PRIORITIZED LIST OF VARIABLES

Variable #	Density of apparition	Variable #	Density of apparition	Variable #	Density of apparition
SNP48	**94.0298%**	SNP34	41.7910%	SNP27	31.3433%
SNP23	**92.5373%**	SNP14	40.2985%	SNP11	29.8507%
SNP29	**92.5373%**	SNP37	40.2985%	SNP32	29.8507%
SNP10	**91.0448%**	SNP24	38.8060%	SNP40	29.8507%
SNP20	76.1194%	SNP47	38.8060%	SNP3	28.3582%
SNP21	56.7164%	SNP1	37.3134%	SNP31	28.3582%
SNP43	56.7164%	SNP2	35.8209%	SNP38	28.3582%
SNP28	52.2388%	SNP22	35.8209%	SNP13	26.8657%
SNP30	52.2388%	SNP35	35.8209%	SNP9	25.3731%
SNP26	50.7463%	SNP36	35.8209%	SNP19	23.8806%
SNP41	50.7463%	SNP4	34.3284%	SNP46	23.8806%
SNP18	49.2537%	SNP44	34.3284%	SNP8	22.3881%
SNP15	47.7612%	SNP12	32.8358%	SNP5	20.8955%
SNP33	46.2687%	SNP6	31.3433%	SNP39	19.4030%
SNP42	44.7761%	SNP7	31.3433%	SNP45	19.4030%
SNP16	43.2836%	SNP17	31.3433%	SNP25	8.9552%

Additionally, this table shows that there is a big difference between the first four SNPs (numbered 48, 23, 29 and 10, with densities 94.03%, 92.54%, 92.54% and 91% respectively) and the rest. The density of apparition of the fifth SNP is much lower, 76.12%, and the following, the sixth, SNP21, has a density of 56.72%. These facts reveal the great importance of these four first SNPs compared to the rest. Furthermore, the fall in the density of apparition is very fast, and a low density of 50% appears in an early 10^{th} position.

TABLE V. DENSITY OF APPARITION FOR PAIRS OF VARIABLES

Variable #	Variable #	Density of apparition
SNP23	**SNP29**	**85.07%**
SNP23	**SNP48**	**85.07%**
SNP29	**SNP48**	**85.07%**
SNP10	**SNP23**	**83.58%**
SNP10	**SNP29**	**82.09%**
SNP10	**SNP48**	**82.09%**
SNP10	SNP20	71.64%
SNP29	SNP20	70.15%
SNP20	SNP48	68.66%
SNP23	SNP20	68.66%
SNP21	SNP48	55.22%
SNP43	SNP48	55.22%
SNP23	SNP21	53.73%
SNP23	SNP43	53.73%
SNP28	SNP48	52.24%
SNP29	SNP43	52.24%
SNP41	SNP42	52.24%
SNP10	SNP43	52.24%

Also, the expressions obtained were analyzed in order to measure the importance of groups of two SNPs. Table V shows the pairs of two SNPs with the highest density of apparition, appearing together in the expressions.

This table shows, for instance, that SNPs 23 and 29 appear together in 85.07% of the expressions. In this case, the pairs with the highest density of apparition correspond to all of the possible combinations of the four SNPs that were considered as the most important after the analysis of Table IV (SNPs 48, 23, 29 and 10).

After these combinations, the following pairs, which have a much lower density, include one of these variables. This fact, again, encourages the affirmation of the importance of these four SNPs.

5 Conclusions and future work

As section 4 shows, this technique allows analyzing databases in order to measure the importance of each variable. This has promising applications in engineering, industrial and medical environments, since many times data is collected and the number of independent variables grows exponentially.

One of these applications is studied in this paper, that is, to associate schizophrenia with SNPs that, initially, may be related to it. As a result of the application of this technique, four different SNPs are revealed to be the most important.

In this work, single and pair density of apparition are analyzed. However, in order to extract more accurate results, more analysis can be done, studying combinations of 3, 4 and more variables together. Additionally, the method will be applied to other biomedical datasets, in order to continue refining it.

Applied graph mining technique to discover consensus graphs from group ranking decisions

Li-Chen Cheng*, Min-Juan Jhang
Computer Science and Information Management, Soochow University, Taipei, Taiwan, ROC

Abstract — *The group ranking approach has been applied in many applications, such as in decision-making support systems, group recommendation systems, and so on. Previous studies have focused on how to generate a total ranking list. When there is no consensus or only slight consensus in the users' opinions or preferences, this kind of result may damage the decision-maker's decision. For this reason, this study proposes a new framework which represents user ranking information as a graph model, and a new algorithm based on the recent work to detect the maximum consensus graphs. The generated visualization results allow decision-makers to make better strategies.*

Keywords: Data mining; graph mining, Group decision making; Maximum consensus sequence

1 Introduction

Recently, the mining of knowledge from users' preferences has come to play a critical role in many applications including decision-making support systems [1-2], group recommendation systems [3], machine learning[4], and webpage search strategies [5-6]. User preference can always be expressed as ranking data. The essence of this problem is to construct a coherent aggregate result from the rankings provided by different sources.

Generally, the traditional group ranking problem can be classified using two aspects: the input format and the type of compromised output results. Among several input formats, ranking list is the most general way to express user preferences regarding the alternatives. This study allows users to provide complete or partial ranking data.

The output results of most research are to determine a fully ordered list of items. When there is no consensus or only slight consensus in the users' opinions or preferences, these studies still generate a total ordering list to represent the consensus using their ranking algorithms. However, these kinds of results will damage the decision and raise some risk to the decision maker. Recently, based on the concept of "consensus decision-making theory", Chen and Cheng proposed a new model which gives the longest ranking lists of items that agree with the majority and disagree with the minority [7]. Although the maximal consensus sequences model can solve the previously mentioned problem, the weakness of this approach may generate many maximum consensus sequences, making the results fragmented and difficult to understand and use.

This study adopts a user-provided total ranking list which is transferred to a user graph during the preprocessing step. The user graph is a directed graph illustrating the user's preference among items. The proposed algorithm will discover the maximum consensus graphs from the collection of users' graphs. A consensus graph means that a majority of users agree upon the relationships between items.

These graphs illustrate several implications which cannot be made by the previous research. The consensus graphs represent several clusters in which the relationship among items is agreed upon by most users. This is useful information for decision-makers.

2 Related work

2.1 Our recent work

The basic idea for our recent work comes from the "decision-making theory", which stresses that a process is needed to achieve the most agreeable decision among participants. It not only explores the agreement of the majority, but also resolves or mitigates the objections of the minority. To understand this decision-making process, Chen and Cheng proposed an algorithm to discover maximum consensus sequences from users' ranking lists, where the maximum consensus sequences represent the maximum possible consensuses that could be achieved among most of the users [7,8]. This algorithm can also identify ambiguous pairs that need further negotiation.

2.2 Graph mining

The graph mining technique can be applied to several different research areas, and has received much attention in recent years [9-18]. The graph model can represent arbitrary relations among objects. Using different mining techniques can detect various kinds of graph patterns. Frequent subgraphs are the most important patterns that can be discovered in a collection of graphs [10-12]. Several well-

known algorithms have been developed to mine frequent substructures [19]. Among these studies, there are two basic approaches to the frequent substructure mining problem: an Apriori-based approach and a pattern-growth approach [13]. The Apriori-based approach can be classified into the vertex-based candidate generation method and the edge-based candidate generation strategy [14-18]. This study follows the idea of the Apriori-based approach and is based on the vertex-based candidate generation scheme to propose the new framework.

3 Problem definition

Let $U = \{u_1, u_2, u_3, \ldots, u_m\}$ denote all users and $I = \{i_1, i_2, i_3, \ldots, i_n\}$ denote the sets of all distinct items. Each user u_i expresses his/her preference using user sequence $S_i = \{i_{a_1} \oplus i_{a_2} \oplus i_{a_3} \oplus \ldots \oplus i_{a_n}\}$, where $i_{a_j} \in I$, $1 \leqq i_{a_j} \leqq n$, and $\oplus \in \{>, =\}$.

3.1 User sequence's relationship function

A user sequence can be represented as $S_i = \{i_{a_1} \oplus_1 .. \oplus_{p-1} i_{a_p} \oplus_p .. \oplus_j . \oplus_{q-1} i_{a_q} \oplus ... i_{a_k}\}$. The relationship between two items i_{a_p} and i_{a_q} in user sequence Si can be represented as $Rel(i_{a_p}, i_{a_q}, S_i)$, whose value is defined below：

- If $\exists \oplus_j \in \{>\}$ $p \leq j \leq q-1$, then $Rel(i_{a_p}, i_{a_q}, S_i) =">"$;
- If $\forall \oplus_j \in \{=\}$ $p \leq j \leq q-1$, then $Rel(i_{a_p}, i_{a_q}, S_i) ="="$

3.2 User graph

A user's preference sequence S_i is transferred to be a user graph $UG_i = (V, E)$. Each item is mapped to a vertex in set $V(UG_i)$. The edge represents the items' relationship denoted as $E(UG_i) = \{e_1, e_2, e_3 \ldots, e_k\}$. UG_1 is a user graph and is shown in Fig. 1.

Example 1. Given a user sequence $S_1 = \{i_2 > i_3 = i_1\}$, user graph $UG_1 = (V, E)$, $V(UG_1) = \{i_1, i_2, i_3\}$, $E(UG_1) = \{e_1, e_2, e_3\}$.

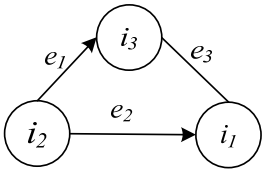

Fig. 1. User graph UG_1

3.3 Isomorphism

The two graphs $G = (V, E)$ and $G' = (V', E')$ are isomorphic. They have the same topology in that $V(G')$ and $V(G)$ are equal. The edges $E(G)$ of the mapping feature functions are equal to the $E(G')$ of the mapping feature functions.

Example 2. There are two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$. The vertices of graph G_1 map to $V(G_1)$ and the vertices of graph G_2 map to $V(G_2)$. $V(G_1) = V(G_2)$ and the feature functions of G_1 are equal to the feature function of G_2.

G_1 and G_2 are isomorphic and are shown in Fig. 2.

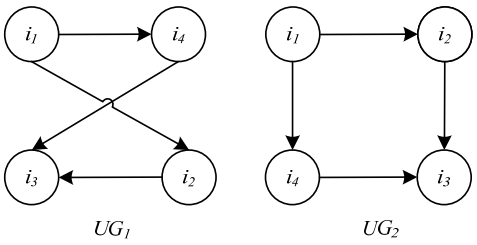

Fig. 2. Isomorphism relationship with two graphs.

3.4 Comply graph support

A subgraph G_m is called a complied graph if it satisfies the relationship $cmp\_sup(G_m) \geq cmp\_minsup$, where cmp_minsup is a threshold given by users.

4 Methodology

4.1 The proposed algorithm

We give an overview of the proposed algorithm. We propose an algorithm to discover the maximum comply graphs from the collection of all user graphs. The cmp_minsup are thresholds given by the user to filter out comply graphs.

(Step 1)

Each user sequence is transferred to a user graph based on the definition.

(Step 2)

The set of candidate graph CG^2 will be filtered. The comply support satisfies the support constraints.

(Step 3)

This step is iteratively executed until $LG^{k-1} = \phi$. We follow the vertex-based candidate generation scheme. In general, candidate CG^k can be generated by $LG^{k-1} \otimes LG^{k-1}$, where $\otimes$ denotes the join operation. After

obtaining CG^k, LG^k is the set of candidates whose *cmp_sup* satisfy the support constraints.

(Step 4)

We obtain all consensus graphs.

4.2 Candidate generation and counting supports

This section explains how to generate candidates from a set of large subgraphs. This study generates candidate subgraphs of size k CG^k by joining two frequent size k-1 subgraphs LG^{k-1}. We follow the vertex-based candidate generation scheme.

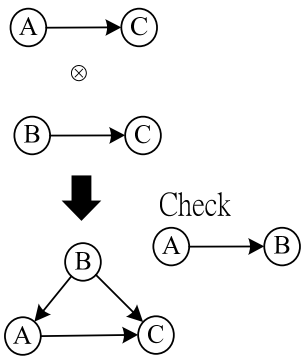

Fig. 3. Join operation of the proposed methodology.

5 An illustrative example

A simple example is demonstrated to show the computation process of the proposed method. There are 5 user sequences illustrated in Table 1.

Table 1 user sequences

1	{A > B > C = D }
2	{D > A = B > C }
3	{C = D > A > B}
4	{B > A > C = D }
5	{B = D > A > C }

Step 3 will be executed several times until the large graphs LG^4 are generated. Finally, the maximum consensus graph will be generated by LG^4 and the result is illustrated in Fig.4.

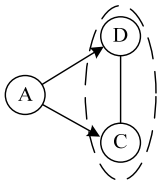

Fig. 4 The Large graph LG_5.

From the maximum consensus graph LG^5, we can discover several interesting facts. First, there are three clusters {A} and {C, D}. Second, several rules can be observed {A > C} and {A > D} and {C = D}. From these observations, the proposed algorithm can discover several consensus graph groups when there is no consensus or only slight consensus of the users' opinions or preferences. The result can still provide the decision-maker with useful information.

6 Conclusions

Existing methods for the group ranking approach always generate a total ranking list. In a recent work, we proposed methods to discover the maximum consensus sequences. Although the result is more reasonable, the weakness of this approach is that it may generate many maximum consensus sequences, making the results fragmented and difficult to understand and use. This current study based on the graph model develops a new methodology to discover the consensus graphs and ambiguous graphs. The proposed method is illustrated with an example. We will conduct extensive experiments to evaluate the effectiveness of the proposed algorithm in the future.

How User Types in Chinese from Keyboard

Analysis of User Behaviors on Chinese Input Software

Abstract - *The standard keyboard is initially designed for native English speakers. In China, people type in Chinese character under the help of Chinese input software which converts the pinyin sequence – the Chinese official phonetic symbol that can be typed in directly from the standard keyboard– into Chinese character sequence. QQ input software is the second most popular Chinese input software by market cap. Under the user agreement, we collect the anonymous user typing records as it uses QQ input software. This paper presents the preliminary results on user typing behaviors by analyzing these records. This work enlightens the way to improve the performance of Chinese input software, so as to improve user experience further*.

Keywords: Chinese Input Software; Data Mining

1 Introduction

The standard keyboard is initially designed for native English speakers. In Asia, such as China, Japan and Thailand, people can not input their language through the standard keyboard directly. Asian text input becomes the challenge for the computer user in Asia. In China, Chinese user types in Chinese text under the help of Chinese input software which converts the pinyin sequence – the Chinese official phonetic symbol that can be typed in directly from the standard keyboard– into Chinese character sequence. There are totally 410 pinyin symbols (without the tone information) which correspond to more than 30,000 Chinese characters. For a certain inputted pinyin sequence, there are many candidates of Chinese character sequence corresponding to it, but only one is what the user really wants to obtain. It's the challenge for Chinese input software to guess what is the user really wants to input, and present it in front of the user.

QQ input software is the second popular Chinese input software in China by market cap. It is developed by Tencent Technology Company Limited which is currently the largest internet company in China. There are more than 200 million users that have installed QQ input software on their computers. More than 25 million users input Chinese by QQ input software daily [1]. We started "user experience plan" since last year. Under the user agreement, we collect the information of anonymous users' typing records. We analyze user behaviors from these information, and get some insights how user input Chinese by Chinese input software. These results are very helpful for us to improve the quality of QQ input software so as to improve user experience on it further.

In the rest of this paper, we present our analysis works on user behaviors in section 2. In section 3, we draw the conclusions and discuss the future works.

2 Analysis OF User Records

2.1 Description of Data Set

We collect several kinds of information with the typing records from anonymous users. They are presented in Table 1 as below:

Table 1. Description of Anonymous User Typing Record

Information Type	*Description*
Host application	The name of host application in which user types in Chinese characters by QQ input software.
Pinyin sequence	How user types in pinyin string, i.e. it types in the full pinyin string or only the brief one.
Word candidate	The Chinese word candidate that QQ input software provides according to user's pinyin string.
User selection	The candidate that user selects as its real input.

There are four kinds of information above with each typing record. For experiments, we collect all the typing records from anonymous users during one week. Totally there are about 1.2 billion records.

2.2 Analysis on Host Application

There is the host information with each typing record. It's the name string of the application in which user inputs Chinese by QQ input software. By making statistics on the host information, we can get the insight of typical scenarios that user inputs Chinese. We stat the distribution for each host in the data set and present the top 10 hosts in Table 2 as below:

Table 2. Top 10 Hosts

Name of Host Application	*Type*	*Ratio*
QQ	Instant Messenger	65.8%
IE	Web Browser	2.64%
360 Explorer	Web Browser	2.54%
Ali Buyer	Instant Messenger	2.34%
Cross Fire	Game	1.99%
The Dream West Travels	Game	1.47%
Dungeon & Fighter	Game	1.39%
Word	Office	1.32%
World of Warcraft	Game	0.76%

Name of Host Application	*Type*	*Ratio*
other	other	19.75

For convenience, we summarize them into Fig. 1 as below:

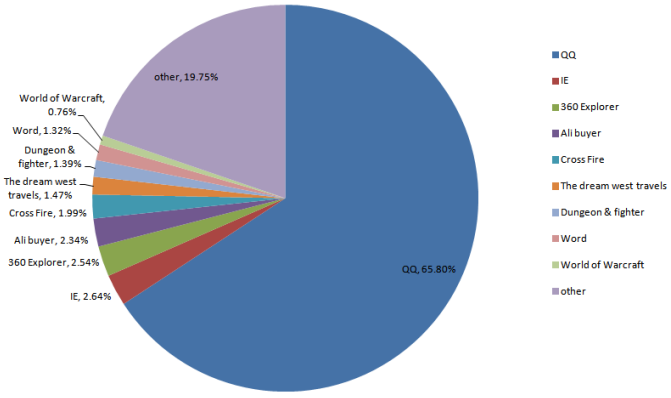

Figure 1. Top 10 hosts

Firstly, as shown in Fig. 1, user inputs Chinese mostly on several typical kinds of applications, such as instant messenger, web browser, game and so on. Each kind of application corresponds to a kind of typical user scenario. It is great helpful for Chinese input software to improve its performance on these limited scenarios. Secondly, instant messenger is the top scenario whose ratio even exceeds the sum of the others. It indicates that social contact becomes the top need for Chinese user. Web browser and game are the 2nd and the 3rd typical scenarios. User also does a lot of social contacts on them. For example, user contact with each other by twitter and blog from web browser; they share information in games. Therefore, it's necessary for Chinese input software to improve its performance on social contact to meet the user needs. For example, it should enhance its lexicon periodically by mining new words from social network. Thirdly, the 'other' type of hosts takes about 20% portion. The ratio of each individual host is no more than 0.5%. It indicates that there is also a 'long tail' in the user input scenarios, as it exists in other areas [2].

2.3 Distribution of Input Length

By the scale of input unit, Chinese input software can be categorized into three types: the character-level one, the word-level one and the sentence-level one. All of the commercial Chinese input softwares are the sentence-level ones which allow user inputs a whole Chinese sentence each time. Language modeling is the key technique to build the sentence-level Chinese input method [3]. However, by intuition, user usually does not type in all the pinyin strings for a whole sentence each time. In fact, it often types in the pinyin strings for a short fragment, that is usually semantic complete, then confirms it into the host application. User inputs the whole sentence by several fragments. For example, the user is going to input "今天下午我们开会" (in this afternoon we are going to have a meeting). It usually confirms the fragment of "今天下午" (in this afternoon) into the host application firstly. Then it inputs "我们开会" (we are going to have a meeting) in the second time.

In this section, we investigate the distribution of length of user input fragment in the typing records. By contrast, we also present the distribution of length of Chinese sentence in our training corpus which is used to build the language model for QQ input software. It is from the QQcom which is the most popular web portal in China [4]. Its scale is about 1TB. The results are described in Fig. 2 as below:

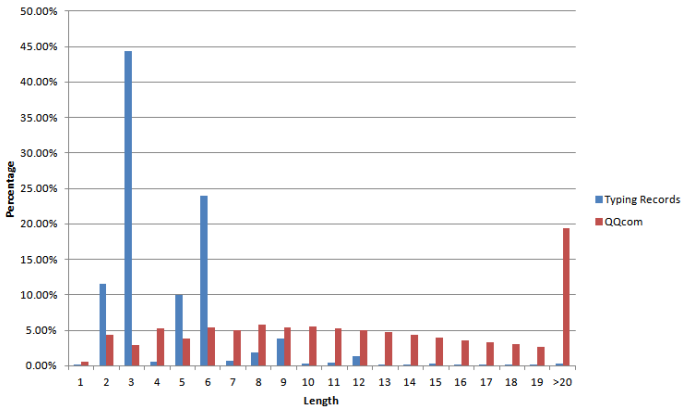

Figure 2. Distribution of Input Length

As shown in Fig.2, there is large portion on short length in user typing records. The average length that user inputs Chinese characters is 4.52. The user inputs that exceed more than 10 characters are very rare. It proves that user is prone to input Chinese by short fragment, rather than the whole sentence. By contrast, the length distribution is much evenly in the Chinese sentences in our training corpus. Its average length is 13.61. There are about 20% sentences whose length exceeds 20 Chinese characters, which indicates that some sentences are very long. Therefore, it's beneficial to build QQ input software on the corpus containing shorter sentences, so as to meet the user input in reality better.

3 Conclusions

In this paper, we study the user input behaviors by analyzing user typing records from QQ input software. We get some insights from it. It enlightens the way to improve the performance of Chinese input software. In our future works, we are going to apply these insights on the new versions of QQ input software, so as to improve user experience on inputting Chinese from keyboard.

From Teleoperation to Autonomy: "Autonomizing" Non-Autonomous Robots

B. Kievit-Kylar[1], **P. Schermerhorn**[1], **and M. Scheutz**[3]
[1]Cognitive Science Program, Indiana University, Bloomington, IN 47404, USA
[2]Department of Computer Science, Tufts University, Medford, MA 02155, USA

Abstract— *Many complex tasks (search and rescue, explosive ordinance disposal, and more) that eventually will be performed by autonomous robots are still performed by human operators via teleoperation. Since the requirements of teleoperation are different from those of autonomous operation, design decisions of teleoperation platforms can make it difficult to convert such platforms for autonomous use. In this paper, we discuss the differences and the potential difficulties involved in this conversion, as well as strategies for overcoming them. And we demonstrate these strategies by "autonomizing" a fully teleoperated robot designed for tasks such as bomb disposal, using an autonomous architecture that has the requisite capabilities.*

Keywords: tele-operation, autonomy, conversion

1. Introduction

Teleoperated robots are becoming widely available for all kinds of activities, from defusing bombs (like the IRobot Packbot in war zones)[1] to remote presence robots (like the Vgo)[2]. These robots are able to go places and do things that would normally be too dangerous for humans, or simply be too expensive to be practical. They include a range of sophisticated equipment and low-level control algorithms, and would seem to be naturally suited, and are certainly highly desirable, for autonomous operation. Compared to autonomous robots, teleoperated robots are easier to build and easier to sell because no control system for autonomous operation has to be designed (all the intelligence and control lies with the human operator instead) and sometimes poorer quality or fewer sensors can be used (as humans can generally make better use of available sensors than current autonomous techniques). Hence, it is unsurprising that increasing the efficacy of teleoperation interfaces is a continued research focus (e.g., [1], [2], [3]).

One obvious drawback of teleoperation is the need to have a live control stream of data for sensors and effectors. However, given the constraints that make robots appealing tools, it may be difficult or impossible to establish the data connection (e.g., because of the distances involved or environmental interference), and requiring a controller to be close to the robotic platform may put the operator in danger, eliminating the primary advantage of using a robot. Even in the absence of such obstacles, the need for constant human attention adds expense and limits the overall effectiveness of the robot. The ability to operate these robots autonomously would avoid many of these limitations, but researchers need access to the robots to continue to improve the performance of autonomous robot architectures to the point where the human operator is not needed.

The common response to the above issues has been the design of "hybrid autonomous/teleoperated" systems that combine the strengths of both approaches. Mixed-initiative architectures are suitable as extraplanetary rover control systems, where prohibitive communication delays necessitate some degree of autonomy, while the higher-level decision-making remains in the hands of a team of human experts [4]. Several groups have examined effective mechanisms for adjustable autonomy, so that the balance between teleoperation and autonomy can be dynamically altered to fit the circumstances [5], [6], [7].

While mixed-initiative systems touch on the autonomization problem, these systems are designed from the ground up with partial autonomy in mind. Very little work has been done on converting systems that were designed to be purely teleoperated into partially or fully autonomous systems. Not only is the literature on the transformation of non-autonomous robots into autonomous ones far sparser, but the existing papers also focus mostly on the integration of one particular robotic platform. E.g., Barreto [8] describes the autonomization of the ANDROS platform using the idea of interchangeable "brick" components to add new sensory capabilities. Similarly, Stewart and Khosla[9] describe a modular control mechanism for a Puma 560 in which a teleoperation module is replaced with an autonomous one.

We believe that a greater understanding of how a conversion can be done would be greatly beneficial to the field. In this paper, we describe our efforts for developing systematic principles for converting non-autonomous teleoperated robots into fully autonomous platforms. We start with a brief background on teleoperated and autonomous robots. We then discuss some of the design philosophies that affect "autonomizing" teleoperated systems. Next we describe our transformation of the Multi-Mission Payload Platform (M2P2) into a general

[1]http://www.irobot.com/gi/ground/510_PackBot
[2]http://www.vgocom.com/what-vgo

purpose autonomous system. After presenting an evaluation of the new system in a "bomb disposal" task, we finish with some discussion about limitations of this technique as well as how generalizable it is to other robotic platforms (`http://www.apitech.com/products/multi-mission-payload-platform-m2p2`).

2. "Autonomizing" Teleoperated Robots

Successfully implementing an autonomous architecture on a robot that has been designed for teleoperation requires overcoming a variety of challenges. All of these challenges are traceable in some way to how different constraints factor into the design of purely teleoperated robots.

While there are some obvious mechanical differences existing in the hardware needed to perform communication with an operator verses an autonomous system, many more subtle assumptions go into the construction of these two types of robotic platforms. Autonomous and teleoperated robots will often require different levels of sophistication in the sensors needed to perform their tasks. For example, while the output of wheel encoders and range-finders may be very useful in allowing a program to determine its position, often humans rely on more expensive sensors such as video cameras to quickly expose them to a high volume of noisy data. As well as sophistication in sensors, complex robots with many moving parts require complex control systems. While a human operator may only be able to focus on a subset of controls at any given time, microchips are able to compartmentalize the various effectors allowing simultaneous meaningful control of all. While more user friendly interfaces or multiple operators may alleviate the control problem to some degree, it can not match the orchestration of a single programmatic control architecture. Similarly, the computational requirements of a remotely-controlled robot can be very low. Hence, there may be no general-purpose onboard computer, or that computer may be underpowered to handle the tasks (problem-solving, sensor processing, etc.) required for autonomous operation.

The same goes for effectors; for example, the design of a gripper that will be actuated via a gamepad in the hands of a skilled user might look very different from what an autonomous robot architect might ideally envision (e.g., because it has fewer safeguards, relying instead on the operator's skill and judgment). Even at the mundane level of connectivity, different requirements are evident; a relatively low-bandwidth wireless connection might be acceptable for teleoperation (e.g., lower frame-rates, lower resolution, or higher noise in a camera feed may be easier for a human operator to deal with than for a vision processing algorithm; similarly for audio streams and voice recognition). Autonomous operation may, therefore, necessitate the addition or replacement of computational, sensing, or effecting equipment on the teleoperation platform.

We now address specific challenges:

a) Physical connection: Sensors and effectors need to be exposed to the control architecture. In some cases it may be possible to make use of the existing teleoperation channel, but (as noted above), this will sometimes not be feasible. In that case, it will be necessary to create alternative interfaces (e.g., RS-232 or USB-based serial or wired Ethernet connections). Moreover, if device drivers and libraries do not provide access at the right level of abstraction, it may be necessary for the control architecture to implement a software interface, as well.

b) General control algorithms for effectors: Similarly, depending on the nature of the particular sensors and effectors, it might be possible to use existing control algorithms (e.g., for a mobile robot base or for an n-degree of freedom manipulator) or to use them after only minor adaptations. In the worst case (typically because a given piece of hardware is used differently under teleoperation than under autonomy), new algorithms need to be developed for particular sensors and effectors. For example, feedback from sensors such as wheel encoders can be used to generate a simple, immediate, computational understanding of an autonomous robot's pose. However, the human operator is unlikely to find encoder counts useful, so they may not be exposed via a software interface, and in the worst case, may not even be present at all. Other sensors, such as cameras, are often easier to access, but may still require additional processing steps (e.g., to extract individual frames for visual processing from a video stream encoded for efficient transmission).

c) Control architecture: Naturally, one of the biggest changes will be the inclusion of the autonomous control architecture itself. A wide variety of configurations is possible; depending on the task, the control architecture will comprise different components, possibly including a planner, an action execution component, components for user interfaces including screen-based and possibly spoken natural language dialog interfaces. The task approach can either be pre-programmed (e.g., in terms of action scripts) or the robot can be dynamically instructed during task execution. The latter requires the control architecture to use problem-solving for new tasks for which no action scripts exist [10].

d) "Plug-and-play" generalizability: Adding an existing control system can be relatively straightforward if it implements and uses a well-defined API structure. Typically, sensors will fall under a particular sensing category, e.g., range sensors, vision sensors, force sensor, etc., thus allowing for a generic interface to be adapted for the particular sensor use. Similarly, typical effectors such as wheels for mobile platforms, grippers, or robotic arms will allow for abstractions that map effector-specific commands and properties to more generic interfaces that can interact with standard algorithms. If the control system is designed with such generic interfaces in mind, the problem can be viewed as one of ensuring that the control system's expected interfaces are mapped properly onto the teleoperated robot's hardware and software

interfaces. The difficulty here is that there is unlikely to be a one-to-one match of functional units between the teleoperation platform and the control architecture. For example, the robot's interface may support driving arm joint motors at a given velocity, in agreement with the control architecture's expectations. However, it may lack a predefined position-based joint motion mechanism, which must be added as part of the integration if the control architecture expects it. Similarly, there is no reason to assume that both architectures will use the same relative sign or units.

e) Programatic interface: Ideally, whether it is implemented as a software library (e.g., C/C++ shared objects, Java classes, etc.), simply given as a communication protocol (e.g., custom serial protocols, standardized infrastructures, etc.), or some combination of the two, the interface for a new piece of hardware will be well-specified and clearly documented. However, given that teleoperated robot platforms are not originally intended to be targets for development, the likelihood of undocumented features or errors in the specification is somewhat higher than normal. In such cases, it may be necessary to examine how the teleoperation controller interfaces with the robot architecture that it was built with. Studying the effects of (or responses to) valid messages sent from the original teleoperated controls, can be very helpful for "filling in" gaps. These messages can then either be analyzed for patterns or stored as a response lookup table to be used later by the software.

f) Simulation: Simulation is a valuable tool for any autonomous robot architecture, and not just to facilitate testing before deploying on the physical robot. Take, for example, the case of arm movement and manipulation. Since human operators inherently have extremely rich mental models of the systems that they are working with, they do not require precise measurements of all of the possible positions in joint space. Simply by viewing a handful of video frames taken from a mounted camera, the operator can determine approximately how that camera is mounted in relation to the robot and the target as well as determining an appropriate movement path. For the autonomous architecture, on the other hand, pre-building a highly accurate model of the known environment (the robot and its manipulators) will allow it to avoid the time-consuming process of building relational models on the fly. Such simulation planning also allows a robotic architecture to plan movements through space that optimally avoid obstacles, which is especially important in cases where feedback from the platform regarding joint positions is of less than ideal fidelity.

2.1 Experimental Platform

The robot we chose to autonomize is the APITech Multi-Mission Payload Platform (M2P2). This robot was designed to be controlled by a human operator primarily via a wireless XBox game controller. The M2P2 is a three wheeled holonomic robot with each wheel capable of rotating independently. It is equipped with a 2 DOF arm terminated by a 2 DOF gripper. The operator can get the robot's view of its environment through two cameras, one mounted on the platform and one mounted on the arm. In addition, the platform includes both a speaker and a microphone, allowing the operator to speak through the robot and hear any sounds near the robot.

Communication in the M2P2 is a subset of JAUS (the *Joint Architecture for Unmanned Systems*, a standard for open interoperability in robotic architectures [11]), augmented by a small number of custom message types. The M2P2 implements a set of core movement functionality as well as including custom messages for the robot arm control and specific sensors. JAUS messages on this robot are passed on two onboard networks, one for sensors and one for effectors. Messages are transmitted wirelessly to a pack based Operator Control Unit (OCU). Video streams are played back on a dedicated tablet PC along with custom built software to facilitate control of robot movement.

We integrated the M2P2 into ADE (the *agent development environment*), a Java-based infrastructure for developing robotic architectures [12], [13], [14]. ADE provides communication mechanisms that allow modular functional components to interact in a distributed fashion using Java remote method invocations. ADE components can register their own services and look up services provided by other components, and connections between components are monitored to ensure robust execution. A well-defined suite of programming interfaces allows consistent access to a variety of sensors (e.g., laser range-finders, GPS sensors, and cameras) and effectors (e.g., robot bases such as the Segway RMP, Mobilerobots Pioneer, and Videre Era). Implementing these interfaces on the M2P2 allows us to take advantage of the existing autonomy facilities in ADE, including problem-solving and goal management.

2.2 Communication

The first step in autonomization is to establish communication pathways between the teleoperated robot base and the computer that will host the autonomous architecture. This meant bypassing the existing wireless RF interface used by the teleoperation rig to instead make direct (wired) Ethernet connections to the robot.

Once the physical connection has been made, it must be tested. Before the cheap availability of high performance micro processors and network adapters, connection types were likely all proprietary and highly compact. Now, developers are moving toward higher bandwidth communication to help improve comprehension of the messaging system. Protocols like the Internet Protocol (IP) both internally provide a lot of functionality (message ordering, routing, etc.) but also have many tools to help receive, send and process information. Robots running such protocols can

often be tested with packaged communication processing tools, while rarer protocols may require testing specific to a given communication design.

g) Communicating with Effectors: Although communications protocols could theoretically be arbitrarily complex, they break down into two parts, syntax and semantics. For each functional ability to be run on the robot, syntax is the set of argument variables with possibly some information on their size and type, and semantics is the generalized understanding of how the bits in each argument are interpreted (as flags, as integers representing feet, doubles representing miles per hour, etc.). When trying to back-engineer a communication protocol, the syntax of the command must be determined first. The syntax alone however is not sufficient for interpreting and generating commands of that type as the variables must be unpacked as values and then those values given in meaningful units or conditions.

For example, when implementing robot arm control for the M2P2, we determined from the JAUS protocol that the command to modify the arm position was a concatenation of values each representing a velocity of one of the arm joints. This information alone was insufficient even to determine the exact syntax of the command. Through feedback from the manufacturer in conjunction with systematic testing of options, and validation of the specifications, we found the ordering of the joints and number of bytes allocated to each joint in the command. While this specified the syntax of the commands, it was still unclear how each set of around four bytes (more for some joints and less for others) translated into a velocity on the physical arm.

Some of the most common encoding variants are; flags, scaled integers, IEEE floating point or doubles, and angles. Flags can be tested through simple trial and error when the outcome of the flag is an obvious physical change in the system. Scaled integers (where the values are interpreted as integer values times a scaler plus an offset), are often easy to detect as similar integer input values will lead to similar output speeds or other output types. Floating point or double precision number should be tested similarly to scaled integers, where similar inputs cause similar outputs however instead of using similar integer representations to test, convert the values into either doubles or floating points. Angles, while a subset to scaled integers or decimal precision numbers, are a special case as they are cyclic in nature and this must be accounted for when trying to determine if a particular encoding is of this form.

When all attempts at understanding the semantics fail (i.e., a systematic test of the possible input space provides no observable consistences), an alternative approach is to build a simple input/output lookup table. Recording what direction a particular joint makes and potentially some gross speed conditions, for a set of given inputs, can allow a simply designed inverse process where a desired speed can be achieved by finding the closest speed known in the lookup table. Some times, it is also sufficient to have the robot operate at a single speed (or more often, one speed in both the positive and negative direction) in which case a hard coded single value can be used.

The JAUS protocol specifies two main types of movement commands: "set velocity" and "move relative". Because this platform was designed to be controlled by a remote human operator, only the "set velocity" commands are implemented. Similarly, although the wheel units almost certainly include wheel encoders, they are not accessible via the JAUS interface. This was a common theme to the design, where simplifying steps were used in terms of what to expose to the external system based on the assumption that the robot would not operate autonomously. However, with the "set velocity" commands, we were able to implement all of the elements of the movement interface expected by the control architecture.

Teleoperated robots are often designed to expect continuous command feedback from an operator. The robot may receive a constant stream of drive commands even though the operator has held the movement joystick at a constant angle. Since the robot can not correct its error if the human operator is disconnected, if no new commands are received in a given amount of time, most designs will stop the robot movement. While this may be logical for an autonomous system as well, there is a stronger bias in a teleoperated system to default to no action and let the human override if this is a problem. While converting a teleoperated system this is important to note as it may require additions such as message repetition at constant intervals to keep the robot performing a desired action.

h) Communicating with Sensors: One of the most important sources of information for an autonomous robot is the camera; we will illustrate the process of establishing communication with a sensor using the example of interfacing with the M2P2 camera. From the programmer's perspective, it would be easiest if it were possible to simply grab fully-formed individual frames from the video stream. However, such an encoding scheme would consume too much bandwidth in many domains, so a variety of protocols take advantage of similarities between adjacent frames to compress the data stream. Moreover, although many of these video encoding protocols are well-known, in some cases proprietary variations may have been added to the standard protocol to meet the needs of the particular robotic platform. This imposes additional challenges when converting a teleoperated robot for autonomous operation, as even the base protocol might be unknown, and any proprietary extensions are unlikely to be published.

As noted above, the main challenge for utilizing the cameras is deciphering the video stream. Primary variations in video streams to be aware of at this stage are, different color models (RGB, CMYK, etc) and streaming verses static video translation (some decoders require the full video buffer to be available before decoding can begin, this will not work

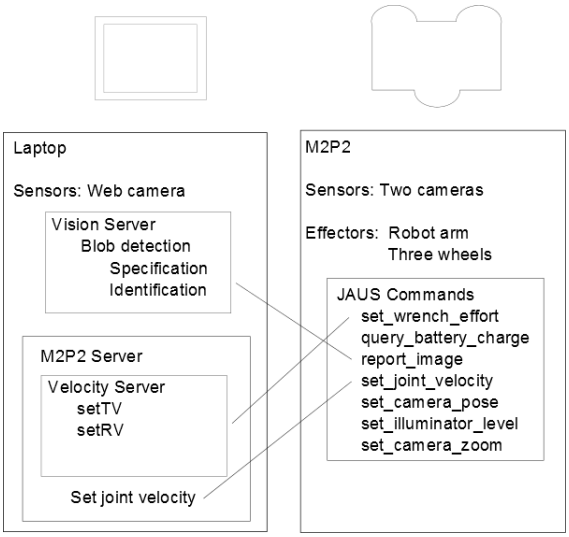

Fig. 1: **Architecture layout of the M2P2 and controller laptop.**

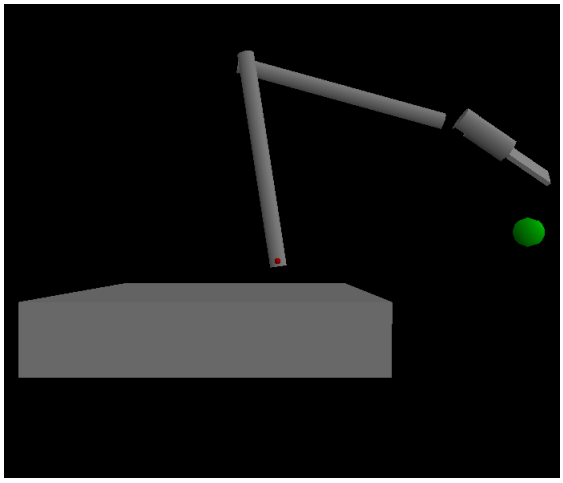

Fig. 2: **Visualization of the robot arm simulator.**

for streaming video feed from a robot).

When decoding the M2P2 video format, we started by searching the data for likely protocol elements, such as sequential markers added to verify order of packets received. This allowed us to discover the higher fidelity "key frames" that were sent at regular intervals to allow cumulative error between frames to be reset. In this particular case, we were able identify the protocol using the key frames and apply standard decoding routines to extract frames from the stream. We determined by the data header, that the M2P2 used a slightly augmented mpeg encoding variant. After removal of the additional formatting, the video stream could be parsed into readable raster images, using the FFMPEG decoder.

2.3 System Configuration and Control

Once basic communication protocols had been established, the system was integrated with the ADE infrastructure. A general purpose JAUS component was written to facilitate creation and interpretation of JAUS messages. Figure 1 shows the connections between the M2P2 control architecture and the architecture on the laptop used to control the newly autonomous robot.

The newly added laptop served as the primary intelligence control for the robot platform. As the M2P2 server is fully ADE compliant, it has access to all other ADE servers and functionality available to other holonomic robots in that environment. This includes a vision server to process incoming camera feeds, planners, and natural language interpreters. The M2P2 becomes a removable module fitting into a larger autonomous robotic infrastructure. As well as adding functionality, the ADE infrastructure adds error handling, security and the ability to offload processes not only from the original robots processors but also from those physically added to the robot. A smaller, less capable control unit can then be used to interface with the robot while the computationally expensive operations such as image processing can be handles by external, more powerful computers.

A web camera was connected to the laptop directly and mounted on the front of the mobile platform. While the robot had built in video feeds, these were slow, of lower quality, and computationally consuming to process directly on the control computer (As the signal had to pass through the JAUS communication protocol first). Connecting a new camera to the laptop helped the software react in real time (while the video feeds from the robot were still accessible). While the built in cameras were not used in this particular experimental paradigm, having the ability to interface directly with the on-board cameras allows future projects to take advantage of views that may be more difficult to introduce with external hardware. The robot arm has a small camera which gives a "dog's mouth" perspective on the gripper. Having an accessible video feed from this camera will allow for much more complex and delicate manipulation in future tasks.

To facilitate planning of arm movements, we developed a simulation environment for the robot joints (Figure 2). The simulation environment is written as an extension of a 3D visualization environment that was designed for the ADE infrastructure. Code is written in native Java and can be run with the visualization on or off. This allows the simulation to be run on either a standard PC with a GUI showing progress or a high performance computational grid to run detailed large-scale searches of the complex arm movement space.

In the simulation environment, a robot arm is specified as a series of rigid blocks connected by joints. Blocks are attached to each other in a familial hierarchy starting with the root block that is connected to the robot frame. Each block is defined as a collection of primitive objects (spheres,

rectangular solids, cylinders, etc.) with affine transformations applied relative to that block's starting position and orientation. As with most 3D tools, sub-objects can be nested in a parent block and an affine transformation specified for the entire block of sub-objects. Each joint is also capable of defining how that joint is allowed to rotate. Rotation can be in any of the three cardinal planes (around the X, Y, and Z axis). A center of rotation is specified both for block that is to be rotated as well as the parent block to which it is attached. A starting rotation angle can be given as well as bounds on rotation in each of the planes. All specifications are stored and read from an XML formatted data file.

When the control architecture determines a goal point to move the arm to, the planning mechanism in the simulation environment begins. A goal is specified as a coordinate in three-dimensional space relative to the root of the robot arm as well as an orientation of the end effector at that point. Planning is carried out using a gradient descent technique which can either be mimicked in real-time by the physical robot (and feedback used from the arm pose of the actual robot if available), or stored as an action sequence and played back at a future time. In the gradient descent algorithm, the robot attempts to move each of its joints a fixed small distance in each direction that the joint is allowed to move in. A fitness function is used to calculate the fitness of each of these new arm locations and the movement with the highest fitness is selected to be performed. This pattern is iterated until a local maximum is found. The fitness function is a scaled combination of the distance of the effector from the goal, the orientation of the effector relative to the desired end orientation and a negative strength from all joints based on their proximity to any collisions in the environment.

While gradient descent will not be sufficient to solve all arm trajectory problems, it is sufficient for many purposes. The M2P2 arm moves in a single vertical plane, with two joints controlling the position of the end effector. Since it also provides real-time (and can be pre-calculated in far faster than real-time) movements, it is ideal for the immediate response time required by tasks such as bomb defusing for which the M2P2 was designed. The simulation environment can also be used by more complex path planning algorithms for more complex environments.

One important complication to arm movement was the lack of "somatosensory" feedback, as there were no sensors to detect the relative arm position. To calculate the relative arm position, we took the arm resting pose as a base (this location was enforced through physical stops on the robot joints). Through experimentation, it was determined that the acceleration time in getting the robot arm from rest to a desired velocity was minimal. The amount of time necessary to move the arm a desired distance could be calculated simply by dividing the distance by the presumed constant speed of the arm. While this works for low fidelity situations, the acceleration will cause problems where fine motor control is required (such as using the grippers to pick up a small object). To reduce the error, all movements were blocked into constant length (or angle) chunks. As the gradient descent approach expected output tests to be constant sized already, constant sized movement blocks was the obvious choice.

If the robot had needed to perform multiple tasks, the cumulative errors would have added up. To combat this, the forced resting pose could be required after a certain amount of movement to recalibrate location.

3. Validating the Integration

To evaluate the integration, we devised a simplified version of the robot's primary function: bomb disposal. In this test, the robot was required to detect a suspicious object ("the bomb"), approach it, and retrieved it. It was then required to detect the ("safe") disposal receptacle, move to it, and deposit the "bomb" inside. This task can be decomposed into five phases, as depicted in Figure 3.

Detect object: Object detection was performed using simple color detection and blob size thresholding. The ADE vision component processed frames from the web camera, producing a description of each detected object that included its relative position in the frame (and hence relative to the robot's heading) and its size in the visual field. The autonomous control system made regular requests to the vision component until a positive identification was made, at which point control progressed to the next phase.

Move to object: Once the object was detected, the control module computed the course adjustments to move to it using a visual servoing approach [15]. Rotational adjustments were made based on the horizontal position of the object in the frame. Given the assumption that the object in question would be on the floor, distance could be estimated using the object's vertical position in the frame. When the object was determined to be in the effective region of the gripper, the approach phase was concluded.

Plan/perform reach: The reach and grasp actions were constructed dynamically using the arm motion planner described above. The "reach" goal was set based on the object's relative location as determined by the vision component. The control system sent the plan steps generated by the gradient descent algorithm to the arm, moving the gripper toward the goal state: poised over the target object.

Detect receptacle: The receptacle was detected in the same way that the target object was detected. A different color was used as the indicator.

Move to receptacle / drop: When the robot moved such that it judged its manipulator was over the receptacle, the block was released and the robot ended its movement pattern.

A video of the bomb disposal demonstration can be viewed at `http://tiny.cc/autonomized`.

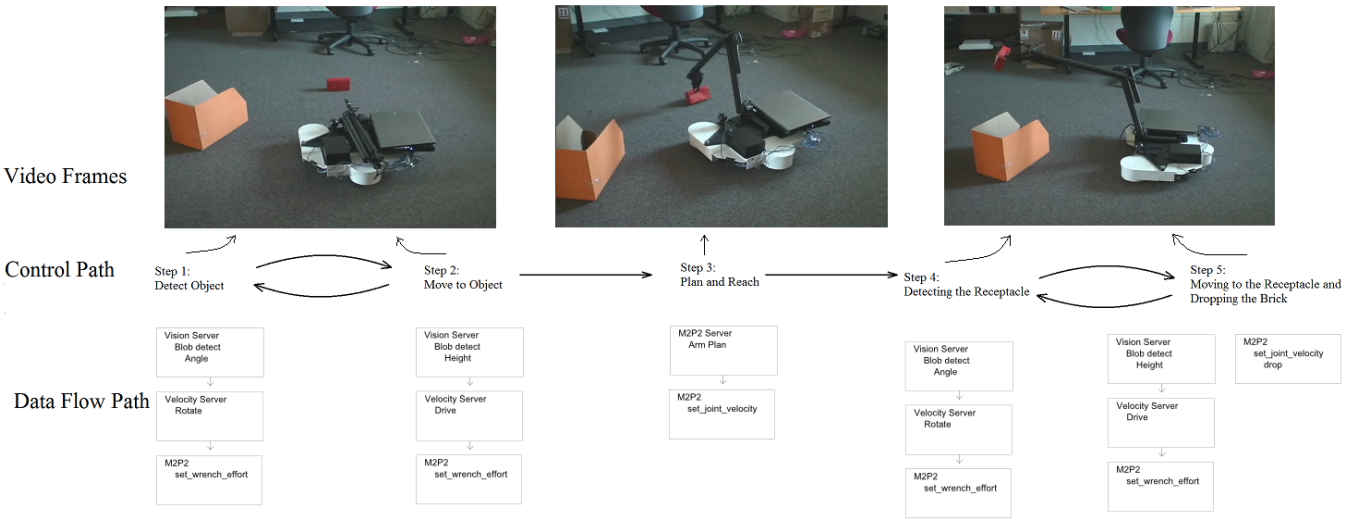

Fig. 3: **The data control path and data flow during the experiment (the control path indicates at what steps different computational units were activated).**

4. Conclusions and Future Work

Limitations to autonomizing teleoperated robots are dictated by the design of the robot in question and the persistence of the group attempting to perform the automation. In general, if basic platform movement can be achieved, most traditional robotic tasks can be performed with the possible addition of necessary sensors and manipulators. To this end, the basic platform can be thought of as an operation module with the potential addition of pre-existing functional modules attached. If very fine control is needed over the robots pose, it may not be feasible to augment a teleoperated system, since such fine feedback may not be available, and extremely difficult to add into the physical architecture. Although we used multiple software infrastructures in our case study integration, we used only one hardware platform (the M2P2 robot). In future work, integration of multiple existing hardware platforms would lead to a more modularized schema for conversion (e.g., a chassis from one manufacturer and a manipulator from another could both be integrated into the same software architecture).

Abstract - *Traditional machine learning algorithms typically employ task specific methods and only the parameters pre-determined by the human programmer are updated. These methods often fail to respond to the dynamically changing states of the uncontrolled environments. Additionally, such methods may not represent a developmental entity, such as a human mind. In contrast, an open-ended developmental robot system can learn simple behaviors and build up more complex behaviors by utilizing the previously learned behaviors. In this paper, we propose a basic framework for visual learning tasks that integrates a perceptual system into a biologically inspired working memory system. A main objective of this research is to provide a general framework for developmental learning and to investigate how well a neuro-computational PFC working memory model performs on a robotic platform in a real world environment with complex tasks. Experimental results given show impressive performance both in terms of accuracy and speed of learning.*

Keywords: Developmental robotics, machine learning, computer vision, working memory, reinforcement learning.

1 Introduction

The ultimate goal in robotics is to build a robotic system, which can develop new skills incrementally, in an autonomous open-ended approach through interactions with the environment without having a pre-designed, task-specific representation [1]. However, traditional machine learning algorithms typically employ task specific methods and often fail to respond to the dynamically changing states of the uncontrolled environments. To fill the gap that machines do not benefit from traditional machine learning and AI techniques, a relatively new area of study, called autonomous mental development (AMD), has been proposed. It was pointed out by Weng et al. that a mental development process must be able to generate representation and architecture autonomously online and directly from raw sensory signals which must also be task nonspecific [2]. In contrast to traditional artificial neural networks, which can only accept a series of fixed size, offline sensory data vectors, a developmental robot runs in the real physical world and has the ability to add new data online that it has never seen before. Furthermore, it can develop simple, basic skills for many different kinds of tasks and these skills may be utilized to learn more complex skills. For example, a human child's brain is not manually trained with data within one training session. Instead, he/she is usually taught by his/her parents from time to time through approving or rejecting behaviors. Following the same idea, to operate in the real unconstrained world, where the environment is highly complex and dynamic and a human designer cannot predict in the initial stage of programming, a developmental robot should be trained by interacting with the environment and with the user through a student-teacher relationship. It is in this sense that there is a necessity for open-ended developmental systems. Table 1 shows the basic differences between the traditional engineering (manual development) paradigm and the proposed mental development paradigm.

Table 1. Main differences between traditional and developmental programs [2]

Properties of Program	Traditional Programs	Developmental Programs
Sensor-specific and effector-specific	Yes	Yes
Program is task-nonspecific	No	Yes
Tasks are unknown at programming time	No	Yes
Generate representation automatically	No	Yes
Animal-like online learning	No	Yes
Open-ended learning of more new tasks	No	Yes

As a bridge crossing between the external world and the internal environment, perception is an awareness of things through the physical senses. Humans perform learning at the perceptual level and perceptual learning has been considered to occur at the cognitive level where identification and categorization is performed with focuses only on the relevant data that is needed by the current learning task. In cognitive science, long-term memory has a very large capacity and the information is considered to be stored indefinitely, while working memory is defined as a theoretical framework which refers to a temporal type of storage that retains elements that are active and being manipulated for a short period of time. In the literature, many working memory models have been proposed, which have commonalities and differences [3], with the most popular one in psychology being the Baddeley and Hitch's three-component model of working memory [4] and the most famous one in neuroscience being the temporal difference (TD) learning model [5] (a very popular machine

learning algorithm describing the midbrain dopamine neurons). Recently based on the TD learning model, an open source software library, written in ANSI C++, called the Working Memory Toolkit (WMtk), has been developed which provides an abstraction layer and can be easily integrated into robotic control mechanisms [6].

A main objective of this research is to integrate a perceptual system into a biologically inspired working memory system in such a way that would yield a basic framework for visual learning tasks. Not being intended to focus on a specific task, the aim of our approach in this work is to provide a general framework for developmental learning, as well as to investigate how well a neuro-computational PFC (prefrontal cortex) working memory model performs on a robotic platform in a real world environment with complex tasks.

In the following, Section II talks about some of related work and efforts that contribute to the area of developmental robotics. Section III describes our proposed vision-based autonomous mobile robot system. In Sections IV, experiments are designed and results presented. Finally, conclusions are made in Section V.

2 Related Work

It was first pointed out by Weng that many traditional machine learning algorithms, including artificial neural networks, are computational frameworks but not developmental frameworks [1]. According to Weng, two types of paradigms exist. The first one labels the traditional machine learning methods as manual development, where the programmer understands the task, chooses a representation, and maps the task to the representation. Thus, the programmer conveys his understanding into the task representation. Next, the programmer writes code which controls the machine to execute the task using the task-specific representation. The second paradigm is called the autonomous developmental paradigm where the programmer writes a developmental program and the robot learns the task by interacting with the user/teacher and the environment. The result of such a mechanism should be that the robot generates its own internal representation.

Arguing that the system must deal with high-dimensional feature space for perceptual learning, Weng developed a structure called the "Incremental Hierarchical Discriminant Regression (IHDR) engine" [7]. To demonstrate the proposed method, a vision-guided navigation experiment using the IHDR system was presented in [1], [7], [8], where a mobile robot, called SAIL and developed at Michigan State University was trained by pushing it around the corridors of the Engineering Building. The robot had two pressure sensors on each side. The difference of the two pressure readings was translated into heading information and associated with the images. The grayscale intensity of the pixels was used as the components of the feature vectors and the resolution of the images was 30-by-40. As a result, the number of dimensions on which the system operates was 30-by-40, i.e., 1200. One feature vector was generated from an entire image and linear discriminant analysis was applied to the feature vectors to select the most discriminative features.

Krichmar and Edelman argue that devices, based on the working principles of the nervous systems, may provide the groundwork for the development of intelligent machines which operate on neurobiological principles rather than computational ones [9]. They have designed a series of theoretical models, called brain-based devices (BBDs), and applied them to physical robots in order to investigate the functionality of different regions of the brain. The robots equipped with these models are used for studying perceptual categorization, operant conditioning, episodic and spatial memory formation and motor control. They emphasize that models of brain function should reflect the dynamics of different brain regions, their structure and the connectivity of these regions, rather than implementing them as a single neuron layer. According to them, to construct such models, detailed neuro-anatomy and neural dynamics should be taken into consideration. To investigate the functional anatomy of the hippocampus region and its surrounding regions, Krichmar et al. [10] programmed a physical robot to solve a dry variant of the Morris water maze task. In the task, the robot was meant to use its spatial and episodic memory by associating perceptual cues in the environment with a particular location. In the experiment, the target location was hidden and can only be detected in close range by the robot's front IR sensor. The robot started a trial in one of the four locations and stopped if it detected the hidden platform or until a time limit of 1000 seconds was reached. The experimental results showed that the robot learned to navigate to the target location from multiple starting positions in about 8 trials.

A slightly modified version of the task, inspired by Krichmar's work, was presented by Bursch, et al. in [11], in a simulation environment. In contrast to Krichmar's experiment, the robot started a trial in random locations without using odometry information. In order to create a mapping between a perceptual state and an action for that state, a Self-Organizing Feature Map (SOFM) [12] was used and the heights (in pixels) of the colored panels were presented as an input to the SOFM. Two navigational approaches were proposed and compared. The first method was based on creating a probabilistic graph between the nodes of the SOFM and then searching for the optimum path in the graph in order to navigate to the target position. The second approach utilized the Working Memory Toolkit (WMtk), which we also chose as a working memory implementation for our system. It was reported that the first approach outperformed the WMtk with relatively little experience. However, as the number of training samples increased, the WMtk actually performed much better than the graph search technique.

3 Our Proposed System

With focuses on issues of developmental robotics, the methodology proposed in this paper is to establish a biologically inspired system that employs perceptual knowledge along with a working memory system in order to

provide broad capabilities for visual learning tasks. Such a requirement necessitates a large set of goals that the system needs to satisfy.

To have the robot operate in real world environments that are not modified by using artificial landmarks, the system learns everything from scratch. To learn and recognize natural landmarks, the images and videos were taken as RGB (red, green, blue) color images, which were next converted to the HSV (Hue Saturation Value) color space for use. To represent a small image region, a color histogram vector of size 10000 was calculated to form color based features and 40 Gabor filters were used to convolve with each image region to form texture based features. As a result, the combination of the color histogram and Gabor texture measures resulted in 10040-dimensional feature vectors. Then an unsupervised learning algorithm, a minimum spanning tree based clustering algorithm, was used to form percepts/objects for the robot vision system which would be used later for segmenting the incoming new images. For new images captured by the robot, feature vectors were first extracted, a nearest neighbor search process was followed to assign an object label to each newly extracted feature vector. Then a connected-component labeling algorithm is applied to find connected regions, called blobs. After the segmentation was done, the final stage of the perceptual system was to produce inputs for the working memory system, referred to as "chunks", in order for the robot to acquire sensory-motor associations to guide its actions. It is important to maintain a strong connection to the features of the percepts in the environment and to their semantic meanings. In other words, the robot should learn what each percept means for itself. In this context, understanding the meanings of the percepts is referred as perceptual grounding.

The limited capacity property of a working memory system provides focus for the robot to search for appropriate actions in order to accomplish a given task. In fact, the key point faced by the working memory system that is utilized in this proposed robot architecture is the determination of which chunks of information should be actively retained in the working memory, and which may be safely discarded, for tasks' success, that is, a prediction scheme in the expected future reward. Learning by associating stimuli with rewards and punishments (the reinforcers) is called reinforcement learning [13]. The particular type of reinforcement learning used in this research is called the *temporal difference (TD) learning* algorithm [5], which is typified by the delayed response tasks, with the main objective being maximizing the total amount of reward that the robot receives over a long run [5].

WMtk essentially implements a neural network version of the TD learning algorithm and contains classes and methods for constructing a working memory system that intelligently decides which chunks to maintain or discard depending on the reward criterion. This criterion is dependent on the current task of the robot and is specified by the user as a requirement for the WMtk. The reward is generated in a discrete-time manner (namely "episodes") and is a real number. Depending on the selected action in the previous episode, as well as the reward signal generated for that particular action, the WMtk updates its internal contents, based on which, the robot can then select and execute an appropriate action. The most distinctive feature of the toolkit is that it explores every possible combination of collection of chunks, which can be fit within the limited capacity of the working memory and selects and retains in the working memory the combination of chunks which provides the highest estimate value of the future reward. This feature of the WMtk can be very useful in robotic applications. The robot is not limited to only one single item to consider. For instance, in many applications a landmark location is represented by only one percept. However, a landmark location may be represented by a combination of percepts, which may help the efficiency of the robot's localization process. In addition, this would also help to increase the number of unique landmark locations in the navigation path of a robot.

The final flowchart of the system is presented in Fig. 1. The top half of the diagram represents the perceptual system. The lower portion represents the working memory system, which is combined with the robot's sensory-motor scheme (i.e., actuators and sensors such as sonars to avoid obstacles). The combination of both the perceptual system and the working memory system yields the cognitive structure for the robot.

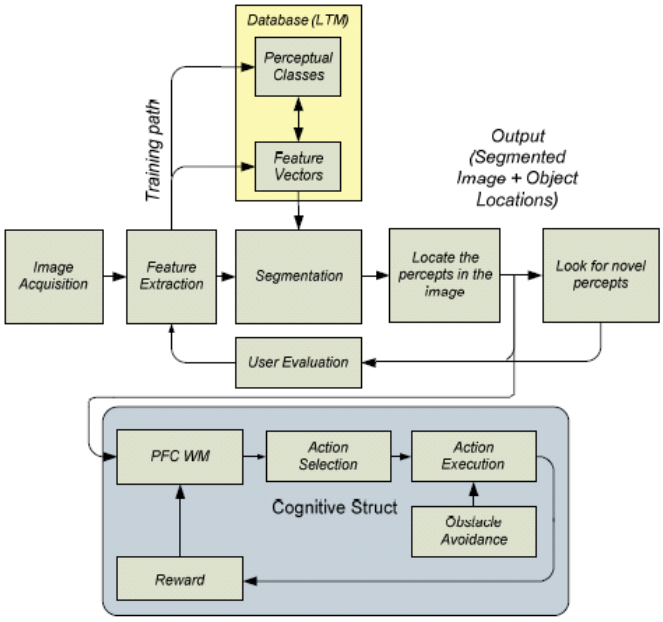

Fig. 1. The proposed system architecture.

In order to demonstrate the proposed method, the methodology proposed in this research is applied to a complex vision-guided navigation task. Part of the complexity of the task is that no a priori information is given to the system, such as a cartesian map or coordinates of objects, etc. Instead, a qualitative navigation approach is taken, where the robot proceeds by detecting natural landmarks that are present in the environment. It is desired that the system is capable of learning new skills and percepts online in uncontrolled environments while performing a task and supporting explanation of its

knowledge to and from the user in an interactive way. In order to achieve the navigation task, simple behaviors are learned and preserved in the system in order to learn more complex behaviors.

4 Methodology and Experiments

A fundamental property of a mobile robot is the ability to navigate safely in an uncertain environment. In order to achieve this task, the system needs to acquire sensory-motor associations to guide the behavior of the robot. To provide a general framework for developmental learning and to investigate how well a neuro-computational PFC working memory model performs on a robotic platform in a real world environment with complex tasks, several experiments are conducted that would exploit the usefulness and capabilities of this framework in mobile robotics. Each experiment is related and built upon each other in order for the robot to navigate successfully.

The testbed robot Skeeter is equipped with a single camera to perceive the environment. The front sonar array is only used for obstacle avoidance purposes. The experiments took place in the hall outside of the Intelligent Robotics Laboratory on the third floor of the Featheringill Hall at Vanderbilt University. A typical view of this hall is shown in Fig. 2. The major objects in this hall include the yellow floor tiles, the white floor tiles, and the black stripes of tiles, wood panel wall, light blue painted wall and a light blue railing. To generate a perceptual model for the environment, 20 images were collected over several days at different times to account the different lighting conditions. Next 66740 feature vectors were extracted from these images and clustered to obtain several percepts that constitute the training database of the system (the system's LTM). A color was assigned to each percept for displaying them in the segmented images. Table 2 shows the obtained percepts and their corresponding denoting color. A sample segmented test image is shown in Fig 2.

Table 2 Percepts and Denoting Colors

Percepts	Denoting Color
WoodPanel	Red
YellowFloor	Yellow
WhiteFloor	White
BlackFloor	Black
LightBlueWall	Light Blue
Bricks	Dark Red
BlueFloor	Blue

Fig. 2. A test image and its segmented version

In our empirical study, three experiments were designed to accomplish the navigation task. The first two experiments have been reported in [14] and are briefly repeated here for reference. The third experiment is a further extension built upon the first two. The objective of these experiments is to reveal the capabilities of the system in uncontrolled environments. In the experiments, the system learns new percepts, as well as new skills so as to ultimately perform a qualitative vision-guided navigation task. Since the task is qualitative navigation, no metric information is involved in the computations. Only the angular positions of the percepts with respect to the robot frame are computed.

4.1 Experiment 1: learning open space

The first step in the navigation task is to learn the percepts that would yield an open path for the robot through the robot's own interaction with the world. Once meaningful blobs or percepts are obtained from the images acquired from the camera, the robot needs to learn the association of the percepts with motion. In other words, the robot needs to determine whether the percept represents an obstacle or an open space. To do so, in this task, the reward criterion for the WM system is selected to be the distance moved by the robot per trial. The procedure for the first experiment is as follows:

- WM size is set to 1.
- Blobs segmented from a captured image are then presented to the WM. The WM system randomly selects one of them.
- The robot tries to move toward the selected chunk for 5 meters or until an obstacle forces it to stop.
- The distance moved by the robot is returned as a reward for the WM system.

The above procedure is followed multiple times, allowing the WM system to intelligently update its internal parameters associated with each chunk in the environment, until the percepts corresponding to an open space eventually dominates the trials. The WMtk has also a reserved position when none of the chunks provided as inputs is selected. With a WM size of 1, the weight parameters inside the WMtk are directly associated with the percepts and the received rewards. In order to evaluate the system's learning performance, two sets of experiments were conducted. In the first set, the robot was put in the middle of the hallway and let to go freely without any user interference. In the second set, the robot started moving from wherever it was. Fig. 3 shows the development of the weights associated with each percept versus the number of the trials, when all the initial weights for percepts were set to 0.5 [15].

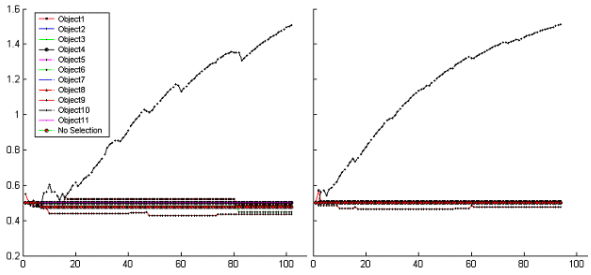

Fig 3. The weight logs for each percept (left) when the robot was let to go freely (right) when the robot was forced back to the center after each trial [15]

In terms of behavior, at the beginning, the robot moved about at random, improving its chances of encountering anything it needs. During the learning, the robot will evolve to activate the sensory inputs that are most likely to reduce the need, that is, to find open space for the robot to move 5 meters without being stopped. Unattended signals or percepts will eventually be excluded from the parts of the motor system engaged in performing the current task.

4.2 Experiment 2: learning landmarks

In a navigation task, the robot not only needs to know which percepts are associated with the open space to move safely, but also learn about landmark locations in order to localize itself in the environment. In this experiment, the appearance of black floor tiles was found to be a convenient indication of a landmark location. For instance, a navigation task could be that the robot might turn 90 ° right or left at the third landmark location. To learn the landmark location, the following steps were taken in this experiment:

- The WM size is set to 1, 2, and 3 to determine percepts to be selected for recognizing a landmark location.
- 80 training images representing landmark (40) and non-landmark (40) locations as in Fig. 4 were collected. The presence of a black floor tile in the foreground indicates a landmark location.

Fig. 4. (a) A landmark image and (b) A non-landmark image

- Images from the training set were selected randomly and processed to obtain the chunks for the WM system.
- Each of the percepts generated for each image was duplicated and presented to the WM system, and marked as a landmark chunk and a nonlandmark chunk, respectively. Once the WM system selected a set of such chunks, a majority vote was taken to determine whether the location is a landmark one or a non-landmark one. If there was a tie in the vote, it was interpreted as a non-landmark one by default. Since the training images were labeled, the WM system received a reward of 1 if the vote agreed with the label of the image, otherwise, it receives a reward of 0.

For each WM size, 1000 and 5000 trials were conducted. The results are summarized in Table 4 and good for all the cases.

Table 4. Percentage of correctness for landmark classification

WM size	1000 trials	5000 trials
1	98.10%	99.52%
2	95.50%	97.42%
3	98.00%	99.38%

4.3 Experiment 3: learning the navigation task

From the previous experiments, the robot acquired the ability to navigate safely through the environment, and the ability to localize itself in the environment. The objective of this experiment is to have the robot utilize its previously learned knowledge and apply them to learn a complex task. Suppose that the robot is positioned in front of the Intelligent Robotics Laboratory, looking towards the window side of the hallway. The black stripes along the hallway indicate the presence of a landmark. The goal of the robot is to navigate along the hallway until it reaches the third landmark. Since the delayed response task is widely used in cognitive neuroscience in order to evaluate the properties of working memory [16], [6], there are two situations to be considered. If the robot recognizes a green ball (which has been added to the system in [17]), as an unexpected, contingent percept along the way, it should remember the green ball until it reaches the last landmark and come back to the starting position. If no green ball is detected along the navigation path, the robot is required to learn to stop at the third landmark. The robot makes a decision, moves with a small distance increment and stops. The time required for this cycle is referred to as one time step. This procedure continues until the navigation is complete. The procedure for Experiment 3 is as follows:

- Initially in the environment, the robot captures an image and segments it to obtain the percepts. Three actions, such as “move”, “stop”, and “turn around”, are also and always presented to the working memory as chunks at each time step. The working memory system is rewarded or punished by the possible actions chosen by the robot along the navigation path. In addition to the action chunks, the working memory is presented with the percepts detected in the environment. However, only “YellowFloor”, “BlackFloor”, and “GreenBall” percepts are presented, if recognized by the perceptual system. Since the task requires only remembering the “GreenBall” chunk, the other percepts are treated as distractors. The working memory has a reserved “Nothing” chunk when the system does not make any selection. Therefore, the maximum number of chunks that can be presented to the working memory is seven.

- The working memory size is set to 2. One slot is for an action chunk and the other one is for a percept chunk. Thus, the working memory is required to learn to select an action chunk as well as a percept chunk.
- Once the candidate input chunk vector is presented to working memory, a decision is made. The robot either moves, stops or turns around depending on the action selection made by the working memory at each time step. Furthermore, if a "GreenBall" percept is detected, the working memory is expected to put the "GreenBall" chunk in its second output slot.
- The robot tries to move towards the open space for one meter and the cycle is repeated until the third landmark is reached. However, if a green ball is detected, it needs to remember that it has detected an indication for a contingent situation. Therefore, as the task requires, it needs to come back to its initial position by passing through each landmark again, in order to demonstrate the bootstrapping effect.

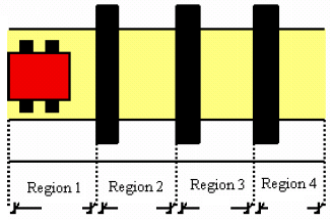

Fig. 5. An illustration of each region of the navigation path.

With the maximum number of input chunk vectors being set to seven, the training is performed in a simulated environment and all the possible chunks are presented to the robot at each time step. The robot is trained for each region of the navigation path as shown in Fig. 5. Each region may be thought of as the state of the robot (i.e., state 0 is being located at region 1, and state 1 is at region 2, etc.). Furthermore, the detection of the contingent percept is also represented as a state of the robot. However, during the training, this state is either randomly set to true once in one of the regions or not set to true at all. This means that the contingent percept has been detected at a particular region if set to true or not detected if the state stays false in the entire trial. In the real world experiment (not in simulation), this state is set true once the perceptual system detects the contingent percept. The robot is required to choose the correct action chunk at each state. In addition, it must learn to remember the contingent percept if recognized along the navigation path. The learning criteria faced by the working memory are not trivial, indeed they are challenging. The robot needs to learn a considerable amount of information from a large combinatorial chunk space in five different states. The robot is trained for each region (each of the states from zero to three) of the navigation path and a reward value is given.

However, in order to speed up the learning, the training state is switched from one to another, only if multiple numbers of positive rewards are received in a row at each state. For instance, assume that the number of positive rewards required to switch the state from one to another, is ten. A successful trial is defined as not receiving any negative reward. Therefore, the system must receive 40 positive rewards (10 for each region) in a row in order the trial to be considered as successful. The number of received positive rewards in a row is referred to as the positive reward threshold (PRT). Fig. 6 shows the learning curve of the system, as a plot of the average reward values over a sliding window of size 25 over 10000 trials for several PRTs. Table 5 shows the number of successful trials for each plot in Fig. 6.

Table 5. Number of successful trials for 10000 trials and for different reward thresholds

Positive reward threshold	Successful trials (Out of 10000)	Percentage of successful trials
1	7591	75.91%
7	8275	82.75%
10	8502	85.02%
20	9330	93.30%

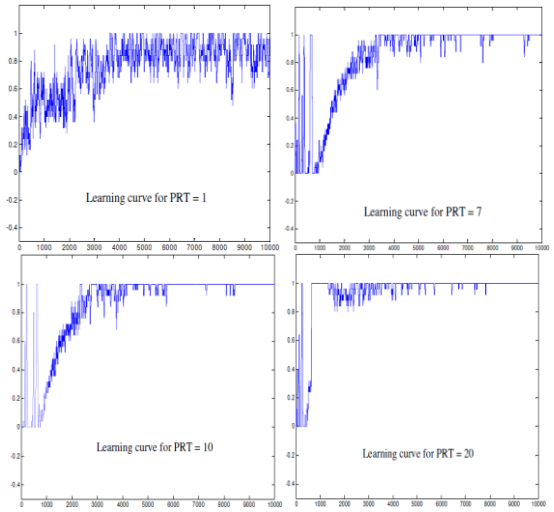

Fig. 6. Learning curves of the system for PRT of values 1,7,10,20

These numbers are reasonable under the very strict rule, that is, receiving multiple positive rewards in a row. Moreover, the initial training stage is also included in these results. If, at any time step of the training, the system fails to choose the correct chunk combination, the whole trial is considered to be an unsuccessful trial. In all of the cases, there is a positive learning trend. As the PRT is increased, the system makes fewer mistakes overall and the speed of the training is significantly increased in terms of episodes. With the system settings described in the above, the time required to train the system, when PRT is set to 10, is 12 minutes and for a PRT set to 20, it takes 15 minutes. Thus, the training time is relatively short in a simulated environment.

In this final experiment, we particularly demonstrated the delayed response effect by holding on to a percept for a period of time. The robot successfully navigated in the hallway and it came back to its initial position when a green ball percept was presented. It chose the correct actions in the action selection slot and the "Nothing" percept, meaning that no percept was held in

the working memory. However, once the contingent percept was presented along the navigation, the robot remembered the contingent percept in the percept selection slot of the working memory at each time step. Thus, the robot has successfully learned a complex task based on previously learned fundamental behaviors.

5 Conclusions

In this work, the robot successfully learned a complex, vision-guided navigation task by means of a powerful and reliable perceptual system combined with a biologically inspired prefrontal cortex working memory model. The task faced by the robot is indeed a challenging task to be learned. The robot initially learned the percepts in the environment and robustly performed segmentation. Next, the robot associated the meanings relative to motion, and landmark detection, to the percepts in the environment and encapsulated them as simple behaviors. These behaviors were then used to build up a more complex behavior.

Abstract— *In this paper, we discuss the problem of multi-robot coordination and propose an approach for coordinated multi-robot motion planning by using a probabilistic roadmap (PRM) based on adaptive cross sampling (ACS). The proposed approach, called ACS-PRM, is a sampling-based method and consists of three steps including C-space sampling, roadmap building and motion planning. In contrast to previous approaches, our approach is designed to plan separate kinematic paths for multiple robots to minimize the problem of congestion and collision in an effective way so as to improve the system efficiency. Our approach has been implemented and evaluated in simulation. The experimental results demonstrate the total planning time can be obviously reduced by our ACS-PRM approach compared with previous approaches.*

Keywords: Multi-robot system; motion planning; multi-robot coordination; sampling-based approach;

1. Introduction

Motion planning is a fundamental problem in robotics. It could be explained as producing a continuous motion for a robot, that connects a start configuration and a goal configuration, and avoid collision with any static obstacles or other robots in an environment. The robot and obstacle geometry are generally described in a 2D or 3D workspace, and the motion could be represented as a path in configuration space. Motion planning algorithms are widely applied in many fields, such as bioinformatics, robotic surgery, industrial automation, planetary exploration, and intelligent transportation system.

The multi-robot system (MRS) is proposed to deal with some problems that are difficult or impossible to be solved by a single robot, or to improve the system implementation efficiency in some missions completed by multi-robot rather than a single robot [1], [2]. The biggest challenge for the MRS is coordination. Without coordination, it will not only lower the system efficiency, but also lead to the failure of the entire system in extreme cases. Figure 1 shows an example of multi-robot coordination, four robots implement a transportation mission cooperatively, the red robot is delivering a goods, the green robot is on its way back after completing a transportation task, the yellow robot is moving to load a goods, and the orange robot is transporting a goods to the destination location. The coordination of these four robots is obtained by assigning them to different room.

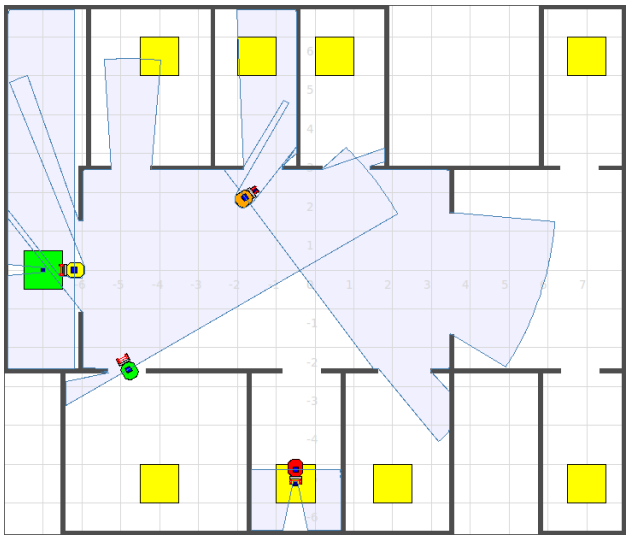

Fig. 1: Four robots implement a transportation mission cooperatively. The dark blue piece signifies the goods to be transported. The green area represents the original position of goods, and the yellow area represents the destination, which corresponds to every room, where the goods should be delivered to by the mobile robot.

In this paper, we consider the issue of coordinated motion planning for a homogeneous team of autonomous mobile robots in structured environments such as office building, warehouse, and container terminal. The larger context of the research is to establish a multi-robot goods transportation system with security, reliability and efficiency. Most of the proposed approaches for multi-robot motion planning usually have the problem of resource conflict such as congestion and collision [3], [4]. For the transportation issue, a desirable result is that robots replan their individual local path to avoid collision and congestion events, however this fashion often needs additional time and thus limit the transportation efficiency. An undesirable result is that robots are blocked, or the goods are lost or damaged, and thus fail the transportation mission. Therefore, we arranged these cases to

the waiting situation problem [5]. To handle this practical problem, this paper presents a novel approach to multi-robot motion planning by using a probabilistic roadmap (PRM) planner which is based on manner of adaptive cross sampling (ACS). This approach called ACS-PRM is decomposed into 3 main steps:

- Firstly, a sufficient number of points should be generated in C-space on an occupancy grid map by using an adaptive cross sampling method.
- Secondly, a roadmap should be built while the potential targets and milestones are extracted by post-processing the result of sampling.
- Finally, the motion of robots should be planned by querying the constructed roadmap.

The rest of the paper is organized as follows: Section 2 describes an overview of some related works; Section 3 discusses the problem of waiting situation; subsequently, Section 4 describes our ACS-PRM approach; Section 5 presents the experimental results obtained with our approach; and the paper is concluded in Section 6 at last.

2. Related Work

Multi-robot motion planning has been extensively studied for more than a decade during which a wide variety of planning frameworks and solutions have been proposed.

Švestka and Overmars [6] presented an approach for multiple nonholonomic car-like robots motion planning in the same static workspace by using probabilistic roadmaps, in which the roadmaps for the composite robot are derived from roadmaps for the underlying simple robots, and the latter is computed by a probabilistic single-robot learning method. The authors introduced the notion of *super-graphs* for multi-robot path planning, and their implementation covered the construction of the simple roadmap and the super-graphs. This approach is probabilistically complete because a given problem could be solved within a finite amount of time.

Moors *et al.* [7] presented a graph-based algorithm for coordinate multi-robot motion planning in 2D indoor environments. The scenario of this research is multi-robot indoor surveillance. The proposed approach takes the limitations and uncertainties of sensors into account, and generates the coordinated motion plan for multiple robots by using A* search algorithm. The authors also introduced a framework based on realistic probabilistic sensor models and worst case assumptions on the intruder's motions in order to compare different approaches and evaluate the coordination performance of the proposed approach.

Clark [8] presented a multi-robot motion planning strategy based on the probabilistic roadmap within a dynamic robot network (DRN) coordination platform. The DRN platform is an ad hoc network, in which single-query PRM is queried as a centralized planner to plan trajectories for all robots. The PRM planner is optimized to speed queries for multi-robot motion planning by using new sampling strategies. At first, a method of sampling PRM milestones is identified to enable fast coverage of the configuration space. Then, a method of generating PRM milestones is introduced to decrease the planning time. Finally, an endgame region is defined to improve the likelihood of finding solutions when goal configurations are highly constrained.

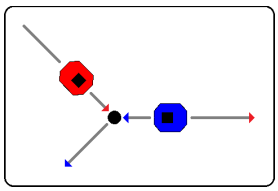

Fig. 2: A typical waypoint mutex. The black dot represents the waypoint, the gray segment represents the path, and the red and blue arrow represent the direction of the motion of the corresponding color robots respectively.

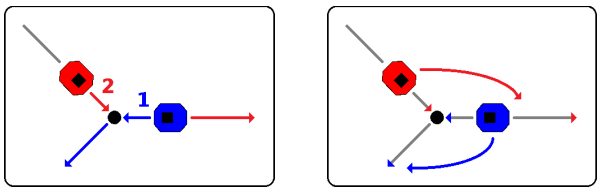
Saha and Isto [9] presented a strategy for decoupled multi-robot motion planning. The proposed strategy, which aims at improving the reliability of the basic decoupled planning approach, partially merges the two phases of the basic approach. The first phase is to compute a collision-free path to avoid the obstacles in the environment and the other robots, the second phase is coordinating the individual robot motions so that only one robot at a time may enter the area of potential inter-robot interference. The proposed approach searches for motions for a robot and coordination of motions of robots along paths already planned while ignoring the robots whose motions have not been planned simultaneously. This approach is inherently incomplete.

Besides, there are some other approaches developed with various strategies [10], [3], [11], [4].

3. Waiting Situation Problem

Multi-agent environments can be cooperative or competitive [12]. Of every agent in a team, the other agents can be considered as teammates (cooperative) or movable obstacles (competitive). One of the most important reasons which limit the efficiency of the multi-robot motion planning is the waiting situation such as the congestion and collision between robots. The core of the problem can be considered as the waypoint mutex in multi-robot motion planning. Figure 2 depicts a typical waypoint mutex. Two robots move to the same waypoint simultaneously: the red robot moves from the top left towards the right and the blue robot moves from the right towards the bottom left. Because of the waypoint can be assigned only to one robot at a time, then the mutex of the waypoint happens.

Generally, there are two ways to deal with the waypoint mutex as shown in Figure 3. One (Figure 3(a)) is to let robots pass the waypoint one by one [6]. The weakness of this strategy is that one robot must wait for another robot to pass. Another way (Figure 3(b)) is to replan the



(a) (b)

Fig. 3: Two ways to deal with the waypoint mutex. The colored lines represent the motion plan for the corresponding color robots respectively. (a) The two robots pass the waypoint in order, the blue robot pass first and the red robot pass later. (b) The two robots take each other as an obstacle and replan its trajectories in real time.

local path in real time for each robot by using some goal seeking obstacle avoidance algorithms such as Vector Field Histogram (VFH+) [13] or Nearness Diagram (ND) Navigation [14]. The weakness of this strategy is that robots need some time to replan their new trajectory. Consequently, the two ways both extend the time of the motion planning and limit the system efficiency.

If we can plan separate kinematic paths for multiple robots, then the waiting situation caused by waypoint mutex will be obviously reduced. In addition, the problem of multi-robot task allocation (MRTA) [15] should also be considered. Our focus in this paper is on the multi-robot motion planning in structured environments. For instance, an office building could be simply divided into three clusters: corridor, doorway and room. The doorway usually connects the corridor with the room, it is a suitable object for task allocation. Therefore, on the one hand, the problem of waiting situation (especially at the corridors) caused by one path for all robots should be solved. On the other hand, a simple and effective way to coordinate multi-robot motion is to assign different robots to different rooms reachable from the corridors. Besides, more complex environments may require more sophisticated methods such as hand labeled training data [16], [17] or more complex reasoning [18], [19].

Because of the complexity of multi-robot systems [10], [20], the target of this paper is not to completely avoid the problem of waiting situation (i.e., waypoint mutex), but to minimize the probability of appearance of the waiting situation by using our ACS-PRM approach. Therefore, the coincidence of the waypoint in the plan of two or more robots should be reduced so as to improve the multi-robot motion planning efficiency.

4. ACS-PRM: Adaptive Cross Sampling Based Probabilistic Roadmap

There are usually two ways to handle the issue of robot motion planning based on the grid representation of the environment in low dimensional space. One is to use the incremental heuristic search algorithm such as A* [21] or D* [22]. Another is to use the topological map [23] generated on top of the grid-based map such as Voronoi diagram and straight skeleton. Nevertheless, the number of grids increases rapidly when the size of the environment expands, which make these methods inappropriate for complex and extensive environments. Moreover, these methods are hard to deal with the multi-robot motion planning and always increase the computational load.

Sampling-based approaches have been proposed to improve the computational efficiency for robot motion planning. The main idea is to avoid the explicit construction of the obstacle region in the C-space (C_{obs}). Unlike the incremental heuristic search and the topological map methods, the sampling-based approaches work well for complex environments and high-dimensional configuration spaces, and they are generally easier to implement. The probabilistic roadmap (PRM) planner[1] is one of the typical sampling-based approaches. The original PRM technique is introduced by Kavraki *et al.* [24], which has been shown to perform well in a variety of situations. On the basis of this method, different extensions have been proposed [25], [26], [27]. The approach described in this paper is also an extension of PRM, which is aimed at performing multi-robot motion planning efficiently.

To deal with the problem of waiting situation in multi-robot motion planning as mentioned in the last section by using the PRM approach, there are substantially two options:

- In the manner of single-query: when two or more robots need to pass the same waypoint simultaneously, each robot resamples the adjacent region and takes the motion of the others into account, then generate a novel local roadmap for local replanning.
- In the manner of multi-query: construct a rich roadmap at the beginning to allow robots to plan a different trajectory from others later.

4.1 C-space Sampling

The ACS-PRM approach presented in this paper is a multi-query approach. The first step is C-space sampling, in which a sufficient number of points should be generated to represent the free space of the environment. The main idea of this step is to let a random point p retracts to a position $P(q)$ with the distance d to the obstacle C_{obs} along horizontal and vertical directions (i.e., cross direction).

For autonomous nonholonomic mobile robots, in two dimensions, there are three representational degrees of freedom (DOFs) which are one rotational DOF and two translational DOFs (along or across), but only two controllable DOFs which only move by a forward motion and a steering

[1] A reference implementation of this method in C++ is available online at: http://www.ai.univ-paris8.fr/ yz

angle, the configuration space C is the special Euclidean group $SE(2) = \mathbb{R}^2 \times SO(2)$ where $SO(2)$ is the special orthogonal group of 2D rotations. To avoid the collision caused by the point retracts too close to the obstacle, we set the distance d as the sum of the positive number w and the radius r of the minimum circle to cover the robot with centering at the rotation center of the robot:

$$d = r + w, \ (w > 0) \tag{1}$$

The set of w is to deal with the negative influence of sensor error and it should be adjusted in practical applications.

C_{obs} represents the set of the obstacle, $\forall q \in C_{obs}$ define a direction r_q, then determine a symmetry point $S(q)$ which is an intersection of the open-ray with end q direction r_q and another C_{obs}:

$$S(q) = \{q + t\overrightarrow{r_q} | t > 0\} \cap C_{obs} \tag{2}$$

where, if $\{q + t\overrightarrow{r_q} | t > 0\} \cap C_{obs} = \{q\}$, then define $S(q) = \infty$. Let $dist(x, y)$ represent the distance between point x and point y, then the retraction function can be described as:

$$P(q) = \begin{cases} q + d\overrightarrow{r_q} & \text{if } dist(q, S(q)) \geq 2d \\ \frac{q+S(q)}{2} & \text{otherwise} \end{cases} \tag{3}$$

where $P(q)$ is the position for the point p to retract. In this way, the random points are adapted around to the obstacle (see Figure 4(b)), then:

$$\text{ACS-PRM} = \{P(q)\} | q \in C_{obs}\} \tag{4}$$

The implementation of this step is summarized in Algorithm 1, where the time complexity is $O(n)$ and the space complexity is $O(1)$. This step corresponds the learning phase of classic implementation of PRM.

4.2 Roadmap Building

The second step is roadmap building, in which the potential targets and the milestones should be extracted and connected to the roadmap. In the previous step C-space sampling, if there are sufficient points generated, then the points will gather into segments. The main idea of this step is post-processing the graph resulted from the previous step while identifying three types of point as follows:

- In the previous step, if $dist(p, q) < d$, then p will retract to $\frac{q+S(q)}{2}$ and be labeled as the medial axis. Therefore, we find those medial axis segments with length l a small fixed value (in our implementation, we took the thickness of obstacle), and the midpoints of segments are marked as *potential target* for task allocation. Figure 4(c) shows the extracted potential targets which are precisely doorways of the structured environment.

Algorithm 1 Adaptive cross sampling

Require: N, the sufficient number of points to generate.
Ensure: N points in C_{free} by adaptive cross sampling.

```
repeat
  Generate a uniformly random point p in C-space.
  if p is free then
    for horizontal and vertical directions do
      Find q ∈ C_obs the nearest distance from p.
      if dist(p, q) ≥ d then
        p retracts to q + d r_q.
      else
        Find {S(q)} = pq ∩ C_obs.
        p retracts to (q+S(q))/2.
      end if
    end for
  end if
until N points have been generated.
```

- For those segments without containing the potential target, we extract both of the endpoints and mark them as *milestone* (see Figure 4(d)).
- The points of intersection between two segments are also extracted and marked as *milestone* (see Figure 4(d)). These milestones have not been used in our experiments, but they will be required for the exploration problem.

This step also corresponds the learning phase of classic implementation of PRM. Figure 4 illustrates the process of generating a roadmap for an example occupancy grid map by using our approach with 200,000 random samples.

4.3 Motion Planning

The third step is motion planning, in which each individual robot's kinematic path should be planned by querying the constructed roadmap. The main idea of this step includes the following three points:

- The potential targets $\{t_i\}$ are considered as the goal nodes for path planning and the objects for task allocation as well. Then, the individual $\{r_i\}$ robots are assigned to different potential target:

$$\{r_i\} \mapsto \{t_i\} \tag{5}$$

- To maximize the difference between the paths, we assign the potential target which is the closest from the robot but further from the previously assigned target to the current individual robot:

$$t = further(closest(\{t_i\}, r), t_{i-1}) \tag{6}$$

- Similar to the classic PRM, we use the fast local planning method (i.e., the straight line planner) for the global path planning, except that we choose the path

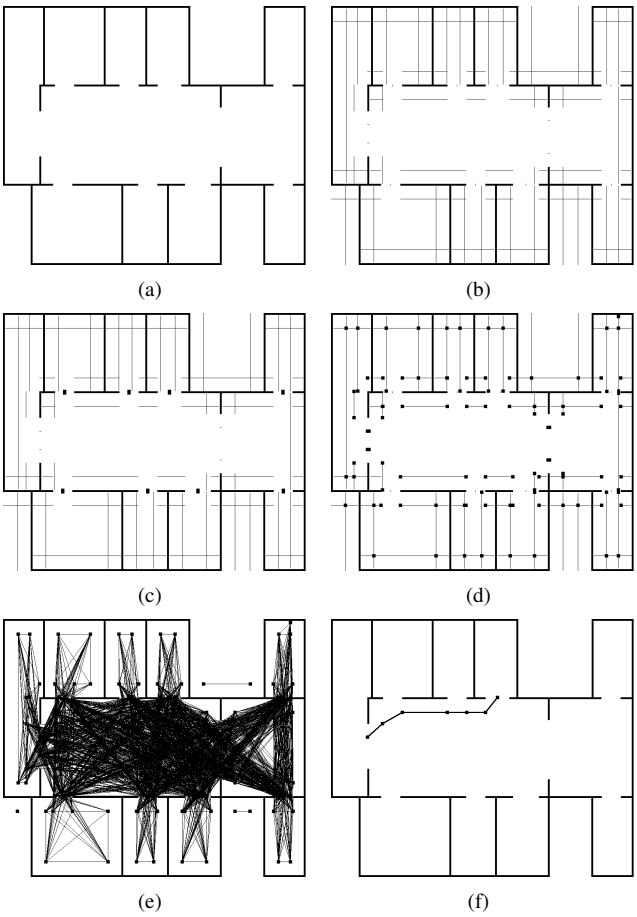


Fig. 4: Generation of the roadmap based on ACS-PRM. (a) The original gridmap, (b) adaptive cross sampling in C-space, (c) the extracted potential targets (doorways), (d) the extracted milestones, (e) the roadmap coverage of environment, and (f) an instance of path.

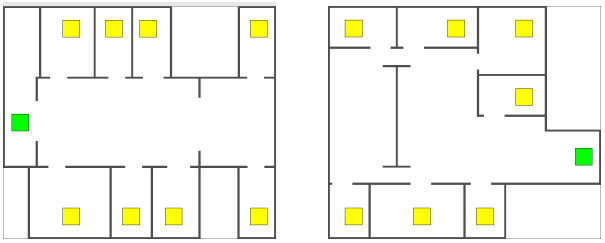
with the minimum number of milestones for the robots invariably.

This step corresponds the query phase of classic implementation of PRM.

5. Experiments

To evaluate our ACS-PRM approach, we conducted a series of simulation experiments with the well-known 2D multi-robot simulator Stage [28]. The experiment is to transport a certain amount of goods from one origination to divers destinations by a fleet of mobile robots. The simulated robot is the Pioneer 2-DX robot equipped with a laser range finder providing 361 samples with 180 degrees field of view and a maximum range of 8 meters. Each robot can localize itself based on an abstract localization device which models the implementation of GPS or SLAM. To transport goods, the robots are equipped with a gripper that enable them to sense, pick up and put down the goods, and the carrying

Fig. 5: A typical prototype of Pioneer 2-DX robot with gripper.



(a) map A (b) map B

Fig. 6: Two environment maps used in our simulation.

capacity is limited to one unit per robot. Figure 5 shows a typical prototype of Pioneer 2-DX robot with gripper.

We used a different number of robots to conduct several experiments in various environments. Two maps (Figure 6) were used in our simulation which are both structured environments. For each map, the green area signifies the original position of goods, and the yellow areas represent the destinations which are always placed in the rooms. For instance, map A has 8 rooms thus 8 destinations, map B has 7 rooms thus 7 destinations. The transportation team size is varied from 2 to 8 robots. On each team size, 10 experimental runs are performed for a transportation mission of 50 goods. The mission objective is to transport the goods to every room equally.

The ratio between real-world time and simulation time is about 1:1. We also compared our approach to the commonly used Voronoi-based approach [23] in which a topological map is built on top of the grid map by using the Voronoi diagram, and the *critical points* are extracted like milestones for mobile robot motion planning. All experiments reported in this paper were carried out on a system with an Intel Core 2 Duo E8400 3.00GHz processor, an Intel Q43 Express chipset and two DDR2 800MHz 1024MB dual channel memory.

In the experiments, we assumed that there exists a central server which is able to communicate with all mobile robots and assign the transportation tasks to each individual robot. The transportation task is to transport the goods from the original position to the destination. We also assumed that all the mobile robots share a common grid map and everyone

Table 1: Statistics of The Number of Occurrences of The Waypoint Mutex

(a) map A

#robots	2	3	4	5	6	7	8
ACS-PRM	1.6	3.1	6.4	7.5	10.0	11.1	16.2
Voronoi-based	15.3	18.7	26.0	26.8	19.9	23.7	27.2

(b) map B

#robots	2	3	4	5	6	7	8
ACS-PRM	3.8	4.3	7.1	14.9	12.8	10.3	16.7
Voronoi-based	17.1	19.2	19.0	26.5	27.4	27.0	29.9

has full information about all others so as to implement path planning and obstacle avoidance in real time coordinately. The ACS-PRM is designed to (but not limited to) plan the kinematic path for nonholonomic mobile robots, and in order to get an objective evaluation of the proposed approach, the drive mode of mobile robot is set to differential-steer, furthermore, the strategy of one pass after the other is applied to deal with the possible waypoint mutex problem.

The results of our experiments are given in Figure 7. We measured the transportation time gained by our approach and compared to the Voronoi-based approach. In each plot, the abscissa denotes the team size of the mobile robots, the ordinate denotes the percentage of the transportation time in the total transportation time, and the error bar indicates the confidence interval of each corresponding gain of robot team size with the 0.95 confidence level. Figure 7 shows that, a transportation time saving of 6.7% to 12.2% in map A and 6.1% to 12.0% in map B is obtainable under our ACS-PRM approach compared to the Voronoi-based approach. These results proved that our technique could obviously improve the system of planning efficiency.

Moreover, we mentioned earlier that our ACS-PRM approach is more effective than our previous approach because the ACS-PRM spends much less time for the learning phase. The experiments show that, with the new approach, the mapping times are respectively 0.321 seconds and 0.329 seconds for map A and map B with 200,000 random samples, which are averages of the 10 runs.

We also counted the average number of occurrences of waypoint mutex in each map as shown in Table 1. This table shows that the problem of waiting situation is obviously reduced by using our ACS-PRM approach, because our approach is able to plan separate paths for robots, especially in the corridor. Unlike the Voronoi-based approach, there is only one path for all robots.

In fact, the technique proposed in this paper also works well with irregular environments. Figure 8 illustrates an example with 20,000 random samples.

6. Conclusion

In this paper, we presented a novel approach for coordinated motion planning of multiple robots by using the probabilistic roadmap planner based on a manner of adaptive cross sampling, which we called ACS-PRM. The basic thought of the proposed approach is to build separate kinematic paths for multiple robots to minimize the problem of waiting situation such as collision and congestion caused

by waypoint mutex in an effective way, thus to improve the efficiency of automated planning and scheduling.

The ACS-PRM mainly consists of three steps: C-space sampling, roadmap building and motion planning. In the first step, a sufficient number of points are generated to represent the free space of the environment. In the second step, the potential targets and the milestones are extracted and connected to the roadmap by post-processing the graph resulted from the previous step. In the third step, the robot's motion planning is done by querying the constructed roadmap. The first two steps correspond the learning phase of classic implementation of PRM, and the last step corresponds the query phase of classic implementation of PRM.

In consideration of the context of the issue of multi-robot goods transportation, the experiments were conducted to transport a certain amount of goods by a fleet of mobile robots in structured environments. The experimental results demonstrate that, by using our ACS-PRM approach, the total time needed to complete the transportation mission has been obviously reduced compared to the Voronoi-based approach.

In our future work, we will expand our experiments to various irregular environments, not just the structured environments. Furthermore, the proposed work in this paper can be also used in some other applications such as exploration mission, automated surveillance, and search and rescue operations. They are our future consideration as well.

A Framework to Control the Darwin-OP Using CLIPS

Brandon Shrewsbury, Ameen Kazerouni, Kenitra Marrow and Dr. Adel Abunawass
Department of Computer Science, University of West Georgia, Carrollton, Georgia, USA

Abstract - *Procedural Paradigms limit the capabilities of an independent system from tackling novel situations. A rule based expert system allows for dynamic expansion of a knowledge base that can be used by an inference engine to challenge a wide variety of situations. The Dynamic Anthropomorphic Robot with Intelligence (DARwIn) proved to be a practical platform for exploring the possibilities of using an expert system to control an independent agent in an uncontrolled environment. Our research revolves around the development of a framework that allows the seamless integration of the C language integrated production system (CLIPS) with the DARwIn framework. This type of control, that approaches a cognitive model rather than a procedural one, allows researchers to focus on expanding the knowledge base of the system and improving functionality and decision making skills on a more abstract level.*

Keywords: DARwIn-OP, Expert Systems, CLIPS

1 Introduction

In 1954 Isaac Asimov stunned the world with the first book of his robot novel series, introducing the world to the concept of Robots that looked and acted like human beings. For decades the minds of children, sci-fi fans and scientists have been entranced by these possibilities. Fiction novels led to sci-fi movies that were coupled with the dawn of anthropomorphic robots. What started off as the pencil sketches of a mad man can now be found in many robotics labs across the world.

The humanoid-research community today, actively researches bipedal movements, kinematics, prosthetics and a wide array of topics many stemming from Asimov's fictional designs. Along with robotics, another topic that emerged was the study of Artificial Intelligence and Human cognition. The scientific world was convinced that if we could build robots that looked like humans, we should be able to program robots to think like humans.

The framework developed in the course of our research investigates the possibility of constructing a localizationist model that could mimic decision making via the use of an Expert system to control the DARwIn - OP.

2 Motivation

Looking at the anthropomorphic form of the DARwIn raises the question; can the DARwIn be programmed to imitate "thinking" or "perceiving". There are several approaches within Artificial Intelligence used to explore cognition. One of these research areas is pattern matching using an Expert System [2]. An Expert System allows a computer to make decisions by sifting through and recalling knowledge similar to an "expert", rather than the procedural forms generally employed [5]. Exploring the possibilities of using an Expert System to control the DARwIn's motion will open various avenues for research in the field of human cognition. We wanted to develop a framework that seamlessly integrates with the DARwIn using a CLIPS expert system. This paper summarizes the implementation of the framework and outlines the communication pathways between various aspects of the project.

3 Approach

In order to provide DARwIN with an unobtrusive use of the inference engine we decided to approach the mimicking of higher functions using a localizationist model as it resembles DARwIN's current architecture. The Clips framework was developed as an external component that interfaces with the Darwin framework using an intermediary controller. The Expert System was designed as a component, and not as the controller itself, in order to keep its priority at the same level with other modules. The intermediary controller houses access to all components of the DARwIN and provides communication pathways throughout.

3.1 DARwIn

The Dynamic Anthropomorphic Robot with Intelligence (DARwIn) is a robotics platform developed at the Robotics and Mechanism Laboratory (RoMeLa) at Virginia Tech for research in kinematics, human-robot interaction, and AI [3]. It comes equipped with a dense array of sensors and expansion capabilities suitable for advanced research an almost any robotics field. DARwIn contains an integrated Fit-PC2i computer running Ubuntu.

Figure 1: DARwIn

3.2 CLIPS

C Language Integrated Production System (CLIPS) is a rule based system that was developed at the NASA-Johnson Space center. [6] CLIPS is fast, efficient, and can easily be integrated with various languages using an extensive API.

3.3 Integration

It was decided to integrate our solution with the source code provided by Robotis as it is uniformly distributed to versions of the DARwIn purchased through Robotis distributors. Versions using LUA have not been tested but the finite state machine can be adapted to interface with our framework.

4 Implementation

There are several segments that must communicate with each other to facilitate the functionality of the framework. The Expert System (ES) must receive data from the DARwIn, representing the current state from a high level. This is done by asserting either pre-processed sensor data or the running state's current classification into the CLIPS fact base. Once information has been asserted, the ES can analyze and determine the next state needed. Instructions are sent back to the intermediary controller for post processing and execution.

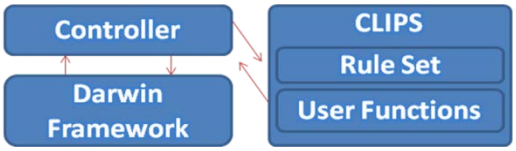

Figure 2: Framework Communication

Development of the framework was broken up into four sections:

- Integrating the CLIPS Library
- Developing communication pathways between CLIPS and the DARwIn Framework
- Creating an output control interface for CLIPS
- Developing a rule set to test the framework

4.1 CLIPS Build

CLIPS version 2.4 was used in this deployment. Installation was not necessary as the source was compiled in library format.

4.2 Communication

Information is transmitted on a pseudo publish-subscribe framework using function pointers. Potential listeners subscribe to "events" by passing function pointers to the controlling classes defined subscribe function. This allows for an easily expandable and lightweight coupling between classes without the overhead of raising events. Function pointers link CLIPS's user functions and the Darwin's framework to the intermediary controller. In both instances, communication is one way.

4.3 Control Interfaces

CLIPS provide a modifiable interface to allow for creating user defined functions. This feature is used for outgoing communications from CLIPS to the intermediate. Declaring user defined functions is facilitated by: DefineFunction(functionName,functionType,functionPointer, actualFunctionName); where the function name is the accessible name used within CLIPS. This links a LISP like call with an external call. Using this, the ES can call the defined function and interact with the intermediary controller to route commands back to the DARwIn framework. In order to decouple the CLIPS library, user defined function can be defined at runtime and stored outside of the library. Code examples can be viewed in Figure 3.

```
c++:
void setDarwinToIdle{
    Walking::GetInstance().X_MOVE_AMPLITUDE = 0;
    Walking::GetInstance().Y_MOVE_AMPLITUDE = 0;
}

int main()
{
    //Initialize CLIPS
    DefineFunction("darwinIdle","v",PTIF setDarwinToIdle,"setDarwinToIdle");
}

CLIPS:
(defrule SendStop
    "Tell Darwin To Stop"
    ?f2 <- (Walk)
    ?f1 <- (stepsToTake(stepsLeftToTake ?v))
    (test(eq ?v 0))
    =>
    (retract ?f1)
    (retract ?f2)
    (darwinIdle)
    (assert(idle))
)
```

Figure 3: External Call

4.4 Rule Set

The CLIPS Expert System has two major components; the knowledge base and an inference engine. The knowledge base consists of facts that are representative of the current state of the DARwIn and production rules. These rules represent heuristic knowledge and follow an "if-then" protocol coupled with the active facts stored in the knowledge base [4]. This implies that if a certain combination of facts has been asserted; the system "infers" a need to update the knowledge base and push new events to its agenda. A portion of the rule-base is displayed in Figure 4:

```
(defrule SendWalk
    "Assert Walk Intent - Remove idle State"
    ?f1 <- (stepsToTake)
    ?f2 <- (idle)
    =>
    (assert(Walk))
    (retract ?f2))
```

Figure 4: Rule Set

Once the production system identifies intent, rules are instantiated and added to the agenda. A rule is instantiated when all of the patterns that constitute the premise of the rule can be matched with facts present in the knowledge base. The inference engine then executes these rules based off various factors that determine the rules priority. Currently no salience was given to any one rule in our rule set. Depending on the construct of the rule, the output may modify the knowledge base or interact outside the confines of CLIPS.

5 Framework Testing

Our chunk primarily demonstrates the viability of using an Expert System to control the Darwin framework. Ideally, the DARwIn's thought process would be broken up in to numerous ESs. Each ES would be an independent component that dealt with domain specific tasks; such as, walking, vision, or auditory systems [1]. The chunk we developed for testing the framework superficially dealt with controlling motion

5.1 Workflow

Our motion control rule set tracks and manages the walking and turning of the DARwIn using state representation of the motion manager and externally registered intent. A number of steps to take or number of degrees to turn would be added to the agenda and the ES would set movement amplitudes and initiate walking. Once the DARwIn begins to move, the intermediate controller would receive updates on the movement from lower levels and relay data to the ES for monitoring. Once the ES has identified completion of the task, it would adjust the movement amplitudes and stop walking. Figure 4 traces various paths the rule-based system follows when intent has been registered.

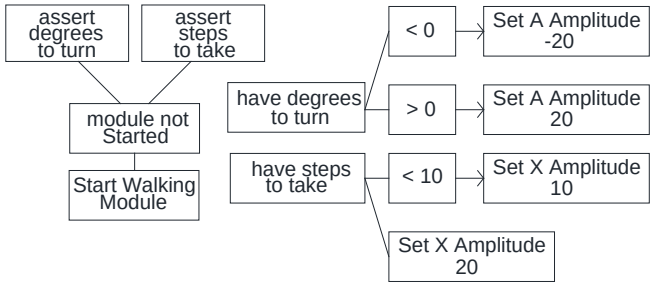

Figure 4: Rule Set – Movement Initiation

5.2 Tracking Movement

Every two steps the DARwIn takes results in a cycle through four phases; Standing -> leg raise -> standing -> leg raise. Following completion of the 1st and 3rd phases, a call is made notifying the controller of a phase change. The controller passes this information to the ES which incorporates it into the knowledge base. Once the information is logged, the ES reruns the agenda to decide when to modify the state of the DARwIn.

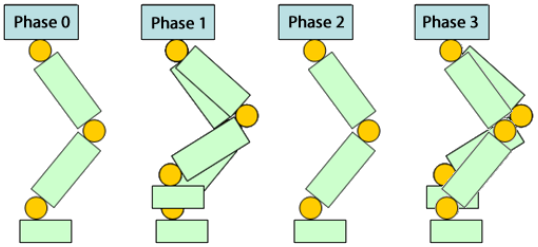

Figure 5: Walking Phase depiction – No forward movement

Table 1: Phase Transitions

Phase 0 - 1: Ankle dorsiflexes, knee is flexed, leg elevates
Phase 1 - 2: pelvis rotates and leg moves forward, knee is extended and foot contacts surface
Phases 2 - 3: Repetition of phases 1 and 2 using opposite leg

5.3 Example Integration

To facilitate our testing, both steps to take and degrees to turn were asserted arbitrarily by the intermediary controller. In order to maintain relative awareness of phase changes efficiently, the motion manager was modified to communicate openly about step phases. The walking module was given an access point, linking to the intermediary controller. With every alternate phase change an event was raised, sending an alert to the ES through the controller.

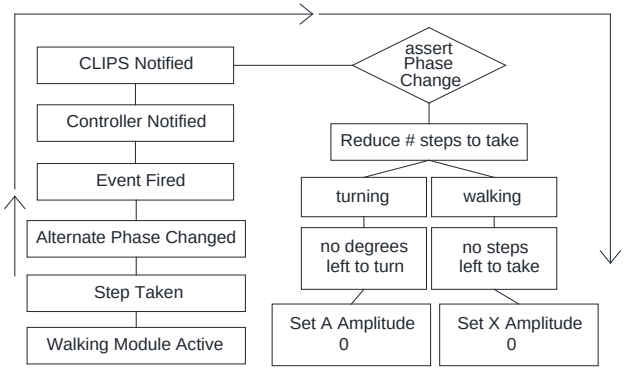

Figure 6: Rule Set – Movement Completion

6 Framework Setup

Clips integration requires minimal modifications to the CLIPS library and the DARwIn Framework. User Defined functions must be defined in the CLIPS library to match the execution requirements of the output space. This step is critical to ensuring proper feedback from the ES. The input space of the ES will pull from an array of data throughout the system and may require modification of the DARwIn's source code to include state listeners. Once communications have been properly defined, the intermediary controller can load the rule set and information can be polled and pushed to the ES through CLIPS's API.

7 Results

A framework was developed that could successfully integrate CLIPS with the DARwIn's framework. The framework was able to control the DARwIn's walking module by sending instructions to the controller based off decisions inferred by the Expert System. The Expert System itself is scalable and can be easily replaced with other Expert Systems of the user's choice. Slight changes to the DARwIn's framework will allow manipulation of almost any aspect of the DARwIn via "expert" control.

8 Acknowledgements

We would like to thank Edwin Rudolph for his guidance and support throughout the development process.

Quasi-optimal Coverage Algorithm for Simple Robot in an Unknown Environment

Dominique DUHAUT
Lab-STICC-CNRS
Université de Bretagne Sud, France
dominique.duhaut@univ-ubs.fr

Abstract

In this paper we present a simple algorithm to make a quasi-optimal coverage of an unknown environment. Under some hypothesis, we demonstrate that it is possible to build a map of the environment and to cover it, without passing two times in the same space, except if it's impossible and we will describe these cases and show that they are very limited.

The robot is supposed to be a non holomomic platform with 2 powered wheels for "tank-like" movements, and a set of 7 distance sensors in front of the robot.

Introduction

In robotics, the problem of the covering the space in an unknown environment is a very standard problem. On this the first relevant synthesis can be found in [1]. SLAM simultaneous localization and mapping can be coupled to cover unknown space [2]. Based on graph description [3] and using a research graph algorithm is another method used to coverage. Another work proposes the Boustrophedon cellular decomposition [4] to build a path for space coverage.

Usually in this paper the sensors are a set of sensor surrounding the robot [5] or a laser sensor [6]. In this paper we will use a very simple sensor.

In this paper we will describe the robot used in the simulation and show that in a discretized environment there is no optimal path to cover the space. We then define the quasi-optimal notion. In part two we present the quasi-optimal algorithm and results of simulation. We finally discuss some perspectives to this work.

1. The robot and the environment

Description of the robot

Like a large set of commercial robots, our work uses a "tank-like" robot with two independent wheels.

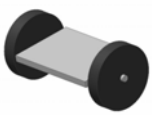

Fig.1. Non holomomic platform with 2 powered wheels for tank-like movements

In this paper we consider that the robot can only move in three directions: front, left, right in a discretized environment decomposed in elementary suares. We assume that the robot fully covers on square.

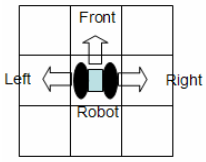

Fig.1. The 3 possible displacements

The robot is supposed to be equipped with distance sensors able to detect an obstacle in the 7 places in front of the robot and measuring a distance of 3 squares.

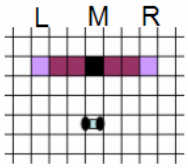

Fig.3. Line of 7 sensors for obstacle detection in front of the robot

Hypothesis on the environement

The hypotheses on the environment are:

- There is no dynamical object in the space, the robot is the only element moving
- The space is large relative to the robot. This means that if the robot covers a elementary square then the minimal distance between two static obstacles is six times this distance: six squares.

In this kind of environment it is possible to decompose the space in rectangles [2] that represents the free space.

The figures 3&4 show that this rectangle decomposition is not unique

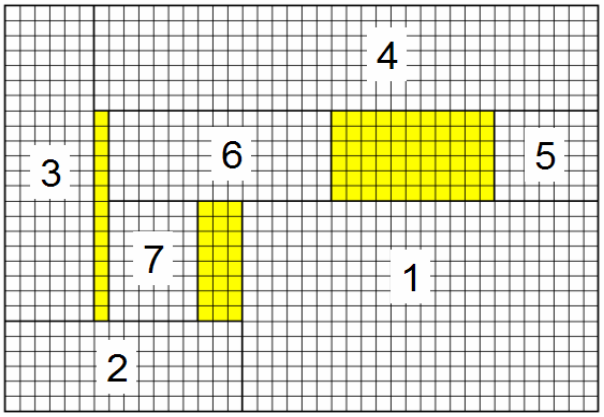

Fig.3. Decomposition of the space in 7 rectangles

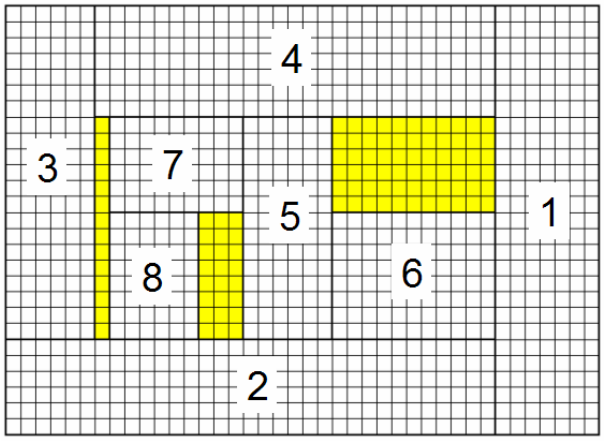

Fig.4. Decomposition of the space in 8 rectangles

Has shown in the proposed algorithm in part 2 the rectangle decomposition will depend of the initial position of the robot. In the following, we will consider that each of the 8 rectangles of the space fig 4 are empty rooms and that a door exist between two adjacent rectangles.

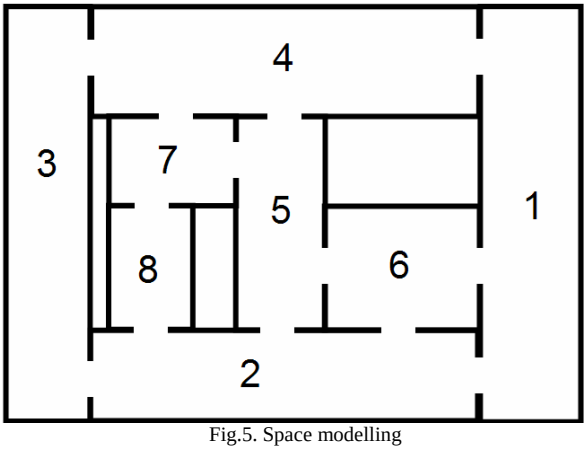

Fig.5. Space modelling

We will then consider that the environment is a set of rooms in which there are communication doors, has presented in fig 5.

No optimal path for covering the space

In this section we want to show that with the type of "tank-like" robot is is not possible to give an optimal path to cover the surface if we fix and entry door and an exit door. By optimal path we mean that the robot passes by all the squares of the environment one time and only one time.

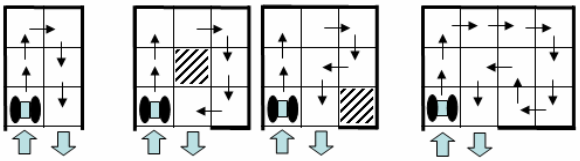

Fig.6. Depending on the size of the environment, this kind of robot cannot find an optimal path

Has shown in the figure 6, with the type if displacement allowed by the robot, an optimal path depends on the number of squares to cover and the position of the entry and the exit door. In the case of 6 or 12 squares a solution exists. But with a 9 squares there is no solution. We have to notice that the result could be different if we change the place or the entry and the exit door see figure 7.

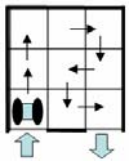

Fig.7. The entry and exit position are also parameters that influences an optimal path

We will define a quasi-optimal path as a path covering the environment, covering a maximum number of squares, without passing two times by the same square and which lets a minimal number of squares non visited.

2. The quasi-optimal algorithm

In this part, we present the principle of the algorithm, the next section will show why and when it is not optimal but only quasi-optimal. The algorithm is in two parts the first one explores the environment and build the corresponding map, the second part will finish the covering of the non visited space and will visit the adjacent rooms while passing in front of a doors.

Part 1: Building the map between obstacles

The robot enters in the room and covers the centre of the space and lets a walkway around the walls of 2 squares large.

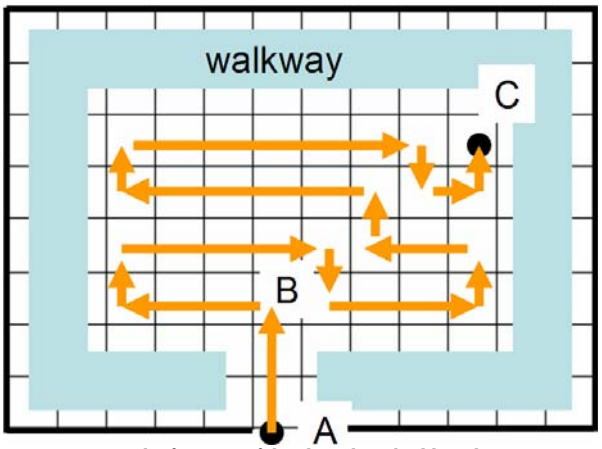

Fig.8. The first part of the algorithm : building the map

The robot enters in A in the first square then moves to the initial position B. Then a boustrophedon [4] path is generated until the sensors detect an obstacle. This path ends in the C position. Due to the distance of obstacle detection the walkway of two squares large as not been visited by the robot (except between A and B).

Part 2 Finishing the coverage

In the second part the robot uses the walkway to access to all the doors surrounding the room and ending the coverage.

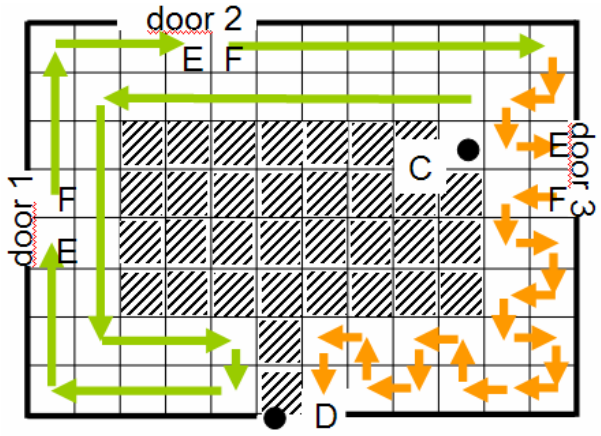

Fig.9. The second part of the algorithm : finishing the coverage

From the C position the robot moves in the opposite direction of the exit door D to finish covering the space. Following the path if a door, connecting to a non visited room, is founded then the robot enters the new room E and will re-enter coming back from this room in the next square of the space F. Then the displacement continues. When the robot exceeds the C position then again a boustrophedon path is generated. If a door if founded then the robot enter this new room at a position E and comes back from the room at the next position F. This is done until the exit position D is reached.

3. It is only quasi-optimal

We run a simulation and show that, as mentioned in fig 11 depending on the geometry of the environment the robot will construct two different freeways: one strictly 2 squares large, the second one depending of the position of the obstacles in the environment will be partially 3 squares large.

Part 1: Building the map between obstacles

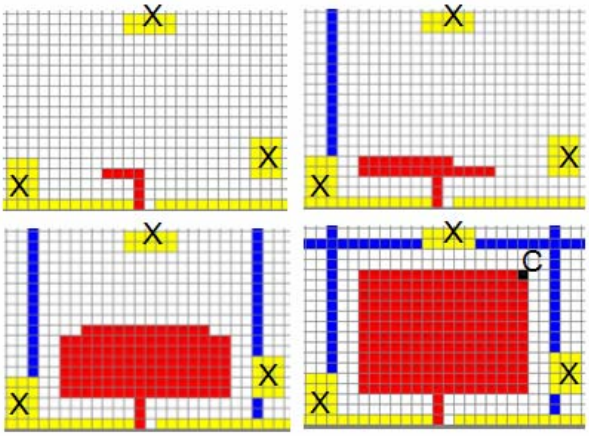

Fig.10. Screen copy of the simulation of the map building

The obstacles are in yellow in the fig 10 and when the robot finds an obstacle in front or on the side, it extends the position of the obstacle by a line (in blue) to figure the limits of the visited “room” see figure 5. If the obstacles are at good position (odd squares horizontal) then the exploration finishes with a covered rectangle (in red) and the robot is in C an angle, the freeway around this rectangle is exactly 2 squares large.

But depending of the distance between obstacles we can have 4 kinds of covering fig 11.

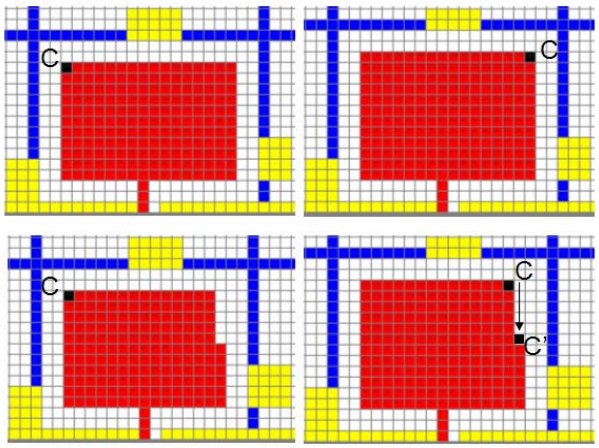

Fig.11. The visited space depending in the position of the obstacles.

In the top of the figure 11 we can see that for the same distance in columns between two obstacles (left and right) the covered surface is a rectangle, the robot finishing in C position on the left or on the right depending on the distance in line between two obstacles (top and down).
On the bottom of fig 11, if we increase the horizontal distance in column of one square then the problem mentioned in fig 6 appears and then the robot must increase the size of the walkway, passing from 2 to 3. In this case, if the robot finishes in C on the right side (bottom right fig 11) then it is possible to "close" the rectangle by moving down the third non visited column of the walkway, reaching the C' position, and then, the walkway is strictly 2 square large. But, in the last case (bottom left fig 11) it is not possible to finish the walkway with a perfect 2 squares large. We will discuss in the 2 part of the algorithm the consequence.

Part 2 Finishing the coverage

Like shown in figure 9 the finishing coverage is divided in two behaviours for the robot : strait line displacement and boustrophedon displacement. The strait doesn't produce any problem of coverage. First the internal part of the walkway is covered and after reaching the A entry point the external of the walkway is covered until de C point.
After overtaking the C point a boustrophedon displacement is used to finish the covering. Here depending on the parity of the quares of the walkway a non covered square can appear in each time that the walkway turns (see fig 7). An other non covered square can appear, for the same reasons, when the walkway it 3 squares large. So finally in the worse case 3 non covered squares can be obtain. The algorithm is not optimal and no solution exist (fig 12&13).

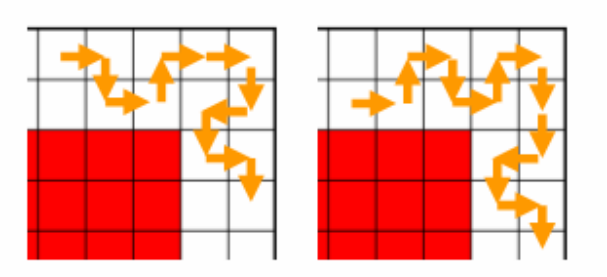

Fig.12. The covering is optimal when the walkway is 2 squares large

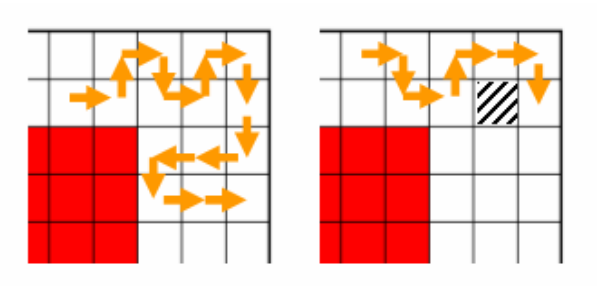

Fig.13. The covering is not optimal when the walkway is 3 squares large it depend on the size.

In this case the robot knows that a square has not been covered because it haves the map of the environment. In this case we can accept that the robot add for instance one backward motion on each of then to finish the coverage.

5. Discussion

In this work we suppose that the robot will exactly move from one square to another. We know that for real robot following a strait line never perfect due to errors introduced by slipping on the floor for instance. For a real application, some trajectory corrections should be added in localisation.
On a second hand, the hypotheses are in figure 3 that the robot is equipped with a line of sensors with 7 elementary obstacle detectors. We did not check it but we believe that only 3 obstacle sensors would enough like in figure.

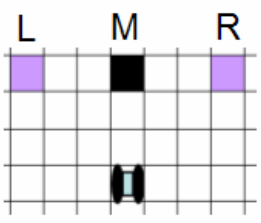

Fig.14. Three sensors should be enough if the obstacles are large

5. Java code for building the map

Here a simplify version of the code used to make the simulation presented in part 3. The full code can be found in [7].

```
void goRobot(JTextArea [][] e,int [][] t,int i,int j){
   int a,fin,odd;
  // Search left
   while ( ! leftObstacle(world,i,j)) {j=j-1; world[i][j]=2;
Red(e,i,j);};
  //draw virtual obstacle in blue
   a=0;
   while(a<20){

    a++;
   }
  // Search rigth
   i=i-1; world[i][j]=2;Red(e,i,j);a=0; // deplace en haut
   while ( ! murDroite(world,i,j)) {
    if ((world[i+1][j]==0)&&(a==0)){i=i+1;j=j-1;a=1;};
    j=j+1; world[i][j]=2; Red(e,i,j);};
  //blue line j+3
  ...
  // something one left or rigth
   fin=0;odd=0;
   i=i-1;world[i][j]=2;Red(e,i,j);a=0;
   while (fin==0){
    while(! leftObstacle(world,i,j)){
     if (world[i][j-1]==2){i=i-1;j=j+1;};
     j=j-1; world[i][j]=2; Red(e,i,j);
     if (isOdd(world,i,j)){odd=1;};
     if (sensorLeftRigth(world,i,j)){fin=1;} //blue line i-3
    };
    if (fin==0){
     i=i-1;world[i][j]=2;Red(e,i,j);a=0;
     while ( rightObstacle(world,i,j,odd)) {
      if ((world[i+1][j]==0)&&(a==0)){i=i+1;j=j-
1;a=1;};
       j=j+1; world[i][j]=2; Red(e,i,j); // blue line i-3
     };
    }
   }
  }
```

5. Conclusion

In this paper we have presented a quasi optimal algorithm to cover an unknown environment. We show that the existence of an optimal path depends on the distance between obstacles and the entry/exit doors positions, we show that in the worst case, the all surface is covered we a maximum of 3 elementary square non visited.
The map construction if done with a robot "tank like" with a line of distance sensors of 7 elements, looking 3 steps in front. This kind of robot is very standard in commercial platform.

Mathematical evidence for target vector type influence on MLP learning improvement

José Ricardo Gonçalves Manzan, Shigueo Nomura and Keiji Yamanaka

Abstract – ICAI - *This work proposes a mathematical proof for the use of orthogonal bipolar vectors (OBV) rather than conventional target vectors in artificial neural network MLP learning. A larger Euclidean distance provided by new target vectors is explored to improve the learning and generalization abilities of MLPs. The proposed proof compares the MLP performances by using different target vectors such as conventional binary and bipolar and orthogonal bipolar vectors. The evidence for performance improvement is shown by the study of updating process for the weights through the backpropagation algorithm. We have concluded that the use of orthogonal bipolar vectors as targets can provide a better keep of each pattern feature and reduce the interference of noises from a training pattern to the other one.*

Keywords: Mathematical proof, pattern recognition, multilayer perceptron, target vectors, orthogonal bipolar vectors

1 Introduction

Computational intelligence is a science field that has emerged as a set of powerful tools capable of solving problems that previously could not be solved. In this context, we have the Artificial Neural Networks (ANN) receiving important contributions from researchers since 80's. It is quite difficult to list all the ANN applications. Some applications are pattern recognition [1], sound signal processing [2], and biomedical signal processing [3].

Related works are presented in Section 2. Section 3 presents a motivation for the work. Hypothesis to be solved by this work is described in Section 4. The different types of target vectors are defined in Section 5. In Section 6, we can verify the mathematical evidence for affecting the MLP performance according to different target vector types. Some results are discussed in Section 7. Section 8 presents the conclusion of this work.

2 Related works

Researches on pattern recognition mainly description and classification have been considered important in the computer field. Several techniques such as statistical approach, theoretical decision and syntactic approach have been adopted [11]. Currently, the ANN techniques have been widely used because of promising results. One of the advantages of using ANN is the ability for training in a supervised or unsupervised form.

It is known that traditional approaches on artificial intelligence use the sequential processing. On the other hand, ANN techniques use a learning mode with parallel and distributed processing. Their training methodology is based on biological neuron activity to learn through examples. Trial and error strategies contribute to the ability to differentiate patterns. ANN has a similar behavior when a large number of neurons send excitatory or inhibitory signals to other neurons composing the network.

Several researchers [4] [5] [6] [7] have focused on improving ANN performances. Some proposed strategies are regarded to input pattern improvement, ANN architecture optimization, learning algorithm enhancement and others.

Experimental results related to this work have been presented in [7] [8] [9] [10] showing the performance improvements.

3 Motivation

The biological cognition has abilities to recognize and distinguish patterns, even if they have a high degree of degradation an their features [12] [13] [14]. In case of ANN, an appropriate adjustment of parameters allows a learning with high degree of generalization. This is good for constructing a model with high flexibility to properly recognize very degraded patterns. However, if the training time is over then, the model becomes too rigid preventing the recognition of degraded patterns.

Several proposals in order to improve the ability to recognize degraded patterns have been carried out. In most cases they have focused on how to treat input vectors [15]. However, studies for the treatment of target vectors are still rare. This work shows effects of adopting orthogonal bipolar vectors as targets on improving the MLP performance to recognize

degraded patterns. The previous works [7] [8] [9] [10] show satisfactory results in using orthogonal bipolar vectors as expectation values for MLP learning.

4 Hypothesis

In case of conventional bipolar vectors (CBV), the inner product between two of them is not null. On the other hand, orthogonal bipolar vectors (OBV) always have null inner product between them. Also, the similarity between two OBVs is lower than that corresponding similarity between two CBVs. Furthermore, the orthogonality between two OBVs leads to the largest Euclidean distance as well as possible. We believe that larger Euclidean distance and lower similarity of OBVs can affect on the MLP performance improvement to recognize degraded patterns.

However, we have realized that there is no investigation studying the influence of target vector type on the MLP learning. This paper proposes a new methodology for the learning. Our hypothesis is on the fact that a target vector type can significantly improve the ability of MLPs in recognized degraded patterns.

This paper presents a mathematical evidence for explaining the performance improvement of MLPs.

5 Representation of vectors

5.1 Orthogonal Bipolar Vector (OBV)

Equations (1) and (2) represent two possible target vectors, the equation (3) represents the inner product and equation (4) the Euclidean distance.

$$\vec{V} = (v_1, v_2, ..., v_n) \tag{1}$$

$$\vec{W} = (w_1, w_2, ..., w_n) \tag{2}$$

$$\vec{V} \cdot \vec{W}^T = v_1 \cdot w_1 + v_2 \cdot w_2 + v_3 \cdot w_3 + ... + v_n \cdot w_n \tag{3}$$

$$d_{v,w} = \sqrt{(w_1 - v_1)^2 + (w_3 - v_3)^2 + (w_3 - v_3)^2 + ... + (w_n - v_n)^2} \tag{4}$$

Consider the case where $\vec{V}$ and $\vec{W}$ are orthogonal with size n. There will be n/2 components whose product is positive and n/2 components whose product is negative. Positive product components is correspond to the ones which the terms have the same signal. These terms do not affect on the result of the Euclidean distance given by equation (4). On the other hand, for the terms with opposite signals, the square of their difference is 4. The squares of differences contribute into the Euclidean distance resolution. Therefore, if we have larger number (n) of components then we have larger Euclidean distances. Equations (5) and (6) represent examples of OBVs. The inner product of those OBVs is given by equation (7). The OBVs can de generated by implementing the algorithm as described in [16].

$$\vec{V} \overset{def}{=} (1,1,1,1,-1,-1,-1,-1) \tag{5}$$

$$\vec{W} \overset{def}{=} (1,1,-1,-1,1,1,-1,-1) \tag{6}$$

$$\vec{V} \bullet \vec{W} = 1 \cdot 1 + 1 \cdot 1 + 1 \cdot (-1) + 1 \cdot (-1) + (-1) \cdot 1 + (-1) \cdot 1 + (-1) \cdot (-1) + (-1) \cdot (-1) = 0 \tag{7}$$

5.2 Conventional Bipolar Vector (CBV)

In case of conventional bipolar vector (CBV), one of its components values 1 at the position i corresponding to the pattern i represented by vector $\vec{V}$. All the other components value – 1 as represented by equation (8).

$$\vec{V} \overset{def}{=} (-1,-1,...,1,...,-1) \tag{8}$$

If $\vec{V}$ and $\vec{W}$ are conventional then the terms equation (4) are null except for two terms corresponding to the positive component of the vector $\vec{V}$ given by equation (8). So, the Euclidean distance for CBVs is smaller than the distance for OBVs.

5.3 Conventional Binary Vector (BV)

The binary vector (BV) is constituted by a unitary component at the position "i" to represent the i^{th} pattern and other null components as given by equation (9).

$$\vec{V} \overset{def}{=} (0,0,...,1,...,0,0) \tag{9}$$

The BVs are orthogonal between them but their Euclidean distance is always equal to $\sqrt{2}$.

6 Improving the weights between the hidden layer and output layer

6.1 Updating the weights between the hidden layer and output layer

We have considered the backpropagation algorithm foundation [16] to develop the mathematical evidence of our

proposal. A pattern of order q is propagated through the error backpropagation (δ_k) is given by equation (10).

$$\overset{q}{\delta_k} = \left(\overset{q}{t_k} - \overset{q}{y_k}\right) \cdot f`\left(\overset{q}{yin_k}\right) \tag{10}$$

Where:

- $\overset{q}{t_k}$ Represents the target vector corresponding to the q[th] pattern that propagates through the network.
- $\overset{q}{y_k}$ Represents the network output for the q[th] pattern propagating through the network.
- $f`\left(\overset{q}{yin_k}\right)$ denotes the differential value for the activation function of the net output considering the q[th] pattern.

The vectorial form of equation (10) is given by equation (11).

$$\overset{q}{\delta_k} = \left(\begin{bmatrix} \overset{q}{t_1} \\ t_2 \\ . \\ . \\ t_k \end{bmatrix} - \begin{bmatrix} \overset{q}{y_1} \\ y_2 \\ . \\ . \\ y_k \end{bmatrix}\right) .*\begin{bmatrix} y_1` & \overset{q}{y_2}` & \dots & y_k` \end{bmatrix}^T \tag{11}$$

Where:

- .* is the symbol for an unusual multiplication of two matrices with the same sizes. In this operation, each component of the first matrix, corresponding to the row i and the column j is multiplied with the corresponding component of the second matrix located at the row i and column j. The result from the operation is a matrix with the same size as the initial matrices.

In case of using BV as target vector we can verity that the k[th] component of this vector is 0. So, the difference (t_i - y_i) from equation (11) is between - 1 and 0. On the other hand when the value of k[th] of target vector element is 1, the difference (t_i - y_i) from equation (11) is between 0 and 1. These differences are always multiplied by the differential result for the activation function in y_i. The differential results will be positive since the activation function is assintotically non-decreasing. Therefore, δ_k will be negative for null components of BV and δ_k will be positive for the component of BV that is not null.

In case of using CBV as target vector we can note that the difference (t_i - y_i) from equation (11) will be from 0 to 2 for + 1 component of this vector. On the other hand, the difference (t_i - y_i) will be from – 2 to 0 for – 1 component of CBV. Therefore, δ_k will be negative for – 1 component of CBV and it will be positive for +1 components.

In case of using OBV as target vector, we can construct the first vector composed by only +1 components. So, δ_k will be positive for all the components of OBV. The second vector and others are composed by +1 and – 1 components in an equal number. Therefore, a OBV with n components will provide at least n/2 negative results and n/2 positive results of δ_k. δ_k is used for calculating Δw_{jk} in equation (12) and $\Delta w0_k$ in equation (13) as follows:

$$\overset{q}{\Delta w_{jk}} = \alpha \cdot \overset{q}{\delta_k} \cdot \overset{q}{z_j} \tag{12}$$

$$\overset{q}{\Delta w0_k} = \alpha \cdot \overset{q}{\delta_k} \tag{13}$$

In case of using CBV or BV as target vector, we can represent equation (12) as follows:

$$\overset{q}{\Delta w_{jk}} = \alpha \cdot \overset{q}{\delta_k} \cdot \overset{q}{z_j} = \left(\alpha \cdot \begin{bmatrix} \overset{q}{+} \\ - \\ . \\ . \\ - \end{bmatrix} \cdot \begin{bmatrix} \overset{q}{+} \\ + \\ . \\ . \\ - \\ + \\ - \end{bmatrix}^T\right)^T = \alpha \cdot \begin{bmatrix} + & + & \dots & - & + & - \\ - & - & \dots & + & - & + \\ . & . & . & & . & \\ . & . & . & & . & \\ - & - & & + & - & + \\ - & - & \dots & + & - & + \end{bmatrix} \tag{14}$$

In case of using OBV as target vector, equation (12) can be represented as follows:

$$\overset{q}{\Delta w_{jk}} = \alpha \cdot \overset{q}{\delta_k} \cdot \overset{q}{z_j} = \left(\alpha \cdot \begin{bmatrix} \overset{q}{+} \\ + \\ . \\ . \\ - \\ + \\ - \end{bmatrix} \cdot \begin{bmatrix} \overset{q}{+} \\ + \\ . \\ . \\ - \\ + \\ - \end{bmatrix}^T\right)^T = \alpha \cdot \begin{bmatrix} + & + & \dots & - & + & - \\ + & + & \dots & - & + & - \\ . & . & . & & . & \\ . & . & . & & . & \\ - & - & & + & - & + \\ - & - & \dots & + & - & + \end{bmatrix} \tag{15}$$

The influence of a target vector type on the term $\Delta w0_k$ can be analyzed as follows:

- In case of using BV or CBV as target vector we can note that the results for $\Delta w0_k$ will be negative for – 1 component of the target vector and only one will be positive as given by equation (16);
- In case of using OBV as target vector, it is possible to get at least half number (n/2) of components from the target vector as positive results for $\Delta w0_k$ as given by equation (17).

$$\overset{q}{\Delta w0}_k = \alpha \cdot \overset{q}{\delta}_k = \alpha \cdot \left[+ \quad - \overset{q}{\ldots} - \right]^T \tag{16}$$

$$\overset{q}{\Delta w0}_k = \alpha \cdot \overset{q}{\delta}_k = \alpha \cdot \left[+ \quad \ldots \quad + \overset{q}{-} \quad \ldots \quad - \right]^T \tag{17}$$

From equations (14) - (17), we can verify that the use of OBVs as target vectors can keep more pattern feature signal during its propagation. So, we can have more efficient mapping for pattern recognition learning.

6.2 Updating the weights between the input layer and hidden layer

A propagation of two consecutive training patterns will be considered: q order pattern and q + 1 order pattern. Equations (18), (19), and (20) are related to the q order pattern. Equation (21) is related to the q + 1 order pattern.

$$\overset{q}{\delta}_k = \left(\overset{q}{t}_k - \overset{q}{y}_k \right) \cdot f`\left(\overset{q}{yin}_k \right) \tag{18}$$

$$\overset{q}{\Delta w}_{jk} = \alpha \cdot \overset{q}{\delta}_k \cdot \overset{q}{z}_j \tag{19}$$

$$\overset{q+1}{w}_{jk} = \overset{q}{w}_{jk} + \overset{q}{\Delta w}_{jk} \tag{20}$$

$$\overset{q+1}{\delta in}_j = \sum_{k=1}^{m} \left[\overset{q+1}{\delta}_k \cdot \overset{q+1}{w}_{jk} \right] \tag{21}$$

Replacing equations (18) and (20) with the terms δ_k and Δw_{jk} from equation (21), we can obtain the following equation (22):

$$\overset{q+1}{\delta in}_j = \sum_{k=1}^{m} \left\{ \left[\left(\overset{q+1}{t}_k - \overset{q+1}{y}_k \right) \cdot f`\left(\overset{q+1}{yin}_k \right) \right] \cdot \left[\overset{q}{w}_{jk} + \overset{q}{\Delta w}_{jk} \right] \right\} \tag{22}$$

Also, replacing equation (19) with the term of equation (22), we can get the following equation (23):

$$\overset{q+1}{\delta in}_j = \sum_{k=1}^{m} \left\{ \left[\overset{q+1}{t}_k \cdot f`\left( \overset{q+1}{yin}_k \right) - \overset{q+1}{y}_k \cdot f`\left(\overset{q+1}{yin}_k \right) \right] \cdot \left[\overset{q}{w}_{jk} + \alpha \cdot \overset{q}{\delta}_k \cdot \overset{q}{z}_j \right] \right\} \tag{23}$$

Furthermore, replacing equation (18) with the term of equation (23), we can obtain equation (24):

$$\overset{q+1}{\delta in}_j = \sum_{k=1}^{m} \left\{ \begin{bmatrix} \overset{q+1}{t}_k \cdot f`\left( \overset{q+1}{yin}_k \right) \\ - \overset{q+1}{y}_k \cdot f`\left(\overset{q+1}{yin}_k \right) \end{bmatrix} \cdot \begin{bmatrix} \overset{q}{w}_{jk} + \\ \alpha \cdot \left(\overset{q}{t}_k - \overset{q}{y}_k \right) \cdot f`\left(\overset{q}{yin}_k \right) \cdot \overset{q}{z}_j \end{bmatrix} \right\} \tag{24}$$

From equation (24), we can obtain equation (25).

$$\overset{q+1}{\delta in}_j = \sum_{k=1}^{m} \left\{ \begin{bmatrix} \overset{q+1}{t}_k \cdot f`\left( \overset{q+1}{yin}_k \right) \\ - \overset{q+1}{y}_k \cdot f`\left(\overset{q+1}{yin}_k \right) \end{bmatrix} \cdot \begin{bmatrix} \overset{q}{w}_{jk} + \alpha \cdot \overset{q}{t}_k \cdot f`\left( \overset{q}{yin}_k \right) \cdot \overset{q}{z}_j \\ - \alpha \cdot \overset{q}{y}_k \cdot f`\left(\overset{q}{yin}_k \right) \cdot \overset{q}{z}_j \end{bmatrix} \right\} \tag{25}$$

Applying the distributive property to the matrix multiplication, we can obtain equation (26).

$$\overset{q+1}{\delta in}_j = \sum_{k=1}^{m} \begin{bmatrix} \left(\overset{q+1}{t}_k \cdot f\left(\overset{q+1}{yin}_k \right) \right) \cdot \left(\overset{q}{w}_{jk} \right) \\ + \left(\overset{q+1}{t}_k \cdot f`\left( \overset{q+1}{yin}_k \right) \right) \cdot \left( \alpha \cdot \overset{q}{t}_k \cdot f`\left(\overset{q}{yin}_k \right) \cdot \overset{q}{z}_j \right) \\ - \left(\overset{q+1}{t}_k \cdot f`\left( \overset{q+1}{yin}_k \right) \right) \cdot \left( \alpha \cdot \overset{q}{y}_k \cdot f`\left(\overset{q}{yin}_k \right) \cdot \overset{q}{z}_j \right) \\ - \left(\overset{q+1}{y}_k \cdot f\left(\overset{q+1}{yin}_k \right) \right) \cdot \left(\overset{q}{w}_{jk} \right) \\ - \left(\overset{q+1}{y}_k \cdot f`\left( \overset{q+1}{yin}_k \right) \right) \cdot \left( \alpha \cdot \overset{q}{t}_k \cdot f`\left(\overset{q}{yin}_k \right) \cdot \overset{q}{z}_j \right) \\ + \left(\overset{q+1}{y}_k \cdot f`\left( \overset{q+1}{yin}_k \right) \right) \cdot \left( \alpha \cdot \overset{q}{y}_k \cdot f`\left(\overset{q}{yin}_k \right) \cdot \overset{q}{z}_j \right) \end{bmatrix} \tag{26}$$

Converting equation (26) into a vector representation, the expression is given by equation (27).

$$\overset{q+1}{\delta in_j} = \begin{bmatrix} t_1 & t_2 & \overset{q+1}{\ldots} & t_k \end{bmatrix} .* \begin{bmatrix} y_1` & y_2` & \overset{q+1}{\ldots} & y_k` \end{bmatrix} \cdot \begin{bmatrix} w_{11} & w_{21} & \overset{q}{\ldots} & w_{j1} \\ w_{12} & w_{22} & \ldots & w_{j2} \\ . & . & . & . \\ . & . & . & . \\ w_{1k} & w_{2k} & \ldots & w_{kj} \end{bmatrix}$$

$$+ \begin{bmatrix} t_1 & t_2 & \overset{q+1}{\ldots} & t_k \end{bmatrix} .* \begin{bmatrix} y_1` & y_2` & \overset{q+1}{\ldots} & y_k` \end{bmatrix} \cdot \alpha \cdot \begin{bmatrix} \overset{q}{t_1} \\ t_2 \\ . \\ . \\ t_k \end{bmatrix} .* \begin{bmatrix} \overset{q}{y_1`} \\ y_2` \\ . \\ . \\ y_k` \end{bmatrix} \cdot \begin{bmatrix} z_1 & z_2 & \overset{q}{\ldots} & z_j \end{bmatrix}$$

$$- \begin{bmatrix} t_1 & t_2 & \overset{q+1}{\ldots} & t_k \end{bmatrix} .* \begin{bmatrix} y_1` & y_2` & \overset{q+1}{\ldots} & y_k` \end{bmatrix} \cdot \alpha \cdot \begin{bmatrix} \overset{q}{y_1} \\ y_2 \\ . \\ . \\ y_k \end{bmatrix} .* \begin{bmatrix} \overset{q}{y_1`} \\ y_2` \\ . \\ . \\ y_k` \end{bmatrix} \cdot \begin{bmatrix} z_1 & z_2 & \overset{q}{\ldots} & z_j \end{bmatrix}$$

$$- \begin{bmatrix} y_1 & y_2 & \overset{q+1}{\ldots} & y_k \end{bmatrix} .* \begin{bmatrix} y_1` & y_2` & \overset{q+1}{\ldots} & y_k` \end{bmatrix} \cdot \begin{bmatrix} w_{11} & w_{21} & \overset{q}{\ldots} & w_{j1} \\ w_{12} & w_{22} & \ldots & w_{j2} \\ . & . & . & . \\ . & . & . & . \\ w_{1k} & w_{2k} & \ldots & w_{kj} \end{bmatrix}$$

$$- \begin{bmatrix} y_1 & y_2 & \overset{q+1}{\ldots} & y_k \end{bmatrix} .* \begin{bmatrix} y_1` & y_2` & \overset{q+1}{\ldots} & y_k` \end{bmatrix} \cdot \alpha \cdot \begin{bmatrix} \overset{q}{t_1} \\ t_2 \\ . \\ . \\ t_k \end{bmatrix} .* \begin{bmatrix} \overset{q}{y_1`} \\ y_2` \\ . \\ . \\ y_k` \end{bmatrix} \cdot \begin{bmatrix} z_1 & z_2 & \overset{q}{\ldots} & z_j \end{bmatrix}$$

$$+ \begin{bmatrix} y_1 & y_2 & \overset{q+1}{\ldots} & y_k \end{bmatrix} .* \begin{bmatrix} y_1` & y_2` & \overset{q+1}{\ldots} & y_k` \end{bmatrix} \cdot \alpha \cdot \begin{bmatrix} \overset{q}{y_1} \\ y_2 \\ . \\ . \\ y_k \end{bmatrix} .* \begin{bmatrix} \overset{q}{y_1`} \\ y_2` \\ . \\ . \\ y_k` \end{bmatrix} \cdot \begin{bmatrix} z_1 & z_2 & \overset{q}{\ldots} & z_j \end{bmatrix} \quad (27)$$

Extracting the second term from equation (27), we have equation (28).

$$\begin{bmatrix} t_1 & t_2 & \overset{q+1}{\ldots} & t_k \end{bmatrix} .* \begin{bmatrix} y_1` & y_2` & \overset{q+1}{\ldots} & y_k` \end{bmatrix} \cdot \alpha \cdot \begin{bmatrix} \overset{q}{t_1} \\ t_2 \\ . \\ . \\ t_k \end{bmatrix} .* \begin{bmatrix} \overset{q}{y_1`} \\ y_2` \\ . \\ . \\ y_k` \end{bmatrix} \cdot \begin{bmatrix} z_1 & z_2 & \overset{q}{\ldots} & z_j \end{bmatrix} \quad (28)$$

In equation (28), we have a positive scalar α representing the learning rate and vectors represented by the following expressions:

$$\overset{q+1}{t_k} = \begin{bmatrix} a_1 & a_2 & \ldots & a_k \end{bmatrix} \quad (29)$$

$$f\left(\overset{q+1}{yin_k}\right) = \begin{bmatrix} m_1 & m_2 & \ldots & m_k \end{bmatrix} \quad (30)$$

$$\overset{q}{t_k} = \begin{bmatrix} b_1 & b_2 & \ldots & b_k \end{bmatrix}^T \quad (31)$$

$$f\left(\overset{q}{yin_k}\right) = \begin{bmatrix} n_1 & n_2 & \ldots & n_k \end{bmatrix}^T \quad (32)$$

$$\overset{q}{z_j} = \begin{bmatrix} z_1 & z_2 & \ldots & z_j \end{bmatrix} \quad (33)$$

From equations (28) – (33), we can obtain equation (34) as follows:

$$\left(\begin{bmatrix} a_1 & a_2 & \ldots & a_k \end{bmatrix} .* \begin{bmatrix} m_1 & m_2 & \ldots & m_k \end{bmatrix} \right) \cdot \left(\alpha \cdot \begin{bmatrix} b_1 \\ b_2 \\ . \\ . \\ b_k \end{bmatrix} .* \begin{bmatrix} n_1 \\ n_2 \\ . \\ . \\ n_k \end{bmatrix} \cdot \begin{bmatrix} z_1 & z_2 & \ldots & z_j \end{bmatrix} \right) \quad (34)$$

Solving only the especial results from multiplication element by element corresponding to ".*", we can get equations (35) and (36):

$$\begin{bmatrix} a_1 m_1 & a_2 m_2 & \ldots & a_k m_k \end{bmatrix} \cdot \alpha \cdot \begin{bmatrix} b_1 n_1 \\ b_2 n_2 \\ . \\ . \\ b_k n_k \end{bmatrix} \cdot \begin{bmatrix} z_1 & z_2 & \ldots & z_j \end{bmatrix} \quad (35)$$

$$\alpha \cdot \begin{bmatrix} a_1 m_1 & a_2 m_2 & \ldots & a_k m_k \end{bmatrix} \cdot \begin{bmatrix} b_1 n_1 \\ b_2 n_2 \\ . \\ . \\ b_k n_k \end{bmatrix} \cdot \begin{bmatrix} z_1 & z_2 & \ldots & z_j \end{bmatrix} \quad (36)$$

From equation (36), we can get equations (37) and (38).

$$\alpha \cdot \left(a_1 m_1 b_1 n_1 + a_2 m_2 b_2 n_2 + \ldots + a_k m_k b_k n_k \right) \cdot \begin{bmatrix} z_1 & z_2 & \ldots & z_j \end{bmatrix} \quad (37)$$

$$\alpha \cdot \left(a_1 b_1 m_1 n_1 + a_2 b_2 m_2 n_2 + \ldots + a_k b_k m_k n_k \right) \cdot \begin{bmatrix} z_1 & z_2 & \ldots & z_j \end{bmatrix} \quad (38)$$

Extracting the scalar term from equation (38), we can obtain equation (39).

$$\left(a_1 b_1 m_1 n_1 + a_2 b_2 m_2 n_2 + \ldots + a_k b_k m_k n_k \right) \quad (39)$$

The products $m_i n_i$ for $1 \le i \le k$ are positive. These results are derived from the activation function that was supposed to be assintotically non-decreasing. The components a_i and b_i for $1 \le i \le k$, depend on the target vector. They can be 0, 1 or – 1 and cause different effects as follows:

- In case of CBV as target vector, the product $a_i b_i$ for $1 \le i \le k$ will be – 1 for two terms of equation (39);
- In case of BV as target vector, the product $a_i b_i$ for $1 \le i \le k$ will be null;
- In case of OBV as target vector, the result from equation (39) will be smaller than for the case of using CBV.

Considering the use of CBVs as target vectors with four or more components, the result from equation (39) will be larger than the case of using OBVs.

7 Discussion

As illustration, we have taken CBVs with 16 components and replace the variables of equations (29) - (32) with numerical values as follows:

$$f\left(\overset{q+1}{yin_k}\right) = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix} \quad (40)$$

$$\left[f\left(\overset{q}{yin_k}\right) \right]^T = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix} \quad (41)$$

$$\overset{q+1}{t_k} = \begin{bmatrix} 1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 \end{bmatrix} \quad (42)$$

$$\left[\overset{q}{t_k} \right]^T = \begin{bmatrix} -1 & 1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 \end{bmatrix} \quad (43)$$

Then, equation (28) can be numerically expressed by equations (44) and (45).

$$= \left(\underbrace{\begin{bmatrix} 1 & -1 & \dots & -1 & -1 \end{bmatrix}}_{1\times 16} .* \underbrace{\begin{bmatrix} 1 & 1 & \dots & 1 & 1 \end{bmatrix}}_{1\times 16} \right) \cdot \alpha \cdot \left(\underbrace{\begin{bmatrix} -1 \\ 1 \\ -1 \\ . \\ . \\ . \\ -1 \end{bmatrix}}_{16\times 1} .* \underbrace{\begin{bmatrix} 1 \\ 1 \\ 1 \\ . \\ . \\ . \\ 1 \end{bmatrix}}_{16\times 1} \right) \cdot \begin{bmatrix} z_1 & z_2^{\,q} & \dots & z_j \end{bmatrix}$$

$$= \left(\underbrace{\begin{bmatrix} 1\cdot 1 & (-1)\cdot 1 & (-1)\cdot 1 & \dots & (-1)\cdot 1 \end{bmatrix}}_{1\times 16} \cdot \alpha \cdot \underbrace{\begin{bmatrix} (-1)\cdot 1 \\ 1\cdot 1 \\ (-1)\cdot 1 \\ . \\ . \\ . \\ (-1)\cdot 1 \end{bmatrix}}_{16\times 1} \right) \cdot \begin{bmatrix} z_1 & z_2^{\,q} & \dots & z_j \end{bmatrix} \quad (44)$$

$$= \begin{bmatrix} 1\cdot 1\cdot (-1)\cdot 1 + (-1)\cdot 1\cdot 1\cdot 1 + (-1)\cdot 1\cdot (-1)\cdot 1 + \dots + (-1)\cdot 1\cdot (-1)\cdot 1 \end{bmatrix} \cdot \alpha \cdot \begin{bmatrix} z_1 & z_2^{\,q} & \dots & z_j \end{bmatrix} \quad (45)$$

$$= 14 \cdot \alpha \cdot \begin{bmatrix} z_1 & z_2^{\,q} & \dots & z_j \end{bmatrix}$$

Also, we have taken OBVs with 16 components and replaced the variables of equations (29) and (31) with numerical values as follows:

$$\overset{q+1}{t_k} = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix} \quad (46)$$

$$\left[\overset{q}{t_k} \right]^T = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 \end{bmatrix} \quad (47)$$

Then, equation (28) can be numerically expressed by equations (48) and (49).

$$= \left(\underbrace{\begin{bmatrix} 1 & 1 & \dots & 1 & 1 \end{bmatrix}}_{1\times 16} .* \underbrace{\begin{bmatrix} 1 & 1 & \dots & 1 & 1 \end{bmatrix}}_{1\times 16} \right) \cdot \alpha \cdot \left(\underbrace{\begin{bmatrix} 1 \\ . \\ . \\ 1 \\ -1 \\ . \\ . \\ . \\ -1 \end{bmatrix}}_{16\times 1} .* \underbrace{\begin{bmatrix} 1 \\ . \\ . \\ 1 \\ 1 \\ . \\ . \\ . \\ 1 \end{bmatrix}}_{16\times 1} \right) \cdot \begin{bmatrix} z_1 & z_2^{\,q} & \dots & z_j \end{bmatrix}$$

$$= \left(\underbrace{\begin{bmatrix} 1\cdot 1 & 1\cdot 1 & \dots & 1\cdot 1 & 1\cdot 1 \end{bmatrix}}_{1\times 16} \cdot \alpha \cdot \underbrace{\begin{bmatrix} 1\cdot 1 \\ . \\ . \\ 1\cdot 1 \\ (-1)\cdot 1 \\ . \\ . \\ (-1)\cdot 1 \end{bmatrix}}_{16\times 1} \right) \cdot \begin{bmatrix} z_1 & z_2^{\,q} & \dots & z_j \end{bmatrix} \quad (48)$$

$$= \begin{bmatrix} 1\cdot 1\cdot 1\cdot 1 + \dots + 1\cdot 1\cdot 1\cdot 1 + 1\cdot 1\cdot (-1)\cdot 1 + \dots + 1\cdot 1\cdot (-1)\cdot 1 \end{bmatrix} \cdot \alpha \cdot \begin{bmatrix} z_1 & z_2^{\,q} & \dots & z_j \end{bmatrix} \quad (49)$$

$$= 0 \cdot \alpha \cdot \begin{bmatrix} z_1 & z_2^{\,q} & \dots & z_j \end{bmatrix}$$

We can verify that the result from equation (48) is null in case of using OBV and the result from equation (45) is always larger than that case. We can consider that the term of equation (39) has worked as an intensification factor for the term represented by equation (28).

Equation (28) is a term from equation (27) for updating weights during the training stage of MLPs. So, we can confirm the influence of target vector type on MLP learning. In case of using OBV as target vector, we can provide a reduced noise propagation contributing into an improved performance of MLPs on pattern recognition.

8 Conclusion

This work presented a mathematical proof to demonstrate the MLP performance improvement by adopting orthogonal bipolar vectors as targets. The mathematical results have shown the effects on noise reduction propagating from layer to layer due to the use of orthogonal bipolar vectors rather than the use of conventional target vectors for MLP learning. We also have verified that the use of orthogonal bipolar vectors provides a better separation of pattern features due to larger Euclidean distance between these vectors. We have concluded that the results can confirm the hypothesis of our work suggesting orthogonal bipolar vectors as expectation values for MLP learning in degraded pattern recognition.

Abstract - *Conventionally, human instructions to a robot are often given by previously designed signals such as voices and images. In this study, one's own "shapes of a hand" is suggested to be instructions in the human-machine interaction system. We proposed a Self-Organizing Map (SOM) with a memory layer named Transient-SOM (T-SOM) and adopted it to a hand image instruction learning system. In this study, instead of T-SOM, an improved SOM, Parameter-Less Growing Self-Organizing Map (PL-G-SOM) is used to improve the hand image instruction learning system. In order to verify the performance of the proposed system, comparison experiments were executed and the results showed the priorities of the new system.*

Keywords: *Human-machine interaction, Self-Organizing Map (SOM), Parameter-Less Growing SOM, Hand image instruction, Pattern recognition*

1 Introduction

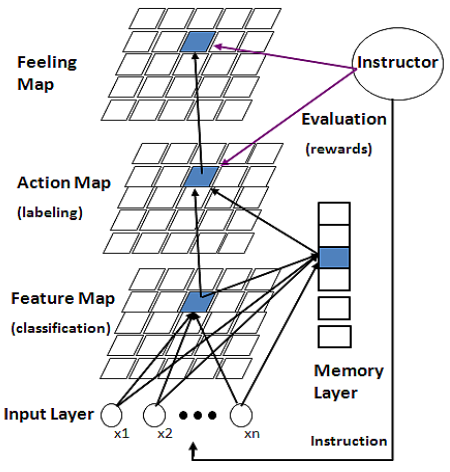
Hand gesture has been introduced to human-machine interaction since the end of last century (Pavlovic et al., 1997). Static images of hand shapes and dynamical videos of hand gestures are recognized by different mathematical models such as Multi-Layer Perceptron (MLP) (Rumelhart et al., 1986), Self-Organizing Map (SOM) (Kohonen, 1982, 1995, 1998), Hidden Markov Model (HMM) (Baum & Petrie, 1966) and so on.

Kohonen's SOM, as a well-known pattern recognition neural network, is a powerful tool to categorize high dimension data to one or two dimension space. In our previous studies, we proposed two kinds of improved SOMs, i.e., Transient SOM (T-SOM) (Kuremoto et al., 2006) which introduced a memory layer to reserve the matured "best much unit" (BMU), and Parameter-Less Growing SOM (PL-G-SOM) which combined the concepts of Berglund & Sitte's Parameter-Less SOM (PLSOM) (Berglund & Sitte, 2006) and Growing SOM (GSOM) (Bauer & Villmann, 1997; Villmann & Bauer, 1998; Dittenbach et al., 2000) to overcome the limitation of the size of map, the collapse of map' topology due to the unlearned data, and reduced the load of computation.

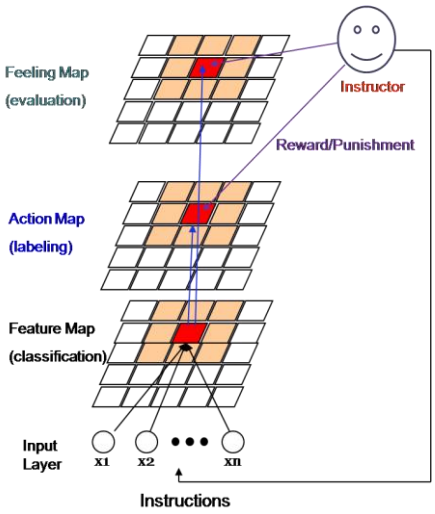
T-SOM has been applied to a hand image instruction learning system for a pet robot "AIBO" (Sony Ltd. Product 2003) successfully (Kuremoto et al., 2006; Hano et al., 2007) and PL-G-SOM succeeded as a voice instruction learning system for the robot (Kuremoto et al., 2010, 2011). In this research, we adopt PL-G-SOM into the hand image instruction learning system instead of T-SOM.

2 The structure of hand image instruction learning systems

The hand image instruction learning systems for partner robots, which are intelligent robots with the abilities of human-machine interaction, have a similar architecture as shown as in Figure 1. Hand images are preprocessed to yield their feature vectors as the input of systems. Three kinds of maps which are Feature Map, Action Map and Feeling Map are combined to realize input data classification, action selection and success rate expression respectively. Feature Map is a layer of T-SOM or PL-G-SOM, it clustering high dimension input data on 2-dimension spaces of maps. The input data of hand image instruction are feature vectors of hand shapes obtained by preprocessed images.



(a) T-SOM



(b) PL-G-SOM

Figure 1: Structures of instruction learning systems: (a) T-SOM (Kuremoto et al., 2006, Hano et al., 2007) for hand image instructions; (b) PL-G-SOM for voice instructions (Kuremoto et al., 2010, 2011), and used in this study for hand image instructions.

2.1 Feature Vector Space of Hand Image Data

2.1.1 Image Processing for hand Extraction

The hand image instruction system is designed for a partner robot learning to select different designed actions according to the different shape of a hand of its instructor. Hand area, i.e., skin area in the image captured by a CCD camera needs to be extracted and regularized at first. For a frame of image in RGB format, it is transformed to HSV format at first, then, using the threshold values of Hue (H), and Saturation (S) (Sherrah & Gong, 2001) and Red (R) threshold in RGB, skin area is extracted as a binary image. Noise elimination and holes filling are also effective to segment a hand area from the binary image. The thresholds for skin of a yellow race people in the room of fluorescent lights (around 500lx) are given as follows as we investigated:

1) When H, $S \in [0, 360]$ degree,
If $10 \leq S < 15$, then $H > 350$;
If $15 \leq S < 20$, then $H > 330$;
If $20 \leq S < 30$, then $H > 300$ or $H < 40$;
If $30 \leq S < 50$, then $H > 250$ or $H < 30$;
If $50 \leq S < 70$, then $H > 230$ or $H < 30$;
If $70 \leq S < 150$, then $H > 220$ or $H < 40$;
If $S < 10$ or $150 \leq S \leq 360$, then $H > 300$ or $H < 40$;
2) When R, G, $B \in [0, 255]$,
$30 < R < 250$.

2.1.2 Feature Space of Hand Shape

The instructions given by the instructor of robot are supposed as the different shapes of a hand. To distinguish the type of a hand shape, feature space definition is important to result high rate of pattern recognition. We discussed the methods of feature space construction in our previous works (Kuremoto et al., 2006; Hano et al., 2009) and proposed a useful feature vector space of hand shapes. The input images are analyzed by an 80-dimension vector space (See Fig. 2). From the origin of the space to the end of the hand area, the lengths in axes each 1.8-degree increased (80 axes) are the values of the feature vector, i.e., (x_1, x_2, …, x_{80}).

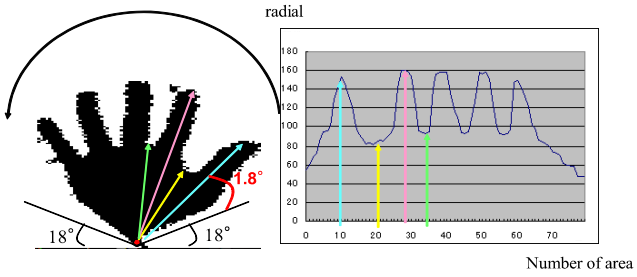


Figure 2: Input space of T-SOM and PL-G-SOM, constructed by an 80-dimension feature vector space of a hand instruction as a binary image. Left: a regularized image; Right: feature (input) space for Feature Map where horizontal axis is the dimension of vectors vertical axis is the value of vectors.

2.2 Action Map

The instructor presents his/her instructions with the different shapes of his/her hand to a robot, and in the view of the robot, hand shapes which are observed mean a state of the environment s_t, the robot intends to select a valuable action a_t (i) adapting to the state, i =*1*, *2*, …, *A*, according to a stochastic action policy π, which is according to Gibbs distribution (Boltzmann distribution) as shown by Eq. (1).

$$\pi_t(a_t(i)\,|\,s_t) = \frac{e^{\frac{Q_t(s_t,a_t(i)}{T}}}{\sum_{j=1}^{A} e^{\frac{Q_t(s_t,a_t(j))}{T}}}, \qquad (1)$$

where T is a parameter named "temperature" which comes from the physical state description of a system (higher temperature lower possibility), t is the iteration time of learning, A is the number of available actions. When an action is selected according to Eq. (1) and performed by the robot, its

instructor evaluates the action by giving a reward/punishment *r* to robot. The reward is accepted and used to modify the value of Q_t by Eq. (2), where Q_t is called "state-action value function" in reinforcement learning (RL) (Sutton & Barto, 1998).

$$Q_{t+1}(s_{t+1}, a_{t+1}(i)) = Q_t(s_t, a_t(i)) + r \quad . (2)$$

Where *s* means the state of environment observed by the robot, *a* is the action selected by the learner, *r* is the reward (scalar) given by the instructor.

2.3 Feeling Map

To express the degree of how an instruction is learned by robot, a Feeling Map which has the same number of units with Action Map is designed as shown in Figure 1. Feeling Map expresses instruction recognition rate, i.e., the feeling of robot: more successful, happier it is. Feelings of partner robots, such as pet robots, entertainment robots, caring robots and so on, are important for human-machine interaction (HMI) when they are able to express vividly by their face expressions or the gestures (Kuremoto et al., 2007). The distance between input pattern and units on Feature Map and the reward from instructor are used to calculate feeling values which is normalized in [-1.0, 1.0] where high positive value means happiness and 0.0 is the initial value of each unit here. The calculation of Feeling Map is given by Eq. (3).

$$F_{t+1}(i) = F_t(i) \pm aC - bD_i, \qquad (3)$$

where $F(i)$ notes the feeling value of unit *i* on the Feeling Map (zero initially), *C* notes the continue times of reward or punishment, D_i is the Euclidean distance (squared error) between the unit *i* on Feature Map and the input data, a, b are constants, and $0 < a < 1,\ 0 < b << 1$.

3 T-SOM

The algorithm of T-SOM (Kuremoto et al., 2006, Hano et al., 2007) and whole system processing is shown as follows:

–Step 1: Initialization. Choose random values (0.0, 1.0) for unit m_i of a *2-dimension* map corresponding to an *n-dimension* input space. $(i = 1,2,\ldots,N \times M)$

– Step 2: Input data. Present a training sample $\mathbf{x}(x_1, x_2 \ldots, x_n)$ to the Input Layer.

– Step 3: Find *BMU*, i.e., the best match unit of Memory Layer or Feature Map. A *BMU c* is decided by using minimum Euclidean distance criterion Eq. (4).

$$\boldsymbol{c} = \arg\min_i(\| \mathbf{x} - \mathbf{m}_i \|), \qquad (4)$$

where $\mathbf{x}$ is input feature vector $(x_1, x_2, \ldots, x_n)$. If *BMU c* is found from Memory Layer, then Feature Map (Step 4) is skipped.

– Step 4: Competitive learning. Using a learning rule given by Eq. (5) to update the value of $\mathbf{m}_i$.

$$\triangle \mathbf{m}_i = \alpha h_{ci}(\mathbf{x} - \mathbf{m}_i), \qquad (5)$$

where α is a learning rate and h_{ci} is a neighborhood function given by Eq. (6).

$$h_{ci} = \exp\left(-\frac{\| \mathbf{c}_i - \mathbf{c} \|^2}{2\sigma^2}\right). \qquad (6)$$

Here, $\boldsymbol{c_i}, \boldsymbol{c}$ denotes the positions of an arbitrary unit on the output map and *BMU*, respectively, $i = 1, 2, \ldots, k \le N \times M$, σ is a constant. Obviously, $h_{ci}(x) \ge 0$, $h_{ci}(0) = 1$, $h_{ci}(\infty) = 0$.

– Step 5: Vector quantization (labeling). After sufficient iterations of Step 3 and Step 4, i.e., if the distance from a *BMU* to the input is less than a threshold value, the input pattern is classified to be a unit of Action Map. This process is as same as LVQ-I (Kohonen, 1995), but labeling those units of Action Map is executed by a reinforcement learning algorithm described in Step 6.

– Step 6 Action learning. Using a reinforcement learning algorithm described in next subsection, robot select "correct actions" according to the reward or punishment from its instructor. The details are described in section 2.2.

– Step 7: Feeling formation. Units on Feeling Map are the levels of learning for actions on Action Map. The details are described in section 2.3.

– Step 8: Additional learning. For new instruction learning, T-SOM stores the succeeded unit weights into Memory Layer, and reset the units of Feature Map into random value. Additional learning or refresh learning then is able to repeat from Step 1.

T-SOM overcomes the limitation of a size fixed map of classic SOM and showed its efficiency as a real robot internal model to learn hand image instruction (Kuremoto et al., 2006; Hano et al., 2009), however, after a matured "BMU" is stored in the Memory Layer and the unit on Feature Map is refreshed with random weights of connections to the input, the distance between units of trained map and untrained input pattern (new data) shows disordered as indicated by Berglund & Sitte (Berglund & Sitte, 2006).

4 PL-G-SOM

Combine the idea of Growing SOMs (GSOM) (Bauer & Villmann, 1997, Dittenbach, Merkl & Rauber 2000) and the Parameter-Less SOM (Berglund and Sitte, 2006) together, we proposed a novel SOM named PL-G-SOM (Kuremoto et al., 2010, 2011) to realize additional learning, optimal

neighborhood preservation, and automatic tuning of parameters and applied it to a voice instruction learning system.

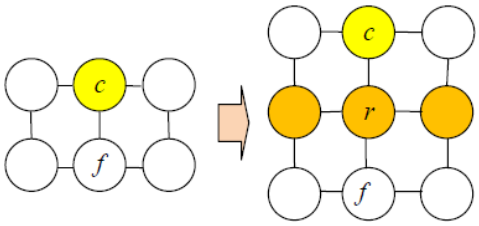

Figure 3: Insert a row/column into the feature map. Unit *c* is a *BMU* and *f* is the farthest unit among the neighbors of *c*, *r* the inserted row/column (Kuremoto et al., 2010).

Instead of the Memory Layer in T-SOM, Parameter-Less Growing Self-Organizing Map (PL-G-SOM) sets a small size of the feature map initially, and when a new input is not able to find a *BMU* from the initial map, that is, the distance between the input and the *BMU* ($\| \mathbf{x} - \mathbf{m}_i \|$) is larger than a threshold, a new row/column is inserted in to enlarge the feature map. For example, in Fig. 3, a new node *r* in the new row/column is inserted into the middle of node *c* and node *f*, where *c* is the nearest node to the new input and *f* is the neighbor of *c*. The weight of connection between the input and the new node has an average value of *c* and *f*,

$$\mathbf{m}_r = 0.5(\mathbf{m}_c + \mathbf{m}_f) \ , \qquad (7)$$

for nodes which are *r*'s neighbors in the new row/column:

$$\mathbf{m}_{r+l} = 0.5(\mathbf{m}_{c+l} + \mathbf{m}_{f+l}) \ , \qquad (8)$$

where *l=1, 2, …, N* or *M*. Unit *f* is chosen which has a largest Euclidean distance from the *BMU*-like *c* among the neighbors of *c*, and after this process, the map size changes to $N\times(M+1)$, or $(N+1)\times M$.

Following adaptive learning rate and neighborhood function are used in PL-G-SOM:

$$\Delta\mathbf{m}_i(t) = \varepsilon(t) h_{ci}^{\varepsilon}(t)(\mathbf{x}(t) - \mathbf{m}_i(t)) \ , \qquad (9)$$

$$\varepsilon(t) = \frac{\| \mathbf{x}(t) - \mathbf{m}_c(t) \|^2}{r(t)} \ , \qquad (10)$$

$$r(t) = \max(\| \mathbf{x}(t) - \mathbf{m}_c(t) \|^2, r(t-1)) \ , \qquad (11)$$

$$r(0) = \| \mathbf{x}(0) - \mathbf{m}_c(0) \|^2 , \qquad (12)$$

$$h_{ci}^{\varepsilon}(t) = \exp(-\frac{\| \mathrm{c}_i - \mathrm{c} \|^2}{(\sigma(\varepsilon(t)))^2}) , \qquad (13)$$

$$\sigma(\varepsilon(t)) = \sigma_{\max} \cdot \varepsilon(t), \ \sigma(\varepsilon(t)) \geq \sigma_{\min} . \qquad (14)$$

Here, $\varepsilon(t)$ is an adaptive learning rate, and $h_{ci}^{\varepsilon}(t)$ is a neighborhood function, $\sigma(t)$ is the neighborhood size. All of them are calculated by the distance between input and the BMU. $\sigma_{\max}, \sigma_{\min}$ are positive parameters, for example, the value may be the size of the map and 1.0, respectively. $\boldsymbol{c_i}, \boldsymbol{c}$ denotes the positions of an arbitrary unit on the output map and *BMU*, respectively, *i=1, 2, …, k* ≤ *N*×*M*. Obviously, $h_{ci}(x) \geq 0$, $h_{ci}(0) = 1$, $h_{ci}(\infty) = 0$.

Table 1: Parameters used in the experiments of SOM, T-SOM and PL-G-SOM.

Description	Symbol	Quantity
Size of image	**Width** ×**Height**	208 x156
Size of initial T-SOM and PL-G-SOM	$N \times M$	5x5
Iteration times	t	800
Temperature	T	1.0
Number of instructions (actions)	$a(i)$	8
Maximum/Minimum neighborhood in PL-G-SOM	$\sigma_{\max}$, $\sigma_{\min}$	$N \times M / 2$, 0.7
Reward for one action selected	r	10.0
Parameters of Feeling Map	$\boldsymbol{a}, \boldsymbol{b}$	0.1, 0.0001

5 The Experiment and Results

5.1 Hand Image Instruction Learning Systems Using T-SOM and PL-G-SOM

Eight kinds of hand shapes meaning 8 instructions of actions available for a robot are shown in Fig. 4 (a)-(g). Regularized binary images of hand shape showed the effectiveness of the preprocessing of images, meanwhile, feature data showed the availability of pattern recognition for their distinguished apparentness. The parameters used in T-SOM and PL-G-SOM are listed in Table 1. The number of units of SOM, T-SOM and PL-G-SOM was 5x5=25 initially. 800 iterations were executed during the learning process because the convergence of Squared Error (SE: distance between input and weights of connections, see Eq. (4)) and

Feeling value (see Eq. (3)).

Figure 4: Hand image instructions used in the experiments: (left) Original images of 8 kinds of gestures; (center) hand shapes obtained by the image processing; (c) Features in the input space (80-dimension on horizontal axis).

5.2 The Results and Analyses

To confirm the efficiency of learning methods, learning curves which are depicted by the graph of training time versus errors or performance of the models are commonly used. We investigated the change of distance between input feature data and units weights and the change of Feeling value according to the training time, and show them by Fig. (5) and Fig. (6). PL-G-SOM showed the furthest convergence in both evaluation figures. The value of Feelings of T-SOM and PL-G-SOM reached their highest altitude 1.0, which means that 100% success rate was achieved as hand image instruction recognition/execution. Classic SOM showed unstable performance for the learning process had not realized convergent result. The reason may be considered that the training time for SOM was not enough, and suitable parameters such as Temperature, learning rate, and neighborhood function were not used, usually they are decided by empirical values.

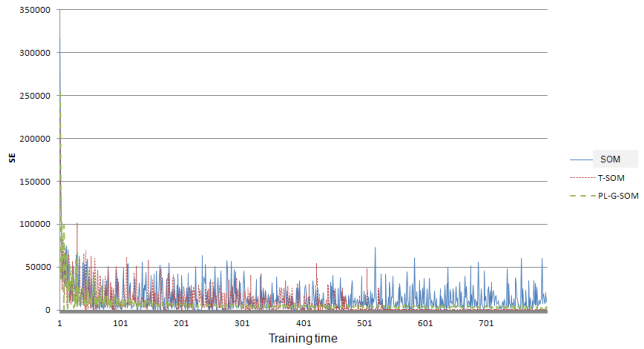

Figure 5: Comparison of different SOMs: the distances (or squared errors: SE) between *BMU* and input vectors (totally 8 kinds of gestures) decreased by training time, PL-G-SOM showed the best performance of learning convergence.

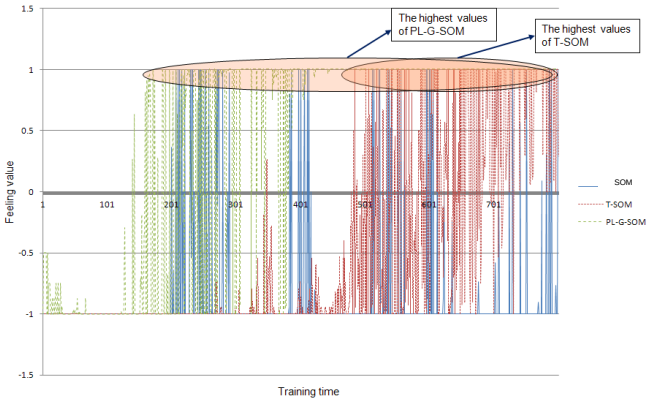

Figure 6: Comparison of different SOMs: the feeling value (totally 8 kinds of gestures) increased according to training time, PL-G-SOM showed the highest performance of learning convergence.

5	0	0	2	4	1	1
4	0	2	2	2	2	2
2	0	6	3	4	7	0
0	3	3	3	3	1	5
0	2	1	7	3	3	3
2	2	3	0	0	0	0

Figure 7: Action Map obtained by PL-G-SOM after training. 42 (6x7) units corresponding to 8 kinds of hand image instructions (0-7) are showed.

Fig. 7 shows the state of Action Map of PL-G-SOM after training. The number of units had grown from 5x5=25 to 6x7=42. Later input training data such as 4, 5, 6, 7 occurred fewer units meanwhile earlier data had more units for the more input times during the training. A method to avoid this situation is that training each instruction for certain times (until it converges) previously, then input all of data to find the global solution.

Fig. 8 shows the growth of the number of units on Feature Map (and Memory Layer) of T-SOM and PL-G-SOM. The speed and the quantity of PL-G-SOM were larger than T-SOM as the same hand image instruction learning systems.

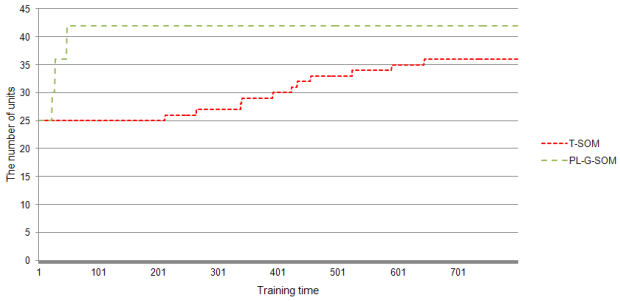

Figure 8: The number of units (neurons) on different maps grew differently during the learning process. The initial sizes of T-SOM and PL-G-SOM were same as 25, and the final sizes were 36 for T-SOM and 42 for PL-G-SOM respectively.

Furthermore, we used untrained samples with different changed variations of the eight shapes of hand, and confirmed the robustness of the trained system using T-SOM and PL-G-SOM. The limitation degree of tilt was about 30, and 45 degree for pan rotation.

From the comparisons of learning performance, it is able to conclude that PL-G-SOM proposed in this study showed more effective than the conventional T-SOM as the hand image instruction learning system.

6 Conclusions

A hand image instruction learning system for partner robot using PL-G-SOM was proposed. Comparing with the conventional system using T-SOM, PL-G-SOM showed better learning performance than T-SOM. Experiments using real robot are expected to confirm the online learning ability of the proposed system in the future.

Abstract— *This paper describes an Automatic Speech Recognition System in the home automation domain for the Brazilian Portuguese. It uses domain knowledge to automatically generate the language model and semantic evaluation of the transcription. The speech command is captured by a mobile device working as a "thin" client which is thereafter recognized by a server connected through. The speech command is then validated by a home automation domain ontology. New commands are added to the ontology which in turn is used to automatically generate a new language model. This approach is somewhat innovative in the ASR literature. Results shows a WIP of* 72% *with a real time factor of* 28% *and improved robustness of the system.*

Keywords: Home Automation, Automatic Speech Recognition, Language Model, Semantic Evaluation

1. Introduction

Current solutions for home automation include centralized control of lighting, heating, air conditioning, audio, video and other different electric and electronic devices in order to achieve comfort, save energy, improve security and provide increased quality of life for the elderly and disabled people. Mainstream operation of a home automation system is done by means of in-wall panels or, more recently, mobile devices. Due to the reduced dimension of keyboards and screens, mobile devices usability is, however, severely bounded [1].

Speech-enabled interfaces may be a good choice, since recent improvement in speech recognition accuracy and processing costs turns affordable the use of such technology.

Regardless the clear general achievements in continuous speech recognition, the lack of corpora and resources are still a huge obstacle for specific languages. Yet, the multitude of different accents and regional pronunciations makes the task even more challenging for the Portuguese language.

In this work we present a continuous Automatic Speech Recognition (ASR) system to perform home automation using Brazilian Portuguese utterances. The utterance is captured by a mobile device working as a client of a home automation server in a networked speech recognition architecture.

The server processes the spoken utterance and outputs a set of most probable candidates. Further, a home automation ontology validates the candidates using domain rules as semantic and syntactic information. The server translates the commands into zigbee codes which are finally transmitted to the respective devices. The language model is automatically generated according to the domain rules in the ontology.

Primary goals are two-fold: (1) evaluate the impact of the using specific domain knowledge provided by the ontology as semantic and syntactic information in the speech recognition accuracy and (2) analyze the feasibility of an automatically generated language model and its impact in the speech recognition accuracy.

In section 2 we present main ASR blocks along with a short review of Portuguese language issues. In section 3 we present the Semantic model we have proposed and added to ASR mainstream architecture. In section 4, we show how domain information can be actually used to validate uttered home automation commands. Experiments and results are provided in section 5. Finally, we present some concluding remarks in section 6.

2. Portuguese Language Automatic Speech Recognition

The first step of an Automatic Speech Recognition (ASR) task is to appropriately represent the speech waveform into an acoustic *feature vector* (or evidence) $X = (x_1, x_2, \cdots, x_t)$ which is generated in the time interval $[1..t]$. Such representation must deal with the drawback of having low dimensionality, which reduces complexity, and keeping the linguistic information. At the same time it must be robust, minimizing the influence of environmental noise. Extraction of the Mel-frequency cepstral coefficients (MFCCs) have been largely used [2]. MFCC warps the linear spectrum of the speech into a nonlinear scale called Mel which attempts to model the human ear sensitivity.

An ASR system can be then mathematically described as a mapping of such acoustic evidence X to a sequence of words $W = (w_1, w_2, \cdots, w_n)$ [3], where each word w_i belongs to a set of candidate words ω. The mapping is

defined in equation 1, where the term $P(W|X)$ has been rewritten using Bayes' Rule. The goal of the recognizer is, thus, to select the sequence of words that maximizes the underlying product.

$$\hat{W} = argmax_{W \in \omega} P(W|X) = P(W)P(X|W) \quad (1)$$

The estimation of the likelihood $P(X|W)$ term is given by an *acoustic model*. The acoustic model is built upon the feature extracted from a raw speech corpus and is usually modeled into Hidden Markov Models (HMMs) [4]. The HMM translate the input into a sequence of phonemes.

The term $P(W)$ is estimated by a *language model*. A popular model is based on a Markovian assumption that the probability of a given word w_i is approximated by the probability of its observing context of $n-1$ words, as shown in equation 2. The 3-gram language model seems to work better for the Brazilian Portuguese [5].

The probabilities are estimated from a corpus of sentences. The estimation of most N-grams is not reliable due to the sparseness of data. Smoothing techniques [3] are used to flatten the probability distribution, thus amending the problem. Two examples of smoothing techniques are Good-Turing [6] and Witten-Bell [7].

$$\begin{aligned} P(w_1, w_2, \cdots, w_m) &= \prod P(w_i|w_1, \cdots, w_{i-1}) \quad (2) \\ &\approx \prod P(w_i|w_{i-1(n-1)}, \cdots, w_{i-1}) \end{aligned}$$

Once the range of candidate sequence of words $W = (w_1, w_2, \cdots, w_n)$ that maximizes the product is huge, a *decoder* algorithm is used to perform an efficient search in the state space. Figure 1 illustrates how these four main blocks of an ASR system are related.

ASR rely on quite amount of preprocessed data. These data consist of labeled speech and text corpora used to the construction of acoustic models and language models, respectively. Other kind of speech-related resources may be required as well. Due to the inherent difficulty in build from scratch such a speech-related corpus and, as a consequence, to find an appropriate one, improving the state-of-the-art of the research in ASR is not an easy job. This is particularly true for natural languages other than the English one. As a consequence, most of the research in the area, regardless the country where it is actually done, has been relied on the use of public and readily available English-based corpora.

In recent years, speech recognition research for Portuguese language have been propelled. The AUDIMUS speech recognizer [8] is one of the most successful initiative and has been used as the platform for several important advances in speech recognition for Portuguese language. The AUDIMUS system uses a HMM 3-gram language model based on the transcriptions news of 51 hours from a European Portuguese corpus with 532,000 words. The output probabilities are estimated by a MLP neural network. Experiments with a 13 hours of broadcast news test data have shown a WER of 21.5%. AUDIMUS has been recently adapted for Brazilian Portuguese broadcast news [9]. Results have shown a WER of 26.9%. Most previous Brazilian Portuguese recognizers used small vocabulary [10], [11].

In addition to the development of speech recognizers, some speech corpora have been produced as a result of academic efforts in advancing speech recognition research for Portuguese language. BDPublico [12] and LECTRA [13] are proprietary speech corpora for European Portuguese language. The Spoltech [14] is probably the most widely used corpus for Brazilian Portuguese. It consists of microphone-recorded speech, with proper phonetic and orthographic transcriptions, of Brazilian men and women with different accents and ages.

Some research groups and cooperative initiatives have contributed to the improvement of Portuguese language speech recognition results, by providing textual corpora, lexicons, phonetic dictionaries, acoustic models and language models. The Nucleo Interinstitucional de Linguistica Computacional (NILC)[1], Linguateca[2] and FalaBrasil[3] are three of the most relevant ones.

3. Semantic Modeling

The method commonly used to modeling natural language for ASR is based on N-gram language modeling. The main purpose of language modeling is to bias an ASR towards sentences appropriate to a particular domain, avoiding meaningless sequences of words. An enhancement on the language model may be achieved by means of a method named structured language modeling (SLM) [15], which uses a bottom-up syntactic parser to find the most likely syntactic parses of a partial sentence. [16] reports an improvement of 2-3% in the WER over N-gram models.

These syntactic parsers, however, are not able to identify main constituents of a sentence that represent concepts and meanings. For limited-domain and task-specific spoken dialog systems, a kind of semantic analysis seems to be more effective. The SOUP parser [17] is an example of semantic analyzer.

In [18], the authors employ a semantic analyzer to enhance the language model used in a spoken dialog system. A statistical model estimates the joint probability of a sentence and its most likely semantic parse. Sentences that have parses with high probability will then be preferred in recognition.

Similarly, we consider the addition of a semantic analysis step to improve ASR results. We propose, however, a domain ontology as a shallow semantic parser. Keywords of the best resulting sequence $\hat{W}$ from ASR decoding phase are

candidate instances of some feasible concept arrangement. Is there is any feasible concept arrangement, the sequence is validated. On the contrary, it is dropped as a false-positive.

3.1 Ontology

An ontology [19] specifies a description of terminologies, concepts, properties, and relationships between these concepts, being them hierarchical or lattice relations relevant to a particular domain or area of interest. In sophisticated cases, suitable axioms are added to constrain concepts intended interpretation.

To be useful for computational purpose, an ontology must be the result of an exhaustive and rigorous attempt to define a conceptual representation of a domain, or a fraction of that domain; in effect, the amount of knowledge to be covered by the ontology is decided by the knowledge engineer. In addition, in order to be machine readable, an ontology should be defined in a semantically strong notation. It must use a representation language that allows both a human community to share a precise, unambiguous under common understanding of the domain and software agents to perform automated reasoning about it. Ontologies are commonly used in artificial intelligence and knowledge-based computer programs. In these cases, they can be used for implementing inductive reasoning, classification algorithms, and for enabling communication and knowledge sharing between different systems. As the central piece of a data classifier system, an ontology can store knowledge rules that reason about the data, thus allowing the system to infer new knowledge. Regardless of the notation or syntax used to define different ontologies, they share many common features such as concepts, partitions, attributes and relationships.

The semantic Web [20] uses a combination of descriptive technologies like XML, RDF (Resource Description Framework) and OWL (Web Ontology Language) [21] to replace the content of Web documents, currently highly encoded in HTML. In fact, OWL is a markup language extended from RDF for publishing and sharing data using ontologies on the Web. Web ontologies improve accuracy and promote completeness through constraints, restrictions, and complex relations among terms that build on/extend the web metadata created in XML. The machine-readable descriptions enable Web content managers to add meaning to the content, facilitating automated information gathering and research by computers.

3.2 Ontology-driven Semantic Parser

Let us define an ontology O as a tuple $< D, A, \gamma^n >$, where D is the domain, A is the set of feasible arrangements of concepts and γ is a total function $\gamma^n : A \mapsto 2^{D^n}$ from A into the set of all n-ary relations on D. As a consequence, for a specific feasible arrangement instance $a \in A$, there is a set of feasible conceptual relations $R_a = \gamma(a)$.

We also define the ontology vocabulary V as set of all lexical terms (words) used to represent the concepts and relations within the ontology. The ontology modeling language Λ can thus be defined as a tuple $< O, V, \mu >$, with $\mu = V \mapsto D \cup R$ as being a function which maps concepts of D and relations of R to suitable lexical terms of V.

Recall now the best sequence of words (sentence) $\hat{W} = (w_1, w_2, \cdots, w_n)$, selected by the "'decoding"' algorithm to a given acoustic evidence X. In addition, consider $K \subseteq \hat{W}$ as the set of keywords of $\hat{W}$ such that $K = \hat{W} - \{stop_1, ..., stop_n\}$, with $stop_i$ being words that do not aggregate meaning (*stopwords*), such as articles, prepositions, conjunctions, pronouns, and punctuation marks. We say that $\hat{W}$ is *semantically validated* by an ontology $O = (D, A, \gamma^n)$ iff $\mu(K) \subseteq A \cup \gamma(A)$ and, as a consequence, $K \subseteq V$.

Once the sequence is semantically validated, it is mapped to an action Δ_j from a set of predefined domain-specific actions Δ (figure 2).

4. Speech-enabling Home Automation Commands

System's main goal is to control electric and electronic devices (e.g. TVs, doors, air conditioning, etc.) and preset

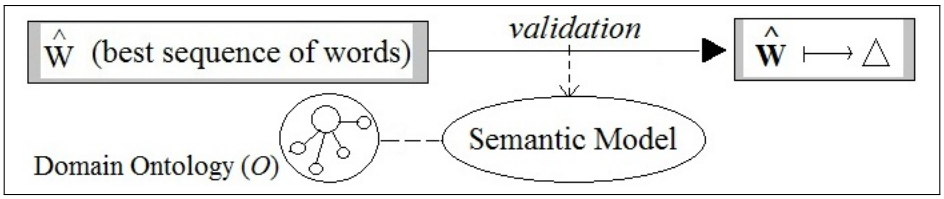

Fig. 2: Semantic validation tests whether the terms in the best sequence $\hat{W}$ can provide a feasible set of concepts and relations according to the domain ontology. In case $\hat{W}$ is validated, an action from Δ is performed.

scenarios in the home environment. A scenario represents the state of a set of controlled devices, usually composed by a large number of isolated items. A *romantic dinner scenario*, for instance, may be assigned to a special activation of lamps in the dinning room, as well as the closure of curtains and setting the air temperature to $20°C$. We have used Julius [22] software for MFCC, acoustic model and language model steps. This work use 3-gram model which seems to work better for the Brazilian Portuguese. We also have used an acoustic model based on triphone units.

Due to small size of the ontology vocabulary V and the nature of the speech utterances (commands), we have performed automatic generation of a language model from O. The resulting custom model bias the recognition to terms related to the home environment.

System's architecture is categorized as Mobile Speech Recognition Architecture [1]. In such architecture, the mobile device works just as a signal transmitter, while the whole processing is done in a server in order to enhance recognition performance and, at the same time, provide mobility in and out of the house.

The major concern with this type of architecture regards the signal (spoken utterance), which is sent to the server, and the quality of the network. In our system, the voice is first normalized and then enhanced using a simple cepstral power measurement. This is done via the Sound Exchange (SoX) tool[4]. Since different mobile devices use different sampling rates to capture voice, we have tested the system with two sampling rates: $16Khz$ and $8Khz$.

4.1 Using Domain Knowledge for Sentence Validation

The domain ontology has been coded as an OWL/RDF ontology [21]. In Figure 3 we illustrate the hierarchy of all concepts in the ontology. The two concepts `#Semantic` and `#Syntax` play primordial role. The `#Semantic` concept and their specializations represent the home's devices and system's commands, whereas the `#Syntax` concept family represents structure of commands.

`#Feature` concept instances are device-related features such as temperature, volume, etc. Features are related to supported commands by means of `#is-Used-By` relationship. `#Rangeable` concept instances are special kind of features, where an interval of values can be applied. `#Control` concept instances are assigned to direct control of predefined scenarios such as *Ativar Cenário Romântico* (*Activate Romantic Scenario*), which synthesizes a complex sequence of actions: *turn off the lights of the dining room, light the candles, close curtains and turn on the sound*, for instance. `#Function` concept instances are commands for device features, where `#Stepable` concept concerns those controls that affect the values in steps, such as Raise and Decrease. Instances of `#Controlable` concept have IDs and can be directly affected by a command by means of a `#is-Used-By` relationship. `#Device` represents the various existent devices that can be controlled, such as lights, Ar conditioner, TVs, and so on. A device may have a specific feature by means of a `#has-Feature` relationship. `#Scenario` is another kind of `#Controlable` which represents various supported scenarios, as the one exemplified so far. `#IDs` are used to uniquely identify devices and scenarios within the system. A `#UserID` enables customization of IDs, such that specified by the system's user.

Consider the following sentence as an example of the best sequence of words generated by decoding phase of the ASR system:

Aumentar temperatura do Arcondicionado do quarto da Julia

This sentence is the Portuguese version of "'Raise the temperature of Julia's room air conditioner"'. The keywords are $K \subseteq \hat{W} = (\textit{Aumentar}, \textit{temperatura}, \textit{Arcondicionado}, \textit{quarto da Julia})$.

This sentence is semantically validated and, thus, recognized as a possible home automation command only if the lexicon of their keywords can be mapped to a feasible arrangement of concepts and relations. Formally, $\mu(K) \subseteq A \cup \gamma(A)$.

Each individual has a set of names/tokens that helps the self-identification in the words sequence. The command (i.e. raise) represents the action that will be taken; the feature is the property (i.e. temperature) that will be changed; the device (i.e. air conditioner) owns the feature operated and

[4] `http://sox.sourceforge.net`

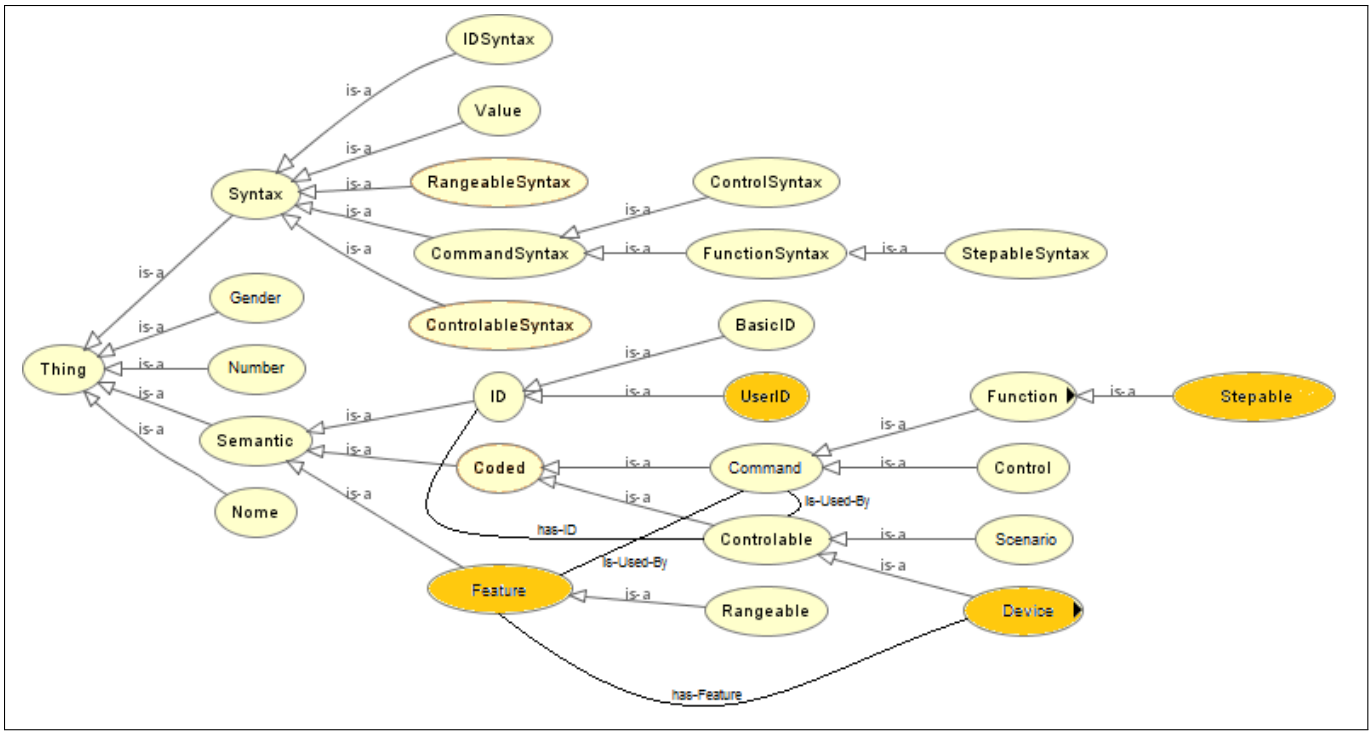

Fig. 3: The ontology class hierarchy. The highlighted slice shows a feasible arrangement of concepts and relations, able to semantically validate a sentence such as "'Raise the temperature of Julia's room air conditioner"'.

the ID (i.e. Julia's room).

For such specific example, the highlighted ontology slice in Figure 3 shows a feasible arrangement of concepts and relations from O. The lexicon "'Aumentar"' is mapped to the `Stepable` command-kind concept, "'temperatura"' is mapped to the property-type concept `Feature`, "'Arcondicionado"' is the `Device` which owns the operated feature and, finally, "'quarto de Julia"' works as an `UserID`. Note that a feasible relationship holds between concepts: (1) the command can be used to that feature, (2) the device has this specific feature, and (3) there is an user ID for that controllable device.

Certain constraints have been considered, though. The first one is that a command must always be the first item in the sentence. This is done in order to bias the grams probabilities in the language model and hopefully improve accuracy. Other words may appear in any order. Another constraint concerns the amount changed in a feature (e.g. raised, lowered). This is inferred from a range of values of a feature in O. This is done in order to make commands more comfortable to the user and to avoid great bias toward the numerous N-grams that would include a number.

4.2 Generating Language Model from Ontology

Manually create a corpus is too time consuming and the lack of domain corpora weighed heavily in the decision of a automatically made alternative. A domain specific corpus can bias the language model to the set of domain-related terms, thus improving the system accuracy. In addition, the automatic generation provides robustness to the system since it can be easily synchronized with the domain ontology and, as a consequence, with the environment updates.

Two artifacts are generated in the process: a *sentence corpus* and a *dictionary of phonetic transcriptions*. The corpus generation is done through the combination of possible command sentences. Basically, there are two kinds of sentences in the system's domain:

```
  Command [article] Device [preposition] ID
  Command [article] Feature [preposition]
Device [preposition] ID
```

The elements surround by brackets are optional. The articles and preposition can vary in gender and number. This information is extracted from the set of transcription from each individual in O. The sentences generated are all valid in the semantic sense.

After the corpus generation, the next step is to generate the phonetic transcriptions of all the words in the corpus. This is automatically done via a grapheme to phoneme tool. However, the automatically generated transcriptions do not account the regional differences in pronunciation. This can be a problem, depending on the user and the acoustic corpora used.

The vocabulary used in the system is small, consisting of 113 words. The generated corpus contained 13994 sentences and contained all possible commands but not all their variations. The manually corpus has 6050 sentences.

5. Experimental Results

The Word Error Rate (WER) measurement is widely used to evaluate continuous ASR performance. It is described in equation 4, where I stands for inserted words, C stands for correctly recognized words, D stands for deleted words and S concerns substitutions. The WER is not always the best choice to evaluation, though. Its value range is not constant $[0..1]$ and can induce abnormal results. The Word Information Preserved (WIP), on the contrary, has a constant range and is described in equation 5.

The responsiveness of the system is an important feature for it's usability. The Real time Factor (xRT) measure can be used to evaluate the system responsiveness. It is calculated using equation 3, where P stands for the processing time and I the audio duration. We have achieved a xRT of $0,29$. This value is achieved by limiting the search of grams and triphones hypothesis on the recognition process.

$$xRT = \frac{P}{I} \tag{3}$$

$$WER = \frac{S + D + I}{C + S + D} \tag{4}$$

$$WIP = \frac{C^2}{[(C + S + P)(C + S + I)]} \tag{5}$$

Moreover minor errors at the word level have no impact at the semantic information that the word sequence carries [23]. For instance, although the sequences *Ligue a luz* (Turn on the lights) and *Ligar luz* (Turn on Lights) accounts for 2 errors (i.e. substitution, and insertion/deletion), they both carry the same semantic information.

The test set been used is composed of 120 utterances for 12 different speakers. The audio has been captured in low to mid noise environment with a mobile device at 16KHzw and is resampled to match the acoustic model sampling rate. The 8KHz samples were generated from the 16KHz sample via resampling.

The table 1 shows the best WER and WIP values for the system. Those results were achieved with the Witten Bell smoothing technique for the language model, as will every measurement mentioned from now on. All the variations used the same phoneme transcriptions

The high deviations are due to a drop of accuracy towards certain types of commands. For example the word "um" (i.e. one in english) is composed of a single phoneme and is hard to recognize and often deleted/included, however it carries relevant semantic information like an ID for a device in "Ligar TV um" (Turn on TV one, in english). This can be avoided by using names instead of numbers for the devices.

The table also shows the variation of accuracy with different sampling rates. It shows a great improvement with the double sample rate. The automatically generated language model achieved a better recognition rate than the manually written one. This probably stem from the fact that the probability distribution on the automatically generated one is better biased toward the application. All the examples from the corpus is a valid command in a semantic sense.

Table 1: WER, WIP and SRR values

	Automatic(16KHz)	Manual(16KHz)	Automatic(8KHz)
WER	$23,69\% \pm 24,05\%$	$33,44\% \pm 27,94\%$	$74,39\% \pm 75,23\%$
WIP	$72,70\% \pm 28,59\%$	$60,01\% \pm 31,56\%$	$35,62\% \pm 33,69\%$
SRR	$75,92\%$	$59,25\%$	$35,00\%$

The Semantic Recognition Rate (SRR) in table 1 stands for the rate of commands fully recognized in a semantic sense. The SRR was calculated by comparing the zigbee codes from the manually transcribed uttered command to the recognized one. It is closely related to the WIP measurement, however it accounts the semantic errors only providing a more precise accuracy measurement.

6. Conclusion

This paper described a continuous ASR system for the Brazilian Portuguese language used in a home automation environment. In that environment, the ASR system was used as the input for controlling the home automation devices. Due to the semantically intrinsic mechanism of human been expose their thoughts, present in the informal discuss, we develop an ontology to perform semantic analysis of sentences provided from the intermediate level layer of the ASR system.

We have also used the domain knowledge in the ontology to generate a language model. It addresses the lack of data for the recognition system and provides a biased model for a specific domain, helping with the recognition accuracy.

The results section highlighted the problem of evaluation of continuous ASR system. Even if the WER measure is widely used it is prone to anomaly. The use of semantic information in the evaluation provided clearer results since it accounts only semantic errors.

Probabilistic Gesture Recognition

Ensembles and Multiple Input Modalities

Abstract *— This paper reports upon ongoing research in the general domain of pattern recognition in the presence of uncertainty. In particular, we are attempting to develop a relatively simple but effective ensemble model for the recognition of gestures. We present a model, INCA, and two gesture recognition application domains using a pen tablet and data glove, where the ensemble methodology is implemented. Using this model, we have built a probabilistically based ensemble system and tested four standard ensemble fusion methods. The accuracy improvements in the domains of handwritten digit and hand-signed digit gesture symbols was 10% to 20% above the weakly trained component classifier performance.*

Submitted to the International Conference on Artificial Intelligence in Las Vegas, Nevada July 16th -19th 2012.

Keywords:Ensembles, Multiple Classifiers, Gesture Recognition

1. Introduction

We define a gesture in a very general way as a temporal sequence of points through *N*-dimensional space. Some examples of gestures would include speech, hand-drawn symbols, hand gestures (e.g. sign-language), facial movements, and brain-waves via electroencephalography. While some gestures consist of low-dimensioned spaces (e.g. 2D or 3D spaces for hand-written gestures), others can consist of 10 or more (e.g. speech recognition).

The proposed model, INCA ("I've No Cute Acronym") [18], assumes the existence of gestural recognition algorithms for a given domain whose performance need not be particularly strong. The goal of the model is to build a meta-algorithm that combines the individual recognition results of the component algorithms to produce an over-all superior performance to any of the participating algorithms involved. Few assumptions are made regarding the internal functionality of said recognition algorithms. Each component algorithm is assumed to receive static or dynamic, temporal, input representing the gesture in question and is expected to produce a recognition result consisting of a symbol from the given gestural alphabet. For example, in the domain of hand-written recognition, the component algorithm might receive a sequence of pen-tip positions (using standard Cartesian coordinates) over the temporal period of drawing a symbol. The algorithm would produce a recognition result indicating the recognition of some specific symbol in a given gestural alphabet (e.g. the digits 0-9, the English alphabet A-Z, etc.).

The INCA model uses a straight-forward Bayesian approach to examine each algorithm's recognition result. The model produces a confidence vector, CV, for each algorithm that represents the probabilistic likelihood that each possible symbol in the alphabet is the truly correct result.

A confidence vector is simply a finite probability space that reflects, for each possible symbol in the gestural alphabet, a probability, $p \in [0,1]$, that the symbol is, in fact, the appropriate result based upon the algorithm's reported recognition result when prior behavior is considered. Simply put, an algorithm that frequently misrecognizes a hand-written 'H' as a 'K' should not, upon recognition of a 'K', be "trusted" to have recognized correctly. Based upon the consistent misrecognition behavior, it should be identified that the probability that the correct result is, in fact, an 'H' is greater than 0. Similarly, we should consider the previous behavior of this algorithm when it identifies the symbol 'K' as it pertains to the actual input of *all* possible symbols. The resulting probabilities for each symbol constitute the confidence vector's finite probability space.

Upon the creation of the confidence vectors for all of the component algorithms, they are combined to produce an overall INCA recognition result. We have explored a variety of combination algorithms and report our results in section 6 of this document. We are currently exploring the effectiveness of these algorithms under a variety of circumstances such as the inclusion of new algorithms whose recognition rates are significantly higher or lower than the existing system's component algorithms.

A. Bayes' Theorem – A Gestural Recognition Application

Bayes' Theorem, or Bayes' Rule, is based upon the concept of conditional probability. Conditional probability P(A|B) is defined as the probability that an unobserved event A has occurred given an actual observation of an event B. Formally it is defined as $P(A|B) = P(A \cap B) / P(B)$. Intuitively, the likelihood that an event A occurs when an event B is observed depends upon how often the two events occur together in relation to how often the observed event B occurs in general [18].

Funding for this research was provided by the Northern Kentucky University Research Foundation Graduate Research Grant

Bayes theorem is presented below. It applies conditional probability to a partition of some sample space of mutually exclusive and exhaustive sets (A_1,A_2,A_3…A_m). The theorem supplies a formula for $P(A_i|B_k)$ where B_k is some empirically observable event. For our purposes, B_k is the recognition result produced by some algorithm and the A_i values represent the event of some symbol having actually been entered as input.

$$P(A_i|B_k)=\frac{P(B_k|A_i)*P(A_i)}{P(B_k)} \qquad (1)$$

B. INCA

The INCA model assumes the existence of *N* different recognition algorithms. For example, if the gestural domain were that of hand-written symbol recognition, then the algorithms might consist of a curve-matching technique, a sequence of directions approach, a neural network, a feature-analysis approach, and possibly others. Each of these algorithms will have specific strengths and weaknesses, in terms of its recognition capabilities. Experience has shown that these algorithms tend to be consistent in their recognition abilities. That is, they tend to be strong in the recognition of some subset(s) of gestures and inconsistent in the recognition of the remaining gestures. The key to the model's effectiveness is this inherent consistency not only in correct recognitions but also in misrecognitions. If an algorithm frequently misrecognizes a handwritten 'H' as a 'K', then this information is useful and allows us to modify the perceived importance of the algorithm's recognition result. Figure 1 depicts the INCA layout.

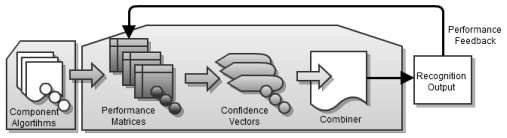

Figure 1 – *INCA Layout*

During training (and optionally during operation) INCA maintains a *performance matrix*, or *confusion matrix*, for each component algorithm. A performance matrix for any component algorithm is an *M*×*M* matrix where *M* is the number of symbols in the gestural alphabet. For any recognition algorithm A_i the performance matrix PM_i [x][y] contains the number of times that, during previous recognitions, the algorithm A_i recognized the actual input gesture S_x as the gesture S_y. In short, these matrices provide a complete, empirically observed distribution of the previous recognition events within the system.

After applying Bayes' theorem to the data stored in the algorithm's performance matrix, we can determine the probability that any gesture S_x was in fact the actual gesture entered given the algorithm's recognition of S_y as its result, based upon previous performance. This corresponds to the conditional probability $P(S_x \mid S_y)$ which simply corresponds to the following formula:

$$P(A_i|B_k)=\frac{PM[S_i,S_k]}{\sum_{j=1}^{N} PM[S_j,s_k]} \qquad (2)$$

Figure 2 indicates the performance or confusion matrix for a sample algorithm and its confidence vector for the recognition of the digit "1".

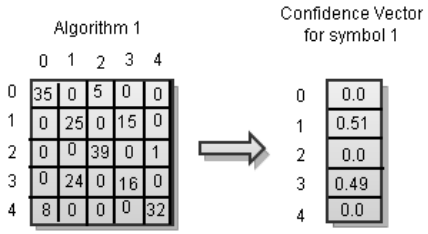

Figure 2 – *Confidence vector representing the probability space for the algorithm recognizing the symbol "1" and the INCA probability that the user did in fact enter a "1".*

Clearly, this is simply the entry PM_i [x][y] in the matrix over the sum of the column PM_i[*][y]. Once this calculation is carried out for each gesture in the given alphabet we can build its confidence vector. We can then proceed to combine it with the vectors of all other algorithms to obtain the overall system recognition result.

The INCA model provides a number of important and interesting results. One key observation is that the model provides the system with the ability to make correct gestural recognitions when all component algorithms have incorrectly identified an unknown gesture. Suppose we have three gestural recognition algorithms *A*, *B*, and *C*. They each, given an unknown input w, produce respective recognition results of *x*, *y*, and *z*. INCA recognition is capable of producing the correct result *w* regardless of the incorrect results of the component algorithms. We show in section 6 recognition improvements when the INCA model is applied to a set of relatively weak recognition algorithms, using a set of strong component algorithms.

The INCA model is also is capable of effectively ignoring, or at least minimizing, the impact upon a particular recognition of an algorithm that is particularly poor at recognizing a specific gesture. An algorithm that is extremely poor at recognizing a given gesture S_x in an inconsistent manner will produce a confidence vector that reflects its historically poor performance, and should have minimal, if any, impact upon the final recognition result of the system.

2. Related Work

Since the 1970's, researchers have studied the benefits of combining classifiers to produce systems that perform better then any of the individual classifiers that make up the ensemble. Some of the first attempts involved combining two liner regression models using a cascade approach where the first model was fit to the training set and the second was fit to the subset that had a lower classification score [6]. However, development in ensembles did not progress impressively until the 1990's when Hansen and Salmon [21] suggested that an

ensemble of neural networks be used to improve the predictive performance of a single network. Concurrently, Schapire in [23] developed the AdaBoost algorithm that empirically demonstrated that a strong classifier can be constructed by incrementally training a series of weaker classifiers by using the performance of previous classifiers as input for the next in the series.

Methods such as bagging and boosting, and many others, have been shown to improve approaches in remote sensing, person recognition [22] and incremental learning systems used for visual quality control in compact disc production systems [11].

Two methods of ensemble classifier construction, generative and non-generative, have been used in the multiple classifier field. Non-generative methods do not actively generate classifiers as in the AdaBoost algorithm above. Instead, non-generative types combine the independent classifiers after the components have produced a recognition result. Since we focus on non-generative ensemble architecture in this work, it is important to consider the three types of classifier output typically found in such methods.

Type 1: Abstract / Exact - Each classifier C_i outputs a single label given an input feature vector x pertaining to an unknown symbol *x*. Type 1 output contains no certainty measure as to the classifiers confidence in the mapping $C_i(x) = L_i$, with L_i representing a label in the classification space.

Type 2: Rank – Each classifier output provides a ranked set of output values. The output is in a ranked order from most plausible to least and can be thought of as the statement "The symbol is most likely a 4, but could be a 3, and less likely a 2." This can be especially suitable for problems with a large number of classes [1].

Type 3: Probability – Each classifier output gives the most information since either a ranking or classification can be produced from it [11]. *Type 3* output is in the form of a probability distribution of the unknown input symbol over the recognition alphabet. Here, $C_i(x) = \{a_1(x), \ldots, a_L(x)\}$, is the set of probabilities that classifier C_i considers the unknown input symbol x as belonging to class $a_1 \ldots a_L$.

Both Parker [1] and Sannen [11] state that a type 1 classifier output provides the least benefit to classifier fusion since alternative solutions are not given. A *type 2* classifier output offers relative information about possible symbol class labels, giving a rank comparison between each symbol. This type does not give absolute information regarding how the classifier performed over the entire sample space. *Type* 3 classifier output offers the most information about alternative class possibilities. One advantage of the INCA model is that algorithms of t*ype 1* and *2* are converted to t*ype 3* via the performance metrics tracking.

3. Component Algorithms

Independent component classifiers are ideal for our model. The independent classifier choice was made because we wish to look at component combinations and their characteristics in varying usage domains. In this section, we briefly describe the component machine learning algorithms we've selected, and refer the reader to the individual references for further information.

A. Contour Profiles

The contour profile algorithm uses a collection of topological features to learn and classify hand written symbols [1]. The algorithm bounds a symbol and partitions the bounded region into left and right profiles. This method uses forty-eight binary features or properties of the symbol to build a feature vector.

The training phase of this algorithm consists of steps that compute all forty-eight features to compose the training symbol feature vectors. The feature vectors contain the binary profile decomposition data, representing whether a feature is part of the symbol or not. For example, a feature of a numeral digit 9 would be true, or binary '1', if the left profile peak value is greater then '5'. This feature represents the number of pixels from the left edge of the input symbol region to the first pixel of the symbol's left profile. Table I depicts an example of small portion of the forty-eight features used in for the profile algorithm in recognizing hand printed digits.

TABLE I. Contour Profile Feature Examples

Feature Number	*Feature Calculation*	*Feature Assignment*
1	$L_{peak} < 10$; $R_{peak} > 10$	1
2	$L_{peak} < 5$; $R_{peak} > 10$	0
(...)	(others)	0 or 1

Examples of the 48 feature vector component calculations.

The measurement of character profiles can be of any discernible method such that a distinction can be made between a feature vector of one symbol and another.

During classification of an unknown input symbol, the profiles are extracted from the input image and an input 48 feature vector is created. This approach uses a training set of *N* symbols to build a database of feature vectors having known class labels. The unknown input symbol is then processed and it's feature vector is matched to the closest set in the database using a Euclidean distance measure in *N* dimensions. Equation 1 gives this measure as the classification metric:

$$argmin(x)(d_{p,q} = \sqrt{\sum_{i=1}^{N}(p_i - q_i)^2}) \qquad (3)$$

where *x* represents each class label, *p* and *q* are data points and *N* is the total number of feature points. Further information can be found in [1], [2] and [3].

B. Artificial Neural Networks

Artificial neural networks have had great success in many areas such as handwritten character recognition, data mining, and even autonomous vehicle navigation [4]. An artificial neural network determines the weights for processing elements, whereby correct classification is achieved when the proper neural connections fire in the correct order.

We constructed a three-layer network consisting of forty-eight input nodes, ninety-six hidden nodes, and ten output nodes. This design was used in [1] and [5] for handwritten digit recognition and reproduced herein.

The 48 input nodes correspond to an eight-by-six pixel square decomposition of an input symbol. During training, each symbol from a dataset is first normalized for pixel color, then the symbol is bounded. This bounded region is then scaled down to the eight-by-six pixel representation and written to a database.

Once the database has been built, we train the network using the the back-propagation method. The back-propagation method uses a steepest decent scheme to minimize the error by adjusting the weights on the network connections from the output layer to the input layer [1]. Each iteration from the database equates to an iteration of the steepest-descent minimization of error on the connection weights.

There are other methods for training artificial neural networks, such as simulated annealing and genetic algorithms. However, we selected a back-propagating artificial neural network due to previous success in handwritten character recognition [5]. Further information can be found in [7], [8] and [12].

C. K-Nearest Neighbor

The K-Nearest Neighbor algorithm classifies unlabeled examples based on the similarity of the input data and examples in the training set. Let x be an unknown symbol. We find the k-closest labeled example in the training data set and assign x to the class that appears most frequently in the k-subset [8]. For example, we have four classes and the goal is to find a class label for an unknown example x. Assuming we use the Euclidean distance metric and we set $k = 5$, we examine the five closest neighbors to x. After feature analysis, we see that of the five closest, three belong to a class labels "2", one sample to "5", and one sample point to class label "7". In this example, the class assigned to the unknown symbol would be the predominate class "2".

The KNN algorithm defers all data processing until a request for a classification is given. This method is also referred to as a memory-based method in that it loads all feature information into memory prior to classification. We use the KNN available in the OpenCV API [10] and the nearest neighbor Euclidean distance measure shown in equation 1.

D. Support Vector Machines

In pattern recognition, linear discriminants involve lines dividing feature values into groups and is an effective way to implement a classifier if there exists in the data a way to divide the classes with a line or plane [1]. A support vector machine, or SVM, is a decision method that uses vectors or distances of data points to a decision boundary that maximize the margin of separation between classification labels [9]. The data points represent the features of a class or set of classes in the sample space. The boundary is represented as a line configured in a way such that the points closest to the boundary define a maximum marginal distance.

If the data is linearly separable, there is a pair (w, b) with w being the weight vector and b representing a bias, such that two lines exist defined by [12]:

$$w^T x_i + b \geqslant 1 \quad (4)$$

$$w^T x_i + b \geqslant -1 \quad (5)$$

with the decision rule as:

$$f_{w,b} = \sin(w^T x_i + b) \quad (6)$$

The optimal hyperplane separating the two classes can be found by minimizing the squared norm:

$$\min_{w,b} \Phi(w) = \frac{1}{2}\|w\|^2 \quad (7)$$

Here, a hyperplane is a linear function that divides N-dimensional data into two parts [1]. The maximum margin hyperplane is always as far from both data sets as possible. A deeper discussion can be found in Kotsiantis [12].

E. Implementation

For the Pen tablet algorithms, we adapted Java implementations from similar algorithms written in the C programming language, and used algorithms from the OpenCV API [10] for the data glove component classifiers. It is important to note that we use only the standard parameters generally advised for the recognition task as we wish our algorithms to be non-specific and somewhat poorly tuned to any specific domain. The Contour Profile algorithm and back-propagating neural network for the pen tablet were adapted from Parker [1]. The K-Nearest Neighbor, Support Vector Machine and additional Neural Network for the data glove were called using the OpenCV API.

4. Classifier Fusion Methods

As discussed in section 1 part *B*, the INCA model produces a c-dimensional vector for each classifier in the system [11]. The strength of this model rests in synthesizing the consistent accuracies and inaccuracies of each classifier. Let such a vector for a classifier D_i for an input label x be written as:

$$D_i(x) = [d_{i,1} \ldots d_{i,c}] \quad (8)$$

where each $d_{i,n}$ represents the support of classifier i for its class label prediction ω_n in the class set ω.Thus, without loss of generality $d_{i,n} \in [0, 1]$.

A final classification is achieved through combining these vectors for an input x using some ensemble methodology. Several approaches and their efficacy in our testing follow.

A. Algebraic Combination: Max-Sum

Algebraic ensembles are appealing for their ease of implementation. They do not need to be trained and are class indifferent. Thus, they are generally computationally inexpensive. A relatively simple combination approach was used for testing.

In this approach, the support for a class label ω_n is summed across each confidence vector $D_{i,m}(x)$ for m classifiers. The class label with the highest support is chosen as the ensembles "final" classification. Thus the output of this ensemble combination method is given by:

$$argmax(x)(\sum_{1}^{m} d_{m,s}) \quad (9)$$

where s represents each class label.

B. Decision Templates

The principle behind the *Decision Template* ensemble combination method is described in [13]. In this method, a "*Decision Template"*, or the "most typical" support seen for each class label ω_n, is defined by batch training over a training set Z [11]:

$$DT_s = \frac{1}{N_s}(\sum_{Z_i \in w_n,\ Z_i \in Z} Di(Z_i)) \quad (10)$$

where N_s is the number of elements of Z_i from class ω. Put simply, the result of the training phase is a vector whose length is the number of class labels, with each vector element representing the average of the support for that label across all confidence vectors $D_{i,1}(x)$ ... $D_{i,m}(x)$.

The ensemble classification compares the Decision Template of each class label to the support of each Confidence Vector for the given label. The class with the least distance (i.e., the "*most similar")* is the output of the ensemble combination method.

While there are many measures of similarity (such as Hamming, Mahalanobis, etc. [11]), in our tests *squared Euclidean distance* is used. Thus the output of this ensemble becomes:

$$argmin(x)(1-\frac{1}{m*c}\sum_{i=1}^{m}\sum_{k=1}^{c}[DT_{i,k}-d_{i,k}(x)]^2) \quad (11)$$

C. Dempster Shafer Theory

This ensemble combination method is an adaptation of the *Decision Templates* method described in *B*, except that the distance between a Decision Template and the support of each Confidence Vector is calculated using the Dempster-Shafer theory of evidence. For a discussion of the theory, the reader is directed to [11].

First, the proximity between each classifier (Confidence Vector) and the Decision Template is calculated [11]:

$$\Phi_j^i = \frac{(1+\|DT_{i,j}-D_i(x)\|^2)^{(-1)}}{\sum_{k=1}^{c}(1+\|DT_{i,j}-D_i(x)\|^2)^{(-1)}} \quad (12)$$

In Dempster Shafer theory, $\|\cdot\|$ can be any matrix norm; here, the Euclidean distance is used. The result of this stage is m proximities for each of the c decision templates.

Using the calculated proximities, *degrees of belief* are then found for each classifier for every class label [11]:

$$b(x)_j^i = \frac{\Phi_j^i(x)\prod_{k\neq j}(1-\Phi_k^i(x))}{1-\Phi_j^i(x)[1-\prod_{k\neq j}(1-\Phi_k^i(x))]} \quad (13)$$

With these degrees of belief, the support for each class label is calculated, and the class with the most similarity to the Decision Template is the output of this ensemble combination method:

$$argmax(x)(\prod_{i=1}^{m} b_j^i(x)),\ j=1,\ldots,c \quad (14)$$

D. Behavior Knowledge Space

The last combination method considered is the Behavior Knowledge Space method, or BKS, developed by Huang and Suen [14]. This method aggregates the decisions of the component classifiers such that all possible tuples representing the possible outcomes of the classifiers are known. Generally, each classifier has *N+1* possible decisions, with *N* representing the number of symbols in the recognition alphabet. The additional of "*1*" allows the method to count misrecognitions indicating that no tuple exists in the BKS.

The BKS is a K-dimensional space, where K represents the number of component classifiers in the ensemble, such that at each intersection of the component classifiers, a BKS unit is represented. A BKS unit contains three important pieces of information:

1. The size of the alphabet.
2. The tuple representing the component guesses.
3. The number of times each symbol has been selected in previous instances of that particular tuple.

We trained our BKS by first running the ensemble system over our training data sets, recording all tuples seen, recording the number of times the ensemble selected each symbol when the tuple was seen in the past. During testing, when a tuple is passed to the BKS, the BKS unit corresponding to the tuple is checked. The final decision is then given by the symbol in the tuple with the maximum counts. In the event of a tie, a naïve "first-come first-serve" is used. This is a known area for improvement and will be addressed in future research. Please refer to [14] for further information.

The classification of an unknown symbol from within a tuple can be characterized by the following equation:

$$argmax(x)_{1\leq m\leq M} n_{e(1)\ldots e(k)}(m) \quad (15)$$

where M is the total number of class labels, m is a given label, and $n_{e(1)\ldots e(k)}$ is the total counts for each symbol in the tuple.

5. Input Modalities

In studying the use of ensembles methods in gesture recognition, we evaluated our model on a pen tablet and data

glove input modalities. Our intent was to study our system in two separate domains, develop a research framework and investigate ensemble-modality performance.

A Wacom Intuos 3 graphics tablet with a pen stylus was first used to develop the proof of concept system. The Wacom tablet was produced by Wacom Company, Ltd. [15] and was used to collect the off-line test sets and for on-line demonstrations. A third party library, JPen [16], was used to gain access to the pen tablet features. The JPen Java application programming interface (API) allowed for full access to *x, y, pressure,* and t*emporal data* from the tablet and pen.

The second input mode is the AnthroTronix data glove, the AcceleGlove [17]. AnthroTronix supplied both the glove and Java API for development and testing. The API gave full access to the raw sensor data and to a sign database, developed by AnthroTronix, for studying American sign language.

6. Datasets and Results

We have chosen a recognition alphabet consisting of the digits "0" through "9" for both the pen tablet and data glove. The pen tablet data consists of images of drawn single digits. The glove data consists of the right hand gestures for the single digits. Figures 3 and 4 depict samples of the hand written character set and sign set.

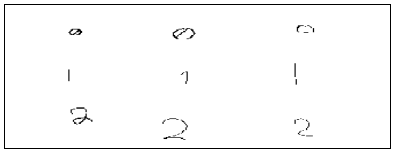

Figure 3 – *Handwritten digit samples from volunteer collection.*

Figure 4 – *American Sign example. Referenced from [25].*

We collected fifty instances of the digits zero through nine from four volunteers using both images drawn on the tablet and the eighteen position sensor data from the glove. Two-thousand total symbols were collected for each input mode.

A. Component Algorithms

We used a four-fold cross validation analysis for both the tablet and data glove evaluation. Table II presents the validation results for all algorithms used. We ran two versions of training using the pen tablet. Two points of interest are:

1. Mixed results involving symbols from the same user in the test and training sets, but not the same instance of the symbol. *User-dependent*.
2. Results involving testing sets of users not in the training sets. *User-independent*.

We chose not to perform the mixed user test for the cross validation on the data glove due to the high accuracy of the user-independent input results.

TABLE II. Four-fold Cross Validation for Component Algorithms

Algorithm	*Input Modality*	*Average %*	
		Dependent	*Independent*
CF	Pen Tablet	78.7	42.0
ANN	Pen Tablet	56.4	39.0
	Data Glove	-	96.0
KNN	Data Glove	-	95.0
SVM	Data Glove	-	80.0

Result for 4-fold cross validation on the pen tablet and data glove. User-dependent results contain instance in the training set of all users, but not all training instances per user. User-independent results had separate user training and testing.

B. Classifier Fusion Methods

We wished to get a sense of the greatest increase in the ensemble over the component algorithm performance. An interesting investigation takes the worst or average validation set results and uses the performance matrices for the component algorithms for the ensemble system. Table III shows each of the four fusion methods' performance characteristics.

We selected the average performance matrices for each algorithm for the classifier fusion step. Again, for the tablet we show user-dependent and user independent results as defined in part *A* of this section.

TABLE III. Classifier Fusion Performance – 2 Classifier Ensembles

Algorithm	*Input Modality*	*Components*	*Average %*	
			Dependent	*Independent*
Maximum Sum	Pen Tablet	CF,ANN	90.2	66.2
	Data Glove	KNN,SVM	0.0	100.0
Decision Templates	Pen Tablet	CF,ANN	77.8	7.8
	Data Glove	KNN,SVM	0.0	77.0
Dempster-Shafer	Pen Tablet	CF,ANN	85.0	34.4
	Data Glove	KNN,SVM	0.0	97.0
Behavior Knowledge Space	Pen Tablet	CF,ANN	89.2	62.4
	Data Glove	KNN,SVM	0.0	96.6

Ensemble results for the pen tablet and data glove. User-dependent results were only measured for the pen tablet as the data glove component algorithms performed highly with the user-independent.

Table IV depicts the addition of a third classifier in the data glove sets, depicting how the model reacts to the introduction of an additional classifier. We are currently investigating the addition of algorithms with higher and lower performance characteristics for results publication in the near future.

TABLE IV. Classifier Fusion Performance – 3 Classifier Ensembles

Algorithm	*Input Modality*	*Components*	*% Accuracy*
Maximum Sum	Data Glove	KNN,SVM, ANN	97.8
Decision Templates	Data Glove	KNN,SVM, ANN	83.1
Dempster-Shafer	Data Glove	KNN,SVM, ANN	85.8
Behavior Knowledge Space	Data Glove	KNN,SVM, ANN	98.3

Addition of an artificial neural network algorithm into the data glove ensemble. Improvements over the two-algorithm ensembles in the BKS and Decision Template methods are seen.

7. Discussion and Future Work

These results are preliminary in our study of the INCA model and classifier fusion techniques. We see that given various levels of classifier strengths, the ensemble methods Maximum Summation and BKS perform best for the user-dependent and user-independent tablet input modality. When considering the data glove, we see that initial results indicate the Dempster-Shafer and Maximum Summation supply strong recognition results.

The addition of the third algorithm in the data glove ensemble gives an increase in performance accuracy for the Decision Templates and BKS algorithms, however, we see a decrease in the Max-Sum and Dempster-Shafer methods. We are continuing to investigate the model to determine the reasons for this result.

We recognize that these preliminary results used a relatively small alphabet and that the model will require testing upon a more useful set of gestures appropriate for effective applications.

We are currently examining the behavior of various classifier fusion techniques as the quantity and quality of the underlying component algorithms change. That is, we wish to determine if some techniques produce significantly superior results over others when additional algorithms of varying quality are added to the INCA model. Do any of these techniques improve, remain stable, or degrade as relatively poor recognition algorithms are inserted in the model?

We have also identified infrequent situations where the inclusion of a recognition algorithm whose ability to identify a small subset of specific gestures is poor and whose inclusion has a significant negative impact upon the overall system performance, with respect to the recognition of these specific gestures. Although at first glance this would appear to be an intuitive result, the Bayesian approach should prevent such a significant degradation unless the underlying component algorithm is both consistently unable to identify the gesture and produces inconsistent incorrect results. For example, the algorithm cannot correctly recognize the symbol 'H', but does not consistently produce the same incorrect result; rather, the algorithm produces many different incorrect results. The resulting confidence vector for the algorithm in this instance begins to resemble an almost random "guessing" of a result with a uniform distribution across all possible recognition results. We believe that if this situation occurs, and if the subset of gestures for which this behavior is exhibited is small in comparison to the alphabet size, then we may be able to modify the resulting confidence vector to reflect this fact and improve the system's overall ability to identify the correct input. We are also exploring whether it is simply best to ignore any such "guess" confidence vectors entirely.

Our long-term goals include an examination of the INCA model's performance in a system implementing multiple gestural input types. For example, a system that accepts simultaneous hand, speech, and electroencephalography inputs would be a prime candidate for exploration. We hope to explore how various classifier fusion algorithms behave in such a system and if the strengths of any particular input-mode can be used to counter the weaknesses of another in order to improve overall system recognition.

Ontology-Based Recognition of Physical Objects in a Virtual World

Geun Jae Jung[1], Jong Hee Park[1]
[1]Kyungpook National University,Department of Electronics,Daegu,Korea
{cooky8884, jhpark}@ee.knu.ac.kr

Abstract: *To construct a virtual world, we develop the recognition capability for agents as its key element. The agents perform this capability by means of comparing the physical properties centered on the shape with the corresponding pieces of their knowledge. Their associated perception capability is against the shapes of the objects in the virtual world simulated in terms of the regular shapes and line segments. Meanwhile, their knowledge about those objects are modelled in terms of an ontology that captures their composition, physical attributes and functions in an integrated manner. The diverse inferencing rules used by the virtual inhabitants to recognize the objects from the perceived properties mimic those logical rules humans use in their real life.*

1 INTRODUCTION

A virtual world becomes an authentic cyber-space where the users feel immersed only when it is inhabited by autonomous agents against a realistic environment. Those agents are to be designed to act appropriately according to information they perceive and infer on the situations they face. These autonomous agents are different from those types of agents designed to pursue only perfection and right answers. Like ordinary humans, these agents may make mistakes or behave in unexpected manners according to their respective knowledges and personalities[1]. To achieve this autonomousness and individuality among agents they need to be equipped with recognition capability for situations in the virtual world as a premise. Considering the situation they would deal with is constructed in terms of entities, relations and activities, the entities are the most basic elements to be recognized in the situations. The other elements are built on top of those entities and especially the physical objects.

We design object recognition capability for the agents in our virtual world. This capability is performed using their shape as the main feature. To describe the shapes of the objects in our virtual world we define a set of regular shapes, in terms of which arbitrary shapes are to be approximated as close as possible[2]. Some objects may be described with just one regular shape while other objects are with two or more shapes combined[2]. We design the virtual objects to actively transmit their contour in terms of lines and arcs in order to save primitive signal processing effort for perception in the real world.

One of the vigorous studies on image recognition vectorizes images including target objects in terms of occurrence frequencies of Visual Words[3]. This method recognizes objects and scenes in images by comparing the amount of input image features with Visual Words in the database[4][5]. However, mere frequency information is not enough to accurately recognize objects and scenes. Our recognition targets at a number of diverse objects occurring in complex situations. These objects are not only diverse in their kinds but also numerous within each kind, so our method is to be able to distinguish among difference instances of the same kind.

We develop a special ontology, which plays a pivotal role as the main knowledge base for the recognition. This ontology provides a comprehensive knowledge about the composition of the cosmos in its entirety. In other words, it describes the objects and concepts composing the real world, and their existence structures and properties changing to the associated principles, rules and constraints[6]. Also, it is used as part of the knowledge structure for the agents[7], which they use for recognition and inference. In addition to the ontology, the Instance Graph and the S-T graph are developed to provide a instantial and historical contexts in our virtual world. The agents perform their recognition of the target object by collectively comparing the information transmitted from the objects with the schematic information from the ontology and instantial and historical information from the other knowledge components above. Besides this comparison the agent is designed to use several human inferencing mechanisms such as deduction and contraposition to derive information that is not explicitly perceptible[2]. This recognition method could be used not only for physical objects but also for relations, events or whole situations not directly perceptible to their associated agents. Furthermore, its use

could be extended to recognition of abstract concepts.

2 ONTOLOGY

2.1 The structure of the ontology

Our ontology is modeled in terms basically of entities, relations and activities. The entity is characterized by its composition and descriptive attributes and functions. The relation is described by its associated entities, descriptive attributes and actions while the activity, a special type of relation, is composed of the pre-condition and procedure and effect parts[8]. The entity, the top class in the ontology, encompasses includes the physical entity and the logical entity as shown in fig.1 below.

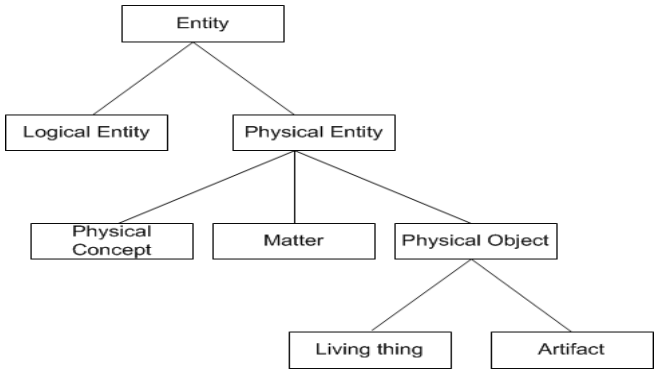

Figure 1.Top part of the ontology

The physical entity is characterized by such properties as composition, descriptive attributes, functions and rules. The descriptive attribute is represented by a variable with its domain values continuous (e.g., 10-20cm) or enumerated range (e.g., red, blue, green.) The functions describes the functional characteristics of an entity. The rules specify the laws and principles relevant to their associated entity.

The physical entity is specializes into the matter, the physical object and the physical concepts. The physical object has as its definitional property a fixed shape, and composed of solid matters or other physical objects in a recursive manner. The matters have characteristics they never disappear, but they just change in their state. They can exist on their own like sand on a beach, but usually as materials of physical objects. The physical concepts such as the light, energy, and force affect physical entities. While they reveal diverse physical characteristics like the other types of physical entity they are distinct in that they do not exclusively occupy the space. The logical entities are defined as abstract things in human's conception. They are exemplified by law, organization, language, etc.

2.2 Characteristic property

Each instance or class has its own identity. Such an identity can be established by comparing one or more properties. When a single property can uniquely distinguish its associated entity from the others, such a property is called Characteristic Property. For example, the action of nurse could identify that animal a mammal. To identify a particular instance within a species we need further characterizing properties in addition to the Characteristic Property as specified in the class. If we can acquire these Characteristic Properties we can easily identify its kind or instance by merely comparing those properties. This section must be in one column.

2.3 Definitional Property

Similar classes have commonalities in their properties. Those classes can conceptually be organized into one or more class hierarchies in terms of such commonalities.

The property distinguishing a class among those similar classes from their common super class is called Definitional Property. A Definitional Property for a class constitutes the additional qualification to that of its super class for the class membership. Consequently, subclass memberships are more restrictive than their super-class so their members each are fewer than their superclass's members. As shown in Fig.2, ‘nurse()’ of

'mammal' class is its Definitional Property that specializes the class from 'vertebrate' class.

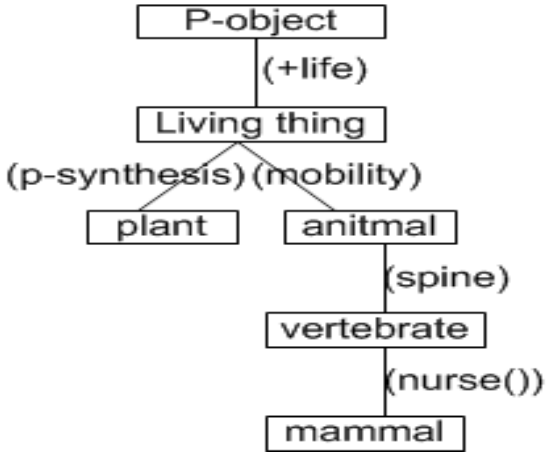

Figure 2 The class hierarchy

Unlike Characteristic Property the Definitional Property by itself cannot uniquely identify the class. Rather all its ancestor Definitional Properties need to be combined in sequence with that of the target class.

3 Perception and recognition of the properties of entities

3.1 Recognition of descriptive attributes

The entity substantiates its existence in terms of its descriptive attributes. The specific values of those properties are perceived via sensory organs or measured using instruments. For example, color, size, or shape are visually perceived and sound is audibly perceived. Moreover, touch or taste could be perceived by tactile sense or palate. Among these properties we focus on visual property in that the vision accounts for the major portion of human perception.

3.2 Perception and recognition of object shape

The perception by an agent in our virtual world starts with extracting from the image in her scope boundaries between regions (ie, shapes) exploiting difference in color. The extracted boundaries are saved in terms of lines. Those lines are used to describe 2-dimensional shapes included in the image. These shapes have their respective attributes and form positional relations with each other. According to their positional relations those 2-D shapes are rearranged to become the faces of 3-D shapes. The agents recognize objects by comparing such attributes as their types of 3-D shapes, sizes and colors with those of the entities stored in their knowledge base. In our perception mechanism we use the Finite Elements Method, where detailed regions are first analyzed and upper regions are described in terms of those detailed regions[9].

3.3 Definition of 2-D shapes

We divide the shape types into connecting lines, regular shapes, and irregular shapes. A connecting line has no internal region, and is only a simple connection. The regular shapes are classified into triangle, tetragon, circle, ellipse, and all the other shapes are regarded as irregular shapes. The regular shapes are the basic shapes to be used to approximately describe object shapes in our virtual world. The basic units to be used in our recognition stage are 3-dimensional shapes, such as sphere, cylinder, box and pyramid.

The agents recognize 3-D objects by combining the 2-D shape informations perceived in different viewing angles. We minimize the kinds of regular shapes since a shape could be seen as different shapes depending on different viewing angles, like a regular triangle seen as an isosceles triangle or a square seen as a diamond shape. However the circle is an exceptional tyoe not to be generalized to ellipse, because of the fact that the shape from any viewing angle is invariably a circle implies the object is spheric. We approximate as possible complex shapes in terms of regular shapes. In such an approximation, two or more regular shapes are combined with

modifications via spatial additions or subtractions to reflect minor deviations from their basic forms[10]. Fig. 3 illustrates how complex shapes could be approximated in terms of regular shapes.

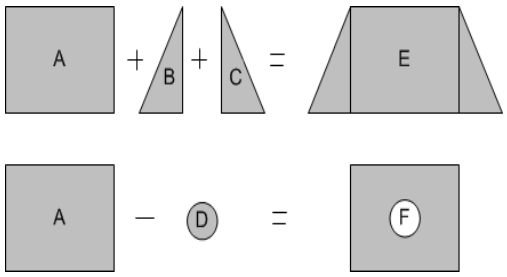

Figure 3 Complex Shape derived through

3.4 Comparison of shapes

The recognition of object shape basically is performed by comparing th approximated representation of a target shape with the corresponding information from the agent's knowledge[8]. However, this basic recognition method is to be enhanced for the points described below.

First, the amount of perceived information could differ significantly according to the distance from the agent to the object. While the agent can see all the details when the target object is close, an object in the distance would be viewed just along its outlines with details blurred. Thus, the detailed information on the object shape may or may not be provided for the agent to recognize the shape of objects.

Second, the target object may be hidden by other objects. In this case, we need reasoning algorithm for restoring the complete shape utilizing the remaining portions of the shape. The reasoning algorithm uses the three methods following.

i) Extrapolate between two line segments enough to connect them. Based on their intersection, the remaining part is inferred.

ii) In case a line is partially broken into line segments, an imaginary line including those line segments is used as the reference line for inferencing the shape.

iii) In case of ellipse, angles and lengths of repetitive arc are first calculated. Then imaginary circumference is recovered by inferring the hidden portions[9].

Third, to handle different shapes due to different viewing angles we utilizes the same method as that for the first point. That is, the perceived shape is compared against its associated composition information from the agent' knowledge.

Fourth, we are to consider an object may change in its shape by time or situation. To overcome those variations we need to judge what are the significant elements in the shape. In fact, this judgement could apply to any aspect.

4 Ontology-based object recognition and relevant logical reasoning methods

4.1 Object recognition

An agent starts the object recognition with comparing the perceived data the agent perceived with the information in the ontology. This recognition of an object could utilize not just its internal properties but its reaction to external stimuli. The most basic property by which a physical entity could be identified is its volume occupying the space. In addition the entity could be further characterized by such reactive properties as its resolution in case of mixture with another entity, its movement in case of collision with another entity, its shadow in case of being lighted etc. Those properties could be acquired through perception unless they are of dimensions too large or small to be perceived.

For example, suppose an agent is trying to find her missing dog. In case she meets a likely animal, she would first recognize its class using such class information as shape and color etc. in the ontology. Then, she would seek further pieces of information to match her knowledge about her dog. Those instantial informations might be a scar on it, a limping pattern when walking, a barking habit, etc.

On the other hand, the physical concepts can only be characterized by their inherent effects rather than their internal properties, e.g., force by the effect of exerting pressure on other materials or objects. Unlike the other physical entity categories the physical concept can share space with other physical entities.

4.2 Logical reasoning methods

Human can infer informations from raw data using diverse inference methods. Such raw data is obtained mainly via perception or indirect experience through learning. In this paper, the agents are designed to use several inference methods as follows.

1) Rule in the general form
The rule in general is represented by the following formula.
C1 -> C2
Where Ci denote clauses expressed in terms of existence and states; -> denotes implies. By instantiating the variables in the clauses we can explicate information implicit in the situation as perceived.

2) Contraposition
Contraposition is described by the following formula.
<C1 *or* C2 -> C3> leads to
<NOT C3 -> NOT C1 *and* NOT C2>
Contraposition is applicable not only to certain links but also to less than certain links. For those uncertain links an additional consideration would be required on their associated exception links[8]. Just as rules of thumb hold good in reality, if probability p from C1 or C2 to C3 $\fallingdotseq$ 1.0 contraposition should still apply. However, if p<< 1.0 or p $\fallingdotseq$ 0 it cannot apply in any case.

3) Necessary and sufficient conditions
We can utilize the necessary and sufficient conditions for inferencing, e.g., to identify a particular class or instance. Consider, for example, that the bio-force a product of the animal is used as **thrust** for its move. This relation between the source of force and the agent of the move *suggests* its move is a self-powered move by an internal force. This property is a necessary condition for being the animal and the only other class that has this necessary condition is the motor vehicle class. Given this reasoning, a self-powered moving object would be judged to be an animal with a certainty if we could somehow rule out possibility of its being a motor vehicle.

4.1 Overall procedure of our ontology based object recognition

Suppose the agent is trying to identify her family car being driven by her father in a crowded parking lot. Following our general recognition process, the comparison between her perceived data and information in the ontology starts at the class about which she can perceive the most detailed information. If the target object is not fully perceivable or there are many instances with the same shape, however, the shape is not a characteristic property so the agent needs to perform inferencing (Section 3.4) in addition to comparison (Section 3.3). When it is dark so the agent can barely figure out the objects' contour, for instance, the physical object class would be the starting class. If needed and possible additional information is deduced by inferencing. To judge (or infer) whether the object is moving, she would use the rule that an object is to be (seen) at different locations at different times. Further, no external power sources are seen (and inferred) it is inferred to be self-powered and consequently, to belong to the animal or motor vehicle class. Likewise the comparison continues along the class hierarchy using additional properties perceived or inferred until its class or instance identity is determined as required. To identify it in the instance level the agent needs to use further information such as its plate number, a dent, its unique wheel shape, etc.

5 CONCLUSIONS

In order to cope with a situation, an agent first needs to recognize objects in the situation. The objects are the most basic elements of the situation on which relationships and activities can be established. We aim to develop an autonomous agent that inhabits in our cyber-world. Such an autonomous agent needs to have perception and recognition capabilities to be able to react actively to diverse situations occurring in the cyber-world. To implement those capabilities we develop a knowledge representation scheme and associated inferencing mechanism for the agent.
We focus on the visual information among various perceptible information to be used to recognize physical objects. We develop a specialized ontology to model the entire world and to represent the agents' knowledge

structure. The object shape is the most distinctive visible property humans use to identify objects with respect to their class or instance. We develop a representation method to approximate complex object shapes in terms of several regular shapes. While these shapes usually characterize objects uniquely, the agents may need additional informations deduced by inferencing in case perception is not complete or many identical instances are considered.

To completely grasp the situations the agents need to recognize diverse imperceptible components such as relationships, activities, logical concepts, etc. Recognition of these categories of concepts demands additional knowledge on instantial and historical information besides elaborated inferencing. We hope you find the information in this template useful in the preparation of your submission.

The potential of BPO (Business Process Outsourcing) in the current Spanish pre-recessive frame

M. Monterrey[1], **D. De La Fuente**[1], **N. Garcia**[1] **and J. Lozano**[1]
[1]Department of Business Management, University of Oviedo, Gijón, Asturias, Spain

Abstract - *The present research is aimed at analyzing the current outsourcing situation in European companies and, particularly, in the Spanish ones, and at establishing the bases to be able to understand the foreseen transition to more developed practices such as the Business Process Outsourcing (BPO). The current macroeconomic frame, especially adverse in the case of Spain, makes this kind of methodologies have a warm welcome among companies, either public or private ones, since they are seen as having important chances to save money. The aim is definitely to take some measures to cut not only general costs in the usual outsourcing field, but also operation and* core *processes costs, following mostly the modern BPO. Moreover, a new economic activity is generated around BPO, which can be interesting for the Spanish strategic consultancy firms. At this time, the limited development of BPO can be determined, to a certain extent, by the little confidence clients have giving "sovereignty" when they make their strategic decisions. Anyway, this kind of initial reluctances are hoped to be saved as time goes by and with the generalization of this sort of practices in all sectors and geographic environments. Some aspects like economies of scale and the consequent obtaining of minor costs or the know-how of the companies which provide this kind of services that could even produce an increase in the chapter of incomes based on economies of scope make that BPO clients think at least of the possibility of including them in some of their processes and sub-processes. Finally, this research makes a brief observation about the relation between BPO and the so-called* Offshoring, *by which growing companies or simply those eager to enhance their income statement accounts, can relocate their productive processes by means of costs.*

Keywords: Outsourcing Process, Subcontracting, Business Process Outsourcing, Core Business, Offshoring

1 Introduction

Since the crisis at the beginning of the 90s, the Spanish economy has had a decade of growth in an environment of sustained expansion. However, since 2008, the country has been suffering from an important worsening in its macroeconomic indexes, to give way to a long period of recession (2008-2010), followed by a weak growth stage with an inter-annual increase of 0.7% in 2011. As it can be seen in Figure 1, it can be expected the Spanish economy will go into a recession phase again during 2012 as a consequence of the crisis in the sovereign debt. Even though there had been previously several indexes that led to symptoms of deceleration, the damages reflected on economy could be seen from January 2008 with the stock market crisis together with the problems in the real- estate market. All this together with an inflationary frame in the increase on petrol prices and food products have led to the current pre-recessive situation. In August 2011 Spanish authorities reacted taking additional fiscal adjustment measures, as well as including a rule of budgetary stability in the Spanish Constitution, which reassured the compromise by the Spanish public finances with the maintenance of a healthy budgetary situation for the medium and long term. According to the forecast by El Banco de España [1], during 2012 and 2013 employment will continue decreasing as to reach an unemployment rate of 23.4%, which is the main structural problem of the Spanish economy. Furthermore, a replacement of domestic markets by external markets has been considered as probable by the Spanish business network in a context where the second ones are relatively stronger than the first ones, which are under a considerable withdrawal in private consumption. On the other hand, importations would support a great decrease – about 5%- having into account the strong adjustment in the national demand

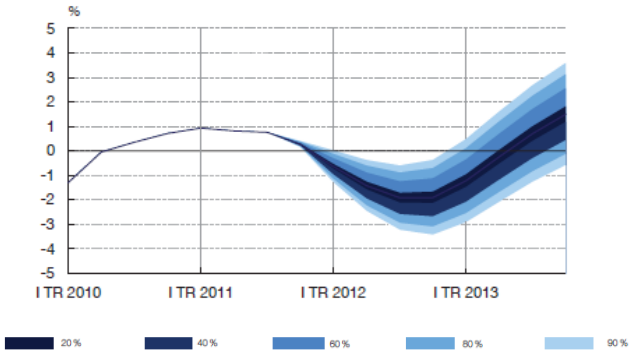

Figure 1. Expected evolution of Spanish GDP
Source: *Banco de España*

In this pre-recessive context of Spanish economy, the current research is aimed at analyzing the opportunity of development of outsourcing techniques as a way to reinforce

the competitive position of Spanish companies or, in some cases, to make even their own survival easier. Even though these practices have been applied for some decades in different ways, authors consider that the current approach to shared facilities, the act of making strategic decisions together with specialized companies, the know-how profit which these ones can contribute and definitely cost-cutting and income increasing that the outsourcing produces, will make some of these companies be able to get competitive positions that strengthen their future for a medium and long term.

On the other hand, outsourcing is evolving fast to processes where each time it is necessary to have a greater specific knowledge as well as having the support of more sophisticated technological tools. In short, we might be witnesses of an increase in the value of these services in relation to their costs. Obviously, the outsourcing business is still far from being well structured, as it is still in the starting phases of settlement as a product. It needs to grow quantitatively and qualitatively not only on the supply – to companies multi-specialized in more and more processes and to more and more *core* processes- but also on the demand – to smaller companies, in a wider environment and in more varied sectors

2 Current Outsourcing approaches: to *Core* Processes Subcontracting

In the *Global Outsourcing Survey 2007* [2], Pricewaterhouse Coopers has reached the conclusion that for a wide majority of clients – 87% of respondents-, outsourcing gets the expected benefits totally or partially. 31% think the aims have been completely achieved, which is important considering the complexity and uncertainty they face before contracting these services. As regards financial institutions, the degree of total satisfaction reaches 46%. On the other hand, 91% of the respondents either satisfied or not with the results, say they will contract outsourcing services again.

The main reasons companies give to outsource processes are the following ones:

- Lower costs (an important or very important factor for 76% of respondents).
- Getting access to know-how (70%).
- Offering services others can do better (63%).
- Increasing the flexibility in business (56%).
- Improving the relationship with clients (42%).
- Developing new products or services (37%).
- Geographic expansion (33%).

Many of the respondents (53%) stated that they outsourced processes considered as core. Obviously, the definition of activity or core process was up to the respondents and it can have different meanings for each of them. An evolution can be noticed from the external ring, (see figure 2) where no-core processes are situated, to a second ring of essentials no-core activities. For instance, in the finance function, this can be understood as an evolution from the outsourcing of payrolls and accounts payable to the technical support in the annual budget calculation, in forecasting and management control.

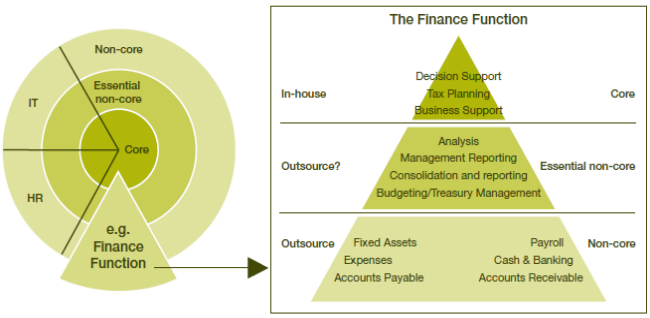

Figure 2. Core vs Non-core in the Finance Function
Source: Pricewaterhouse Coopers

ICT services are still the most widely outsourced activity for 57% of the respondents. In general, 70% of them outsource one or more activities which are intrinsically strategic:

- 53% outsource the production or delivery of core products or services.
- 33% outsource sales and marketing (including third party distribution channels)
- 32% outsource innovation, research and development.

Figure 3. Outsourcing is intensifying. Source:Pricewaterhouse Coopers Global Outsourcing Survey 2007

Financial institutions, with 40%, are especially prone to outsource sales and marketing – for instance, to insurance brokers and financial agents. Civil engineering, mass media and ICT firms are less inclined to outsource core activities although nearly 40% of them do it. Companies that operate in

mature, medium markets like Australia, Canada and New Zealand, are especially aggressive contracting outsourcing for strategic activities (up to 71%). 48% of respondents outsource sales and marketing. Growing companies from these countries have small domestic markets, which can cause the necessary pressure to force them to contract strategic capacities which enable their growth abroad. Over the last years there has been a phenomenon which affects a small number of big clients: outsourcing customer service by contracting call centers in emerging countries with low salary costs. In some cases, this option has found a serious competitor in the switchboard managed by an ICT company and without enough staff. Outsourcing is spreading in a dynamic way to areas like R+D from much more static positions in a long term, with contracts between a provider company and a client company. The freedom each one had to act was very limited. At present, as we go into the second era of outsourcing with many mature ICT contracts, clients admit that the new approaches present a rich variety of opportunities. Nowadays, the senior management team of a company must take into account culture, structures and processes attached to the geographic and sectorial markets they compete in. For this reason, they must be eager to establish alliances and collaborations which enable them to design an innovative business model. They are important factors when business people start thinking about outsourcing new functions and the joint management of shared services like human resources and accountancy. Depending on their business activity, geographical setting or size, between 27% and 55% of the respondents showed their interest to widen their current outsourcing levels within five years later than the survey was made (2007). There is still a margin to grow the ICT outsourcing services: 55% of the present clients of these services hope to increase their outsourcing levels. The key points in the outsourcing growth would be the following ones:

- For big mature markets: purchases (53%), call centers and customer services (45%) and financial and accountancy activities (44%).
- For emerging markets: Worldwide, the highest forecast growth is based on contracting *call centers* and customer service centers (56%), *core* products and services (54%) and delivery /logistic (53%). The relocation strategy is linked to these answers to a certain extent.
- Financial services: *core* products and services (56%), *call centers* customer service centers (46%) and sales/marketing (40%).
- Mass media/telecommunications/ICT: R+D (64%), *call centers* and customer service centers (73%) and finances/accountancy (50%). In these so highly competitive sectors, companies are especially pressured into taking on new initiatives.

3 The potential of BPO as a competitiveness alternative in times of crisis.

The constant improvements in Information & Communication Technologies (ICT), together with the global availability of skilled labor and the reduction of international business barriers have caused the value services supply has been broken off ([3], [4] and [5]). Many companies have gone from an asset ownership strategy to one of outsourcing a part or all the components of a service for cost-cutting, to enhance the cycle times and to get innovation capacity [6]. In this context, Business Process Outsourcing (BPO) means a further step in the strategy of outsourcing organizations. It consists of integrating several processes, even key or core processes in organizational structures unconnected with their own ones. So, in this way a new economic activity of companies specialized in making processes for third parties arises. Obviously, a great part of the competitive advantage of these companies, either back office or front office of their activity, lies on the economy of scale that is reached and, therefore, on the optimum competitive position that means to offer lower unit costs.

It is worth to mention the traditional purchasing centers, which are based on the joint realization of the purchasing process by several companies. Obviously, the management of this purchasing method can be outsourced to only one company, such as it is the case of Fortia. This company is founded as a way to adjust the great consumers to the disappearance of industrial electricity charges in Spain. It is formed by 17 business parties of different economic sectors and it develops a service that benefits all the parties involved and the economy in general, ensuring competitiveness of the Spanish basic industries. The previously mentioned groups of companies employ 40,000 workers directly in 70 factories all over the country. They have a joint turnover of about € 15,000 millions, which stands for 12% of the Spanish industrial electricity consumption. The structure of Fortia is divided into iron and steel (47,2%), cement (25,8%), metallurgical (20,8%), gas fitter (6,20%) and paper (0,07%) industries. Therefore, Fortia is in charge of another part more of the activities of the specialized companies in BPO, where the purchasing process- generally no core component or services – is outsourced.

In Spain, there is a second example of purchasing center, but with some specific features that make it different from Fortia. It is a private consultancy- Compras58, placed in Valencia, whose main features are the following ones :

- It is a transversal purchasing center dedicated to the negotiation of contracts of any type of purchases, either raw or auxiliary material or services. It is not like Fortia, whose purchase is focused on energy.

- Its potential clients are sectorial business associations and, even more, those which operate regionally. Therefore, the Compras58 activity is mainly aimed at industrial clusters.
- Compras58 cannot be said to be strictly a BPO company, since as it has been mentioned before, it only deals with purchasing process and, indeed, contract negotiation. In short, it is a classic sub-process outsourcing- contract negotiation.

From the previously mentioned aspects, it can be deduced that the only competence the Compras 58 client clusters subcontract – the renegotiation of contracts- will be for a short time and it will finish when the new purchasing contracts are signed. This does not stay integrated in processes and sub-processes series that their client companies make, which, for instance, eliminates logistic part concerning provisioning, which is an habitual purchasing process. The competitive tool used in this case is the economy of scale, obtaining a bigger purchasing power as a result of an increase in the purchasing volume. There is also a reduction in the number of providers and, therefore, a greater efficiency in the contract negotiation management. Finally, the number of purchasing references is reduced, which makes Compras58 – on behalf of its clients- become a preferential client for its providers. According to the last data obtained (year 2007), Compras58 owns a client portfolio with 300 client companies, grouped in 12 clusters from 6 Spanish regions. These clusters belong to the following sectors: textile, automobile industry, plastics and maintenance. The closed negotiations during 2012 appear in this Table:

Table 1. Savings achieved in 2010. Source : Compras58.

Item	*Negotiated amount (€)*	*Savings (€)*	*Savings (%)*
Telephony	*3,815,968*	*772,828*	*20%*
National courier	*368,637*	*113,075*	*31%*
Electricity	*29,965,668*	*2,647,355*	*9%*
Office supplies	*382,658*	*86,568*	*23%*
International courier	*899,651*	*196,975*	*22%*
Lab supplies	*434,422*	*111,579*	*26%*
Road transport	*2,341,805*	*131,425*	*6%*

Waste Management	*7,372*	*601,000*	*8%*
TOTAL	***40,479,794***	***4,260,257***	***11%***

According to the above description, then BPO companies could be classified in two types:

- Companies which exploit benefits of economies of scale applied to a kind of process (ICT, Purchasing, Maintenance, etc.), that is, the classic outsourcing.
- Companies which, in a way, are integrated vertically into their client companies from a more strategic position. These companies are still very incipient and cover any kind of process susceptible of being outsourced. This is called BPO.

When BPO activities are placed in a specific geographical frame and, particularly, when the relocation of processes from developed countries into emerging economies takes place, we have a kind of BPO known as offshoring. This practice has attracted a considerable public attention over the last years [7]. Companies which manage this type of BPO play an important role, allowing their clients to specialize in their core competences and they are used as extension of them [8]. Without detriment to the possible savings reached, many companies are unable to value BPO advantages. Alster [9] foretold that 60% of the BPO companies would face the client desertion and the appearance of hidden costs that could cancel the savings between 2005 and 2008. Aron and Singh [8] claim that half of the companies which dealt with offshoring processes have not been able to generate the expected benefits. Robinson et al. [10] states that most of 75% of BPO providers believe their clients were not prepared enough for the initiative and lacked of a very well developed strategy when facing how outsourcing could work. These anecdotic findings state that the BPO companies' management is still not in accordance with their clients expectations. An important reason for this problem could be the inability of service providers and clients to handle with interdependences of processes, which leads to failure ([11] and [8]). The effective integration process between the service provider and its client should be made strongly and decisively in the highest collaboration frame. We must remember that BPO providing companies are usually strategic consultancy firms which do not offer a generalist view but a multi-specialist one in contrast with the only specialization of the classic outsourcing companies. The problem lies on the fact that on almost any occasion there is a distrust by the senior management team of the client company to the BPO provider requirements about "giving sovereignty" when making organizational and strategic decisions that affect the company as a whole. Anyway, these problems that rise systematically in BPO projects are determined by the business immaturity and its still scarce visibility by potential clients. The break-even point will be determined by the component of the corporate strategy that the senior management team of the client company will be willing not to transfer, but to share with its BPO provider. Obviously, the opposite point is found in keeping the brand name by the client, having outsourced the majority of processes, either core or not. There is an interesting debate concerning this, which accepts opinions in all senses, without any solution of continuity.

Although some researchers have expressed their need of a close relationship between the members of the supply chain [12], only recently has the possibility of suggesting a systematic approach to study the supply chain integration been raised. The current competitiveness in industrial and service markets has made several companies reconsider the need of establishing cooperation alliances, mutual benefit and joint improvement of transversal processes, which have become a high priority [13]. At this point we should mention the comakership techniques, which have worked so well in sectors like automobile, where the intermediate margin cutting has reached very high points. The capacity to integrate different processes into different contexts can provide BPO companies with unique competitive and irreplaceable positions that will allow those companies which contract their services to reduce failure risks in the process to improve the client service levels and performance. Given this, it is assumed that BPO can mean not only cost savings by cost-cutting and by economies of scale, but also an increase in incomes as a consequence of economies of scope, which the new core processes a BPO company can do for its client involve.

BPO range of services (maintenance, legal services, purchasing, marketing logistics, etc..) is as wide as varied the functional division of the company is, obviously assuming intermediate proposals of outsourcing of areas, sections or hierarchically less important units in a traditional organization. Clients can only contract one BPO supplier, provide him with work specifications or procedures and wait for a good supply [8]. The provider will make more mistakes and will work more inefficiently than the client company employees, until he can manage these tasks easily. This fact must be considered and quantified in ROI terms when thinking of a BPO project. Obviously, this situation is produced when the outsourced processes belong to core business and this is usually the reason that makes organizations not contract BPO companies for this kind of processes. This also means discouragement for the senior management team of companies planning to relocate a great part of its key processes, which must be considered when they decide whether making the project with their own means - through expatriate - or with other's - by contracting an offshoring company. There are other failure risks for BPO companies related to the contractual obligations that they have with their clients. The effective integration can make these problems disappear. The lack of effective integration in a service environment can lead to a deficient performance, so this is an important area to explore. Many of BPO tasks have complex knowledge components [14]. Therefore, tasks can vary the complexity grade and so the result of the execution. The quality of these services can often depend on the coordination between different processes and sub-processes within the same process. Consider that part of the sub-processes or processes are made by BPO companies and other part by the client company. The most convenient thing might be to make a maximalist approach when contracting BPO companies, that is, to outsource no core complete processes. In this way, integration problems and starting up costs would be avoided and a less payback of the investment in reducing staff to outsource it would be obtained. The border of BPO with the simple employment of workers, outsourced to a temporary work agency, can mean a sign that the BPO project has not been completely understood.

4 Conclusions

In the current work, the intention has been to make an analysis of the different aspects of the classic outsourcing and the promising future of the BPO variant in a pre-recessive context such as the present one in Spain. It has been seen that the motivations that make companies outsource their process and sub-processes are different. The satisfaction that the application of these techniques in the different productive sectors, in different geographic contexts and in companies and public capital organizations generates in contrast to the private capital ones have also been analyzed. The attitude of companies to give or, in all case, to share some of the strategic decisions with companies specialized in BPO seems to be very far. This fact can be sharply seen in small and medium size companies, where BPO has entered less than in big corporations.

As addition to the current work, the possibility of establishing an Outsourcing/BPO observatory in Spain is proposed here. It will allow to evaluate the integration degree of these techniques in the Spanish company and to feature it according to several parameters like the region where they are placed, sector they belong to, size or company ownership. The aforementioned observatory will have a department responsible for the characterization and evaluation of the services demand. In short, it means to quantify and know the evolution of this economic activity in detail.

Evaluation of Perceived Security in B2C Web Sites by means of a FDSS

Parreño J. [1], **Castro A.**[1], **Puente J.**[1] **and Gómez A.** [1]
[1]Business Administration Department, University of Oviedo, Gijón, Asturias, Spain.

Abstract *- Nowadays, increasingly more costumers use the Internet to purchase. However, the fear and the distrust of the online consumers to supply their bank account number and personal data is still an unresolved factor in some web sites. It has been acknowledged that those web sites in which customers perceive an increased security level achieve greater success in completing purchases than those that provide a lower one.*

This study aims to establish a methodology based on a Fuzzy Decision Support System (FDSS) capable of evaluating security perceived by customers in B2C websites. This technology allows to process the knowledge of decision inserted into the rule data base of the system to qualify the safety in B2C web sites according to the customer's perceptions.

Keywords: B2C, Fuzzy Decision, Security, E-commerce, Weighted Point.

1 Introduction

As the information technologies increase and the electronic communications improve, internet users are more informed and the companies consider it more important to gain new customers by using the Internet as a mean of communication and purchase.

However, security in web sites is a conditioning factor for online customers since if customers perceive that security is adequate, they may purchase. On the other hand, if the perceived security is low, customers will quit the operation, no matter the assessments given to the other key variables.

The present paper, in addition to this brief introduction, is divided into the following sections. Section 2, describes the most relevant variables regarding B2C web sites security and the authors that back these variables. In Section 3, an initial model is proposed to evaluate the perceived security in these web sites by using two different evaluation techniques: one based on weighs and the other based on fuzzy logic. Finally, in Section 4 the final conclusions of the study are shown.

2 Literature Review

In this section, it has been reviewed the literature pertaining the most frequently used variables to evaluate the perceived security in B2C web sites. The ones that are to be highlighted because of their importance are: payment security, service privacy and confidence. Table 1 defines these variables, as well as the authors that support them.

Table 1: **Relevant variables in the evaluation of perceived security.**

VARIABLE	AUTORES
Payment Security: Protection guarantee regarding transactions and means of payment used during the purchase procedure.	Szymansky y Hise (2000), Ranganathan y Ganapathy (2001), Madu y Madu (2002), Francis y White (2002), Otim y Varum (2006), Venkataiahgari et al. (2006) Oppenheim y Ward (2010), Ramanathan (2011).
Service Privacy: Protection guarantee of important data supplied by the customer regarding filing, treatment and maintenance.	Ranganathan y Ganapathy (2001), Zeithaml et al. (2002), Oppenheim y Ward (2010), Stefani y Xenos (2011).
Trust: Firm hope on someone or something. In e-commerce, specifically, refers to the hope an online customer has that the purchase made by using a web site is to fulfil his expectations.	Mayer et al. (1995), Houston y Taylor (1999), Mauldin y Arunachalam (2002), Lala et al., (2002), Kaplan y Nieschwietz (2003), Yousafzai et al., (2003), Oppenheim y Ward (2010), Hong y Cho (2011).

3 Proposed Model

The proposed model stems from a global model for B2C web sites evaluation that is the result of a Delphi Method performed nationwide by experts on Market Online. The model consists of three subsystems of partial evaluation (web site quality, offered service and security) that combine to achieve the final evaluation of the B2C web site.

In this research, we will focus on the analysis of the subsystem of evaluation of B2C web sites security by using two methods: one of weights factors and another based on a fuzzy inference system.

It has been decided, as a criterion for the good operational policy of the model, not to make the value of a variable depend on more than three others. What is more, since not all influencing factors can be measured by using

easily quantifiable variables and their measurement may depend on the expert knowledge of the evaluator, it is intended to develop an easy relational tool that allows to evaluate B2C commerce platforms with the highest possible degree of objectivity, in spite of the uncertainty associated to the evaluation of some of these influencing variables.

Figure 1 shows the parameters involved in the evaluation of the three variables that play a part in the model proposed to evaluate the security of a B2C web site.

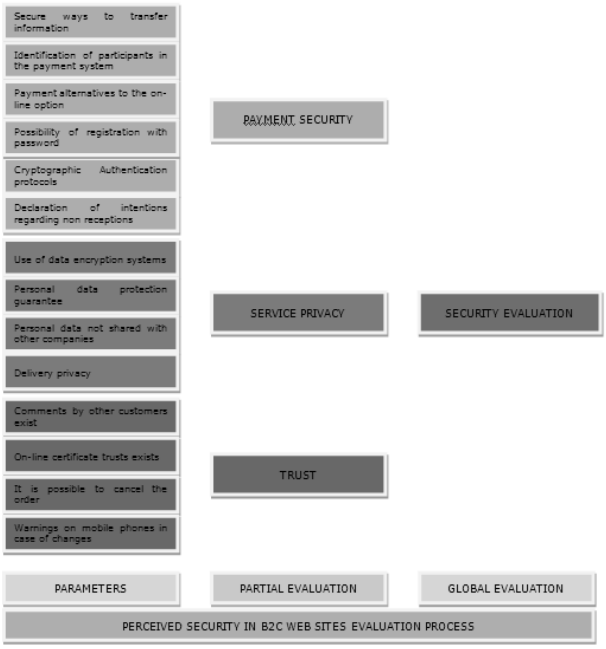

Figure 1: System for the evaluation of the perceived security in B2C web sites.

To evaluate the variable [Payment Security], the customers of the B2C web platform are asked to fill in a little questionnaire to qualify the perception of the payment security. The questionnaire evaluates the customer's degree of satisfaction (from 1 to 7) about different items related to this variable. Aspects as the availability of secure modes to transmit information or the identification of the participants of the payment system are evaluated.

For the variable [Privacy Service] it will be needed to evaluate if privacy regarding data sent really exists or if it is not explicit. With this aim, customers fill in a questionnaire in which they are asked about different items as the use of data encryption systems, personal data protection guarantee or the privacy in delivery.

Finally, variable [Trust] refers to the trust or faith on a person or thing. Regarding B2C, confidence refers to the hope that the customer has that the purchase is made according to his expectations. The existence of certificate trusts, comments made by real customers evaluating the service or the possibility of cancelling the order are factors that condition the qualification of this variable.

Taking into account the evaluations obtained for these three variables and applying some available evaluation methods–in this paper two methodologies are shown– the final qualification is obtained.

3.1 Techniques to evaluate the model

Out of the different available calculation methodologies to evaluate the dependent variables within the proposed model, two have been chosen to be depicted as examples, showing their pros and cons. These two methods are: a traditional variable weights model (Weighted Point Model) and a fuzzy inference system.

3.1.1 Weighing Method (Weighted Point Model)

In the weighing method (Timmerman, 1986), the assessments of the dependent variables defined in an evaluation model are calculated by arithmetic weighing of the assessments of the variables that have influence in their determination.

The qualification of each variable can be calculated as a function of the expert knowledge on perceived security in the B2C web platforms targets of this study or by making a poll among usual customers of these platforms.

The final obtained qualification will be a function of the score of its three determining variables: Payment Security [H1], Service Privacy [H2], and Trust [H3], taking into account their respective weights defined as [W_{S1}, W_{S2}, W_{S3}]. For instance, privacy as well as security are considered critical factors in payments, therefore the weights for the evaluation of the B2C web site security will be: [0,4; 0,4; 0,2].

Next, Table 2 shows a numerical example of the results obtained by five B2C web sites by using this method with the aforementioned weights. It must be reiterated that these weights might be eventually varied according to the expert's criterion or according to the customers' feelings obtained through polls.

Table 2: **Five B2C web sites final Evaluation.**

	H1	H2	H3	Total	
WEB 1	0,3	0,2	0,2	2,40	VERY LOW
WEB 2	0,55	0,6	0,55	5,70	MEDIUM
WEB 3	0,9	0,8	0,9	8,60	VERY HIGH
WEB 4	0,8	0,9	0,2	7,20	HIGH
WEB 5	0,4	0,4	0,1	6,92	HIGH

Intuitively, it is verified the ease to calculate of the weights model. However, this method does not allow to aggregate the knowledge to make decisions in the evaluation of the dependent variables in an intuitive way as the decision systems based on rules do allow. This fact makes it difficult to conceptualise the model of evaluation of the perceived security in B2C web sites and enforces a much too linear behaviour in that assessment. This linear behaviour may also make it difficult to adequate the evaluation to the reality if the

platform wishes to set a minimum acceptance threshold to some of the variables (i.e. security in payment) because of the importance it has to its online customer.

On the other hand, the nature of the decisions of B2C e-commerce customers is complex and little structured and the estimate of some quantitative and qualitative factors that are involved in the process has a high degree of uncertainty and subjectivity (Meziane and Nefti, 2006). That is why it is proposed to analyse an assessment method that mitigates the described inconveniences and that is able to simulate the human reasoning procedure in making decisions from inaccurate or vague data (Bevilacqua and Petroni, 2002).

Thus, it is feasible to expand the previous model to a fuzzy system able to infer the evaluation of the perceived security in different web platforms according to the opinion of their purchasing customers so that it is possible to establish a ranking depending on the perceived security.

3.1.2 Fuzzy Inference System (FDSS)

Fuzzy Decision Support Systems are based on the Fuzzy Sets Theory (Zadeh 1965). They allow to aggregate into the models a component of uncertainty which makes them more efficient when it comes to approximate to reality (Lootsma, 1997). In these systems, linguistic-type variables allow to process qualitative or quantitative information since the values that these variables take may be associated to concepts of ordinary language instead of the numeric values that the traditional variables take (Driankov et al., 1996). In the case of the perceived security in B2C web sites, the subjectivity of the evaluation they undergo may, in some cases, be high. That is why the use of artificial intelligence tools based on fuzzy logic and the use of linguistic labels as valid values for the variables of the model to be designed permits a better adaptation to the evaluation criteria supplied by the users or the expert in this type of business. It will also be proved that the design of a fuzzy system in this area will redound in a better interpretation of the knowledge inserted in the decision system, improving the behaviour of the evaluation in comparison to other more simple qualification systems–i.e. those based in weights–and achieving nonlinear behaviours in the evaluation. To perform the study in this area, we will use a fuzzy decision support system with the assistance of the application Matlab fuzzy logic toolbox ® version 2.0.

To adapt the developed model to the fuzzy environment, it is necessary to transform the aforementioned variables into their fuzzy homologues (input variables as well as output ones), in such a way that they can take linguistic values within previously defined ranges. Then, the knowledge necessary to develop the process will be aggregated as rules, with the final goal of obtaining a qualification for the portal. The rules have conditional structure, and this structure must allow to intuitively assign linguistic labels to all variables.

In this case, the labels used to perform the evaluation of the perceived security in a B2C web site are shown in Figures 2 and 3.

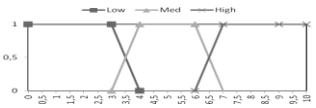

Figure 2: Labels for the input var.

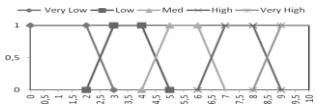

Figure 3: Labels for the output var.

Next, as a function of the expert knowledge on evaluation, the rule base shown in Table 3 is proposed.

Table 3**: Rule base to evaluate the security of the service of the B2C web site.**

SECURITY		TRUST								
		LOW	MED	HIGH	LOW	MED	HIGH	LOW	MED	HIGH
PRIVACY SERVICE	LOW	VL	VL	VL	L	L	M	M	M	VH
	MED	VL	L	L	L	M	M	M	M	VH
	HIGH	VL	L	M	M	M	H	H	H	VH
		LOW			MED			HIGH		
		PAYMENT SECURITY								

For instance, the shaded rule would suggest that if the score of the security in the payment is medium, the privacy of the service is low and the trust in the web site is high, then, the final qualification will be medium.

Once the fuzzy subsystem is designed, the evaluation of a web site can be inferred as a function of the crisp values assigned to its input variables. Besides, it is easy and intuitive to analyse the congruence of the obtained evaluations by using the inference maps supplied by each subsystem of the model. In these maps, the scores of the output variables are represented by the surface's height in each point.

This way, for instance, for a low assessment in payment security, the maximum qualification would be around 5.5 points in a little area (see Figure 4), which would determine that the user quits the process of online purchasing in that web site. However, for medium and high values in payment security, an important increase of the assessment of the web site takes place which reaches 7.5 and 9 points respectively. In addition, in this last case, for trust values over 6 points, high final qualifications are obtained, no matter the value of the privacy of the service. This behaviour would be explained because a customer that perceives that a service is secure and reliable awards the service with a high qualification regardless of the service's privacy.

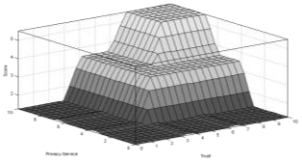

Figure 4: Map of solutions with low payment security.

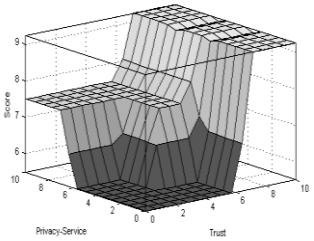

Figure 5: Map of solutions with high payment security.

4 Conclusions

In the paper, the variables that play a part in the perception of the security of B2C web sites are analysed. A model is proposed to evaluate the security in those web sites by using two different methods. The first one, based on different weights assigned to the influential variables, poses different inconveniences: too much linearity in the output variable or the difficulty of conceptualising the behaviour of the assessment given to the security of the B2C web site, which is usually described vaguely and inaccurately. The second one is a fuzzy system that not only does it mitigates the aforementioned inconveniences but also allows the introduction of the knowledge for the assessment as linguistic rules in a guided and intuitive manner (based on the expert knowledge or in the perceptions provided by the users). The results put forth a better interpretation of the security assessments of a B2C web site. These results are more in agreement with a not so much linear behaviour as the one assigned by the weights traditional methods. To broaden the research, the model will be validated through web analytics by using different available metrics: number of visits and/or unique visitors, rebound rate or conversion rate among others. The final goal will be to achieve a dynamic model that adequately adapts to the online customer necessities.

Application of GRASP methodology to Vehicle Routing Problem (VRP)

R. Pino[1], C. Martínez[1], V. Villanueva[1], P. Priore[1], and I. Fernández[1]
[1]Department of Business Management, University of Oviedo, Gijón, Asturias, Spain

Abstract - *In this work the development and implementation of a Decision Support System is described. It will assist in the route calculation process and in optimizing the filling of the trucks that have to transport a considerably number of vehicles from near of 8 origins to more than 3,000 possible destinations spread over Spain and Portugal, and some in France, Germany, etc. The problem can be classified as VRP (Vehicle Routing Problem), been a hybrid between the VRPTW (VRP with Time Windows) and MDVRP (Multi Depot VRP). For its resolution, a Web application using a GRASP methodology as an optimization tool has been developed. The experiments carried out prove an improvement in the results of the freights/routes planning when the DSS is used. The improvement is measured trough the percentage of daily vehicles dispatched, the decrease of the shipment delay, and truck use, among others.*

Keywords: VRP, Heuristic Optimization, GRASP

1 Introduction

The aim of the this work is to present the results obtained in the development of a research project in which heuristics techniques are applied to solve vehicle routing problems. This research was developed as an independent subproject within the project called SITIM[1], whose aims are to study, evaluate and develop methodologies and systems to improve the Intermodal Transportation through scientific and technological knowledge. For this purpose, a number of actors participate in the project, among which are: Research Groups of various Spanish universities (Universities of Valladolid and Oviedo), public Logistics and Transportation-related institutions and several private companies of these sectors.

The subproject aims at analyzing how operational optimization and routing calculation techniques may help a logistics operator to be more effective and efficient. Specifically, the case of a logistics company specialized in the automotive sector has been studied. It provides distribution services, mainly by road transport, for those companies that have the need for vehicle shipments to / from any point of the Iberian Peninsula as well as some strategic points in France and Germany. The planning necessary to carry out these services is currently performed by a team of technicians that make an optimization between service demand and available resources (fleet of trucks). On the basis of their experience, they decide what vehicles travel in each of the available trucks, in order to meet all requirements (specially delivering freight on time), objectives and/or restrictions that the business strategy. These technicians use an ERP platform that manages ordering, billing,... but does not implement any support for transportation planning.

The above mentioned procedure presents a series of drawbacks. Basically the search for optimal routes causes a delay in shipments, resulting in having to face penalties more often than desirable. The achievement of an optimized planning after evaluating all (or most) possible combinations of transport which satisfy the objectives and/or restrictions would be necessary.

When the dimension of the problem is large as in the present case, a person is not able to evaluate all possible combinations, unless he makes a thorough and detailed study for each transport mean, a fact that becomes functionally and economically impractical. A *Support System for Decision Making* (DSS: Decision Support Systems) is a software application that, using artificial intelligence algorithms, will provide the user with a better loads/routes planning. As a result, the technicians work would be more efficient and effective, and the objectives achieved to a greater extent.

The paper is organized as follows. In the remaining of this section a literature review is made to analyze different options for solving the addressed problem. In second section, the problem and current operational process is presented, emphasizing those aspects that should be improved for achieving greater efficiency work levels. Then, the proposed solution, the chosen heuristics techniques (GRASP methodology) and the developed Web application are described. In the fourth section, the solution is analyzed and compared with the current situation. The paper ends with a section summarizing the final conclusions of the work.

From the point of view of operational optimization, the problem tackled in this paper is a Vehicle Routing Problem (VRP), as first established Dantzig and Ramser [1], and

[1] *Análisis, desarrollo y evaluación de Sistemas Inteligentes de Transporte Intermodal*. Proyecto MFOM-08-E12/08 del *Subprograma para la Movilidad Sostenible y el Cambio Modal en el Transporte* del Ministerio de Fomento, Gobierno de España.

subsequently studied Bodin et al. [2], Magnanti [3] and Laporte and Nobert [4]. Under the VPR umbrella, there are a huge number of problem types to be dealt with . More specifically, our study was found to fit VRPTW (VRP with Time Windows) and MDVRP (Multi Depot VRP) types. The VRPTW type, as Savelsbergh [5] established, is used in problems where there is a time window for transport; in our case, there is a deadline for completing the delivery. In the MDVRP type, transport planning has to be performed taking into account several warehouses or depots, as explained by Kulkarni and Bhave [6]. Those are problems where the delivery is not usually centralized at a particular point. A delivery route starts from a given depot and when the truck service ends, a new route is started from a different depot.

The resolution of the above problem can be reached by using exact or approximate algorithms ([7], [8], [9] and [10]). There are interesting solutions for the "Local Search" and "Tabu Search" algorithms, especially the one proposed by Pisinger and Ropke [11] who established a framework by means of which it is possible to solve different VRP problems. On the other hand, the “two stage” algorithms use some kind of informed search and make an improvement on the heuristic based on making the resolution in two separate phases (see [12]). An interesting algorithm to be applied in this type of problems is the so called GRASP (Greedy Randomized Adaptive Search Procedure) introduced by Feo et al. [13], which combines techniques and concepts of other algorithms.

There is a large family of algorithms that involve collective intelligence or collaborative, "Evolutionary Algorithms", "Swarm Intelligence" and "Multi-Agent". Within the category of Evolutionary Algorithms, which try to simulate natural selection processes, the most prominent are genetic algorithms [14]. In recent years, swarm algorithms have blossomed, being analized by numerous researchers ([15], [16]). The basis of how these algorithms operate, is by imitating swarm systems behavior. Mainly, the most widely used in solving routing and VRP problems are based on Ant Colony. More recently, the Bees Algorithms (BA) has begun to be used in optimization problems [17]. Finally there are the so-called Multi-Agent Systems. This is a field with many possibilities in solving problems which must take into account different variables for decision-making and in problems where the information is taken from various sources [18].

2 Current System for building Route Planning

The current system for route/loads planning is based on the use of an ERP system for managing customers ordering as well as the transport to be made. Currently there is a lack of a system to carry out the transport planning or, at least, to assist the technician in this task. The software application used just only tracks orders and serves to support the other functions in company: accounting, administration, etc.., Thus, the technician should do the load/route planning relying on his experience.

When planning, the objective pursued is threefold: to maximize the load factor of trucks (the trucks are wanted to have the maximum occupation at the origin); to minimize the mileage (especially in trucks with little or no load at all) and to meet deadlines. With these three objectives in mind, the different operators perform the 9 planning over the 9 established Logistics Areas: 8 zones for Spain and Portugal, plus an additional area for international destinations. In these areas, there are 10 possible depots (origins) and 3,000 possible destinations (dealers, rent-a-car, etc.)

The company has a fleet of approximately 270 trucks, spread across the different areas. To carry out the transport planning, operators receive through the software application, information about the orders and the trucks available in their zone. The usual way of planning is to group the orders by destination and try to fill trucks to a single destination, having priority those orders whose expiration date is closer. Once the filling of trucks with orders for the most requested destinations have finished, a final check is made to assure there is not an urgent order that needs to be introduced because its deadline is very close or has expired. In that case, if possible, this order (vehicle) will replace an order planned before in a route that would be as close as possible to the new order delivery point.

When the operator fills a truck and confirms the route, he uploads the expedition orders to the system, which checks if the order is correct and produces the orders for loading the vehicles in the corresponding transport truck. The entire process is depicted in Figure 1.

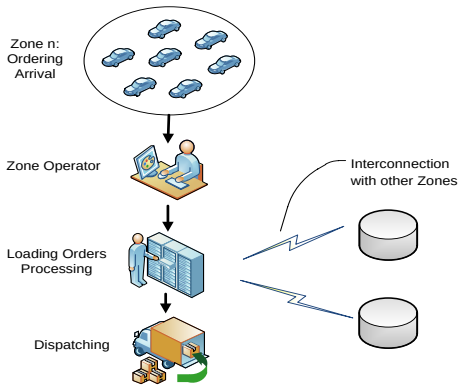

Figure 1. Current System.

It can be seen how, despite the fact that the aim is to achieve the objectives for planning (especially concerning the delivery of the vehicles on time), not all possible combinations of destinations are evaluated because the planning is done, primarily, configuring trucks to the most popular destinations. Those vehicles traveling to any

destination with little demand would be on hold until more orders for this destination arrive and have a critical mass to fill up a truck, or more orders arrive for a nearby destination in such a way that combining both a truck load could be completed. This strategy has the risk of not meeting delivery deadlines, causing uneconomic settings if, for example, is necessary to introduce a single vehicle on a route because it needs to be shipped for not exceeding the delivery deadline.

Since the work system cannot assess all possible combinations of loads, a system based on a heuristic algorithm would improve the solutions due to its higher capacity to do so. Among all these combinations could arise some cargo configurations that would better meet the objectives and/or avoiding having vehicles waiting for more orders to the same destination.

3 Planning System Proposed

The proposed model consists in a DSS (Decision Support System) that will support operators in their task of planning routes for the trucks that must deliver vehicles. A Web application in which the user (zone operator) is identified by its assigned logistics area was developed. Initially, the data of the problem to solve are uploaded (complete information of ordering and the trucks available in the zone). The algorithm parameters are adjusted and the optimizer will calculate a solution based on the evaluation and comparison of different possibilities by using the GRASP algorithm. The solution consists of a set of routes that meet the requirements of maximum truck utilization, fulfillment of vehicles delivery deadline, etc. The operator will analyze the proposed solution and will totally or partially validate it.

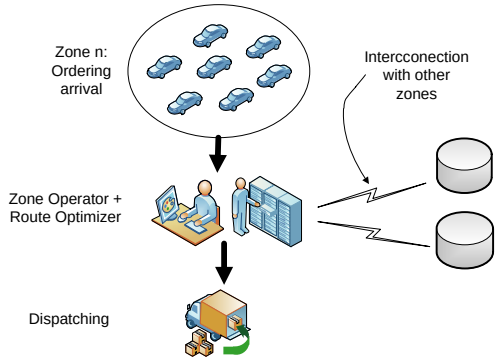

Figure 2. System Proposed.

The operational process (shown in Figure 2) is, generally speaking, based on configuring and running the algorithm. Once the result is obtained, it must be analyzed to be accepted as a valid solution (or a part of), and reconfigure any of the parameters to run the algorithm again and get new solutions.

Throughout the day, orders (vehicles to be transported to a specific destination) are continuously coming to the company software system. A zone operator performs a planning (load trucks configuration), twice during the day; a first one in the morning and another in the afternoon. In this way he manages the new orders that have arrived and those remaining from previous days.

When the operator starts the application, he identified himself as belonging to a specific logistic zone. Automatically, the information about the orders that have the origin among the operator's logistic zone will be uploaded on the application (all orders that have come to the system since the last time the planner was ran and those who have not been planned on previous uploads). These data include: vehicle identification, category, size, origin, destination, delivery deadline, priority level, etc. It also informs him about the available fleet trucks his logistic area to be used in planning.

Subsequently, the operator proceeds to assign values to the algorithm parameters according to the relative importance of the objectives to be met (immediate delivery of an order, minimizing the distance between potential destinations, maximizing the load factor, etc.)

Noteworthy that the application already has a pre-set parameters such as the maximum number of stops a truck can make on a route. This parameter is critical, because the loading and unloading of trucks represents a significant cost for the company. Therefore, it was considered that the maximum number of stops would be 4, being the first one the starting point where the truck is loaded.

Another parameter is the load factor of a truck, that is, the filling percentage of it, which depends on its capacity and the number and size of the vehicles carried. It has been established a minimum and maximum values (which could be changed by the operator in certain cases), which define the load factor which a truck should reach to be considered as valid.

Other parameters relate to the constant cost functions used, which give greater or lesser weight to the truck load factor, the distance between the possible stops, the total distance traveled by all routes forming the solution, the distance traveled without load, the urgency of delivery, etc. These values would be modified by the operator in each of the executions of the algorithm taking into account the requirements that should be prioritized at that time.

Once the settings have been configured, the execution of the algorithm will bring a solution that consists of a number of routes and loads that meet all specifications and constraints of the problem. The operator will analyze the solution, validating those loads that he considers acceptable, and will rerun the algorithm after making appropriate changes in the parameters for calculating other solution (set of routes). The process is repeated as many times as necessary until all orders were placed on acceptable routes or it runs out of available trucks.

In the latter case, there is the possibility of using trucks that are initially assigned to a close logistic zone and have not been used by the operator of its area.

The optimization algorithm can be run with or without what we call "pre-analysis". This consists of a preliminary examination of all orders looking for destinations that can fully load a truck. That is, if there is a destination with enough orders to fully fill a truck, priority will be given to the preparation of such orders. This type of route (which we called "obvious") will be almost certainly validated by the operator, thereby reducing the dimension of the problem and facilitating the subsequent optimization work of the algorithm. This execution mode has, as an advantage, to be similar to the working mode of the operator, but has the disadvantage of reducing the size of the problem and delete orders in the "pre-analysis"; due to this, the optimizer may not be able to reach an optimal solution since there are combinations of orders that cannot be considered because they contain orders as part of any of the "obvious" loads that have resulted from "pre-analysis".

3.1 Aplicación Software

This section describes the architecture involved in the previously described processes. Figure 3 briefly shows the internal functioning of the application. The following can be observed:

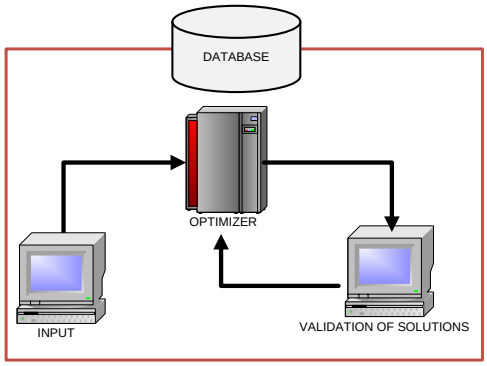

Figure 3. Application Architecture.

- The application input is the orders stored in the company database.
- When the area operator is identified, the application automatically loads the information related to orders and available trucks. This ensures that the orders and trucks stored in the application match those which are actually available in the logistic area when the operator runs the optimizer.
- The application database contains several master data such as a table of distances and the truck fleet. Master data can be created, viewed, edited, or deleted.
- After running the optimizer to find suitable solutions, the operator validates the loads and the correspondent routes. This information is provided to the company's computer system so that the delivery order is generated with the usual format.

Moreover, the application architecture follows the Model View Controller pattern, which defines the tasks to be carried out by the different modules (usually programs, libraries, …) Thus, any change in the specifications, can be programmed independently in the different modules without it affecting or interfering in the rest.

The aim is, therefore, to gain flexibility and agility, and operating with "open" standards and technologies. Figure 4 shows an outline of the application architecture: the architecture is common to J2EE-based web applications. Specifically, the implementation uses the Jboss SEAM Framework.

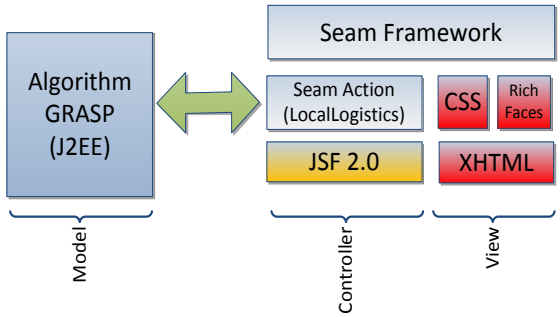

Figure 4. General architecture of the application.

3.2 GRASP

The optimizer key element is the GRASP algorithm. The metaheuristic algorithm GRASP (Greedy Randomized Adaptive Search Procedure), is a multi-start iterative process with two phases iterations: a construction phase, in which a feasible solution is built, and a local search phase, which starts from the built solution and improves it by examining its neighborhood, until it finds a local optimum. For each iteration, the best solution found so far is kept as a final result. The GRASP algorithm creates a list of candidates using a random factor in order to avoid the wrong selection of a local maximum on the base of what's called the "greedy approach". It is precisely this randomness that makes the GRASP algorithm an alternative of superior efficacy compared to many other heuristic algorithms.

Although GRASP features can be found also in other heuristic search methods, the practical implementation is different. This method has a great ability to obtain solutions for large combinational optimization problems, which suits the present case. Unlike other metaheuristic techniques, once the construction and local search strategies are defined, it is only necessary to adjust two parameters: the size of the list of candidates and the number of iterations to perform. Furthermore, this method also adapts easily to new

restrictions or conditions imposed by the problem. The GRASP algorithm consists of a continuous series of iterations, through which it attempts to select a good solution to the problem.

Compared to other popular metaheuristic techniques such as Tabu Search, Simulated Annealing and Genetic Algorithms, the GRASP procedure is fast and competitive, as it provides better quality solutions in less computational time ([19], [20]). This is mainly due to the fact that it combines the advantages of its random and greedy nature to build solutions.

Another major advantage of the GRASP algorithm compared to other metaheuristic methods is its ability to generate a large number of good quality alternative solutions. This feature is important in vehicle routing applications, because often the arrival times are estimates and thus may vary widely depending on unpredictable factors.

The elements that determine the GRASP technique are: the preprocessing method, the heuristic function, the way it builds the list of candidates, the post-processing method and the stopping criterion.

GRASP is an iterative technique of random sampling: the procedure is repeated a defined number of times in order to generate good solutions. The number of iterations "n" to be performed with the algorithm GRASP is to be determined before the execution of the main experiment, using a calibration process that implements the algorithm several times, each of them with a different "n" value, until it determines a value which provides good results in an acceptable time.

4 Analysis of the obtained results

As an example of implementing the system developed, we have chosen an operator working in a particular zone, in this case the Catalonia-Tarragona zone. This Operator must plan delivery routes for all orders which have the origin in his area (an average of 250 vehicles per day, most of them will have as origin the Tarragona depot), and as destination, any of over 3,000 possible destinations, using the trucks available in his area. The number of trucks is variable because it depends on the routes planned by other operators, ending in the Tarragona area of Catalonia (it can be estimated an average of 27 trucks per day).

As discussed in the previous section, it is possible to run the algorithm with "pre-analysis", where the algorithm "mimics" the way an operator proceed without the support of an optimizer software, that is, trying to fill trucks to serve the more demanded destinations and, therefore, be able to fill a truck without being added orders for other destinations.

This may not be quite optimal since those destinations with little demand, may experience delivery delays due to the fact that they are only planned when the delivery deadline is so close and a feasible route could not be found. That leads to deliver orders out of time, or in time but being included in a non-optimal route.

A classification of the routes/loads, based on the truck load factor, was made. It would be desirable that most of the vehicles were part of Optimal or Good Routes:

Table 1. Classification of Solutions.

	Nº of stops on the route	*Average Load Factor on the route*
Optimal Route	*1 ó 2*	*≥ 95 %*
Good Route	*≤ 4*	*≥ 80 %*
Acceptable Route	*≤ 4*	*≥ 70 %*
Bad Route	*≤ 4*	*< 70 %*

A comparison between the solution proposed by the operator without using the optimizer (using only their experience) and that achieved by the same operator but being supported by the optimizer, has been made. In it, the ratio between the Orders (vehicles) which are sent as part of each of the 4 types of route/load defined above and the total orders planned, has been measured.

Table 2. Comparison of the Orders Dispatched for each type.

	Operator Solution	*Operator + Optimizer*
Orders dispatched as "Optimal Route"	*75 %*	*73 %*
Orders dispatched as "Good Route"	*14 %*	*13 %*
Orders dispatched as "Acceptable Route"	*6 %*	*12 %*
Orders dispatched as "Bad Route"	*5 %*	*2 %*

As can be seen, in the first two categories (optimal and good routes), the operator solutions with and without optimizer are similar. But when the optimizer is used, more vehicles are introduced in acceptable routes, provoking that more vehicles are dispatched per day and deliveries out of time are reduced. These results can be seen from the figures shown in the table below (the data shown refer to average daily value):

Table 3. Comparison Orders and Deadline Fulfillment.

	Operator	*Operator + Optimizer*
Dispatched Vehicles/day	*63 %*	*85 %*

Trucks used/day	*67 %*	*80 %*
Average output time	*~3.2 days*	*~1.5 days*
Vehicles out of time	*18 %*	*5 %*

These results are mainly due to the fact that the operators (if not using the optimizer) try to plan trucks for the most demanded destinations, leaving on hold the orders of the less demanded destinations. As the deadline approaches, the operator must decide whether or not to maintain on hold the order, provoking a late delivery, or to place it in a truck that will make an "Acceptable" or even a "Bad" route.

In contrast, when the operator uses the optimizer, the algorithm tries to find combinations among all destinations to ensure that the maximum number of orders are sent in the best possible condition and trying not to exceed the deadline. Table 4 shows an example:

Table 4. Configuration of Routes/Loads.

	Route	*Nº of Vehicles*	*Load Factor*
TRUCK 1	*Tarragona – Bilbao*	*8*	*98 %*
TRUCK 2	*Tarragona - Valladolid*	*9*	*100 %*
TRUCK 3	*Tarragona – Madrid*	*8*	*98 %*
TRUCK 4	*Tarragona – Teruel*	*9*	*100 %*
	Teruel - Valencia	*8*	*90 %*
TRUCK 5	*Tarragona – Orense*	*8*	*98 %*
	Orense – Viana do Castelo	*6*	*74 %*
	Viana do Castelo - Porto	*3*	*37 %*

The table shows the solution proposed by the optimizer for a set of orders. Five routes with their assigned trucks have been configured.

The first 3 routes corresponding to the trucks 1, 2 and 3, would fit the category defined as "Optimal Route".

In the case of the route taken by the Truck 4, it would be a "Good Route". A single vehicle has to be delivered in Teruel. Therefore, the operator would hold it on waiting for more orders with the same destination; that would allow filling a truck. If no more orders appeared before the deadline, that vehicle would be introduced in some near route and delivered late with the corresponding penalty. However, the optimizer looks for the best possible routes, in which this order could be placed and delivered without delay. In this case, it has been introduced on a truck with destination Valencia, that initially was an "Optimal Route". The order for Teruel makes this route an only a "Good Route" but the order will be delivered on time instead.

In the case of the last route/load named as "Truck 5", it would be classified as "Acceptable Route" because it makes several stops and has a high load factor along the route. However, it is a valid solution because it allows to group orders by areas with low-demand destinations. In this particular case orders for the south of Galicia are grouped with those of the north of Portugal. As already mentioned, this solution is not the optimal from the point of view of the direct costs it implies. However it allows removing the praxis of paralyzing orders for less profitable destinations until more orders for those destinations would come up or either the deadline is about to fulfilled.

In summary, it could be established that the aim of improving the service efficiency by getting lower penalties for vehicle out-of-time deliveries is reached. From our point of view, this improvement, in spite of increasing the number of sub-optimal solutions (Acceptable Solutions), is offset by the reduction in penalties. Furthermore, trucks are earlier dispatched thus the percentage of non-operating time decreases and, the image of the company would benefit from an increase in the fulfillment of the fixed deadline.

5 Conclusions

In this paper the use of a DSS to aid in optimization tasks of filling trucks and route planning is presented. The current mode of planning leads to, in many cases and due to the priority of fill full trucks, delays in the dispatch of orders while the deadline is not exceeded. If this date is exceeded, the company will have to face penalties that contribute to reducing the economic performance of business operation. If delay penalties are not admissible, it may occur that certain deliveries must be sent in uneconomical routes because the truck load factor does not reaches the minimum acceptable.

The use of a DSS based on the GRASP methodology is proposed. It assists the operator in planning tasks, proposing solutions that meet all restrictions and achieve the stated objectives. Although the use of a heuristic algorithm as GRASP causes not to reach the optimal solution, it does reach a fair solution in a reasonable time by exploring multiple combinations that the operator itself would be unable to evaluate in a reasonable time. The solution proposed by the DSS, will be analyzed by the operator, who can fully or partially validate it. In the latter case, new executions of the algorithm allows to keep on improving the initial solution obtained until reaching a satisfactory solution that meets all requirements and restrictions posed.

A set of experiments from actual data provided by one of the leading Spanish transport companies have been made.

From their results, it can be concluded that the use of the developed application, clearly improves previous solutions in terms of percentage of vehicles dispatched per day, the average delay of orders, the minimization of out-of-time deliveries, and the general use of the transport trucks.

Abstract – *The aim of this paper is to develop a trading system based on Support Vector Machines (SVM) in order to use it in the S&P500 index. The data covers the period between 03/01/2000 and 30/12/2011. The inputs of the SVM are different forecasting algorithms: Relative Strength Index (RSI), Moving Average Convergence Divergence (MACD), Momentum, Bollinger Bands and the Chicago Board Options Exchange Volatility Index (VIX). A SVM Classifier has been used in order to develop the trading system with a weekly forecast. The output of the SVM is the decision making for investors. The trading system works better in bearish movement of the S&P500 than bullish movement of the S&P500.*

Keywords: Quantitative analysis, SVM, trading system.

1 Introduction

Trading systems are being extremely used in stock markets. Nowadays, there are a lot of Hedge Funds that are using artificial intelligence in order to forecast the stock markets and chose the best decision.

The aim of this study is to develop a trading system based on SVM. SVMs are being used in a lot of studies of researchers with very promising results. Technical trading algorithms are used in this article, such as RSI, MACD, Momentum and Bollinger Bands. It is also used the VIX. The VIX is really relevant in this study because has a negative correlation with S&P500 index and this circumstance makes better the results of the SVM.

The trading system helps investor in their decision making. The trading system output is the movement of the market (up or down) for the next week. The market trend is forecasted by the SVM algorithm.

The rest of the paper is structured as follows. In Section 2, the state of the art to Bollinger Bands, RSI, MACD, VIX and SVM is presented. Section 3 explains the kernel of the trading system. Section 4 shows the results of the trading system. Finally, Section 5 provides some concluding remarks.

2 The state of the art

The rules of the different algorithms are presented in this section.

2.1 Bollinger Bands

The Bollinger Bands were created by John Bollinger. A complete explanation of this algorithm can be seen in [1]. In the following lines, a brief explanation is shown.

As it is described in [2], Bollinger Bands consist of a set of three curves drawn in relation to securities prices. The middle band is a measure of the intermediate-term trend, usually a weighted moving average or a simple moving average, that serves as the base for the upper and lower bands. The interval between the upper and lower bands and the middle band is determined by volatility. Because the standard deviation is a measure of volatility, Bollinger Bands adjust themselves to the market conditions.

The stock price is overbought if it is situated at the upper band. The stock price is oversold if it is situated at the lower band. The Bollinger Bands definition is described below:

Middle Bollinger Band = SMA(20days) (1)

Upper Bollinger Band = SMA(20days) + SD(20days)*0.9974

Lower Bollinger Band = SMA(20days) - SD(20days)*0.9974

Where SMA is Simple Moving Average and SD is Standard Deviation.

2.2 RSI

The RSI is an oscillator that shows the strength or speed of the asset price by means of the comparison of the individual upward or downward movements of the consecutive closing prices.

It was designed by J. Welles Wilder Jr. [3]. A brief explanation of this indicator is shown below as it can be seen in [4]. If more details are needed it can be seen in J. Welles Wilder Jr. [3].

For each day, an upward change (U) or downward change (D) is calculated. "Down days" are characterised by the daily close being lower than the close of previous day.

U = closet - closet-1

D = 0

"Up days" are characterised by the daily close being higher than the close of previous day.

U = 0

D = closet - closet-1

$$RS = \frac{EMA[N]\_of\_U}{EMA[N]\_of\_D} \tag{2}$$

$$RSI = 100 - 100\frac{1}{1+RS}$$

where RSI_t is the Relative Strength Index at time t.

The 14-day RSI, a popular length of time utilized by traders, is also applied in this study. The RSI ranges from 0 to 100 however the range has been normalized between -1 and +1 in order to place it in the SVM.

2.3 MACD

The MACD is designed mainly to identify trend changes. As it is described in [4], it is constructed based on moving averages and is calculated by subtracting a longer exponential moving average (EMA) from a shorter EMA. The MACD is shown below:

$$MACD\ (n) = \sum_{i=1}^{n} EMA_k(i) - \sum_{i=1}^{n} EMA_d(i) \tag{3}$$

Where k=12 and d=26 [8]

$$EMA_n(i) = \alpha * p(i) + (1-\alpha) * EMA_n(i-1)$$

$$\alpha = \frac{2}{1+n}$$

Where n is number of days and p(i) is asset price on i^{th} day.

In this article, 12 and 26-day EMAs are selected, which are commonly used time spans in order to calculate MACD.

The range of MACD has been normalized between -1 and +1 in order to use it in the SVM.

2.4 Momentum

The Momentum is and indicator that measures the strength of the tendency of an index or a company, and it expresses the percentage variation of the price in a concrete period of time. As it is describes in [9], the Momentum is represented by a difference that is showed below:

$$M = C - C_n \tag{4}$$

where M is the Momentum, C is the last price quoted and C_n is the previous price quoted in n sessions which we take as a reference. This variable n is a number to be optimized in each title, but we take the value 12 as a reference because it is the standard. The Momentum study the speed of the movement of the price quotes related to the previous sessions and in most cases when the price quote is still upwards or downwards, the Momentum anticipates and turns, making the next change of tendency.

If the Momentum value is transferred to a chart, a line that oscillated around a neutral line (zero) will be obtained. A purchase order is generated by the Momentum if Momentum(n) is greater than 0 and Momentum(n-1) is less than or equal to 0. A sell order is generated by the Momentum if Momentum(n) is less than 0 and Momentum(n-1) is greater than or equal to 0.

2.5 VIX

CBOE Volatility Index (VIX) is a key measure of market expectations of near-term volatility based in the informational content of the SP&500 index option prices.

The VIX calculation method is an average of weighted prices of out-the-money puts and calls options on the S&P500 index.

Volatility index has several characteristics that make it interesting to use in order to forecast stock markets. It grows when uncertainty and risks increase. During falling markets, the VIX rises, reflecting increasing market fear. Volatility index reverts to the mean after high volatility situations and after low volatility situations such us interest rates. Rising markets usually the VIX goes down, reflecting a reduction of fear. So VIX is negatively correlated with stock or index level, and usually stays high after large downward moves in the market.

2.6 SVM

SVMs were originally developed by Vapnik [5]. SVMs are a specific learning algorithms characterized by the

capacity control of the decision function and the use of kernel functions [6]. It is very important the correct selection of the kernel function.

A brief explanation is described in [4].

The methods based on kernel functions suggest that instead of attaching to each element of the input domain represented by

$$\Phi : X \rightarrow F$$

a kernel function

$$K : X \times X \rightarrow R$$

is used to calculate the similarity of each pair of objects in the input set, an example is illustrated in Figure 1 [7].

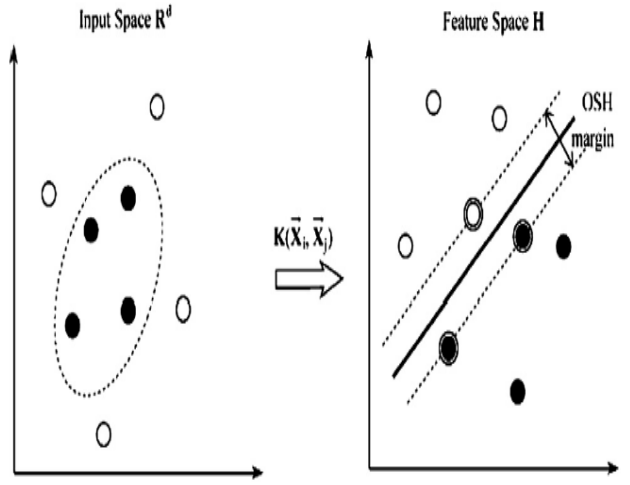

Fig. 1: An example of how a kernel function works

The biggest difference between SVMs and other more traditional methods of learning is that SVMs do not focus on an optimization protocol that makes few errors like other techniques. SVMs try to make forecasts in which the user can be very confident that the results will be correct, although it can have a lot of errors for a specific period.

Traditionally, most learning algorithms have focused on minimizing errors generated by the model. They are based on what is called the principle of Empirical Risk Minimization (ERM). The focus of SVM is different. It does not seek to reduce the empirical risk of making just a few mistakes, but pretends to build reliable models. This principle is called Structural Risk Minimization. The SVM searches a structural model that has little risk of making mistakes with future data.

The main idea of SVMs is to construct a hyperplane as the decision surface such that the margin of separation between positive and negative examples is maximized [8]; it is called the Optimum Separation Hyperplane (OSH), as shown in Figure 1.

3 Trading rule

The trading rule is created by the SVM. The inputs of the SVM are VIX, VIX-1, VIX-2, RSI, RSI-1, RSI-2, MACD, MACD-1, MACD-2, Middle Bollinger Band, Upper Bollinger Band, Lower Bollinger Band, Momentum, Momentum-1, Momentum-2 and the daily return.

The Heavy Tailed Radial Basis Function has been chosen as kernel of the SVM. The C parameter has been tested and the best value for the trading rule is 10. The SVM has been used in Classification way.

The training period has been designed with 249 days and the next day is tested by the SVM in order to know if the result is a good decision or not. The total of data for each experiment is 250 days, very similar to one business year. The trading strategy relies on a weekly prediction of the S&P 500 index price move. A weekly forecast was selected as the expected price move, up or down, over a week is more significant.

The only problem that has been detected is the situation when the SVM is being trained and it does not exit data to compare in order to make the decision to buy or sell. This situation happens for the last 5 days of the training period. In this way, the study is more real. In order to fix this, we compare the 5 days with a simple moving average of the 5 days.

The design of the trading rule is described below:

The SVM analyses the inputs classified in a purchase situation or a sell situation. After that, the SVM tries to separate the different prices of the S&P 500 in two classes knowing the inputs. The SVM uses the kernel function Heavy Tailed Radial Basis Function (HTRBF) in order to make the forecasting. The parameter C of the SVM is tested in several tests and its optimal value is 10. Finally, the SVM predicts the upward or downward movement for the following week and the intensity of that movement.

The outputs of the SVM are the up or down movements, expected for the following week of S&P 500, and its degree of set membership.

4 Results

The results of the trading rule appear in table 1.

As it can be seen in table 1, different indicators have been analysed.

Different ratios have been calculated in order to compare the two strategies.

Annualized return:

$$R^A = 250 * \frac{1}{n}\sum_{i=1}^{n} r_i \tag{6}$$

Standard deviation:

$$\sigma^A = \sqrt{250}\sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(r_i - \bar{r})^2} \tag{7}$$

Sharpe ratio:

$$SR = \frac{R^A}{\sigma^A} \tag{8}$$

Maximum Drawdown calculated in S&P 500 points:

$$MDD = \min_{t=1,\ldots,n}\left(F_t - \max_{t=1,\ldots,t}(F_t)\right) \tag{9}$$

where Ft is the accumulated fund with each different strategy.

Table 1. Yearly results of the trading rule (Boll) and Buy&Hold strategy.

	SP Points		R		σ		SR		MDD (Points)	
Year	Boll	BH	Boll	BH	Boll	BH	Boll	BH	Boll	BH
2000	**311**	-707	**0.043**	-0.104	**0.078**	0.092	**0.547**	-1.126	**720**	1129
2001	**92**	-844	**0.014**	-0.139	**0.074**	0.097	**0.190**	-1.434	**515**	1859
2002	**359**	-1344	**0.059**	-0.260	**0.070**	0.107	**0.855**	-2.427	**421**	1853

2006	690	**811**	0.102	**0.119**	**0.036**	0.040	2.831	**2.955**	**212**	412
2007	**438**	320	**0.060**	0.044	**0.053**	0.062	**1.128**	0.716	**364**	664
2008	**1431**	-3013	**0.181**	-0.544	**0.081**	0.148	**2.242**	-3.667	**312**	3300
2009	-103	**1218**	-0.022	**0.233**	**0.103**	0.110	-0.218	**2.118**	**843**	1159
2010	42	**669**	0.007	**0.110**	**0.070**	0.076	0.104	**1.450**	**421**	901
2011	**1470**	10	**0.206**	0.002	**0.079**	0.095	**2.600**	0.016	**529**	1139
00-05	**482**	-1026	**0.011**	-0.026	**0.052**	0.083	**0.209**	-0.310	**893**	3630
06-11	**3969**	15	**0.080**	0.000	**0.055**	0.094	**1.453**	0.004	**843**	4345
00-11	**4450**	-1011	**0.040**	-0.013	**0.050**	0.092	**0.804**	-0.139	**893**	4345

The bold numbers mean the trading rule that is better for each indicator. When the S&P 500 is bullish our trading rule beats the Buy&Hold strategy.

In figure 2, a chart of Buy&Hold strategy and our trading system is shown. The upper line is our trading system and the lower line is the Buy&Hold strategy. The x-axe shows the dates and the y-axe shows the accumulative S&P 500 points that have been achieved by each strategy.

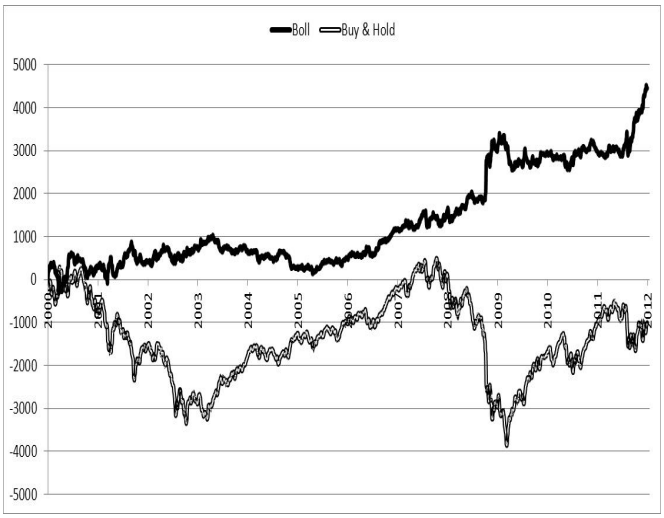

Fig. 2: The chart of the two strategies.

As it can be seen in figure 2, the best trading strategy is Boll which is our trading system.

5 Conclusions

The trading system works better in bearish movements of the S&P500 than bullish movements of the S&P500.

Vehicle Routing Optimization Using a Visual Web Model in a Logistical Application

Ara I.[1], **Lena F.**[1], **Alonso M.**[1], **De la Fuente D.**[2]
[1]Department Business Administration, University of Cantabria, Santander, Spain
[2]Department Business Administration, University of Oviedo, Oviedo, Spain

Abstract – *The search for flexibility in accessing logistics information is implemented in a Web solution to provide some agility to a distribution management problem. The aim is to provide the user of the information with a simple, attractive, graphic visualization in real time, making the logistics information readily available and easily accessible.*

The Web application manages the existence of different user roles with different permissions for accessing the application and also enables access through mobile devices and next generation technologies.

This solution is adopted to follow the criteria for access from any location that has an internet connection, regardless of the platform on which the application runs.

Keywords: Vehicule routing, web model, google maps, mobile devices.

1 Introduction

The distribution sector in Europe grew by 11.7% in the period 2005 to 2010, as indicated in the trading records according to the "Eurostat" balance of payments. A major challenge for companies in the management of the Supply Chain is to achieve "agility", that is to make the chain flexible enough to adapt quickly to changes in its environment.

The importance of the time variable as a competitive element in the supply chain has been recognized for many years [1]. The ability to meet the demands of the customers through ever shorter delivery times, and to ensure that supply can be synchronized to meet the peaks and valleys in demand, is critical today. The increased sensitivity to the needs of the market requires a faster response that goes hand in hand with a greater level of maneuverability, incorporating the concept of "agility".

Agility is the capacity of the company, taking in the organizational structures, information systems, logistics processes and in particular, ways of thinking. The web application discussed in this paper proposes a flexible and agile solution for distribution management in a logistics company.

2 System

In any software application, it is essential to define the objectives to be met, considering previously and in great detail the functions and features that the application requires.

This initial approach will take into account the definition of the methodology to be applied, the tools used, and, finally, the structure of the application developed.

2.1 Methodology

In order to develop a system, it is considered essential to control each stage through the use of an appropriate methodology to structure, plan and control each of these stages. In developing this application, a methodology based on the Rational Unified Process (RUP) was used [2].

This RUP is the standard methodology most widely used in analysis, implementation and documentation in systems like the one developed here.

The RUP approach is based on defining differential life cycles established in stages over series of cyclical iterations as shown in [Fig.1].

The different stages of the RUP methodology followed in the development of the system are described below [3]:

1. Business Modeling and Requirements: Specification both of the products to be obtained and the existing restrictions.

2. Analysis, Design and Implementation: Study of the causes of the possible threats and probable undesired events.

3. Test and Deployment: Implementation of the tasks of the activity itself and testing of these. Analysis of alternatives and risk identification.

4. Evaluation: Revision of work performed and decision-taking.

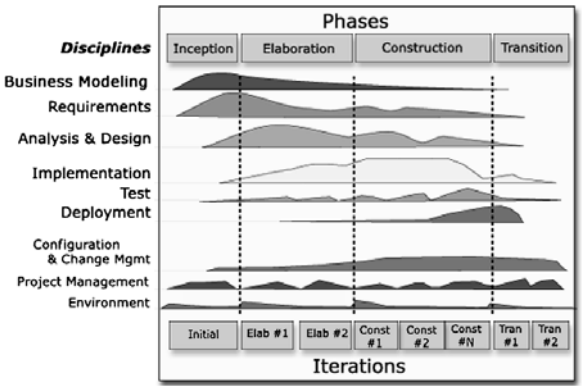

Fig. 1 Phases of RUP

2.2 Tools

As this is a web-based system, the tools chosen are the most widely used in this type of environments in their latest versions, so that many of the problems associated with their obsolescence have been eliminated:

- HTML5 (HyperText Markup Language): is the language in which websites are built. The current version HTML4 dates from 1999, meaning that the program code has not been reviewed for over 10 years. Solutions were provided, such as Flash for interactivity, but none of these were open source and compatible as HTML5. [4][5]

- CSS3 (Cascade Style Sheets): is the language used to shape the websites. CSS2 was tweaked in 2007 so designers have to do tricks to give websites the desired look, until CSS3 arrives. [6][7]

- Javascript: The programming language that allows the user to make changes to a website without having to reload each time he changes something. The code is reviewed regularly, with new versions of each browser released every month. Characterizing Insecure JavaScript Practices on the Web [8]

- PHP: Server-side language originally designed for web development to produce dynamic web pages. It is always embedded into an HTML source document. [9]

- MySQL: Most used relational database management system that runs as a server providing multi-user access to a number of databases. It runs under the terms of the GNU General Public License. [10][11]

- Google Maps: Web mapping service that powers many map-based services. The API is a free service which has the possibility to embed maps in HTML. [12]

2.3 Structure

The typical structure of a web-based technology application is defined by three differentiated layers [Fig.2]:

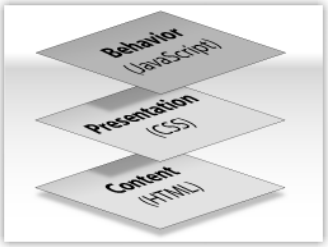

Fig. 2 Structure of a web

1. Content: The content or structure layer is what users will see when they come to the web application. Content can consist of text or images and includes the pointers that readers need to navigate around the application.

2. Presentation or Style: The style or presentation layer is how the document will look to users. This layer is defined by the CSS or styles that indicate how the document should be displayed and in what media types.

3. Behaviour: The behavior layer is the layer of a Web application that helps user interaction. In our case, as jQuery and PHP are used, it is JavaScript and PHP that make the page take actions when user clicks.

3 Web model application

The next step required after defining the system structure is the design and development of the application [13] which is divided into several levels of definition depending on the stage of development: User roles, functions and adaptation to mobile terminals.

3.1 User roles

The application is based on the implementation of a system of access with different users [14]. It was considered appropriate, after analyzing and evaluating the requirements of the user, to establish four types of access:

- Administrator: Actor with responsibility for administering the system in its entirety. Receives all the privileges of access and manipulation within the application and is considered a user with the knowledge and skills needed to manage the application.

- Transport Coordinator: Actor who controls and manages the transport fleets, with access to medium-level functions that do not require any knowledge or skills for their management, without jeopardizing the integrity of the system. This is, then, a user with certain limited privileges.

- Car Sales Manager: Has limited access to the information about his order. Will not have access to the rest of the application and, therefore, will also be a limited user so as not to be able to jeopardize the integrity of the application, being limited to consulting and handling the information that affects his area.

- Client: Actor with fewer privileges among the set of users [Fig.3]. His options will be limited to consulting data on the vehicles assigned to him.

3.2 Functions

After defining in detail the set of users and their roles, it is necessary now to define the functions available in the application.

- Index: The beginning of the application contains a brief explanation of the whole project.

- How it works: Explaining the different steps of the application.

- Upload a file: Data upload is the first step in the application. The entire process is automatic, from choosing the file to transferring it to a database. It includes the double conversion: from Excel to HTML format and from HTML to SQL format.

- Show data: Two ways to view the data: directly from the uploaded file or by querying the database from the application.

- View fleet: The data represented graphically. The first page shows the fleet with all available transport. By clicking on a truck, we access its properties. The vehicle page itself has three tabs: first the routes with full details, second the cars it carries and the final tab with full details of the transport.

- Manage Users: Section for managing the different user roles. It only shows the information according to the user that is currently viewing the page, so that everything is secure and private.

Having defined above the user roles, the access privileges are as follows [Fig.3]:

	index	How	Upload	Data	Fleet	Car	Users
Admin	T	T	T	T	T	T	T
Transport	T	F	F	T	T	T	F
Manager	T	F	F	T*	T*	T	T*
Client	T	F	F	F	T*	T	F

Fig. 3 Table of permits

T (True): The user can access to the section

F (False): The user cannot access the section.

T* (True*): The user can access to the section, but with limitations. e.g. Only its transport.

The permits are basic requirements of access to the application, an example of classes with UML. [15]

3.3 Adaptation to mobile terminals

Given the widespread and increasing use of mobile devices with broadband connection and smartphones, it was considered worthwhile developing the application with the versatility required for its use from this type of devices, adapting both the design and content for maximum operability [Fig.4]. Thanks to the appropriate selection of the technologies used and the advanced development of these, the application has been optimally adapted without too much difficulty.

Fig. 4 Application in terminals iOs and Android

The system detects on time and automatically any user accessing the application through the use of a mobile terminal and redirects him to an environment optimized for this type of devices, much lighter and less demanding on bandwidth, generating a new interface adapted to the size of the terminal screen.

The adaptation of developments to this type of terminals is a real challenge that is becoming a trend nowadays thanks to the large and ever-increasing number of users that these devices now have [16].

Optimization was performed for two types of mobile terminal operating systems:

- Apple iOs: Terminals supported: Apple iPod Touch, Apple iPad, Apple iPhone EDGE, 3G, 3GS, 4, 4S for versions iOs 4.0 and onwards.

- Google Android: Terminals from version 2.2 Froyo up to 4.0 Ice Cream Sandwich.

4 Google Maps

the content, is View Fleet. This section includes a geolocalization both of the departure point and of the arrival point of the transport and all the stops to be made during the journey.

The Google API (Application Programing Interface) is based on the direct implementation of the Travelling Salesman algorithm (Travelling Salesman Problem) [17] [18] which, roughly, is described as a Branch-and-cut algorithm [19] [20].

In this case, the implementation is developed for the study of the shortest path as a reference to the optimum transfer between two locations using the shortest distance traveled [21][22].

The section is divided into three parts

The first represents the visual route by means of a map showing the different points where the various stops will be made [Fig.5]:

Fig. 5 Visual route by means of map

The second represents the summary of the routes followed by the transport. The figure below shows a lorry covering two routes with a stop in the middle of them [Fig.6]:

Fig. 6 Summary of routes

Finally, element indicates, using points, the directions to be followed to reach the different destinations of the transport [Fig.7]:

Fig. 7 Directions using points

5 Conclusions

A flexible solution for providing access to information logistics, incorporating agility in the distribution management has been proposed for supply chain management.

The proposed solution takes the form of a Web application that incorporates a diversity of Open Source tools with the aim of providing the different users with interactive and visual access to the distribution information of interest to them. The application implements a system of access to information through the necessary security controls, which allows access from any geographic location with an Internet connection and from any platform recognized by the application.

Virtual Agent Oriented to e-Learning Processes

Celia G. Róspide[1], **Cristina Puente**[1]
[1] Advanced Technical Faculty of Engineering – ICAI, Comillas Pontifical University, Madrid, Spain

Abstract –*In this paper we explore the benefits that a virtual agent could provide to an e-Learning platform. The system uses Natural Language techniques as a basis, which makes it capable of elaborating a flexible answer according to the student requirements. The Software procedures to perform these task are also introduced s.*

Keywords: Virtual agent, Flexible answer, e-Learning.

1 Introduction

The arrival of a new educational model, with less theoretical lessons and more work on the student side, has in many cases caused extra work when solving problems via email or through other means.

To alleviate this problem, in this paper we present a virtual agent oriented towards educational environments. The purpose of this is to solve as many questions as possible, emulating the possible answers that a real professor could give. To do so, we have developed an architecture divided into modules in which the original query is analysed in order to understand the requirements of the student to return a suitable answer.

The construction of a chatbot able to emulate a flexible conversation is highly complex. Nowadays, the so called virtual robot has not been developed in its totality, and the 'perfect chatbot'still does not exist. For this reason, there are several enterprises with good reputations in the computer market, like IBM, working on these types of projects to improve their performance [1].

The idea of a virtual agent to answer questions is not new. An intelligent virtual agent is an entity capable of perceiving its environment and processing those perceptions in a rational way [2]. To be considered as AI systems, they have to fulfil the following characteristics [3]:

- Learn new problems and improve the range of solutions.
- Real time adaptation.
- Analysis of a situation in terms of behaviour, evaluating the possibilities of success and failure.
- Evolve through interaction with the environment.
- Manage great amounts of data in order to choose the best solution.

One of the greatest problems in the implementation of a virtual agent is the design of its 'personality', as it has to be original and intelligent. However, the behavior of an agent many times is not what is expected, especially when there are many restrictions or when the problem is not defined precisely.

Among the diversity of virtual agents, we can find the group of Intelligent Tutoring Systems (ITS). These type of agents were created in the eighties with the idea of sharing knowledge using an intelligent way to guide the student in their learning process. So a intelligent tutor can be defined as [4] " *a software system which employs AI techniques to represent knowledge, and interacts with the students to transfer it*" or as [5] "*systems to model teaching, learning, communication and knowledge domain of the specialist and the understanding of the student in that domain*".

Recent research is focused on finding an alternative to a human tutor. However, most of the tutoring systems do not acquire the expected level of rationality due to the difficulty involved with modelling human behavior, beyond the application of the most advanced programming techniques.

Taking these premises as a basis, the proposed chatbot is an ITS, which serves as support in the learning process of a student in a given subject. The system is composed of a hardware and software architecture which is explained in the following sections, as well as the interaction among the software modules that make understanding possible and the composition of a flexible answer. Finally, we will conclude with some guidelines for future work as well as some conclusions about the proposed work.

2 Bot Architecture

The platform used to develop this educational bot was a web environment. The hardware used was typical client-server architecture, where the client is a browser like Mozilla or

Explorer, and the server is an Apache with some other additions like a lexical analyzer.

The software is composed of several modules written in different programming languages (like Php, Javascript, C, Lex), which interact among themselves to understand the user's question and propose a suitable answer. The software model proposed to carry out this task is a Model-View-Controller, where the model interacts with a MySQL database to extract information, the View part is the interface, written in HTML5 plus Javascript, and the Model contains the interaction with the lexical analyzer plus the specific modules written in Php. In a graphic form, figure 1 represents the interaction of all these components:

.

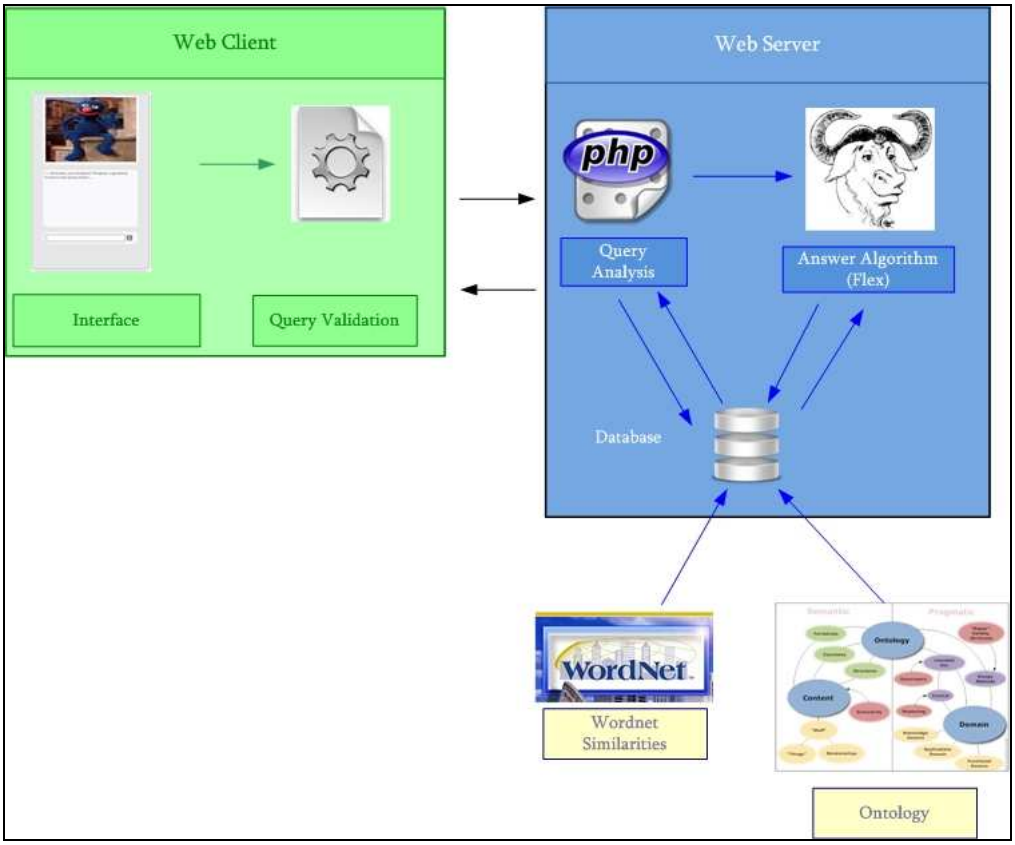

Fig. 1 Software and Hardware architecture of the bot

As seen in figure 1, the client part is composed of two parts, the interface, and another algorithm to validate the question. The interface is composed of those graphical elements which serve as input and output for information, and has three elements, an image which varies according to the answer, a text area where the dialog between user and the machine is displayed, and an input textbox where the user must write his query.

The algorithm used to validate a question was programmed using AJAX, and is in charge of sending the query to the server and waiting for an answer to be added at the end of the text area.

The web server is divided in three main parts, the query analysis module, the answer algorithm, programmed using the lexical analyzer FLEX[1], and a terminology database built through an ontology (hand-made), with the terms used in each part of the subject and the platform Wordnet Similarities[2] [6].

3 Query Analysis Module

The query analysis module is the one in charge of providing a suitable answer, and is composed of other four sub-modules: bad words, welcome, general information and complex answer (in fig. 1 represented as answer algorithm).

[1] http://www.gnu.org.
[2] wn-similarity.sourceforge.net/.

When a question is posed, the first thing to be done is to dispatch it to the appropriate module. In this way, the first module that evaluates the query is the bad words' one.

This algorithm detects if there are any bad words within the input received. If so, the user will be warned up to a maximum of three times, after which they will be expelled. To do so, we have implemented a procedure that checks the query words against a database table with a complete list of these words. The result is as seen in figure 2, where the user proposes three questions with some of these words mixed in:

Fig. 2 Example of bad words output (grey text)

If there are no bad words in the query, the input query will access the welcome module. This algorithm notices if the user is being nice or polite to it, separating the technical query (if one exists) from the welcoming greeting. In this case the answer will be a composition of answers. As in the previous case, the number of times that the user says hello to the bot is controlled, in order to focus the conversation. If the user repeats a greeting message many times, the system will encourage him to ask more specific questions, without being expelled in this case, as seen in the following figure:

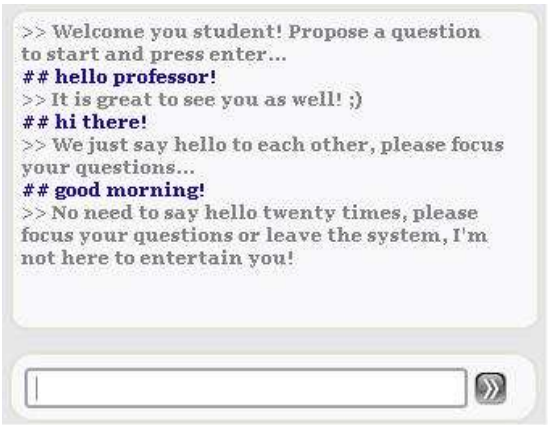

Fig. 3 Example of welcoming output (grey text)

One of the more frequent uses of a chatbot is to answer FAQs. We have included a set (through the database) of questions related to the subject such as the day of the exam, the hour, class, name of the professors and contact information, and many other useful pieces of information.

This third module, is entirely written in Php, and by matching the query keywords against those stored in the database is able to answer a wide range of questions proposed in a different way. This algorithm also evaluates the question pronouns, like how, what, when, etc., for instance, if the user begins his question with 'when', the system will know that he is asking for time. Added to the textual answer, in some cases the system has additional stored information, like schedules, etc. so this information will be displayed along with the answer in a new window:

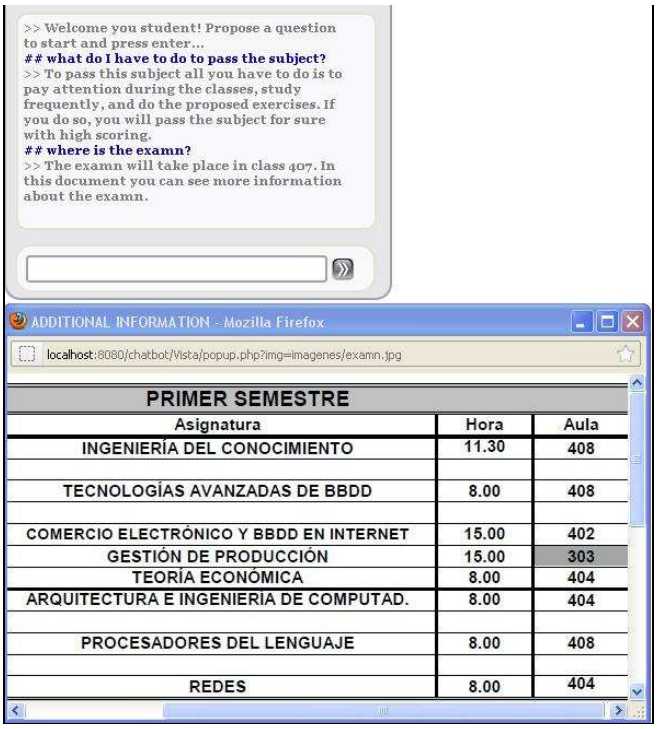

Fig. 4 Example of general information output

If the query is more specific and related to the subject's lessons, then it will be processed by a lexical analyzer, composed of an automaton which will process the input through a set of states.

4 Query Analysis Module

The query analysis algorithm was developed using the morphological analyzer FLEX plus the C programming language. This program is able to detect and locate certain lexical patterns within a text by means of an automaton.

For our specific purpose, this automaton is composed of six states which will be able to recognize:

- Concepts related to the studied subject
- Terms and keywords specifying what the user wants to know about those concepts (like definitions, how it works, and so on).
- Interrogative pronouns.
- Words and expressions commonly used to quit the system or say goodbye.
- Words and expressions used to express gratitude.
- Clauses used to lead the conversation in a friendly way.

The automaton created in FLEX has a [Pattern]-[Action] structure, so if the automaton detects any of the defined patterns, the associated action, written in C code, will be dispatched.

The defined states control the structure of the input query, so in the first place an interrogative pronoun should appear, followed by a word or set of words which will determine what the user wants to know specifically about a concept related with the subject, followed by a concept related with the subject. The query "*What is a token?*" follows this structure, but not all queries have to, for example "*How does a lexical analyzer work?*" where the concept related to the subject is not at the end of the query. To take these problems into account, we have created six states which control the possible structures of a query.

In order to ascertain the answer to the proposed question, we have classified the types of questions on the basis of their type and priority:

- Low priority: those not related with the subject's contents.
- High priority: those containing keywords or relevant patterns.
- Guiding questions: when there is not a clear answer to the proposed question, the system will answer back with another question to check if the prediction was correct. Otherwise it will encourage the student to propose the question in a different way.

This way, if the input is correct, the algorithm will recognize the type of question and a set of keywords, and will look up the related information in the database .

The database algorithm will compare the type of question first, and with the possible results will match the input keywords with those contained in each record. The 'priority' of the matches will be taken ; so many times a record that has two keywords with high priority matched will be selected instead of another with three keywords with lower priority. To do so, we have used a scoring system. The record that after the matching obtains the highest number of points is selected and its answer displayed. If this record has addition information associated, it will be displayed as well, as in the following example, where the user asks "What is a token?" and the bot gives him the definition along with the slide that contains more information related:

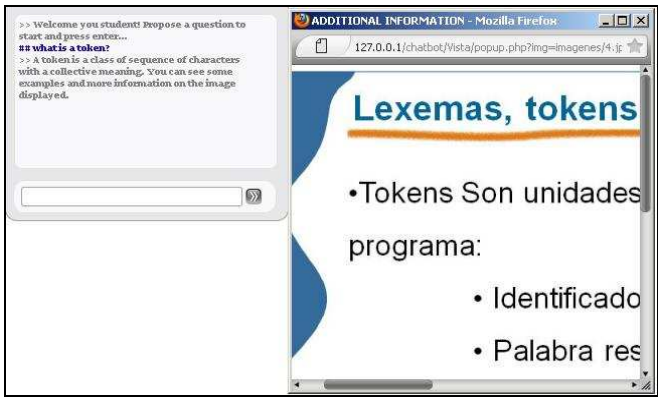

Fig. 5 Example of general information output

Many times the users are not specific with their questions, so the system will try to guess what they mean to say. The prediction algorithm is in charge of this part. The function of this process is to add flexibility and realism to the communication. So we have implemented the following considerations:

- Create the illusion of listening by introducing substrings of the input query in the answer.
- Admit its ignorance about certain issues.
- Control the date (if it is close to the exam date) to offer review exercises, for example, or make comments about how late it is, or say "*Good night*" when leaving the system.
- Redirect the conversation when the user asks for questions which have little or nothing to do with the subject.

- Introduce friendly substring in the answer like "*friend*", "*colleague*", "*dude*", etc.

- Calculate the length of the conversation, and if it is too short, encourage him to solve more problems.

Here is an example of conversation using the prediction module:

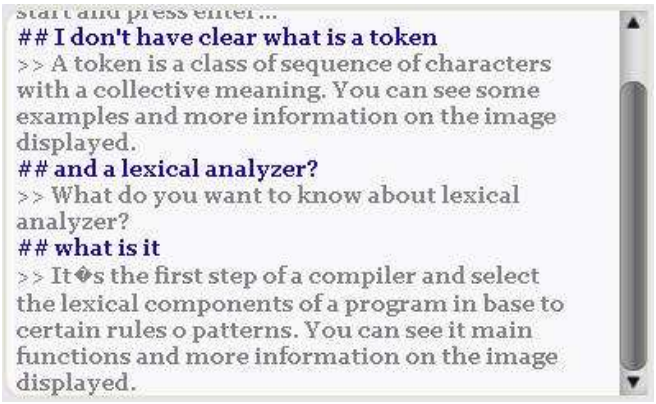

Fig. 6 Example of the prediction module

5 Conclusions

This work has introduced a prototype of an intelligent virtual agent able to answer questions related to an academic subject. Using typical client-server architecture and several modules to analyze questions and answers, the system is able to dispatch, in the majority of cases, a suitable answer for the proposed question.

There are some lines that could be improved upon in future work, like proposing exercises to the student based upon their scores, or creating a specific study plan for every student to be controlled through the bot.

6 Acknoledgements

Abstract— *This paper shows how some fuzzy logic techniques applied to a recommender engine can be used in a Electronic Medical Records Repository. A Fuzzy Linguistic model based on three dimensions: intrinsic, contextual, personal is proposed. The contextual and personal dimensions are modeled using domain ontologies and a automatically built fuzzy ontology, respectively. The experiment results indicate that the presented approach is useful and warrants further research in recommending and retrieval information.*

Keywords: Recommender Systems, Fuzzy Ontology, healthcare Information Management, Fuzzy Logic

1. Introduction

Nowadays, new ways of managing and accessing to health care information are continuously appearing. Electronical Medical Records (EMRs) have the potential to make data about health care available to clinicians, researchers and students in different medical contexts and applications. Hundreds of Medical Records are stored and interchanged in Medical Records Repositories. One of the biggest challenges faced by healthcare systems is the growth of information accessible, i.e. the amount of information accessible has grown enormously and as a result health care professionals are currently burdened with more and more data, which unfortunately has not always the adequate levels of quality, making that their work cannot always be as successful as expected. A way of alleviating this situation consists in limiting somehow the number of Medical Records in a repository that are displayed for users. This can be done by means of filtering or recommendation techniques being capable to be adapted to different requirements for each one of the users. Therefore, the need of an efficient and reliable recommendation process is critical in order to provide a more personalized and tailored knowledge to clinicians, researchers and students..

In this paper, we propose the integration of the analysis of different dimensions in a recommendation system. This recommendation engine could be a useful tool to support Health Information Management in a Health Information and Management Systems, in order to improve information filtering and retrieval, as well as their classification. The analyzed dimensions in this proposal are the following: intrinsic (is the EMR complete or accurate?), contextual (is the EMR adequate according to the user context?) and personal (is the EMR adequate according to the user preferences?)

The intrinsic dimension is modeled using measures as completeness and timeliness; the contextual dimension is modeled using a domain ontology, for example, Medical Subject Headings (MeSH) [1] and the personal dimension is modeled by a fuzzy ontology automatically built from the EMR's provided or selected by the user [1]. Within this context, and taking advantage of Fuzzy Logic [2], we addressed the definition, implementation and validation of a process to construct the recommendation system. The main purpose of this work is to provide a method to describe the recommendation process as well as a linguistic model, i.e., we can only describe the whole recommendation system by using natural language.

The remainder of the work is structured as follows: Section 2 describes the background contents of this paper, i.e, recommendation systems and fuzzy ontologies. Section 3 describes the recommendation model and how the user profiles are built. In Section 4 the experiments that have been conducted to validate our proposal are explained and analyzed, and in Section 5 some conclusions and future works are pointed out.

2. Background

This section presents some concepts related to this research and proposed process. It starts describing recommendation systems, their general characteristics and their applications. Then, we discuss how the fuzzy ontologies can be used to represent user's preferences and some works about this topic.

2.1 Recommender Systems

According to [3], recommender systems are defined as systems that produce individualized recommendations as output, or have the effect of guiding the user in a personalized way to interesting or useful objects in a large space of possible options. [4] enumerate the main characteristics of recommender systems: 1) Can be applied to unstructured data and semi-structured (for example, Web documents or e-mail messages); 2) Based on user profiles, rather than

[1]http://www.geneontology.org/

users expressing their needs through consultation; 3) Manage large amounts of information; 4) Works primarily with information in text mode; 5) Its goal is to eliminate irrelevant information from the input stream. Recommendation systems share similar tasks with information filters such as removing redundant or unwanted information and reducing overload.

In recent years, there are several studies about the applications of the recommender systems in healthcare environments, for example, in [5] a recommendation system is presented with the aim of making health events accessible in personalized way. The proposed system uses a set of "signal definitions", i.e., a predefined structured queries with parameters related to kinds of health threats the users' interest's. The systems provides ratings according to this "signal definitions" to give recommendations. The method to compare the queries and the documets is very straight forward (tf-idf representations and cosine similarity measure) but its results are satisfactory.

On the other hand, there are some proposal that include fuzzy logic in recommendation techniques. For example, Chao et al. [8], propose a recommendation mechanism focused on teachers in a content management system. The main components of these systems are: data pre-processing, association rule mining, associative classification, sequential pattern mining and fuzzy sets. In [6] propose a recommender system multi-granular fuzzy linguistic approach, where the solution alternatives are the digital resources stored into the library, and the criteria to satisfy in the user profiles. This recommender system, allows users to provide preferences on some research resources and from this information are calculate their respective preference vectors on topics of interest. The user profile is completed with user preferences on the collaboration possibilities with other users, with the objective of creating academic communities.

2.2 Ontologies and User Preferences

Ontologies have proved to be successful in handling a machine-processable information representation. They can take the simple form of a taxonomy (i.e., knowledge encoded in a minimal hierarchical structure) or as a vocabulary with standardized machine-interpretable terminology supplemented with natural language definitions. Furthermore, ontology-based user profiles are being widely applied in context representation and application customization so that they meet user requirements.

FCOU [7] is a fuzzy clustering method of ontology-based user profiles construction. The method employs fuzzy clustering techniques combined with optimization techniques and an augmented Lagrangian function to create a fuzzy clustering model for the construction of user profiles. The method allows some information to belong to several user profiles simultaneously with different degrees of accuracy, and makes it possible for a user profile to be represented by one or more ontologies.

In [8], the authors propose an approach that uses locally stored desktop documents to extract terms that will be used in query expansion for web search. Three possible techniques have been investigated. The first one proposes summarizing the entire desktop using term clustering methods. The second technique issues the original web user query on the desktop and extracts expansion keywords from the most significant sentences within the Top-30 documents selected by a scoring function. Similarly, the third technique suggests selecting query expansion keywords from the most dispersive lexical compounds within the Top-30 documents returned to the user's initial web query. Some experiments have also been performed to compare the proposed method with a regular Google web search.

Another approach to represent user preferences is by a domain ontology. This domain user preferences are called "user context" in this work. Lau et al [9] present a text mining methodology for the automatic discovery of fuzzy domain ontology from a collection of on line messages posted to blogs, emails, chat rooms, web pages, and so on. The collection of messages is treated as a textual corpus. The method consists of a document parsing (stop word removal, part-of-speech tagging, and entity tagging and stemming), concept extraction (pattern filtering, text windowing, and mutual information computation), dimensionality reduction (concept pruning and term space reduction), fuzzy relation extraction (computing fuzzy relation membership) and fuzzy taxonomy extraction (taxonomy generation and taxonomy pruning).

On the other hand, [10] show how a fuzzy ontology-based approach can improve semantic documents retrieval. The proposal is illustrated using an information retrieval algorithm based on an object-fuzzy concept network.

3. Fuzzy-Based Recommender System Approach

In this section we present a new fuzzy recommender system based on a matching process developed between user preferences and the EMR representation. For this purpose, we take into account the following parameters that can be assessed in the system: the intrinsic quality of the EMR, the compatibility between the EMR and the user context and the EMR and user preferences.

This system is applied to advise EMR repository users on the best EMR's that could satisfy their information needs. This recommender system also improves the services that a EMR repository provides to users, because it is easier to obtain the knowledge about users and it allows to decrease the time cost to establish the user preferences.

The model is based on a recommendation degree used to deliver the information resources to the fitting users (Eq. 1).

$$\Psi = \sqrt{\Upsilon\left(a, k, c, t\right)} \otimes \left(\chi \oplus \Phi\right) \quad (1)$$

where Ψ represent the recommendation degree, Υ represents the intrinsic quality degree of the EMR based on the calculation of completeness c, reliability r and timeliness t, χ represents the contextual compatibility between the new EMR and the user context, and Φ represents the compatibility between the user preferences (represented by an ontology automatically built) and the EMR. The square root is used as the linguistic hedge "more or less" according to the explained in [11] about the decision criteria results. $\otimes$ denotes the fuzzy conjunction operator (t-norm). The product as t-norm allows us to obtain the best results on the empirical experiments carried out in this work. $\oplus$ denotes a fuzzy disjunction operator (t-conorm). The use of the algebraic sum as t-conorm allows us to obtain better results than applying classical functions on the empirical experiments carried out in this work.

Only those EMR's which have a recommendation degree, calculated according to the defined model, higher than a pre-established threshold are taken into account ($\Psi \geq \gamma$). This threshold (γ) is pre-established by the user as a part of the configuration process.

The model can be shown as a linguistic model, i.e., we can only describe the whole recommendation system by using natural language, for example, the model can be described as follows: "If the document has more or less quality AND is relevant to the user then it will be processed". The linguistic hedge, the fuzzy operators, the fuzzy rules and the considered intrinsic quality criterion dimensions can be changed to build an efficient recommendation system in any domain context. Each component of this approach is explained in the following subsection.

3.1 Intrinsic Quality

In order to determine if a EMR is useful enough for a user, data contained in it must be analyzed to check if it reaches an adequate level of quality according to certain parameters. Taking into account that the "fitness for use" depends on the task and role of the users who handle both EMR's and their sources, it is necessary to identify a set of dimensions that better represents quality requirements from user requirements specification. Intrinsic Dimensions denote that information has quality in its own right. These dimensions are independent of the userŠs context. They are capturing whether information correctly represents the real world and whether information is logically consistent in itself [12]

For making operative our proposal, three dimensions of a data quality (DQ) model for assessing data of new EMR's have been chosen in order to improve the performance of the proposed recommender system. These dimensions are the following:

- *Accuracy* (a): is the degree of correctness and precision with which information in an information system represents states of the real world [12].
- *Consistency* (k): implies that two or more values do not conflict with each other [13].
- *Completeness* (c): is the degree to which information is not missing [14], i.e. every item of a document is fulfilled and has information
- *Timeliness* (t): is the degree to which information is up-to-date, i. e. received information is adequate for the temporal context in which its topic is set [15].

Whole dimensions are calculated according to the specification shown in [16]. In order to get a summarized measure for a document we must take into account that the perception of quality is both subjective and inaccurate, and consequently it would be appropriate to use a fuzzy operator to measure/determine/assess DQ properly. In this work a Mamdani-style fuzzy system has been employed [17]. Linguistic labels and a set of rules were defined and optimized by a panel of experts. $\Upsilon\left(a, k, c, t\right)$ is a value obtained after a defuzzification process.

3.2 Contextual Compatibility

The Contextual Relevance (χ) of a EMR and a user is computed by using the compatibility between the EMR contents and the ontological definition of the user area of interests. This contextual representation based on ontologies is extracted from the definitions stored in domain ontologies, for example, MeSH [2], UMLS [3]

The degree of representativeness of each keyword is computed using different measures of similarity existing for this thesauri, for example, WordNetSimilarity [18] , UMLSSimilarity [19]. For example, some keywords that define the context "Pulmonary Medicine" in healthcare context using UMLS and UMLSSimilarity are shown in Table 1.

Table 1: Excerpt of "Pulmonary Medicine" Context Definition

Word	Degree
respiratory, lung	1.00
trachea, bronchial	0.50
bronchitis, pneumothorax, chest	0.25
thoracolumbar, abdominal	0.10

In this case the context and the EMR could be considered as fuzzy sets because they consist of words that have a membership degree. Therefore, the compatibility between context and document could be computed by using the generalized Jaccard coefficient as used in [20].

[2]http://www.nlm.nih.gov/pubs/factsheets/mesh.html
[3]http://www.nlm.nih.gov/research/umls/

3.3 Personal Compatibility

In this work, the user preferences will be represented as a fuzzy ontology automatically obtained from a set of EMR's previously selected by the user. A fuzzy ontology, in this context, may be considered as a set of directed graphs where each node represents an item and the edges denote that a term "is related with" other term. The proposal includes several stages of data processing, which were divided into five steps: linguistic pre-processing, term indexing (called pre-ontology), user relevant terms extraction, user ontology generation and user profile update as can be seen in [1]. In this fuzzy ontology, a relatedness degree (RD) is associated with each edge to represent the strength of the "is related with" association. In this way, the relatedness degree (RD) between two terms t_i and t_j is defined as (Eq. 2).

$$RD\left(t_i, t_j\right) = \frac{\sum_{o \in O} f - occur\left(t_i, o\right) \otimes f - occur\left(t_j, o\right)}{\sum_{o \in O} f - occur\left(t_i, o\right)} \tag{2}$$

where o is a EMR, O is the set of EMR's selected from the LOR by the user, $f - occur$ is the function of the relative frequency of a term in a EMR and $\otimes$ denotes a fuzzy conjunction operator.

The compatibility degree between the EMR and the user profile Φ assesses if the interests of the user are expressed in the EMR. The value 0 indicates that users preferences are totally different of the EMR content, i.e., the ontology extracted from the EMR and the user ontology represent different concepts, not necessarily contrary; whereas the value 1 indicates that the EMR contents are included in the users' preferences.

The EMR's ontology is built using a modification of the RD equation, where s is a section (or paragraph according to the kind of document) of the EMR δ (Eq. 3):

$$RD\left(t_i, t_j\right) = \frac{\sum_{s \in \delta} f - occur\left(t_i, s\right) \otimes f - occur\left(t_j, s\right)}{\sum_{s \in \delta} \widehat{f - occur}\left(t_i, s\right)} \tag{3}$$

The process to compute this value consists of the comparison between two ontologies. The comparison method is inspired by a set of ontology similarity measures proposed by [21]. In this case, the vector model is used to represent each concept in the ontology. Let v^i be the corresponding vector that represents a concept c_i, int v^i_j, the value in the position j, will be the RD degree between c_i and c_j when c_j belongs to the set of possible concepts that define a user profile, i.e., $v^i_j = RD(c_i, c_j)$. The detailed procedure is illustrated in Alg. 1, where $jaccard(v_1, v_2)$ represents the jaccard similarity function between two vectors.

Algorithm 1 Compatibility Degree Algorithm

```
O are the ontology corresponding to the new EMR
U are the ontology corresponding to the user
|O| and |U| are the size of each ontology
for c ∈ U do
  if c ∈ O then
    v_O = vector that represents the concept c in the ontology O
    v_U = vector that represents the concept c in the ontology U
    SC = jaccard( v_O, v_U)
  end if
  β = AVERAGE(SC) {β represents the similarity of common concepts}
end for
Φ = (|O ∩ C| ⊗ β) /min (|O|, |U|) {⊗ is a t-norm}
```

4. Experiment

An experiment was carried out to evaluate the performance of the proposed recommender system. In this section, the experiment, the performance measures used and the obtained results are described.

4.1 Experiment Description

The study group was shaped by 10 users from a healthcare organization. Most of them had experience in e-health technology as a researcher or as a physician. Each user has selected one of the following areas: traumatology (TRA), oftalmology (OFT), otolaryngology (OTO), surgery (SUR) and urology (URO). These areas and their ontological representation based on MeSH are the base for the user context definition. On the other hand, each user has selected 11 Medical Records as relevant in the Healthcare Information System. Once the selection process was finished, the user context and user preferences ontological definition were created for each participant, applying the methodology and algorithms described previously.

4.2 Experiment Results

In order to evaluate the feasibility of our approach, we compared the recommendations made by the system and the preferences for each new user of each new EMR. The contingency table (Table 2) used for this purpose is similar as the explained by [22] and by [6].

Table 2: Contingency Table

	Selected	Not Selected	Total
Relevant	Nrs	Nrn	Nr
Irrelevant	Nis	Nin	Ni
Total	Ns	Nn	N

Precision, recall and F-measure are measures useful to evaluate the quality of the recommendations [23] . Here, precision measures the probability of a selected item being

relevant, recall represents the probability of a relevant items being selected and F-measure is the harmonic mean between precision and recall (Equations 4, 5, 6).

$$P = \frac{N_{rs}}{N_s} \tag{4}$$

$$R = \frac{N_{rs}}{N_r} \tag{5}$$

$$F = \frac{(2 * R * P)}{(R + P)} \tag{6}$$

We considered a test data set with 100 EMR's of different areas. The system filtered these EMR's and recommends them to the suitable users. Then, we compared the recommendations provided by the systems with the recommendations provided by the users. After this comparison the corresponding precision, recall and F-measure are obtained. The results of this process are shown in Table 3 (the values are in the range [0,1]).

Table 3: Results.

User	Precision	Recall	F-measure
TRA	0.98	0.81	0.89
OFT	0.95	0.91	0.93
OTO	0.94	0.89	0.91
SUR	0.86	0.91	0.88
URO	0.92	0.85	0.88

The average of precision, recall and F-measure are 0.93, 0.87% and 0.90%, respectively. These values reveal a good performance of the proposed system if compared with those obtained by using non-ontological approaches (0.70, 0.61 y 0.65, respectively). We have achieved a substantial improvement in precision and recall values, which means that the proposed system is flexible enough to provide good recommendations using our approach.

5. Conclusions and Future Work

In this paper, a recommendation method based on the fuzzy representation of user preferences was proposed. This approach has been applied to provide recommendations about new Medical Records that could be interesting for a user. This is an efficient solution to minimize the problem of access relevant information in Medical Records Repositories. The proposal combines the analysis of intrinsic and conceptual features for making decisions about recommendation. User preferences are represented by domain ontologies for user context and automatically built fuzzy ontologies. This combination allows us to make recommendations based on a richer description of the user preferences.

An experiment has been carried out in order to determine if the recommended EMR's are useful and interesting for the users. Experimental results show that the proposed system is reasonably effective in terms of precision and recall.

Further research is directed towards the task of improving the user profile quality considering the information provided by the user as feedback, and the application of some techniques of collaborative filtering. Moreover, more detailed evaluation experiments also will be necessary.

Suré: A tool for pattern identification and sentiment detection in microtexts

Carlos Zuniga-Solis, Jose A. Olivas
SMILE Research Group, University of Castilla-La Mancha, Ciudad Real, Castilla-La Mancha, Spain

Abstract – *Knowledge exchange and opinion sharing over the Internet has reached levels never experienced before. People from different regions and socio-cultural backgrounds now have the possibility to create as much web content as they wish. This data represents a massive source of information useful to understand many aspects of society. Through sentiment analysis it is possible to leverage this highly topical data to identify people's perception of a certain topic. Different approaches have been implemented in order to detect sentiment in microtexts using mainly lexical ontologies and classification models. In this work, a tool designed for sentiment detection in microtexts named Suré is presented. This tool leverages inductive learning in order to find differentiating patterns in opinions about a given topic. Using the identified patterns Suré creates decision trees to classify microtexts as supportive or unsupportive towards the analyzed topic.*

Keywords: Induction, Microtexts, Sentiment Analysis.

1 Introduction

The advancement in web technologies over the last decade has allowed users to generate as much content on internet as they wish. This has led to knowledge exchange and opinion sharing at levels never experienced before, and the social networks have been crucial facilitators of this process.

The ease with which people can create social network messages is one of the key success factors of these web sites. According to Twitter Blog, in June of 2011, Twitter users sent 200 million tweets per day, enough text to fill a 10 million-page book every day. Through these 140 characters long, unstructured and conversational toned writings, 100 million users express what they are doing, what they are thinking and how they are feeling.

By reading a person's tweets, it is possible to understand many things about her. Therefore, studying the data of hundreds of thousands of tweets might help to develop a better understanding of our society at large. A powerful technique to leverage this huge amount of data is sentiment analysis.

Sentiment analysis is the task of identifying positive and negative opinions, emotions, and evaluations [1]. Through sentiment analysis of tweets, researchers have found that Americans seem considerably happier on Sunday morning than Thursday evening, and that West Coast American residents might be happier than their East Coast counterpart[2].

Different approaches converge in the search for the optimal sentiment detection technique. A very straightforward method is to use sets of terms with positive and negative connotations, to classify the sentiment of the words forming a message. However, the explosion of the web 2.0 and a larger internet coverage, have allowed people worldwide, to express their opinion about any topic. In this scenario, positive or negative meaning of a word becomes relative to the region or sociocultural context of a debate or a conversation. For this reason it might be more suitable to use an approach that learns from the contextual relationships of words, instead of their linguistic relationships. This could be accomplished through inductive learning, leveraging its capabilities to discover distinguishing patterns, and thus indetifying recurrent concepts in positive or negative messages in any context.

In this work a tool for sentiment detection in microtexts is presented. The developed tool named Suré leverages inductive learning and decision trees to classify microtexts as supportive or unsupportive towards a given topic. A test case using real life data is also presented showing promising results.

2 State of the art

After the release of Twitter developer platform in 2006, researchers obtained instant access to what might be the largest dataset in history, with lots of new highly topical messages available every second. This provided a great opportunity to analyze thousands of points of views and to find useful information for many different fields using specialized software for sentiment detection.

Twitter developer platform consists of a set of APIs that allow developers to integrate their custom applications with this social network. One of these APIs, the Search API is particularly useful for data extraction tasks since it allows to query for tweets from a custom application, thus it is possible

to obtain and store thousands of tweets about a certain topic within a given date range in a matter of seconds.

The increasing number of studies about sentiment analysis, published since the release of Twitter developer platform, and the growing number of countries developing researches about this topic, may be good indicators of the facilities given by this platform.

The ease with which messages on social networks can be created has been one of the key factors for the success of the most popular social network web sites. A message on a social network falls under the category of Microtext. Microtexts are very short individual contributions, often consisting of a single sentence that can be as short as a single word. They are further characterized by using an informal and unstructured grammar. These messages have a conversational tone, usually including colloquial expressions. Usually these messages are not edited before being sent, which makes them error prone [3].

These characteristics of the microtexts allow inexperienced users to quickly become creators of content. Nevertheless, these characteristics also make microtexts particularly hard to analyze for sentiment detection. Extracting sentiment information out of a sentence consisting of just a few words is not an easy task.

For these reason researchers have implemented different methodological approaches in order to obtain the best results out of the available data. Lexical ontologies and classification models highlight as the preferred techniques.

As a result of a literature review of studies related to sentiment detection in microtexts, 24 studies were found. Implementations of classification models were found in 14 of the reviewed works, lexical ontologies were found in 7 studies and the remaining 3 works used third party software or other techniques.

According to the literature review performed, when classification models were implemented, the use of Naive Bayes classifiers and SVM method were predominant. To a lesser extent, Bag of words and K-nearest neighbor classification model were used. On the other hand, in those cases about sentiment detection using lexical ontologies, a strong tendency towards the use of lexical English database WordNet® and derivates of this, such as WordNet-Affect or SentiWordNet was found.

The reason why classification models seem to be more popular between sentiment detection researchers is their capacity to leverage the context information, without depending on it. The same classification model could be used for sentiment detection in different languages. On the other hand, lexical ontologies are domain dependent, and require a significant effort to generate lists of words for each domain [4].

To avoid the burden of creating a lexical ontology for every domain universe a simple approach was identified. In several studies a generic ontology such as WordNet was used. However, this method is not always suitable, since the meaning of many terms and expression is often context dependent.

The importance of the context where a term is used becomes clear when a variety of practical applications found in the reviewed literature is analyzed. As suggested by many studies, sentiment detection in social network messages could be a useful tool to quickly identify or even to anticipate situations affecting, positively or negatively, a certain group of the people. Flu outbreaks, radicalization of opinions, and popularity loss of a touristic place are some of the examples found. As can be seen, the variety of the topics addressed might generate accuracy problems if a generic lexical ontology is used.

3 Architecture and Methodology

In order to classify microtexts as supportive or unsupportive towards a given topic leveraging the context of the information, the sentiment detection software Suré[1] was created. Suré consists of two modules: Microtext extraction and Text analysis.

3.1 Microtext extraction

The module for data extraction allows extracting microtexts from 5 sources: The digital versions of Spanish newspapers El País, El Mundo and ABC, Twitter and Facebook.

To obtain microtexts from the digital version of El País, El Mundo and ABC newspapers, a custom process was built to obtain the comments out of a web article.

To recover microtexts from Twitter, an interface was built on top of Twitter's Search API, allowing querying for Twitter content, in the same way a user would search for tweets using this social network search engine. Once the search is done, the tweets found can be stored for later analysis. Whilst Twitter's Search API allows retrieving thousands of tweets in a matter of seconds, a very important limitation must be considered: Twitter's index includes only the last 6 - 9 days of tweets.

[1] Suré is a Bribri word that means "fishing arrow", however for the native Costa Rican tribe Bribris, arrows are capable of creating cracks through which light and thinking may pass through.

To obtain microtexts from Facebook, Suré leverages the Facebook's Graph API[2]. This interface grants access to different objects of this social network, and allows navigating through the relationships of these objects.

For microtext extraction from Facebook Suré offers an interface to access comments on posts on public pages. This API grants access to the social network's different objects and to the relationships between them. The user must introduce the URL of a Facebook public page and a date range to search for its posts. Once the search is finished, Suré shows to the user the posts found, their creation date, and the number of comments received. The last step is to select one of the retrieved posts, and its comments will be extracted and stored for later analysis.

3.2 Text analysis

The text analysis capabilities offered by Suré are designed to be used after a dataset about a certain topic has been obtained through the Microtext extraction module.

The Text analysis module allows using the retrieved microtexts as a training set or as an evaluation set. The evaluation set is used for automatic sentiment detection supported by a training set previously created.

In order to create a training set, Suré allows experts to classify the microtexts by its sentiment as positive, negative, neutral or noise. The noise category should be used on those cases where a message does not offer any point of view strictly related to the subject matter addressed.

Once the microtexts have been classified, they receive a linguistic pre-processing and then the resulting data is stored in a text index. The pre-processing consists of the following tasks:

- Tokenization
- Punctuation removal
- Lowercasing
- Stopwords removal
- Stemming

Once the training set has been pre-processed and indexed, Suré permits users knowing the term-frequency distribution of the classified microtexts, filtered by the sentiment given by the expert.

Suré also has the ability to find recurring groups of terms in the positive and negative training sets. This functionality allows finding differentiating patterns between positive and negative microtexts of a certain subject. This function has been implemented following the rules of the First Order Inductive Learner algorithm [5] in order to obtain exclusive patterns for positive and negative comments. It is worth noticing that, rarely used words are not useful to find representative patterns, for this reason, Suré ignores words that appear in less than the 20% of microtexts forming the positive or negative training set. To find and remove these words Suré internally uses its term-frequency functionality.

When searching for differentiating term patterns, it is necessary to choose the number of terms included in the patterns to find. This permits to identify the patterns with the widest coverage throughout the training sets.

After a training set has been stored in a text index, it is possible to perform automatic sentiment detection on evaluation sets by creating decision trees based on the differentiating term patterns of the training set. This process is performed by Suré through implementations of the ID3 and CART algorithms. To create the ID3 or CART decision tree the user must choose the number of terms that make up the patterns to find. For this reason, it is recommended to perform prior tests on the training set using Suré's pattern identification functionality, in order to determine the appropriate number of terms to cover the maximum amount of microtexts possible.

The set of terms of the patterns found will be used later to create the nodes of the decision trees. For this reason, Suré offers the possibility to specify a minimal number of occurrences for the patterns to use. Doing this allows to prune the tree before it is created. The following step is to decide whether to use an ID3 or a CART algorithm to create the decision tree.

For the ID3 algorithm, the terms of the patterns found will be the nodes of the tree, the possible values for every term will be whether or not the term is present in a given microtext, in other words true or false. For the CART algorithm the nodes of the tree will be a condition composed of a term and one of its possible values in a microtext: true or false. Given the nature of the CART algorithm, every node will have two children, one for those cases where the condition is met, and another one for those cases where the condition is not met. The leafs on the ID3 and CART trees will be sentiment classifiers 'positive' and 'negative'. Because of the characteristics of the methodology used in Suré, both algorithms produce binary trees. Once the decision tree has been created, the user will be able to use it for sentiment detection on individual examples.

[2] https://developers.facebook.com/docs/reference/api/

4 Practical case

In order to test Suré's sentiment detection accuracy a relevant topic to Spanish society was selected: The conviction of former Spanish judge Baltasar Garzon Real.

The reason to choose this topic was that the generated views about it on social networks were so opposing that it would be very easy for a slightly informed person to tell if a comment supports or rejects Garzon's convitcion.

Nevertheless, despite of the ease with which a person could detect the sentiment in the related microtexts, the automatic classification of messages as supportive or rejective faces significant challenges. This trivial case illustrates the complexities of Artificial Intelligence and Natural Language processing.

The first step was to find articles related to Garzon's conviction in the digital version of Spanish newspapers El Mundo and El Pais. These two daily newspapers were selected because of the opposite political tendencies of its frequent readers. Once the articles were chosen, a total of 9760 comments were retrieved by Suré, 2780 from El Mundo and 6980 from El Pais. Subsequently, 4000 of the retrieved comments were classified by an expert, 2000 from El Pais, and 2000 from El Mundo. For mere classification purposes, those comments supporting Garzon's conviction were categorized as positive and those rejecting it as negative. A total of 963 comments were classified as positive and 675 as negative, the remaining 2362 were marked as noise. The positive and negative microtexts received linguistic pre-processing and were stored in an index text as the training set for this test case.

Following the linguistic pre-processing of microtexts an interesting problem related to the context of this particular case of analysis emerged. Both Spanish terms "derecho" and "derecha" stems to "derech". Nevertheless, in the microtexts retrieved, "derecho" was frequently used as a part of expressions such as: "estado de derecho" (rule of law) and "derecho de defensa" (right of defense), very common expression in opinions in favor of the Garzon's convition. On the other hand, the term "derecha" referred to right-wing politics, a very usual reference in the microtexts rejecting the above mentioned judgement. In this case, the stemming truncates the contextual value of the term. This problem might be subsequently solved leveraging synonyms and multi-term expressions in the linguistic pre-processing stage.

The next step was to identify the best differentiating patterns in order to determine the optimal parameters to specify later on when the decision trees were created. It was determined that only those terms with a frequency equal or greater than the 20% of the total of microtexts in the training set will be taken into account for pattern identification. Thus, thousands of seldom used terms were removed, improving system performance and result quality.

Very few patterns consisting of 5 and 4 terms were found. Besides, those patterns covered only a minimal percentage of the microtexts of the dataset. On the other hand, an important amount of 3 words patterns emerged, enough to cover the entire dataset if put together. Table 1 shows a sample of the most frequently found patterns.

Table 1. Frequently found patterns sample

Pattern	Occurrences	Sentiment
[garzon, juez, ley]	53	Positive
[derech, juez, ley]	38	Positive
[españ, gazon, juez]	31	Negative
[garzon, juez, pais]	28	Negative

Because of the differentiating capabilities of the patterns, and given that 3 words patterns offered great dataset coverage, it was decided to use these patterns for the later creation of the decision trees.

In order to test the sentiment detection capabilities of the presented approach, the 4000 microtexts classified by an expert were used as the training set to create ID3 and CART decision trees. Subsequently, a set of 186 comments from articles related to Garzon's sentence from the digital version of Spanish newspaper ABC was retrieved. Only comments expressing positive or negative opinions were taken into account.

Of the 186 retrieved comments, an expert classified 130 as positive and 56 as negative. Subsequently, these 186 comments were automatically classified by Suré and compared to the results given by the expert to determine Suré's accuracy. Table 2 shows the results of the comparison.

Table 2. Automatic classification accuracy

Method	Accurate positive	Accurate negative	Average accuracy
CART	107	37	77.4%
ID3	105	38	76.8%

As the results show, none of the classification methods is considerably more accurate than the other. It is also worth mentioning that both methods do better classifying the positive examples than negatives. By analyzing the negative patterns found, a large number of different sets, but with a low average number of occurrences can be seen. This evidences a trend to use a richer variety of terms used in negative microtexts than that in the positives for this particular topic, which might make negative sentiment harder to spot.

5 Conclusions and open issues

This works presents a tool for pattern identification and sentiment detection in microtexts based on inductive learning and classification trees. The tool named Suré is still a prototype; however is it capable of leveraging the vast amount of available data to extract information from context instead of using linguistic relationships. Suré has only been tested with the data previously discussed, shortly it will be tested using different data sources such as Twitter and analyzing new topics. Moreover, adding new functionality such as multi-term expression detection and synonym pre-processing will probably improve the accuracy of the results, which for this first test may be considered good.

A Grammatical-Error Tolerant Parser

W. Faris and K.H. Cheng
Computer Science Department, University of Houston, Houston, Texas, USA

Abstract – *The proper application of usage rules are required to construct grammatically correct sentences. For most speakers, the likelihood of writing a grammatically incorrect sentence is quite high. However, for most sentences that may have violated some grammatical rules, their correct intentions may still be inferred intuitively. Consequently when communicating with humans using a natural language, a computer program should not reject but tolerate such sentences. In this paper, we define a grammatical rule as a syntax-restriction rule if the intention of the sentence may still be intuitively inferred even when the rule is violated. In addition, we define a sentence as semantically sufficient if it is free of grammatical errors or only syntax-restriction rules are violated. If only syntax-restriction rules are violated, we have modified our parsing program to accept and interpret, instead of rejecting, the given sentence.*

Keywords: Natural Language Processing, Grammatical Error, Tolerance, Parser, Context-Based, Semantic Interpretation

1 Introduction

It is desirable for an artificial intelligence program to communicate with humans using a natural language, specifically, English. However, in today's world, many people may not be communicating in their own native language. Since the grammar of a natural language is normally complex and has many rules, many individuals may not know all the rules. Even when they do, they may not always follow them. As a result, it is unlikely that they will consistently communicate perfectly in their non-native language, and it would be unreasonable to expect correct sentences all the time. When presented with a grammatically incorrect sentence, an individual could ignore the mistake and still intuitively infer the correct meaning of the sentence. Similarly, in order to communicate effectively with humans, a computer program should be prepared to tolerate grammatically incorrect sentences as long as the most probable conveyed idea may be understood. Otherwise, it would reject sentences excessively. This attitude can also be seen in systems such as chatbots and Question/Answering expert systems to reduce the frustration of the users. They are designed to extract pertinent information from a sentence by mapping keywords to built-in functionality [1]. However, this approach is not adequate to handle normal communication since it is limited to a small number of functionalities.

We define a sentence to be semantically sufficient when the correct intent of the sentence may be determined intuitively even when syntactical errors are present. By intuitively, we mean that the interpretation is most likely the actual intention of the speaker. To give the flexibility to handle semantically sufficient sentences but still detect grammatical inconsistencies, we define a new category of rules: syntax-restriction. These rules reflect the correct syntax and morphology, but are not absolutely necessary in interpreting sentences. One characteristic for rules in this category is that it matches a property of an item with that of another, such as agreement rules. As a result, the criteria for syntax-restriction rules are that the same information can be obtained from at least two items in the given sentence, and the information obtained from one item is normally considered more reliable over the other when they are in conflict. Consequently, using the information obtained from the more reliable item, the inferred semantic interpretation is most likely the correct intention. For example, one aspect of the subject-verb agreement rule matches the number properties of the subject and the verb. Since the subject is the focal point of a sentence, it is considered much more reliable than the verb. Therefore, when there is a mismatch, understanding the sentence using the number property of the subject rather than the verb is most likely correct. A mismatch in subject-verb agreement is an example of a context-based grammatical error, in which a word differs from what is expected, based on surrounding words. In this paper, we discuss how to use this new category of rules to detect context-based errors and generate a warning, instead of rejecting the sentence as illegal. A warning is information that when displayed will notify the person communicating with the program about the grammatical error. In addition, we will illustrate how such rules can be used to resolve an ambiguous term, but still be used to generate warnings when the involved term is not ambiguous.

The objective of a context-based grammar checker is to help people write grammatically correct sentences by notifying them if a mistake is made, and ideally with an explanation of the error, so that they may correct the error. Context-based checkers can be found in applications such as word processors and machine translators. There are three

predominant models of a grammar checker [2]: syntax based, statistics based, and rule based. Syntax based checkers use parse trees to identify incorrect sentences, and unless they implement some form of rules as was done in CRITIQUE [3], they cannot identify the exact type of error. CLAWS [4], is an example of a statistics based part-of-speech (*pos*) tagger that uses the frequency of a sentence structure within a corpus to determine the validity of the sentence. Those that do not meet a defined threshold are assumed to contain errors. However, this technique is not capable of identifying the types of errors, thus leaving the individual uninformed on the reasons why the sentence is invalid. In [5], a grammar checker for a machine translator is used to automatically correct what it determines to be errors. A bottom-up parser creates chunks of related terms and phrases. The probability of a chunk is then compared to that of a corpus. For invalid sentences, Markov chains are used to determine missing or incorrect chunks that can be applied to produce a valid sentence. Regardless of which statistical model is used, the precision and recall rates depend on the size of the corpus and the threshold value, and a combination may not exist to detect all errors and to correctly identify all valid sentences. Arguments are provided in [6] to support why a rule based approach is necessary for identifying the types of grammatical errors. It proposes to use meta-rules, replacing regular grammar rules that fail, to re-parse the given sentence. Although our approach also uses rules to detect errors, these rules are normal grammar rules of the natural language. They are applied during parsing, and only one run of the parser is needed.

Recently, we have implemented a parser in a learning program system (ALPS) [7] to parse English sentences using a grammar that is acquired incrementally [8]. Subsequently, solutions have been developed to understand declarative sentences [9, 10], including identifying the correct knowledge referenced by various forms of pronouns [11]. We have also developed an algorithm to generate a sentence that reflects the contents of a logical thought using a transformation of the acquired grammar [12]. Five major components were introduced to define how a grammar term (or *pos*) is used in the language: structure, kind, role, control and rule. The structure of a grammar term defines exactly the grammatical format of the term, which may be either a sequence or an alternative. A term may have multiple kinds, which are subsets that may share the same structure but must have different roles. The role of a grammar term defines its purpose, and the intention of the role is implied by the presence of the term within a sentence. The idea of the control is to notify the parser which role within the term is responsible for organizing the various knowledge objects identified in the parsing process. A rule specifies a condition [13] satisfied by either the grammar term or its structure. They are used to either guide the parser towards the correct grammar structure or restrict certain terms from being accepted. The use of rules in a grammar enhances its scope while maintaining a manageable size. In this paper, we discuss how to use a new category of rules to detect and tolerate grammatical errors, so that a warning may be generated rather than outright rejecting the given sentence as invalid.

The rest of the paper is organized as follows. Section 2 describes briefly the original categories of grammatical rules in [8] and how they are used in parsing. It also introduces syntax-restriction rules, a new category of rules allowing the parser to handle grammatically incorrect but semantically sufficient sentences. Section 3 explains how to construct a syntax-restriction rule to be used by our program, and then presents how to check five grammatical requirements: punctuation usage, subject-predicate agreement, subject-verb agreement, verb phrase usage, and number agreement. It also presents the reasoning on why each rule can be a syntax-restriction rule, and why a certain component is more reliable in determining the semantic intention of the given sentence. Section 4 presents an example on using a syntax-restriction rule to disambiguate a term that could be used as multiple *pos*. Finally, Section 5 concludes the paper and discusses some situations when the context within the sentence is insufficient to correct grammatical mistakes.

2 Grammatical Rules

Rules have already been used in defining part of a grammar and applied when parsing a sentence. A rule is classified as one of four categories, each with a specific purpose during the parsing process. The four categories are defined by two independent dimensions: the first determines what the rule is for, and the second defines whether it is a restriction or a choice rule. A rule can be for the grammar term itself or its kind (role). A restriction rule is a necessary condition that needs to be satisfied, and a choice rule specifies a sufficient condition to make a choice when the condition is satisfied. The resulting four combinations of rules are kind-restriction, term-restriction, kind-choice, and term-choice. A kind-restriction rule specifies a necessary condition that the kind must satisfy. For example, the kind-restriction rule for a decision question states that its complete subject must not be fulfilled by an interrogative pronoun. An input sentence such as "Is how a human?" follows the sequence structure of a decision question (verb, subject, predicate), but it is rejected as invalid because this restriction rule is violated. A term-restriction rule defines the necessary condition that a grammar term must satisfy. For instance, in the structure of a noun phrase, the term-restriction rule requires that the noun cannot be fulfilled by a pronoun when an article or constant is present. This prevents 'a he' or '3 you' to be a legitimate noun phrase. A kind-choice rule defines the sufficient condition to decide the kind of the grammar term. If the condition is satisfied, the kind is chosen and its associated role is used. For example, a sequence structure of a sentence (subject, verb, predicate) may be fulfilled as

one of several kinds of sentences, such as a declarative sentence or an interrogative sentence. If the noun of the subject is an interrogative pronoun, then it is an interrogative sentence. Finally, a term-choice rule defines the condition sufficient for a grammar term to be fulfilled by one of its alternatives. This type of rule may be used to guide the parser to use a specific grammar term to parse the next part of the sentence. Take for instance the two alternatives of the complement of a sentence: subject and object complements. The English grammar states that if the main verb is an action verb, then the complement must be an object complement [14]. Otherwise, a subject complement should be used as the complement. Consequently, this type of rule can guide the parser to look for the correct complement in a sentence based on the type of the main verb.

Originally, our program only handled grammatically correct sentences. It rejected all incorrect sentences, even those with a minor grammatical error. In order to allow such sentences, a new category of rules is used: syntax-restriction. A grammatical rule is classified as a syntax-restriction rule when enough information is available in the sentence to compensate for the grammatical error or when one grammar term may be trusted to provide more reliable information than another term. For example, the semantic content of a given declarative or interrogative sentence is complete even when the punctuation mark is incorrect or missing, such as "Who is John." Consider another grammatically incorrect example, the phrase '3 apple'; the cardinal number should be a more reliable indicator of the correct number property than the noun. Similarly, since the subject of a sentence is considered the focal point of a given sentence, properties obtained from the subject may be considered more reliable than those obtained from the verb or predicate. In all these cases, the correct intention of the given sentence may be intuitively inferred, with a high degree of confidence, using the more reliable component. As a result, our program is more flexible in allowing and still understanding sentences with certain grammatical errors.

In the parsing algorithm, each rule category is applied at a specific point in the parsing process. Term-choice rules are applied before parsing a term. The term to be parsed is determined based on the parsed result of an earlier term. Other rules are applied after a term is parsed to check the validity and to decide the role of the parsed result. They are applied in the following order: term-restriction, kind-choice, and kind-restriction. A minor change to the parsing algorithm is to add a step to check the syntax-restriction rules after checking these other categories of rules. The reason is that this new category of rules is not used to determine the parse results and will have no impact on the *pos* tagging of the words. Finally, unlike other restriction rules, when a syntax-restriction rule is not satisfied, a warning unique to the rule is generated. This warning is based on the rule's purpose, which is taught along with its condition.

3 Syntax-Restriction Rules

All rules, regardless of their classification, rely on the use of conditions to determine whether the rule is satisfied or not. If the condition of the rule is met, then the rule is satisfied; otherwise, the rule is violated. In either case, appropriate actions are taken depending on the rule category. For syntax-restriction rules, this simply involves generating a warning indicating that the condition has not been met, but the parsing of the sentence will continue.

In ALPS, several condition classes have been developed and used in composing a rule. The syntax-restriction rules discussed in this section are built using fulfill, pattern, role, and composite conditions. A fulfill condition may check whether a grammar term or role has been fulfilled or not, such as checking that a helping verb appears within a verb phrase. Furthermore, if fulfilled, the condition may check whether or not it had been fulfilled by a specific grammar term; for example, a helping verb being fulfilled by a forms-of-be verb is a part of a passive voice rule. The pattern condition checks that a word begins, contains or ends with a certain sub-string, or that a sequence begins or ends with a certain grammar term. For example, a regular noun can be made plural by adding –es when it ends in –s, –x, or –ch. The role condition compares the properties of one grammar term or role to literal values or the corresponding properties of another term or role. One instance of a role condition is to check that a gerund noun is an action verb with a progressive tense property, such as 'flying', 'baking', or 'solving'. Finally, two conditions can be combined by using logical *and* or logical *or* to form a composite condition. Our implementation of a composite condition uses a lazy evaluation strategy, meaning the second condition is only evaluated if necessary. For instance, in a composite *or* condition, the second condition is evaluated only when the first condition fails. This allows for rules in which the first condition checks to see if a grammar term is not fulfilled; while the second checks to see that it is fulfilled by a specific grammar term. For example, if the purpose of a rule is to assert that a helping verb, when present, is fulfilled by a specific type of verb, then the first condition is used to allow instances in which a helping verb does not exist in the given sentence. Conversely, for a composite *and* condition, the second condition is evaluated only when the first condition is satisfied.

3.1 Punctuation Usage

In languages such as English, punctuations are used to mark the end of structures, such as the period for declarative sentences and the question mark for interrogative sentences and decision questions. However, one can generally discern the kind of a sentence based on its structure and content.

For example, the structure of a decision question is unique in that it begins with a helping verb, such as 'is', 'can', and 'did'. Although, both declarative and interrogative sentences share the same structure, an interrogative sentence must begin with an interrogative pronoun, such as 'who', 'why', and 'how', while a declarative sentence should not. Consequently, without punctuation, a reader should still know that "What is the next prime number after 7" is a question because of the subject 'what'. Similarly, the sentence "11 is the next prime number after 7" can easily be recognized as a declarative sentence. Given the ability to intuitively infer the kind of sentence from its makeup, the ending punctuation mark may be redundant. As a result, a punctuation mark that conflicts with the recognized kind of a given sentence should not limit the acceptability of the sentence, but should simply generate an appropriate warning. The condition for checking punctuations may use a pattern condition such as a declaration must end in a period, and an interrogative sentence ends in a question mark.

3.2 Subject-Predicate agreement

In English, declarative sentences that have the linking verb 'be' as the main verb serve a distinct purpose: the predicate defines a characteristic or a state of the subject. For example, the purpose of the sentence "John is a doctor" is to define the occupation of John to be that of a doctor. Similarly, "Gorillas are primates" categorizes gorillas as a species of primates. Due to this association between the subject and the predicate, the subject-predicate agreement rule asserts that their number properties be the same. It would not make sense for John, a singular entity, to be defined as multiple doctors nor for a plural number of gorillas being classified as a singular primate. However, since the intention of the sentence is relatively clear, when such a situation occurs, a warning is generated instead of rejecting the sentence as invalid. Since the subject is the focal point of a declarative sentence, we assume the number property of the predicate should be changed to match that of the subject.

The syntactic stage of the parser transforms all the words into their base form. This process of stemming will identify and store the number property of nouns and verbs, allowing them to be accessed when checking rules. The condition for the subject-predicate agreement rule can then be used to ensure that the number property of the subject is equal to that of the predicate. However, exceptions exist in which the subject-predicate agreement is not required, such as for sentences that do not have a predicate, e.g., "John runs home." As a result, the complete condition is a composite condition combining two conditions with a logical *or*. The first condition allows sentences that have exceptions to pass without checking any agreement, while the second compares the number property of the subject with that of the predicate.

3.3 Subject-verb agreement

One of the better-known usage rules in most spoken languages is the subject-verb agreement where properties shared by the subject and verb should match. For instance in English, if the subject is the pronoun 'I', i.e., the properties of the subject are first-person singular, then the properties of the verb should also be first-person singular, such as 'am'. If the meaning of the sentence is clear from the rest of the sentence, then it is unnecessary to reject the given sentence as illegal when the subject-verb agreement rule is not satisfied. Similar to subject-predicate agreement, since the subject is the focal point of a declarative sentence, the properties of the verb will assume those of the subject when a mismatch is found.

In English, the subject-verb agreement depends on several factors and we will focus on the parts of the rule when the sentence is in present tense and active voice. When the verb is an action verb, there are two possibilities. If the subject is in third-person, then the number property of the subject and verb must match, e.g., 'John gives' and 'They fix'. On the other hand, for all other person properties of the subject, the number property of the action verb must be plural, e.g., "I give" and "You receive". When the verb is not an action verb, which includes forms of be, have, and do verbs, then based on the specific person and number properties of the subject, a specific form of the verb is used. In other words, the specific verb form must have the exact person and number properties as the subject. For instance, if the subject is the pronoun 'I', having the properties first-person singular, then the forms-of-be verb is 'am'; and if the properties of the subject are second-person singular, i.e., the pronoun 'You', then the forms-of-do verb is 'do'. These tables of usage for the various forms of verbs have been taught as part of the grammar, and have been implemented using a data structure called the multi-dimensional data organization (MDDO) for easy retrieval and matching [15]. The MDDO organizes the verb forms in a table structure indexed by the property combinations that define when they are used. Our implementation of the role condition assumes the use of such a data structure when matching the properties of the subject and the main verb. Figure 1 shows the conditions of the subject-verb agreement for sentences in present tense and active voice.

Note that if the verb is either in past tense or is preceded by one or more helping verbs or the sentence is an interrogative sentence, then none of these rules should apply. For example, an action verb in the past tense will have the same form regardless of the subject, e.g., 'John walked' and 'we walked'. The impact of a helping verb is similar and will be discussed in the next section. As for interrogative sentences, the subject is an interrogative pronoun which can be used for all verb forms. In fact, the verb should agree with the predicate instead of the subject, such as "Where am I?" and "Where are they?" As a result, a predicate-verb agreement rule should be introduced as a

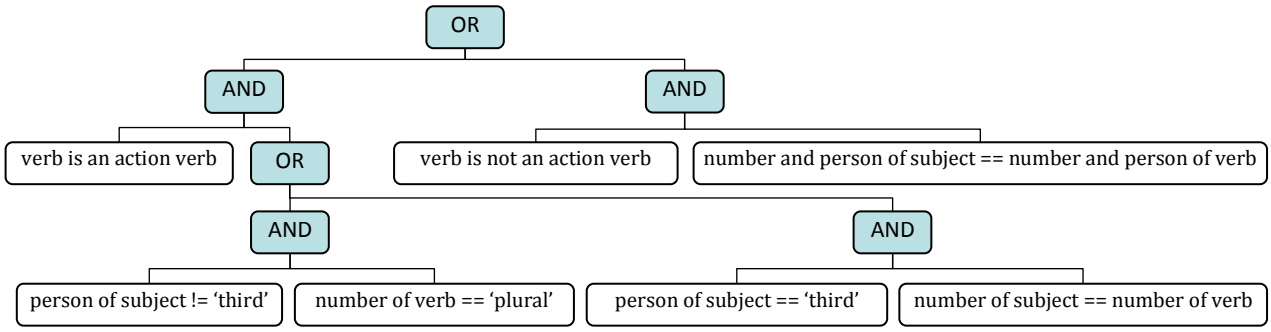

Figure 1: Conditions for subject–verb agreement.

syntax-restriction rule to handle that. Additional sub-conditions not shown in the figure are needed to exclude all these cases from violating the subject-verb agreement rule.

3.4 Verb phrase usage

The English language has four types of helping verbs: be, have, do, and modal helping verbs. As previously mentioned, the presence of helping verbs in a sentence makes the subject-verb agreement rules irrelevant. Instead, each type of helping verb has its own rules regarding the proper form of the main verb. The forms-of-be helping verbs indicate either a progressive tense such as "He is reading a book" or a passive voice "The book was given to him." As a result, the main verb needs to be in the progressive or past participle form, respectively. The forms-of-have verb is used for the perfect tense, and therefore, requires the main verb to be in the past participle form, such as "I have spent all my money." When used, forms-of-do helping verbs can either form a negative or show emphasis of the main verb. On the other hand, modal verbs, such as 'can', 'might', and 'would', modify the meaning of the sentence in some way; e.g., the modal verb 'can' asserts the ability of the subject to perform the action. Both the forms-of-do verb and modal verbs require the main verb to be in its base form, e.g., "John might go to the store tonight" or "Kate does not have her ticket." The base form of a verb is the form listed in a dictionary, such as 'eat' for the words 'eat', 'eats', 'eaten', and 'ate'.

Even though an English verb phrase can have up to three helping verbs, only the helping verb immediately preceding the main verb, known as the primary helping verb, determines the main verb's form. With the primary helping verb being the focal point, if a mismatch occurs between it and the main verb, we use the primary helping verb to determine the correct tense of the main verb. This helping verb agreement can be built by combining a composite condition for each form of helping verbs using a composite *or* condition. The first part of each individual composite condition would determine if the primary helping verb is fulfilled by the respective helping verb. The second condition would use a role condition to ensure the tense of the main verb matches what is expected for that helping verb. In our implementation, we determine that a linking verb is in its base form if no properties are associated to it, and utilize the fact that the base form of an action verb is its plural present tense form. In addition, since the semantic distinction cannot be made between its use as the main verb and helping verb, the condition for the forms-of-do helping verb is not included currently.

3.5 Number Agreement

The number agreement rule compares the number properties of a determiner and the noun that is being modified. Some examples of determiners in the English language are cardinal values, articles, demonstratives, and quantifiers. The number 1 indicates a singular entity and therefore should be followed by a singular noun. All other numbers, including negatives and the number zero should be followed by a plural noun: such as '3 cats', '0 conditions', and '-1 degrees.' Singularity is also inferred by non-unique articles 'a' and 'an'. However, the unique article 'the' can apply to both singular and plural nouns. Similarly, demonstrative pronouns and quantifiers also have the singular forms, such as 'this', 'that', 'every', and 'each' and plural forms such as 'these', 'those', 'all', and 'some'.

In English, some nouns have the same singular and plural form, such as 'sheep'. When reading the statement, 'a sheep' or '1 sheep', it is clear there is a singular animal. On the other hand, '3 sheep' represents multiple numbers. Since the number property of the noun in situations like these is irrelevant, when the number properties do not match in other situations, the value of the determiner is assumed to define the proper amount of the noun. In addition, some nouns have an irregular plural form or have complicated rules to form the plural, such as 'ox' to the plural 'oxen' versus 'fox' to 'foxes', and 'buy' to 'buys' but 'country' to 'countries'. These make it unlikely that the correct form will be used all the time. As a result, the number agreement rule should be a syntax-restriction rule with the determiner used as the basis when it fails. To illustrate how to detect number agreement, we have included a rule on cardinal values and articles. The first condition in the rule checks if

there is no determiner present or the determiner is the article 'the'. In either case the number property of the noun is irrelevant and the rule passes. The second condition compares the number property of the noun to that of the determiner as described above. The complete details of the rule are shown in Figure 2.

4 An Example in Resolving Ambiguity

In the English language, singular countable nouns such as 'computer' or 'phone' are modified by a determiner within a noun phrase. For instance, phrases like 'turn on the computer' and 'hand me my phone' are of proper grammar, while the phrases 'turn on computer' and 'hand me phone', are considered improper. Given the fact that there are enough contexts for these phrases to still be understood in light of the missing determiners, this particular rule may be implemented as a syntax-restriction rule, which would then generate a warning when the determiner was missing. However, classifying this rule as syntax-restriction presents a problem for the parsing algorithm. The reason is that for ambiguous words such as 'seal', which could represent a noun as well as an action, a phrase like 'to seal' could represent an infinitive or a directional prepositional phrase that was typed without a determiner, 'to (the) seal'. With the syntax-restriction rule in place, the phrase could sufficiently pass as an erroneous prepositional phrase even if it was intended to be an infinitive. Since our current parsing algorithm does not return multiple sentence structures, the parser would recognize the phrase of 'to seal' as a prepositional phrase instead of an infinitive based on the fact that this alternative was tried first. For ambiguous situations such as this, it would be beneficial for the syntax-restriction rule to act like a semantics restriction rule and restrict the prepositional phrase to include a determiner for singular countable nouns. If the determiner is missing, then parsing as a prepositional phrase fails. On the other hand, if the term is not ambiguous, such as 'car', then the missing determiner will result in the generation of a warning only.

It is for this reason that syntax-restriction rules have been implemented in a manner that could detect and adjust to ambiguous terms. This works by indicating to the rule which terms in the sequence to check for ambiguity. If the rule fails, and the word fulfilling the term is ambiguous, the fulfillment of the sequence fails. On the other hand, if the rule fails but the word fulfilling the term is not ambiguous, then the sequence is fulfilled sufficiently, the parsing continues, and a warning is generated. In this example, by specifying to the rule that the noun in the prepositional phrase may be ambiguous, the parsing of the phrase 'to seal' as a prepositional phrase will fail, allowing the parser to parse it successfully as an infinitive. In other words, the ambiguous term 'seal' is disambiguated as a noun by using the syntax-restriction rule when fulfilling a prepositional phrase and as an action verb when fulfilling an infinitive. A term is determined to be ambiguous if it is known within ALPS to represent multiple knowledge objects of different knowledge kinds. For example, the word 'seal' is ambiguous if ALPS is aware that it can mean an action or a category of objects. The details on how ALPS handles the word sense disambiguation problem may be found in [16].

5 Conclusion

In this paper, we showed how a parser tolerates sentences containing context-based grammatical errors. Unlike word processors that use context-based grammar checkers to alert improper grammar, ALPS uses a new category of rules, syntax-restriction, to make assumptions about the intended meaning. This is accomplished by using context in the sentence, domain knowledge, and knowledge about the grammar. When a sentence is determined to be grammatically incorrect, a warning is generated and may be shown to the user allowing them to determine if the assumed intent is correct. This category of rules gives ALPS an edge over other natural language processors by enabling it to accept and interpret sentences regardless of their grammatical correctness. The five grammatical rules shown in this paper only present a subset of what is possible with syntax-restriction rules. The incremental nature of the ALPS grammar, along with the versatility of defining rules, allows additional syntax-restriction rules to be added later. The end-result is a learning program that can accept a range of semantically sufficient sentences, including those with grammatical errors, while allowing the option of notifying the user about these errors through warnings.

In discussing syntax-restriction rules, it was stated that the more reliable of the two terms would be used when their

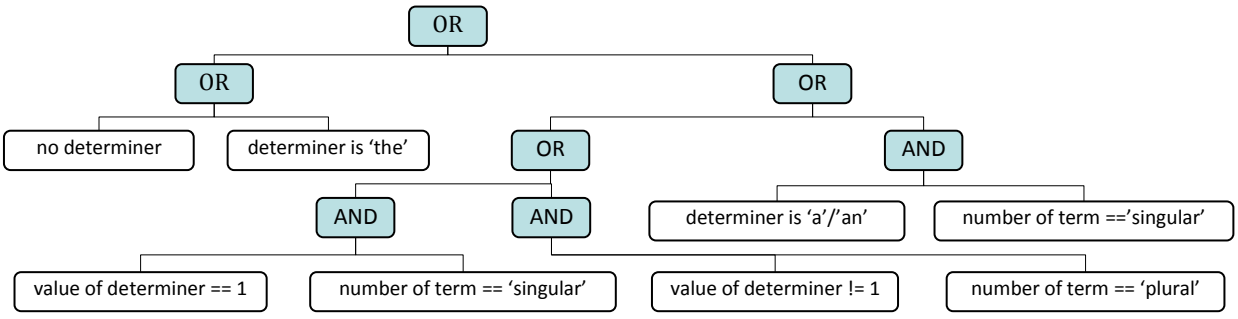

Figure 2: Conditions for number agreement.

properties conflicted. With the examples illustrated in this paper, the decision on what makes one term more reliable than the other is intuitive and obvious. For example, when presented with the verb phrase 'can goes', it is more logical to assume the helping verb was used intentionally and correctly instead of the main verb being used correctly. There may be occasions when determining the more likely intent is less obvious: for instance, when an apostrophe is missing from a possessive noun that could be either singular or plural. In the sentence "Hand me the teachers books", one interpretation could be the books of a single teacher. Alternatively, it could also be the books of many teachers. In situations like these, it is unclear which alternative would be the correct intention. Additional knowledge before the sentence is presented may be required to make the decision.

In addition, this paper has shown a situation when a syntax-restriction rule must be used to determine the correct meaning of an ambiguous term. Other ambiguity cannot be solved simply using the words in the given sentence. For example, although the punctuation usage rule may be used to verify whether a period or a question mark is used correctly, the same cannot be said between a period and an exclamation mark. This is because the most likely difference between declarative and exclamatory sentences is a sense of urgency or emotion, a distinction not evident in the text alone. The statement "I am angry" could either be an exclamation or a declaration based on the tone or the use of the appropriate punctuation. Consequently, the punctuation usage rule is required to disambiguate the intention for written sentences, but may be used as a syntax-restriction rule to understand oral conversation if the tone of the sentence heard can be distinguished by the system.

Abstract

Web pages generally contain a large amount of information that is not part of their main content, such as navigation panels, copyright and privacy notices, and advertisements. Such irrelevant information, known as Web page noise, can seriously affect the accuracy of search and other web mining applications; the act of removing it is called "cleaning." Previously published work on web page cleaning is based on the observation that Web pages tend to follow fixed layouts and presentation styles, which can be recognized and parsed. Structural trees were generated, mostly by sampling pages of a particular website, to identify noisy blocks and eliminate them. In this paper, we introduce a different approach based on heuristics that extract the main text on the basis of its characteristics rather than any previously recognized structural pattern. The key insight is that the main text consists of blocks of relatively long lines that include high-frequency (common) words, while headlines and "noise" consist of smaller amounts of text, isolated from each other, with a higher proportion of rare words.

Keywords: Natural language processing, Artificial intelligence, Webpage cleaning, Content extraction

1 Introduction

A web page consists of numerous types of information which can be seen or heard by the end user, including the main text, subsidiary texts, non-textual information (static images, animated images, audio, video etc.), "on-page" interaction information (interactive text, interactive illustrations, and buttons), "between-page" interaction information (hyperlinks, forms), and internal (hidden) information (comments, scripts, metadata etc.). When a web page is to be analyzed by computer rather than viewed by a human being, extracting the main content can be a challenge; all the other content constitutes noise.

We present a technique to "clean" a retrieved web page, i.e., extract the main text of a web page from the "noise." Examples of noise in news websites, in general, include advertisements, navigation panels, copyright and private notices, side articles, user comments, and headlines of other stories. Although such information items are functionally useful for human viewers and necessary for website owners, they can seriously harm automated information collection and mining on the web. Classifying or mining noise-free web pages will improve the accuracy of search results as well as search speed and may benefit web page organization applications.

Web noise can be grouped into two categories: global noise (redundancy) and local (intra-page) noise. Global noise refers to redundant objects with large granularities, which are no smaller than individual pages. Global noise includes mirror sites, duplicated Web pages and old versioned Web pages to be deleted, etc. Local noise refers to irrelevant items within a Web page. It is usually incoherent with the main content of the page. Such noise includes images, advertisements, copyright information etc. This project deals with only local noise in Web pages.

Part of the challenge is that the goal is ambiguous — what constitutes "noise" depends on the purpose. For example, a news article from Yahoo contains side articles and user comments which may be considered as a part of the main text if useful in the sense that they talk about the same topic as the main content. However, there may be user comments that are not relevant to the main content. The challenge is to distinguish useful from noisy information. Surprisingly, despite its importance, relatively little work has been done in this field.

We developed heuristics based on the following initial observations of common news websites:

1. Headlines are short lines with a high proportion of low-frequency words or unique words.
2. The main text contains longer lines with more high-frequency (common) words.
3. News articles generally follow the inverted pyramid structure, with the most important content at the beginning.

Our approach presumes nothing about the structure of particular web pages, and with minor adjustment, should work equally well for websites in any language. To handle the fuzzy nature of the users requirements, the users are allowed to turn heuristic features on or off and set thresholds depending on how lenient they like their text stripper to be.

2 Related Work

Web page cleaning is a challenging problem. Given its importance for any type of automatic reading of the Web, it is surprising to note that relatively little work about it has been published. In 2002, Lin and Ho (Lin and Ho 2002) proposed a method to identify informative blocks in Web pages. However, their work was limited by the following two assumptions: (1) the system knows a priori how a Web page can be partitioned into coherent content blocks; and (2) the system knows a priori which blocks are the same blocks in different Web pages. Their work views a web page as a flat collection of blocks, and each block is viewed as a collection of words. Bar-Yossef and Rajagopalan (Bar-Yossef and Rajagopalan 2002) defined web cleaning as a frequent template detection problem. Their work is not concerned with the context of a Web site, which can give useful clues for page cleaning. Their techniques developed so far work under the observation that Web pages have some structures which are reflected by their nested HTML tags. Kushmerick (Kushmerick 1999) proposes some learning mechanisms to recognize banner ads, redundant and irrelevant links of Web pages. However, these techniques are not automatic. They require a large set of manually labeled training data and also domain knowledge to generate classification rules. Techniques that analyze the text itself roughly fall into two categories: lexical cohesion methods (Beeferman, Berger, and Lafferty 1999; Kaufmann 1999) and multi-source methods (Beeferman, Berger, and Lafferty 1999). The former identifies coherent blocks of text with similar vocabulary. The latter combines lexical cohesion with other indicators of topic shift, such as relative performance of two statistical language models and cue words. Hearst and Plaunt (Hearst and Plaunt 1993) discussed the merits of imposing structure on full-length text documents and reported good results of using local structures for information retrieval. Instead of using pure text, which is unstructured, Lan Yi and Bing Liu (Yi and Liu 2003) processes semi-structured data. They make use of the semi-structures present in Web pages to help with the cleaning task. They propose a new tree structure called the compressed tree structure to concisely capture the commonalities of a Web site. It then uses an information based measure to evaluate the importance of each node in the compressed structure tree. Based on the tree and its node importance values, their method assigns a weight to each word feature in its content block.

Our approach to web cleaning is different from all of the existing technologies and is comparatively very simple. Its advantage is that it completely ignores the structure of web pages. It does not detect blocks or structures of web pages from their HTML tags or tree nodes. No pre-learning is required and hence training data or domain knowledge are not necessary. Our method is based on general characteristics of web pages, especially from news web sites, and is predicted to work almost equally well for websites in any language.

3 Key Challenges

As mentioned earlier, Web pages are multimedia. Since the objective is to extract just the main text from the web page, the first task is to eliminate non-textual information (images, audio, and video). The bigger challenge, however, is to distinguish relevant text from the rest. The main text is often observed to contain longer sentences and grammatical connectives like *and, or, the, if, is, to, from, for,* etc. (called "stop words" in information retrieval because they do not indicate subject matter). Some violations of these generalizations (e.g., short lines, lines containing only low-frequency words, or both) do occur within the main text. Side articles and user comments tend to appear after the main article. They may be relevant could be included as a part of the main text after extraction. However, if the end user is not motivated to include them, there will be problems because not only do they contain long sentences, they also contain "stop words" just like the main text. The words that appear in the headline, although uncommon, appear frequently within the main article because they define its subject matter. However, most often, names of people being referred to in the article are replaced by pronouns after their first occurrence. For example, if the article is about Roger Federer winning the Grand Slam, *Roger Federer* will be replaced by *he, him,* etc., after its first occurrence. News articles are often structured as an "inverted pyramid" — the most important part of a news article occurs at the top. This way, at any point of time, the reader can stop after reading the first few lines and still get an account of the story that is accurate as far as it goes. But a challenge arises if the news story is badly written or unconventionally structured.

4 The Proposed Heuristic

The experimental algorithm for extracting the main text from a web page (mainly from news websites) and eliminating local noise (such as other headlines, banner advertisements, non-textual information, navigation panels, copyright and privacy notices, useless side articles, and user comments) was written in Prolog.

Figure 1 shows a sample page from Yahoo News.[1] This page contains a news article about how a man built a huge ball out of rubber bands. The main content (boxed segment) only occupies approximately 1/3 of the original web page, and the rest of the page contains many advertisements, side articles, other news headlines, comics, copyright notices, etc. Such items are irrelevant and should be removed. Since each web site has its own unique structure, it would be necessary to find a suitable data structure dynamically in order to represent both the presentation styles and actual contents of the web page in the site. However, our approach eliminates such a requirement by completely ignoring the structure and basing the noise elimination wholly on the textual content in the page.

The first step of the algorithm is to take the downloaded web page and strip off all its HTML tags. After this step, all that remains is a file containing only textual information.

The next step, the *line-length stripper,* eliminates very short lines. This is necessary to account for the observation that the main text has relatively long lines. The threshold for

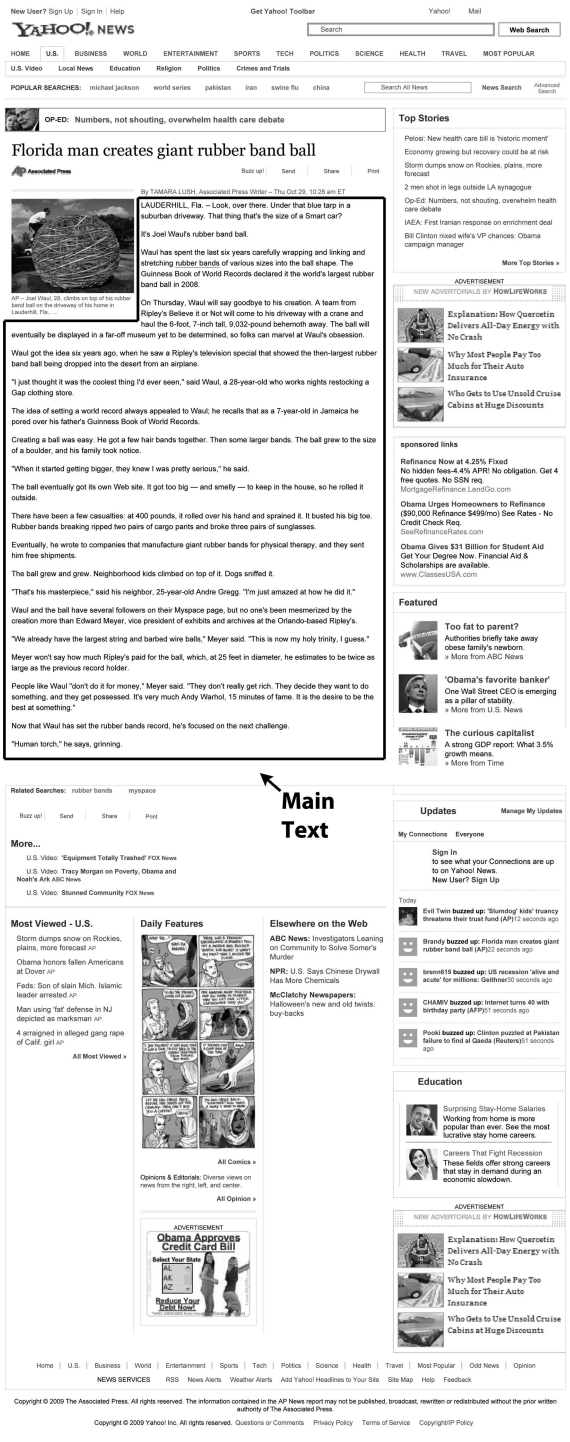

Figure 1: The main text in a web page with noise.

```
AP -- Joel Waul, 28, climbs on top of his rubber band ball
on the driveway of his home in Lauderhill, Fla.  ...

LAUDERHILL, Fla.  -- Look, over there.  Under that blue tarp
in a suburban driveway.  That thing that's the size of a
Smart car?  It's Joel Waul's rubber band ball.

Waul has spent the last six years carefully wrapping and
linking and stretching rubber bands of various sizes into
the ball shape.  The Guinness Book of World Records declared
it the world's largest rubber band ball in 2008.

On Thursday, Waul will say goodbye to his creation.  A team
from Ripley's Believe it or Not will come to his driveway
with a crane and haul the 6-foot, 7-inch tall, 9,032-pound
behemoth away.  The ball will eventually be displayed in a
far-off museum yet to be determined, so folks can marvel at
Waul's obsession.

Waul got the idea six years ago, when he saw a Ripley's
television special that showed the then-largest rubber band
ball being dropped into the desert from an airplane.

"I just thought it was the coolest thing I'd ever seen,"
said Waul, a 28-year-old who works nights restocking a Gap
clothing store.  The idea of setting a world record always
appealed to Waul; he recalls that as a 7-year-old in Jamaica
he pored over his father's Guinness Book of World Records.

Creating a ball was easy.  He got a few hair bands together.
Then some larger bands.  The ball grew to the size of a
boulder, and his family took notice.

The ball eventually got its own Web site.  It got too big --
and smelly -- to keep in the house, so he rolled it outside.

There have been a few casualties:  at 400 pounds, it rolled
over his hand and sprained it.  It busted his big toe.
Rubber bands breaking ripped two pairs of cargo pants and
broke three pairs of sunglasses.

Eventually, he wrote to companies that manufacture giant
rubber bands for physical therapy, and they sent him free
shipments.

The ball grew and grew.  Neighborhood kids climbed on top of
it.  Dogs sniffed it.

"That's his masterpiece," said his neighbor, 25-year-old
Andre Gregg.  "I'm just amazed at how he did it."

Waul and the ball have several followers on their Myspace
page, but no one's been mesmerized by the creation more than
Edward Meyer, vice president of exhibits and archives at the
Orlando-based Ripley's.

"We already have the largest string and barbed wire balls,"
Meyer said.  "This is now my holy trinity, I guess."

Meyer won't say how much Ripley's paid for the ball, which,
at 25 feet in diameter, he estimates to be twice as large as
the previous record holder.

People like Waul "don't do it for money," Meyer said.  "They
don't really get rich.  They decide they want to do
something, and they get possessed.  It's very much Andy
Warhol, 15 minutes of fame.  It is the desire to be the best
at something."

Now that Waul has set the rubber bands record, he's focused
on the next challenge.

Parameters: $T_1 = 0.6$, $T_2 = 0.9$ **(no window), "inverted pyramid" on.**

Slightly too much material is included because it could not be distinguished from the main text. The last line was missed because it was too small and towards the end of the document. Also, Figs. 1 and 2 were captured at different times and some rotating headlines had changed.

Figure 2: Text extracted from web page in Fig. 1.

number of words allowed per line in this step is indirectly obtained from the user so as to allow the user to control the elimination process in this step. However, to help the user to make an educated choice of threshold values, some good threshold values are suggested in the discussion section (later in this paper) based on their performance after the testing of the algorithm. The minimum number of words allowed per line is computed as follows:

$$\text{Minimum number of words} = T_1 \times \sqrt{\frac{\sum_{k=1}^{n}(x_k - \mu_1)^2}{n}}$$

That is, the minimum number of words allowed per line is user-supplied threshold T_1 times the standard deviation of the line length in words. Here n is the number of lines in the text, x_k is the number of words in line k, and μ_1 is the average number of words per line. This formula may seem too simple, but recall that the line length ranges all the way down to zero, so the standard deviation implicitly contains information about the mean as well as the variation.

After that step, some moderately short lines (like some headlines/captions or side articles) which are still in the text should be removed because they are not part of the main article. This is quite a challenge for a computer because it fails to recognize where these moderately short lines occur within the article. One way to differentiate those lines occurring in the main text from those that do not is by finding and comparing their subject matter with the main subject matter of the page. The ones that match in subject matter are considered to be within the main article and the ones that do not are considered to be noise.

A fair indicator of subject matter is the vocabulary. Consider the same example illustrated in Figure 1. The web page is about a man from Florida creating a rubber band ball. So, even if the words *rubber, band,* or even *ball* occur in a short line within the main text, the *word frequency stripper* (the program component that removes lines with the wrong word frequencies) will classify it with the main article because those are words with high frequencies in the story as a whole. Also, according to one of the initial observations, headlines (or captions) and side articles often comprise relatively short lines containing less-frequently-occurring words (see Figure 1), indicating that they are less likely to be a part of the main text.

The word frequency stripper decides whether to keep each line by computing a word frequency score for it and comparing this score to a threshold that is indirectly obtained from the user. The frequency score for each line is obtained by adding up the individual frequencies of each word in the line. Thus, lines containing common words or high frequency words have a high frequency score.

Again, to help the user to make an educated choice of threshold values, some good threshold values are suggested in the discussion section later in this paper. The threshold frequency score is computed as follows:

$$\text{Threshold frequency score} = T_2 \times \sqrt{\frac{\sum_{k=1}^{n}(y_k - \mu_2)^2}{n}}$$

That is, the threshold frequency score, to warrant keeping a line in the text, is user-supplied parameter T_2 times the standard deviation of the frequency scores y_k of the lines (μ_2 being their mean).

In the next pass, all the lines that begin with any character other than letters, numbers, parentheses, and single or double quotes are removed using the *character stripper* as it was observed to be very unlikely for sentences or words in the main text to begin with special characters.

The last step, *window/blur selection*, resembles vision more than text processing. Human beings recognize the main content of the web page visually, grouping characters and lines into sections of the text. Crucially, individual lines are grouped with the material in their immediate vicinity even if they, individually, do not meet the criterial for placement there. Thus a very short line at the end of a paragraph, or an individually anomalous line in the middle of a text, is not thrown out. To achieve this, we have to view the text "blurred," so to speak.

In window/blur selection, moving windows of 3 or 4 lines were considered and the frequency scores of each line in the window were combined. If the total score of a window was below a threshold, the shortest line in the window was removed but if the total score of the window was above the threshold, the shortest line remained.

In order to account for the possibility that reasonably long lines that may not be a part of the main content, could occur after it, higher scores are assigned to the lines occurring at the top of the article. The motivation behind this feature came from the concept of "inverted pyramid," which is a common news style followed by journalists all over the world. As mentioned earlier, important parts of the news article always occur at the top. Hence, it is intuitive to assign higher scores to the lines that occur at the top of the article because they are generally more important than the lines at the bottom. It is better to underestimate in the lower parts of the main article than to underestimate at the top. The datasets used in our experiments are described below followed by the goodness criteria discussion and evaluation measures.

5 Experiment Setup

For testing the above mentioned heuristics, 125 different news articles were collected, 25 each from the RSS feeds of popular news web sites such as BBC news,[2] CNN news,[3] Taipei Times,[4] ABC News,[5] and Yahoo News.[6]. As can be seen, each of these websites has its own unique structure and presentation style. Table 1 shows the different inputs from the user. The threshold ranges for which the proposed cleaning technique was implemented are also mentioned in the table. The results were then examined manually one by one and categorized based on a goodness score ranging from 0 to 10. A goodness score of 0 implies that none of the lines from the main content of the website appeared after the elimination process and a score of 10 implies that the extraction

FEATURE	USER INPUT
Short line Threshold - T_1	0.5 - 0.8 (in 0.1 intervals)
Frequency Threshold - T_2	0.5 - 1.2 (in 0.1 intervals)
Window Length - *w*	3 - 4 lines/window
Inverted Pyramid	on/off
Window Selection	on/off

Table 1: User inputs, feature selection options.

accuracy was 100% — none of the lines were over-estimated or under-estimated. The goodness criteria will be discussed in detail in the next section.

The heuristic was implemented on all 125 news articles, using each of the 64 threshold combinations, resulting in a total of 8000 output files, which were examined manually and goodness scores were assigned to each of them as described in the following section.

6 Discussion of Results

The performance of the proposed heuristic for the purpose of noise elimination and main textual content extraction was evaluated based on some goodness criteria. It is to be noted that for our experiments, side articles, user comments, copyright and privacy notices will be considered as noise. It is also assumed that over-estimation of the content is preferred over under-estimation. The headline or the caption of the main content may or may not be included as a part of the result, and the goodness score will not be affected by it. Because common news styles follow the Inverted Pyramid rule, over-estimation at the top is considered to be worse than over-estimation at the bottom. Based on these assumptions and the extent of over/under-estimation, goodness scores ranging from 0 to 10 are assigned as indicated in Table 2.

Figure 2 shows the result of processing the web page shown in Figure 1, with the specified threshold values. For those threshold values, the extraction was 100% accurate, with no over/underestimation. Hence, a goodness score of 100 is assigned to the output. All 8000 output files were evaluated in the same way. Table 3 shows the top five parameter combinations (on the left) for each web site and the total number of files that had goodness scores ≥ 9 with those parameters (broken up in the middle columns and summed on the right).

The table shows that 101 out of 125 files received goodness scores of 9 when the parameter combination of $T_1 = 0.5$, $T_2 = 1.1$ was used. Fewer articles from Yahoo news website received high goodness scores, possibly because most of them contained sections where some experts commented on the particular event. Hence, most of the Yahoo articles were assigned a score of 8, implying that 100 percent of the main textual content was extracted but there was over-estimation of more than 10 words at the bottom due to inclusion of related user comments. It is to be noted that these evaluations are done after manually examining all the output files. Table 4, showing the distribution of goodness scores, gives a clearer picture of how well the proposed technique worked. Note that 93.6 percent of the files had a goodness score ≥ 7, implying very high accuracy of the noise elimination process. Most of the files with a score of 8 came from web sites such as Yahoo News which contained lengthy and relevant user comments that were included as a part of the main text. Almost all output files received goodness scores greater than or equal to 5; none at all got a score below 4, implying that for the given range of thresholds, this technique ended up extracting more than 90 percent of the main textual content almost all the time. Those with scores of 4 resulted from experimenting with extreme threshold values.

7 Conclusion

This heuristic method of extracting the main text of a web page is a success. It does not make any presuppositions about the structure of the web page. Future improvements might include determining the parameters automatically by machine learning, testing heuristics on pages written in languages other than English, and testing the system as part of a web page clustering or classification system.

GOODNESS SCORE	EXPLANATION
10	Extraction accuracy was 100 % - none of the lines were over-estimated or under-estimated
9	100% main textual content extraction with over-estimation of less than 10 words at the bottom
8	100% main textual content extraction with over-estimation of more than 10 words due to inclusion of related user comments
7	100% main textual content extraction with over-estimation of less than 10 words at the top
6	Greater than 90 % textual content extraction and/or with under-estimation in the middle
5	Under- estimated extraction – Less than 90 % of the main textual content remained after elimination
4	Under- estimated extraction – Less than 70 % of the main textual content remained after elimination
3	Under-estimated extraction – Only less than 50% of the main textual content remained after elimination
2	Highly under-estimated extraction – Less than 30% of the main textual content remained after elimination
1	Grossly under-estimated extraction – Less than 10% of the main textual content remained after elimination
0	None of the lines from the main textual content of the website remained after elimination

Machine learning (ML) methods are used to extract new knowledge from existing datasets. Ensemble methods (EM) were introduced to improve the ML performance. While EM's offer performance improvements, they limit the amount of control and general understanding of how the final result was achieved. We are researching the possibility to verify ML results with formalization of research results accessible in natural language. We propose to use the extracted information from scientific papers for the verification of ML results. In order to be able to extract the information, relevant to the ML results, an approach to extract specific information rich segments from scientific papers is needed. We present an approach to automated selection of relevant segments from large repositories.

Keywords:natural language processing, information retrieval, machine learning, content segmentation

I. I. INTRODUCTION

A typical ML task is to induce a model using a training set with the final goal of predicting the classification class of new, unseen examples. A number of methods that solve this problem with varying success exist [3], [4]. One possibility to improve performance is the use of ensemble methods, which are also known as classifier fusion, committees of classifiers or multiple classifier systems. The main drawback of ensemble methods is the non-transparency of the final classification. As the final decision is a combination of multiple individual classifiers, it is necessary to understand the working logic of every ensemble member as well as the combination strategy used by the ensemble. Manual oversight of the ensemble results is several times more complex than the oversight of a single classifier. In many domains the verification and validation of results is of primary meaning. Any application of ML in the domain of medicine and biomedicine needs to be transparent. Domain experts have to be able to understand the underlying reasoning process that resulted in the final results. Since this is very time consuming the alternative is the validation by independent verification of the results.

If we are able to confirm the results of an ML ensemble, the time consuming process of manual inspection of each ensemble member and the combination policy can be significantly reduced. For the validation a reliable source is required. We believe that scientific papers preprocessed using natural language processing (NLP) and knowledge extraction (KE), offer the ability to automatically verify ML results. A precondition to the verification and validation of ML observations is the selection of relevant segments from large document repositories. The selection policy is dependent on the type of validation being carried out. For some tasks longer more detailed passages are required while other tasks require short passages with concentrated facts.

This paper is segmented into five sections: in Section 2 (motivation) we introduce ML and present EM's. Section 3 introduces theoretical background on information retrieval (IR) from document repositories. Section 4 represents the proposed algorithm for document segmentation. In Section 5 we present the experiment, in which our approach vas evaluated on a large document repository. Section 6 is the conclusion.

II. MACHINE LEARNING

A supervised learning problem is solved by providing a set of examples in the form of $f(e_i; r_i)$ [1], where the unknown function maps examples e_i to results r_i. Examples are usually vectors with real or discrete valued components; each component is a feature of x_i (x_{if} represents the f-th feature of x_i). The results r_i (for classification) are a discrete set of classes. Fig. 1 represents a simple decision tree classifier which uses, as features, the number of relapses in past 2 years, patient age and patients expanded disability status scale. The decision tree is used to classify patients into two classes: receive treatment and don't receive treatment. The classifier proposes a hypothesis on the true class to which the individual belongs. Example classifier represented in Fig. 1 hypothesizes that a patient with two or more relapses in the past two years who is between eighteen and fifty years old and whose EDSS is under 5.5 should receive treatment. The classifier has made such a hypothesis based on the training data it was supplied.

The accuracy of the classifier relies on the ability to form good hypotheses. Ability to form good hypotheses is very limited when size of training data is not proportional to the search space. The problem can be underrepresented (training data is too small) or the amount of data is so large it is not

feasible to learn a model on the entire data set. Without sufficient data, classifiers can form many different hypotheses and the model is unstable (if a small number of examples are removed the model changes drastically). In general EM's improve performance when the classifier needs to overcome these types of problems: small/large datasets, complex problems and heterogeneous datasets [5].

Ensembles are groups of models whose output is combined into a single result (output or prediction). The accuracy of ensembles is higher that of individual constituent models [1], [6] for both classification and regression. The theoretical basis for the improved performance of ensembles was provided in [7], [8], [9]. Ensemble learning is a two-step process: 1) learning of constituent models and 2) learning of the combination strategy. In order to ensure, that ensemble performance is better than the performance of individual members, the ensemble should be composed from diverse models. Diverse models make different classification errors and a good combination strategy can make the final results better. The diversity of the individual models can be achieved by either modifying the training dataset or by changing the learning algorithm. Modification of the dataset can be implemented with resampling techniques.

The most common method of combining individual predictions into the final result is voting [5], bagging [10], boosting [11] and random forests [12].

III. EXTRACTION OF RELEVANT DOCUMENT SEGMENTS

NLP required for the verification of potential new knowledge, discovered by ML, is typically a two-step process. First the document repository used for verification must be preprocessed. In the second step the actual verification of potential new knowledge is performed. The extraction of relevant text segments is a prerequisite to the extraction of information on individual ML generated rules.

Generally the document repositories can be classified into two categories: general and domain-specific. General repositories can contain documents from diverse scientific areas while domain-specific repositories contain only documents from the domain in question. If the source documents are a collection of scientific papers the repository is of a general nature (unless all of the papers focus on a specific area). An example of a domain specific repository would be a collection of patient data (admission form, symptoms on arrival etc.) from a specific hospital ward. With general repositories there is always the possibility that none of the documents would be relevant to the verification process. Therefore general repositories require an additional preprocessing step: the selection of relevant documents

A. Preprocessing

Preprocessing involves transformation to plain-text, tokenization and index creation. Transformation to plain-text depends on the source format of the document repositories, for scientific papers, which are usually written in PDF, this is a challenging process. For the document repository used in our experiments individual documents were stored in XML format. Consequently the extraction of plain-text required was a simple task of parsing the content from appropriate tags.

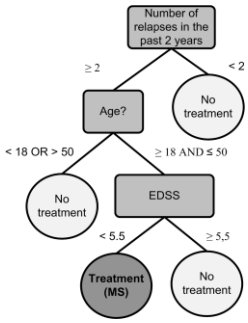

Figure 1. Decision tree classifier with three features (number of relapses, age, and expanded disability status scale. The classification classes are: receive treatment for multiple sclerosis and no treatment

Tokenization is the process of separating the text into tokens, individual lexical units (e.g. words). Tokens are not just words; in general a token is a sequence of characters that are grouped into a semantic unit [13]. Tokenization is an example of a more general problem, segmentation [14]. Manipulating text at the level of individual words is preconditioned with the ability to extract individual sentences. Segmentation into sentences is difficult because sentence-ending punctuations are ambiguous. Symbols that end sentences are also used within the sentence (abbreviations, numbers). We can view sentence segmentation as a classification task: each character that could end a sentence should be evaluated if it actually ends the previous sentence.

After the text has been tokenized the tokens are added to a unique index. This index is then used to create an inverted index with *tokenID* and *documentID* pairs. The inverted index enables quick scanning of large repositories. The index can be constructed with the use of singe-pass in-memory indexing algorithm [13]. Fig 2 represents the preprocessing: each document is transformed to a plain-text stream of text. The text is tokenized and a unique index of documents is constructed. Finally the inverted index linking terms to documents is created.

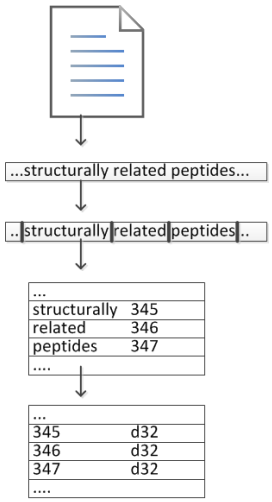

Figure 2. Preprocessing steps (bottom down): transformation to plain-text, tokenization and indexing (tokenID → documentID)

B. *Extraction of relevant segments*

The selection of relevant segments is dependent on the interests of the individual research. In general, scientific statements can be classified into some general dimensions. When selecting individual segments the approach needs to take into account the characteristics of individual phrases, sentences or paragraphs [15]. Scientific papers are already segmented into logical areas. Predefined units are: title, abstract, introduction, content sections/chapters (*1-n*), conclusion and references. These visual segments are then further segmented into paragraphs which are approximations of discourse changes. New paragraph inherently implies topic change or focusing on a smaller detail of the general topic.

The main problem with visual segmentation is that it is done without machine readable annotations of segments, in binary stored documents. When transforming the binary documents into stream of plain-text much of the formatting is lost. Therefore it is necessary to recreate much of the author's effort that went into determining boundaries of discourse. Extraction of knowledge from natural language documents requires automated discourse segmentation. The process segments individual documents into units where topic is uniform. Units are usually sentences or paragraphs. To segment a document a technique for the identification of borders is required. A border is defined as the area in text where a shift of topic occurs. A general algorithm for detecting areas where shifts of topic occurs is represented in Fig. 3. First the document is split into fixed units. In [16] it is suggested that the size of fixed units would be 20 words. Then the algorithm loops over every fixed-size unit and evaluates if two neighboring units have the same topic. If the topics are identical the two neighbors are joined and the search continues. Once a change of topic has been detected the left hand unit (which can be composed of several fixed-size units with coherent topic) is added to the list of coherently uniform segments. The search ends once all borders of the fixed size units have been evaluated and classified as either coherent uniform borders or not. The most difficult is the detection of topic coherency. The detection is done on the amount of "evidence" that the same topic is prevailing in both segments. Coherency is usually correlated to the position in the original text: introductions try to give a broad overview of the entire paper and are therefore much more diverse in covered topics, main sections of papers are longer and can discuss a the same topic for several paragraphs.

Well-known methods to evaluate cohesion that have been developed [18] are: *Vector Space Scoring* (VSM), *Block comparison* (BC) and *Vocabulary introduction* (VI). VSM evaluates the number of shared terms in the previous and the next two units of text. BC uses one unit on either side and does not consider inverse document frequency. VI is evaluated on the negative number of new terms in the left and right text units. Coherency measures need to be adapted to account for different types of text. One approach to achieve this is represented in Fig. 4, where a low pass filter is used to smooth the points in text where topic changes. This allows a certain degree of adapting the size of the segments to the type of text (longer segments on rare topic changes).

```
COHERENCY_DETECTION(document d)

fixed_segments ← SEPARATEINTOSEGMENTS (d)
t_coherent_seg ← ALLOCATEMEMORY ()
current_segment ← ALLOCATEMEMORY ()
borderIndex ← 1
while (all units have been processed)
do (borderIndex ← borderIndex + 1)
    if empty (current_segment)
        leftSegment = GETLASTITEM(fixed_segments)
    else
        leftSegment= current_segment

    rightSegment = GETNEXTITEM(fixed_segments)
    topic_left =  DETECTTOPIC(leftSegment)
    topic_right = DETECTTOPIC(rightSegment)
    if topic_left ≠ topic_right
        ADDTOLIST (topic_coherent_seg, leftSegment)
        current_segment ← DELETECONTENT()
    else
        APPEND(current_segment, rightSegment)
return topic_coherent_seg
```

tokens ← TOKENIZEDOCUMENT (startPosition)
maxDistance ← SETMAXDISTANCE ()
current_distance ← 0
relevant_segment ← ALLOCATEMEMORY ()

tokenCounter ← 1
while (max distance has been reached)
do (tokenCounter ← tokenCounter + 1)
    currentToken = tokens [tokenCounter]
    ADDTOKEN(relevant_segment, currentToken)
    if TOKENISENTITY (currentToken) OR
    if TOKENISREFTOENTITY (currentToken)
        current_distance ← 0
    else
        current_distance ← current_distance + 1

    if current_distance = maxDistance
        break;

return relevant_segment
```

Figure 5. Algorithm for the extraction of relevant segments with the use of term and term-reference occurrences.

IV. ALGORITHM FOR EXTRACTION OF RELEVANT SEGMENTS

The approach we are proposing is a modification of Vocabulary Introduction. The entire algorithm is represented on Fig. 5. Instead of measuring the amount of newly introduced vocabulary we are measuring the distance from the last mention of the target entity or a reference to it. The starting point of the processing is at the index of target entity occurrence in the document. From then onward each of the following tokens are evaluated if it is the target entity or a reference to it. The end of the relevant segment is determined when a certain number of tokens have been found not to be a mention of an entity or a reference to it. The number of tokens which defines the maximum distance from the last mention of the entity or entity-reference is set at the average number of words per sentence in the entire repository.

Evaluation if the token is the mention of the target entity is comprised of two verifications. First is the evaluation if the token is a direct representation of the target entity: the entity itself, a synonym or an abbreviation of the entity. Much more difficult is the determination if the token is a reference to the entity itself. In fact the most challenging task in the algorithm is the resolution if a token is the reference to the target entity. This relies on the part-of-speech processing of the text. Using part of speech tags, together with hand-written rules, tokens are linked to previously encountered entities. If a link between the current token and a previously scanned token is found then the current token is treated as a reference to the target entity.

We have manually defined several types of frequently occurring sentence types. For instance: a definition type sentence begins with the target entity followed by a form of the verb "to-be" followed by a noun-phrase, optionally added with an additional description. Consider the following sentence where the target entity is "Crohn's disease":

"Crohn's disease is an inflammatory disease, which may affect any part of the digestive system."

The part-of-speech analysis of the sentence produces the following tags (using Brown corpus tag-set):

[('Crohns', NP$), ('disease', 'NN'), ('is', 'BEZ'), ('an', 'AT'), ('inflammatory', None), ('disease', 'NN'), (',', ','), ('which', 'WDT'), ('may', 'MD'), ('effect', 'NN'), ('any', 'DTI'), ('part', 'NN'), ('of', 'IN'), ('the','AT'), ('digestive', 'JJ'), ('system', 'NN')].

Our algorithm would try to match the input sentence to one of the predefined sentence types and find a match for the *definition* type of sentence. This type would suggest a specialization relation between "Crohn's disease" and "inflammatory disease" consequently meaning that the rest of the sentence refers either to the target entity or the more general category of the target entity. In any case, the word "which", tagged as a determiner can be categorized as a reference to the target entity since it refers to either the target entity itself or its general category.

V. EXPERIMENTAL EVALUATION

The experiment was done on a freely accessible dataset of scientific papers [17]. The dataset is a general repository. The dataset used for the experiments is a collection of scientific papers from the BioMed Central corpora [17]. The dataset contains 110.345 files. 3367 files don't contain full-text but a link to a PDF published online. We used only the files with full content. Statistics on file count, number of sentences and words in the dataset used in the experiment is represented in Table 1.

TABLE I. STATISTICS ON THE DOCUMENT REPOSITORY

Metric	***Value***
Number of files	110 345
Number of processed files	106 978
Number of sentences in processed files	35 377 906
Number of words in processed files	416 009 219
Average words per sentence	11.88
Average words per file	3888.74
Average sentences per file	330.70

A. Preprocessing

As the dataset contains documents in XML format the extraction of plain-text was done by extracting the relevant node and stripping away unnecessary tags. Tokenization was performed with a modified NLTK tokenizer [14]. NLTK tokenizer is a simple tokenizer that uses white space as a delimiter. Given many domain-specific terms in biomedical texts this type of tokenizer is not appropriate as it is unable to handle the complexity of punctuations in papers. Therefore some modifications were required. Considering that the final task of our research is the validation of new knowledge produced by ML, we have determined that, it is more profitable to have more tokens: the entities in the rule have to be located in the repository in order to extract knowledge on them. Therefore to improve retrieval the text should be split into all reasonable tokens (therefore white space splitting is insufficient). A hyphenated word "bottle-fed" should be tokenized into three tokens: "bottle", "fed" and "bottle-fed". This offers the possibility of matching a rule "IF food = bottle THEN …". The modification that we made to the NLTK tagger is an additional step after the initial tokenization on white-space. Each token from the first step is evaluated if it is reasonable to split it into multiple tokens. The initial white-space separated token is used for token normalization: it is converted to lowercase and all punctuations are removed. "Bottle-fed" becomes "bottlefed" with equivalence tokens: "Bottle-fed", "bottle-fed", "bottle" and "fed", ordered by relative token match ("bottle" and "fed" only match 50% of the original tokens). Relative token match is used at the retrieval of relevant documents.

B. Automated segmentation of documents

The repository was searched for all references of various diseases. Documents that contain names of well-known diseases were identified and a hundred documents were randomly selected to perform the evaluation of the approach. The set was split into three subsets and each was processed individually. Each document in each set was run through the algorithm to extract the relevant segments. The same documents were also manually inspected and human operators performed the segmentation and extraction of the segments in which, according to their judgment, relevant information on the target entities could be found. Table 2 presents the results of the algorithm compared to the results of manual segmentation. The average number of words (tokens) in extracted segments is compared to the values of manual extraction. Standard measure of the algorithm's ability to extract relevant segments is *recall.* The recall of the presented algorithm in the conducted experiment is 70.1%. The standard measure of *precision*, the ability to present only relevant items is somewhat altered: in our case the number of words in segments obtained by the algorithm is divided by the number of words in manually extracted segments. Consequently the precision of the presented algorithm is 78%. Given the precision and recall the F_1 score for the presented approach of document segmentation is 73.84%.

TABLE II. SEGMENTATION RESULTS

Set	*Evaluated property*	*Human*	*Algorithm*
S1	Avg. length of relevant segments [words]	63.4	39.6
S2	Avg. length of relevant segments [words]	49.2	55.4
S3	Avg. length of relevant segments [words]	58.9	42.1
S1	Num. of segments extracted [segment]	33	27
S2	Num. of segments extracted [segment]	33	22
S3	Num. of segments extracted [segment]	34	26

VI. CONCLUSION

We have presented an approach to automatically extract segments of natural language documents. The segments are used as source information for the verification and validation of ML results. It has been shown that a wider use of machine learning is inhibited by the effort that is required to validate the results. If we consider EM's that were introduced to improve the performance, the effort required to verify the final result grows exponentially. An approach that lessens the burden of manual validation is the filtering of ML results with the facts, research results found in scientific papers. The ability to extract relevant information from natural text relies on the ability of finding relevant documents and extracting topic coherent segments which discuss the entities from ML results. Extraction of relevant segments from large documents inherently introduces the problem of border definition. This paper presents an algorithm that uses a distance metric to determine the point where the segment is no longer topic coherent. The start of the relevant segment is the point where the target entity is introduced in the document. From that point on the text is tokenized and each token is evaluated if it is a mention of the target entity or a reference to it. Part-of-speech tags combined with inference rules are used to determine if the token is the entity, an abbreviation of the entity or a direct/indirect reference to it. The algorithm was evaluated on a set of 100 documents which were first manually processed to extract relevant passages. The experiment shows that the algorithm is capable of extracting the relevant passages; however it is dependent on the rules that allow it to classify individual tokens. In our future work we will focus on developing the rules that enable classification of tokens. We believe that a richer set of rules will allow the algorithm to recognize more obfuscated references to the target entities and consequently perform better.

Abstract - *Humans communicate with others using natural language. Because many expressions in natural language can convey the same message, humans interpret these expressions flexibly based on their knowledge of words and association skills. An Association System was constructed on a computer by applying Concept Bases and the degree of association. This paper proposes a method for generating an association word from several other words with the Association System to show that it can achieve humanlike associative abilities on a computer. The proposed method generated a natural human association with 61.0% accuracy and 77.0% recall.*

Keywords: Concept Base, degree of association, association mechanism

1 Introduction

Recently, robots have been in demand not only for simple mechanical tasks but also for conveying information that is useful in everyday life. To do this, robots need to communicate with ordinary people. The most important factor in human communication is natural language conversation. So, it is important for robots to achieve humanlike conversational capabilities for easy communications with humans.

Humans can converse flexibly with natural language based on their knowledge of words, common sense, and ability to associate one concept with other concepts. This paper proposes a method for generating an association word from several other words. Humans can associate words such as "fishing, sewing, injections, prick…" from the word "needle." Words such as "fishing, sewing" are associative with the words "needle" and "thread." Humans associate only the related words, so if three words such as "needle," "thread," and "fish," are stated, humans associate only "fishing."

As mentioned, humans can make flexible multi-word associations by using their own knowledge of words. In this paper, an Association System, which consists of Concept Bases [1] [2] and degrees of association [3], achieves this kind of associative ability on a computer. A Concept Base is the modeling of the knowledge of a word, so the system is able to get knowledge about several words. In addition, the degree of association can choose the correct association word by determining whether a relationship exists between several entered words and the association word.

In this paper, we show the method for generating an association word from several other words to achieve humanlike associative abilities on a computer.

2 Association System

2.1 Concept Base

A Concept Base is a knowledge base that defines words as concepts. A concept is defined in the following equation.

$$A = \{(a_1, w_1), (a_2, w_2), ...(a_L, w_L)\} \quad (1)$$

A is the concept label, is the attribute, and is the weight of the attribute. The Concept Base in the Association System builds up to 87242 concepts. Table 1 shows a specific example of some concepts.

Table 1: Specific example of concepts

Concept	(Attribute, Weight)
Summer	(summertime, 0.34) (summer vacation, 0.11) ...
Summertime	(heat, 0.18) (sun, 0.04) ...
...	...

An attribute of the concept is called the first-order attribute. In the Concept Base, words defined as concepts also form the attributes. In addition, attributes can be derived from attributes. Attributes derived from attributes are called second-order attributes of the original concept.

In the example, the "summertime" attribute of the "summer" concept has been defined as a concept. So, the "heat" and "sun" attributes of the "summertime" concept are second-order attributes of the "summer" concept.

2.2 The degree of association

The degree of association (*DoA*) quantifies the relationship between concepts by using attributes that characterize the chain-reaction structure of the Concept Base. The relationship between multiple concepts is expressed quantitatively in this process. The following shows how to calculate the degree of association between concept A and concept B. This is defined as *DoA (A, B)*.

For concepts A and B with primary attributes ai and bi, weights ui and vj, and numbers of attributes L and M, respectively (L ≤ M), the concepts can be expressed as follows:

$$A = \{(a_1, u_1), (a_2, u_2), ...(a_L, u_L)\} \quad (2)$$

$$B = \{(b_1, v_1), (b_2, v_2), ...(b_M, v_M)\} \quad (3)$$

The degree of match DoM(A,B) between concepts A and B is defined as follows, where the sum of the weights of the various concepts is normalized to 1:

$$DoM(A,B) = \sum_{a_i = b_j} \min(u_L, v_j) \quad (4)$$

The degree of association is calculated by calculating the degree of match for all of the targeted primary attribute combinations and then determining the relation between the primary attributes. Specifically, priority is given to the correspondence between matching primary attributes. For primary attributes that do not match, the correspondence between primary attributes is determined to maximize the total degree of matching. By using the degree of matching, it is possible to give consideration to the degree of association, even for primary attributes that do not match perfectly. When the correspondences are thus determined, the degree of association DoM(A,B) between concepts A and B is as follows:

$$DoA(A,B) = \sum_{i=1}^{L} DoM(a_i, b_{xi}) \times \frac{(u_i + v_{xi})}{2} \times \frac{\min(u_i, v_{xi})}{\max(u_i, v_{xi})} \quad (5)$$

In other words, the degree of association is proportional to the degree of identity of the corresponding primary attributes, the average of the weights of those attributes, and the weight ratios.

3 A method for generating association words

The proposed method generates association words from the input of several words. Figure 1 shows a flowchart of the proposed method.

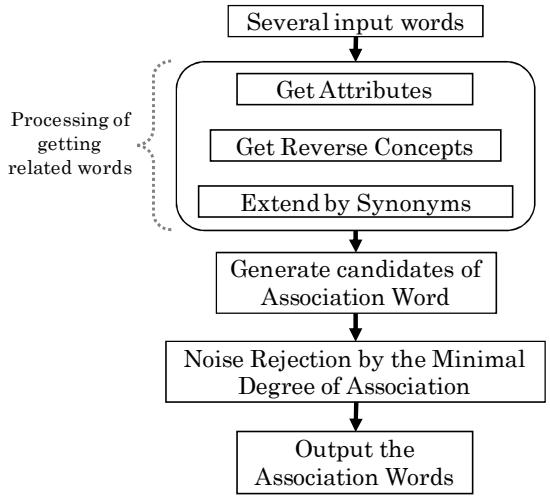

Figure 1: Flowchart of the proposed method

The input is several words which are defined in the Concept Base. There is no limit to the number of words. First, words related to the entered words are acquired from the three processes of Get Attributes, Get Reverse Concepts, and Extend by Synonyms. After acquiring the related words from the entered words, the related words generated for all entered words are considered as common related words. Before the output of association words, potential association words are processed by Noise Rejection by the Minimal Degree of Association to remove the noise from the common related words. The following sections explain each process in detail.

3.1 Get Attributes

A set of attributes defines the meaning of a concept, so the relation between concepts and attributes is relevant. To acquire attributes as related words in this process, the entered words are considered as concepts.

For the range of attributes to be acquired, the first-order attributes define the meaning of a concept directly, so the relevance is considered strong between the entered words and their first-order attributes. In addition, the second-order attributes define the meaning of the first-order attributes when these are viewed as a concept. This means that second-order attributes are considered potentially relevant with the original entered words. So, in the Get Attributes process, both first-order attributes and second-order attributes are generated as related words.

Figure 2 shows a specific example of Get Attributes from the entered word "summer."

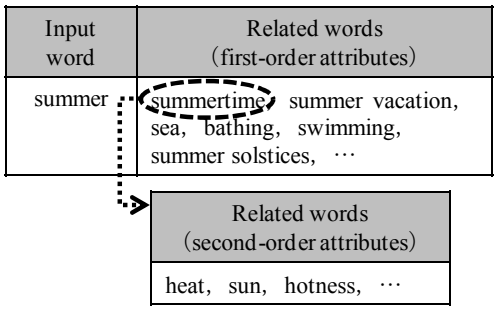

Figure 2: Specific example of Get Attributes from entered word "summer"

Related words such as "summer, summer vacation, sea…" are generated when getting only the first-order attributes. Second-order attributes such as "heat, sun…" are generated when first-order attributes such as "summer" are viewed as a concept.

A problem that occurs is an entered word with numerous attributes has too many related words. Therefore, second-order attributes are limited to 100 words. Specifically, first-order attributes can generate the top 10 words in weight and second-order attributes are generated from each of these first-order attributes.

3.2 Get Reverse Concepts

A concept Y is called the reverse concept of X when concept X is defined as an attribute of concept Y. A concept Y having concept X as an attribute means that reverse concept Y is defined by concept X. Thus, concept X and reverse concept Y are considered related. So, in this process, reverse concepts of entered words are acquired as related words.

Figure 3 shows specific an example of the Get Reverse Concepts.

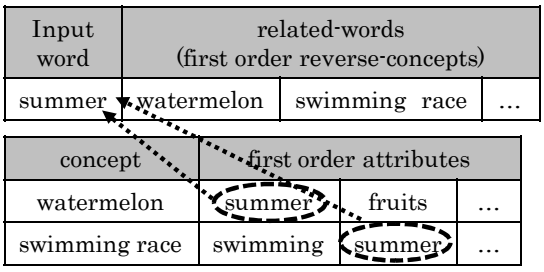

Figure 3: Specific example of Get Reverse Concepts from entered word "summer"

The entered word is "summer," so the concepts defined by "summer" as an attribute means that the reverse concepts of "summer" are acquired as related words. In this case, "summer" exists in concepts such as "watermelon" and "swimming" and also as attributes. Thus, these words are acquired as reverse concepts of "summer."

In addition, Get Reverse Concepts was performed with the same two patterns used for Get Attributes. That is, getting only first-order reverse concepts or getting first-order reverse concepts and second-order reverse concepts generate related words.

The second-order reverse concept is defined by an attribute defined with the entered word as an attribute. Second-order reverse concepts are also limited to 100 words. The top ten first-order reverse concepts are taken according to weight and second-order reverse concepts are generated from each of the first-order attributes.

3.3 Extend by Synonyms

In the Extend by Synonyms process, new related words are obtained from the synonyms of entered words. Specifically, the synonyms of entered words are considered as concepts to acquire first-order attributes and first-order reverse concepts as related words. Synonyms are acquired by a synonyms dictionary that is created automatically [4]. The synonyms dictionary is registered as a set of relations that consists of a head word and its synonyms. The number of registered relations is 31657 sets.

3.4 Generate Candidates of Association Word

In this process, related words that are generated for all entered words are acquired as common related words. Common related words have an association with all entered words, so these words are acquired as candidates of the final output (candidates of the association word).

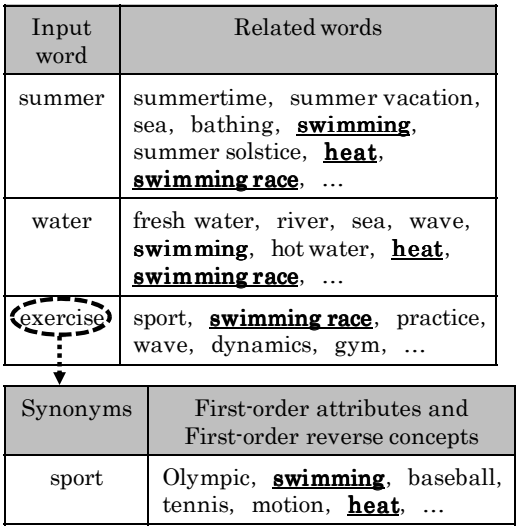

Figure 4: Specific example of Generate Candidates of Association Word from the entered words "summer," "water," and "exercise"

Figure 4 shows a specific example of Generate Candidates of Association Word from the entered words "summer," "water," and "exercise."

In this example, each entered word has the related words shown in the figure. The candidates of the association word are "swimming" and "heat".

3.5 Noise Refection by the Minimal Degree of Association

Due to noise, candidates of the association word obtained in the previous sections may be inconsistent with human association. So, the process in this section removes the noise of candidates of an association word according to the degree of association between entered words and candidates of the association word.

Candidates of association word C are obtained from entered words A and B. At this time, this process calculates each of the degrees of association between A and C, A and B. Then, the smaller value is defined as the lowest degree of association of C. The lowest degree of association is set as the threshold. If the lowest degree of association of C is lower than the threshold, candidates of association word C would be considered noise. In addition, the threshold of the lowest degree of association was determined experimentally as 0.05.

Figure 5 shows a specific example of Noise Rejection by the Minimal Degree of Association.

Candidates of association word	Input word	Degree of association
swimming	summer	0.10
	water	0.08
	exercise	0.06

Candidates of association word	Input word	Degree of association
heat	summer	0.04
	water	0.03
	exercise	0.02

Minimal degree of association is lower than the threshold

Figure 5: Specific example of Noise Rejection by the Minimal Degree of Association

In this case, candidates of the association word "swimming" and "heat" are obtained from the entered words "summer," "water," and "exercise." At this time, the process calculates the degree of association between each entered word and candidates of the association word. First, the lowest degree of association of "swimming" is 0.06 with the entered word "exercise." It is larger than the threshold, so the process is not performed. Next, the lowest degree of association of "heat" is 0.02 with the entered word "exercise." It can be determined that the association between the entered word "exercise" and candidates of the association word "heat" is slight since the lowest degree of association of "heat" is less than the threshold.

Therefore, one candidate of the association word "heat" is considered noise. The final output (association word) is "swimming" from the entered words "summer," "water," and "exercise."

4 Evaluation

An evaluation was performed using 100 test sets of several entered words and association word pairs created by a questionnaire. The test sets were created so that two or more entered words were needed to associate the association word. Precision and recall were evaluated by generating the association words by the proposed method with several entered words.

The precision was calculated by the percentage of correct association words determined correctly by more than two people in a visual assessment by three people. The recall was calculated to count the number of test sets generated for the association word described in the test set.

The evaluation was performed in two ways to obtain the related words. The patterns are as follows.

A: First-order attributes and first-order reverse concepts

B: A and second-order attributes and second-order reverse concepts

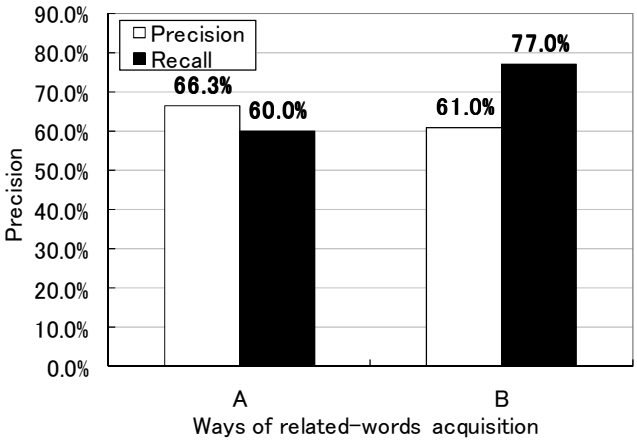

Figure 6: Evaluation

In addition, the process of Extend by Synonyms was applied to both patterns. Figure 6 shows the evaluation.

The precision of A is more than 5.3% higher than that of B. In contrast, the recall of B is more than 17.0% higher than that of A. The F-measure is 0.630 for A, 0.681 for B. Based on the above, method B (first-order attributes, first-order reverse concepts, second-order attributes, and second-order reverse concepts) in the acquisition of related words is proposed, since the precision was 61.0% and the recall was 77.0%.

5 Conclusion

This paper proposes a method of generating an association word from several other words by using the Association System. The proposed method was able to acquire related words by leveraging the knowledge of words defined in the Concept Base to generate the association words. The proposed method (first-order attributes, first-order reverse concepts, second-order attributes, and second-order reverse concepts) obtained a natural human association with 61.0% accuracy and 77.0% recall. This result shows that this study was able to achieve humanlike associative abilities on a computer.

Approaching Textual Entailment with Sentiment Polarity

Antonio Fernández[1], Yoan Gutiérrez[1], Rafael Muñoz[1] and Andrés Montoyo[1]
[1]Department of Software and Computing Systems, University of Alicante, Alicante, Spain

Abstract - *We present a study about the influence of sentiment polarity (positive, negative and neutral) in the Textual Entailment Recognition. The main idea of this paper is guided to identify the behavior of the sentiment polarity (obtained by a method of sentiment polarity classification based at the construction of Relevant Polarity Trees) on the Recognition of textual Entailment. Our analysis was conducted from a semantic conceptual point of view using a multidimensional resource. We also describe an experiment to evaluate the proposal in the Textual Entailment Recognition tack. The well knows dataset from Pascal Challenger RTE-1, RTE-2, RTE-3, RT4 and others like BPI, ENGARTE2 and Lexical were used as a corpus for testing our idea. Considering that only the sentiment polarity is utilized, we get an acceptable 66% of accuracy detecting the entailment relation between text-hypothesis pairs.*

Keywords: Textual Entailment, Sentiment Polarity, Opinion Mining, Multidimensional Semantic Analysis.

1. Introduction

The goal of Recognizing Textual Entailment (RTE) is to determine when one piece of text entails another. The ability to make such determinations is considered essential for several natural language processing tasks, such as information extraction, summarization, question answering and machine translation [1].

In this paper, we address the problem of RTE by treating it as a classification task. The main and unique feature we used was the recognition of the polarity in the text-hypothesis pair. Using for this, like dataset, those that were offered by the Pascal Challengers RT1 [2], RT2 [3], RT3 [4], RTE-4 (2-way only) dataset at TAC 2008 [5]. Also dataset from and ENGARTE[1], Lexical and BPI[2] had been used in order to increase the quantity of text-hypothesis pairs to examine. Of course, we used only dataset tagged with entailment information. Our principal objective is not to create a system for entailment detection, but appraising the influence of sentiment polarity in this task.

There are several resources involved in the sentiment polarity detection. *ISR-WN* [6] is a resource that allows us the integration of several semantic resources mapped to WordNet [7]. It is used as a core to link several resources like *SUMO* [8], WordNet Domains [9], WordNet Affect [10], Semantic Class [11] and SentiWordNet [12]. The integrated resource allows us to navigate inside the semantic network.

Using *ISR-WN* we tagged all the text-hypothesis entailment pairs with polarity information. Then we checked the relation between an entailment condition and polarity relation. We conduct several experiments to determine the influence of sentiment polarity in the Textual Entailment Recognition task.

The sections that follow present a brief overview of the related work, some important background and preliminaries for our idea, a description of the resource we used, the experiments that were performed, and the results obtained. In the last section, we offer our conclusions concerning to the influence of polarity in RTE task.

2. Related Work

Our word is partially related to [13], they presented and strategy for detecting author commitment to the truth/falsity of complement clauses based on their syntactic type and on the meaning of their embedding predicate. In addition, they showed that the implications of a predicate at an arbitrary depth of embedding about it complement clause depend on a globally determined notion of relative polarity. Finally, they demonstrate that different classes of complement-taking verbs have a different effect on the polarity of their complement clauses and that this effect recursively depends on their own embedding.

Other research [14] has been conducted in analyzing a methodology to detect phrases related to different characteristics and the employment of RTE for opinion mining. They test the entailment relation in a window of three consecutive phrases. In this work we can see from the obtained results, textual entailment can be useful at the time of performing category based opinion mining. However, such and as they mention, much remains to be done at the level of computing semantic similarity between opinionated texts.

There are not plenty of works about the influence of polarity in RTE. We only find a few of them that touch very lightly this theme. As far as we are aware of, such those researches has not been done in the same way, neither with our same purpose.

3. Some background and preliminaries

There are many resources implicated in our front sight. These have been applied in order to conceptualize the analyzed sentences since different point of view. For example:

- WordNet (WN) [7] as taxonomy,
- SUMO (Suggested Upper Merged Ontology)3 [15] categories,
- WordNet Domains (WND) [9],
- WordNet Affect (WNA) [16],
- Semantic Classes (SC) labels [11],
- SentiWordNet (SWN) [12].

Amount these resources only SentiWordNet is a lexical resource where each synset of *WN* is associated to three numerical scores Obj(s), Pos(s) and Neg(s). Each score describes how Objective, Positive, and Negative the terms contained in the synset are respectively. That means that one synset would have three opinion-related properties with a certain degree (e.g. atrocious#3 [Pos: 0|Neg: 0.625 |Obj: 0.375]).

4. Integration of Semantic Resources based on WordNet (ISR-WN)

ISR-WN [6] is a resource that allows the integration of several semantic resources (the aforementioned resources) mapped to *WordNet*. In *ISR-WN*, *WordNet1.6* or *2.0* is used as a core to link those resources. As Gutiérrez et. al. [17] describe, the integrated resource allows navigate inside the semantic network, creating new virtual links amount elements of the different resources.

In order to apply the multidimensional polarity that *ISR-WN* can provide, we have analyzed related approaches like [18], [19], [20] and others published on NTCIR-8 MOAT competition [21] that take into account the polarity on the sentences. Then, we have decided to use Senti-RST [20] because it is an approach capable of being applied over several dimensions (resources) at once to obtain the polarity of the sentences, and it results are considered relevant to the polarity detection task.

5. Senti-RST

We propose to use an unsupervised knowledge-based method that uses the Relevant Semantic Trees (*RST*) [22] technique combined with *SentiWordNet*3.0 [12]. The aim of this method named by us *Senti-RST* [20], is to obtain a *RST* of each sentence and then associate this *RST* with sentiment polarity values. The process involves the following resources: *WND*, *WNA*, the *WN* taxonomy, *SUMO* and Semantic Classes (*SC*). Because of *SC* does not have a tree structure we simply obtain the Relevant Semantic Classes. Subsequently, we determine the polarities collected for each label of each *RST* obtained according to the analyzed sentence.

[3]http://www.ontologyportal.org/

Is important to remark that, the original RST is a method able to solve de word sense disambiguation task building relevant semantic trees of the sentences based on each semantic dimension of *ISR-WN*. In order to measure the association between concepts and words in each sentence according to a multidimensional perspective, *RST* uses the Association Ratio (AR) measure [23]. Our purpose is to include the Multidimensional Semantic Analysis into the Opinion Analysis using *RSTs*. The proposal involves four steps presented on next sections 5.1, 5.2, 5.3, 5.4.

5.1. Obtaining the Relevant Semantic Trees

In this section, we use a fragment of the original *RST* method with the aim of obtaining Relevant Semantic Trees of the sentences. Notice that this step must be applied for each resource.

Once each sentence is analyzed, the *AR* value is obtained and related to each concept in the trees. Equation (1) is used to measure and to obtain the values of Relevant Concepts:

$$AR(C, f) = \sum_{i=1}^{n} AR(C, f_i) \quad (1)$$

Where:

$$AR(C, w) = P(C, w) * log_2 \frac{P(C,\ w)}{P(C)} \quad (2)$$

In both equations *C* is a concept; *f* is a sentence or set of words (w); f_i is the *i-th* word of the sentence *f*; *P (C, w)* is the joint probability distribution; *P(C)* is the marginal probability.

Using the *WND* resource, we show the manner in which we obtain the *RST*. The first stage involves the lemmatization of the words in the sentence. Next, each lemma is looked up in *ISR-WN* and it is correlated with the *WND* concepts.

After obtaining the Initial Concept Vector of Domains, we apply Equation (3) in order to obtain the Relevant Semantic Tree related to the sentence.

$$AR(PC, f) = AR(ChC, f) - ND(IC, PC) \quad (3)$$

Where:

$$ND(IC, PC) = \frac{MP(IC, PC)}{TD} \quad (4)$$

Here $AR(PC, f)$ represents the AR value of PC related to the sentence *f*; $AR(ChC, f)$ is the AR value calculated with Equation (1) in case of ChC was included in the Initial Vector, otherwise is calculated with the Equation (3); ChC is the Child Concept of PC; ND is a Normalized Distance; IC is the Initial Concept from we have to add the ancestors; PC is Parent Concept; TD is Depth of the hierarchic tree of the resource to use; and MP is Minimal Path.

Applying the Equation (3), the algorithm to decide which parent concept will be added to the vector is shown here:

if ($AR(PC, f)$ $value$ $>$ 0){
if (PC had not been added to vector)
PC is added to the vector with $AR(PC, f)$ $value$;
else PC $value$ $=$ PC $value$ $+$ $AR(PC, f)$ $value$;}

The obtained vector represents the Domain tree associated to the sentence. After the Relevant Semantic Tree is obtained, the Factotum Domain is eliminated from the tree (it does not provide useful information [9] and experimentally we confirmed that it introduced errors).

5.2. Obtaining the Positive Semantic Trees

In order to obtain the Positive Semantic Trees (PST) of the sentence, we will follow the same process described in section 5.1. In this case, the AR values will be replaced by the polarity value pertaining to the analyzed sense. The polarity is obtained from the *SentiWordNet 3.0* resource, where each given word sense from *ISR-WN* for *WordNet* version 2.0 is mapped to *WordNet* version 3.0. Hence, we can find each given sense from *ISR-WN* in *SentiWordNet 3.0* and obtain the respective polarities. This new value will be called Positive Association ($PosA$). The $PosA$ value is calculated using Equation (5).

$$PosA(C, f) = \sum_{i=1}^{n} PosA(C, f_i) \quad (5)$$

Where:

$$PosA(C, w) = \sum_{i=1}^{n} PosA(C, w_i) \quad (6)$$

Where C is a concept; f is a sentence or set of words (w); f_i is a *i-th* word of the sentence *f*; $PosA(C, w_i)$ is the positive value of the sense (w_i) related to C.

The $PosA$ is used to measure the positive value associated to the leaves of the Semantic Trees where Concepts are placed. Subsequently, using the same structure of RST we create new Semantic Trees without *AR* values. Instead, the leaves with Concepts of this new Semantic Trees will be annotated with the $PosA$ value.

Later, to assign some Positive value to the parent Concepts, each parent Concept will accumulate the positive values from child Concepts. Equation (7) shows the bottom-up process.

$$PosA(PC) = \sum_{i=1}^{n} PosA(ChC) \quad (7)$$

Where PC is the Parent Concept; ChC is the Child Concept of PC; and $PosA(ChC)$ represents the positive value of the ChC.

5.3. Obtaining the Negative Semantic Trees (*NST*)

In this phase, we repeat the step described in Section 5.2, but for negative values.

5.4. Obtaining polarities of the sentences

In this step, we concentrate on detecting which polarity is more representative according to the Semantic Trees obtained for each resource (dimension). For that, we combine the RST with PST and RST with NST. Depending on the obtained results, we classify the sentence as Positive, Negative or Neutral. Of course, if there is not RST the sentence is tagged as UNKNOWN (UNK). Before performing this step, we have not to normalize the three types of Semantic Trees (RST, PST and NST) for each dimension to work with values between 0 and 1, because the original paper demonstrated that it introduce errors.

The goal is to assign more weight to the polarities related to the most relevant Concepts in each Relevant Semantic Tree. Equation (8) shows the steps followed in order to obtain the positive semantic value.

$$ACPosA(RST, PST) = \sum_{i=1} RST_i * PST_i \quad (8)$$

Where $ACPosA$ is the Positive Semantic Value of the analyzed sentence obtained for one Dimension, *RST* is the Relevant Semantic Tree sorted with the format: *RST [Concept| AR]*; *PST* is the Positive Semantic Tree sorted according *RST* structure with format: *PST [Concept|PosA]*; RST_i is the *i-th AR* value of Concept *i;* PST_i is the *i-th PosA* value of the concept *i.*

In order to measure the negative semantic value (*ACNegA*), we employ a similar equation replacing *PST* with *NST*. After obtaining the semantic opinion requirements, we evaluate our approach over thirteen annotated datasets from RTE for the monolingual English tasks.

This proposal consists of accumulating the $ACPos$ values and $ACNeg$ values of all Dimensions and comparing them. For a shorter representation we named this method $ALLRec$. The accumulated values will be named $ACPosD$ and $ACNegD$ respectively. In case $ACPosD > ACNegD$ the assigned value is POS, if $ACPosD < ACNegD$ the assigned value is NEG. Contrary to as Gutierrez in [20] did, in our proposal if it is not possible to create the RST for the analyzed phrase, therefore, there is not NST and PST neither $ACPosD$ and $ACNegD$ nor polarity result. In this case the assigned value is UNK (Unknown answer). Otherwise, the assigned value is NEU.

5.5. Calculating polarity for Text-Hypothesis pair

In order to evaluate our approach we used the rules and corpus that concern to the English Textual Entailment monolingual task (RTE-1, RTE-2, RTE-3, RT4, ENGARTE2, Lexical and BPI). Those data sets have not the same structure, for example, RTE3 and RTE4 includes the 3-way classification.

First, all the datasets were normalized converting them to the same format, in order to use the same structure for

classification of the entailment. We used only files annotated with the entailment condition. Table 1 shows all parameters of the dataset transformation.

Table 1. Parameters for Text-Hypothesis pair.

Id	pair identification number
entailment	condition of the entailment
task	task of which the pair was extracted from
length	pair length
<t>“”</t>	words from text
<h>“”</h>	Words from the hypothesis

The entailment parameter takes the values: entailment or non-entailment. All values were converted to this kind of classification.

After that, all datasets are processed with *Senti-RST*. Then, the steps explained in topic 5.1, 5.2, 5.3 and 5.4 are executed. The output is a collection of six file tagged with polarity information (Pos, Neg and Neu), one file for each resource (*WNA*, *WND*, *SC*, *SUMO*, *WN* and *ALLRec* described in topic 5.4 according to $ACNegD$ and $ACPosD$). As aforementioned in topic 5.4 each dimension (resource) was combined with *SentiWordNet* as a core for polarity detection.

Finally, 6484[5] text-hypothesis pairs from 13 datasets files with polarity information and entailment relation were tagged, departing of the following statement:

- If a text-hypothesis pair has an unequal polarity and there is not entailment, we tagged this relation as TRUE.
- If a text-hypothesis pair has an unequal polarity and there is entailment, we tagged this relation as FALSE.
- If a text-hypothesis pair has an equal polarity and there is entailment, we tagged this relation as TRUE.
- If a text-hypothesis pair has an equal polarity and there is not entailment, we tagged this relation as possible (POS).
- If at least one a text-hypothesis pair was tagged *Senti-RST* with UNK in its polarities, this pair will be excluded from any calculation.

Principally we attempted to find the truth of the first supposition through an experiment. This will be introduced in the following epigraph.

5.6. The experiment

We accomplished an experiment aimed at to verify the effect of the polarity on RTE datasets, specifically, looking for what kind of polarity relation the entailment and non-entailment text-hypothesis pairs would have.

As we have several resources that give us the opportunity to obtain the polarity, we attempted uniting these criteria to give a definite polarity to the text-hypothesis pair. Using the output getting from *Senti-RST*, we made a voting decision in order to assign the final polarity of the phrases. The voting took into account the polarity results (13 datasets files with text-hypothesis pair tagged with polarity and entailment information) obtaining from *WNA*, *WND*, *SC*, *SUMO*, *WN* and *ALLRec*:

The condition for voting was:

- If two resources agree with positive decision of polarity and two with negative, then we decided to assign neutral polarity, since there is no agreement between them.
- If two resources agree with negative polarity decision and two with neutral, we decide to assign negative polarity.
- If two resources agree with positive polarity decision and two with neutral, we decide to assign positive polarity.
- Other way, a resource with a greatest value decides the phrase polarity.

At last, we obtained 6484 text-hypothesis pairs from 13 datasets, tagged with polarity information assignee by six different ways. As well as the voting decision considering all of them.

Table 4 shows a summary of our experiment. The rows from one to four exhibits the obtained analysis for pairs with Unequal Polarity and Non-Entailment relation (*UPNE*), pairs with Unequal Polarity and Entailment relation (*UPE*), pairs with Equal Polarity and Entailment relation (*EPE*) and pairs with Equal Polarity and Non-Entailment relation (*EPNE*). Columns from two to six contain the results of every resource. Column seven display the result for *ALLRec* and in last column it can be seen the result for our voting technique.

The terms on the rows six to nine of Table 4 were calculated with the fallowing equations:

$$PNE = \frac{UPNE}{UPNE + EPNE} \tag{9}$$

Where, *PNE* is the precision detecting non-entailment relation. *UPNE*, the number of non-entailment pairs with unequal polarity is considered as CORRECT Non-Entailment detected and *EPNE*, the number of non-entailment pair with equal polarity, still when we know than a non-entailment relation can has equal polarity; this parameter is considered as INCORRECT Non-Entailment detected, because it contrasts with our purpose of determining the non-entailment condition from an unequal polarity relation of the text-hypothesis pairs.

$$PPE = \frac{EPE}{EPE + UPE} \tag{10}$$

Where, PPE is the precision detecting possible entailment relation; EPE, the number of entailment pairs with equal polarity is considered as CORRECT Entailment detected; and UPE, the number of entailment pairs with unequal polarity is considered INCORRECT Non-Entailment detected.

Also accuracy is calculated as follows:

$$A = \frac{H}{H + F} \tag{11}$$

Where, A is the accuracy, H is the number of successes detecting the non-entailment and possible entailment

[5]RTE1, RTE2, RTE3, RT4, Lexical, Engarte2 and BPI datasets.

relation and F is the number of failures committed also detecting the non-entailment and possible entailment relation.

The Average Precision is calculated as in [3]:

$$AP = \frac{1}{R}\sum_{i=1}^{n}\frac{E(i)x\#EntailmentUptopair(i)}{i} \quad (12)$$

Where n is the number of the pairs in the test set, R is the total number of positive pairs in the test set, $E(i)$ is 1 if the *i-th* pair is positive and 0 otherwise, and i ranges over the pairs, ordered by their ranking. As it was aforementioned in topic 5.5, pairs tagged with POS or UNK were excluded from this analysis. The pairs tagged with POS, because we cannot say that they are errors. Those tagged with UNK, because we did not find some kind of polarity information for tagging them, so this is not an error of our method.

6. Results and Discussion

It is important to remark that phrases polarity relation systems still show great inaccuracy [21], being 51% the best f-measure result. The system that obtained this punctuation, UNINE [18], targeted to get the relevant terms identified with one kind of specific polarity in order to get the polarity of the sentence.

Our elected method (*Senti-RST*) to detect the polarity of the sentences, presents a difference of 10 points regarding UNINE when it was evaluated over MOAT's corpus [20]. However, we elected this method because we wished to evaluate the influence of polarity, obtained from each resource integrated in *ISR-WN*, in recognizing textual entailment relation.

Doing an analysis of Table 4 we can see that *SUMO* gets the greatest number (1801) of *UPNE*, but also it gets the greatest number of *UPE* (1816). Seeing the quantity of *UPNE*, we can think that *SUMO* would be able to have the best value of *PNE*, but it comes as no surprise that our voting technique obtain the better result for this parameter (*PNE*=0.562). If we take a look at *UPNE* and *EPNE* relation, this behavior will be understood.

Taking in to consideration the relation between *UPE* and *EPE*, *WNA* obtains the best result (*PPE* (0.455)) detecting the entailment relation from equal polarity. Also the best value of Average Precision (see Table 3). Unfortunately, this resource contains labels of affective dominions that are correlated only with words that denote emotional statuses. *WNA*, it is not enough populated as if to offer a label to each examined word, failing in many instances (38.5%). Of course, *WNA* cannot be utilized isolated, but it is a good complement for improving other resources. We decide to maintain *WNA* in our voting in spite of his problems, because when it can act it does very well.

On the other hand, Table 4 also shows more cases tagged with *UPE* than *EPE*, it has no sense an entailment with unequal polarity relation, and this is due to *Senti-RST* error estimating the polarity. Consider the following two examples from RTE1 dataset (dev.xml, pair id=19):

- <t>Researchers at the Harvard School of Public Health say that people who drink coffee may be doing a lot more than keeping themselves awake - this kind of consumption apparently also can help reduce the risk of diseases.</t>
- <h>Coffee drinking has health benefits.</h>

These two phrases seem to be positive, but the polarity relation estimated by *Senti-RST* does not show that (see Table 2). Then also, the voting assigns a wrong polarity to the pair.

Table 2. Polarity assigned by *Senti-RST* and the voting.

Pair	WNA	WND	SC	SUMO	WN	ALLRec	Voting
T	Neu	Pos	Pos	Pos	Neg	Pos	Pos
H	Neu	Neu	Neu	Neg	Pos	Neg	Neu

Table 3. The Average Precision from 13 datasets.

	WNA	*WND*	*SC*	*SUMO*	*WN*	*ALLRec*	*Voting*
1	0.77	0.64	0.71	0.71	0.67	0.71	0.70
2	0.79	0.65	0.66	0.59	0.74	0.71	0.67
3	1.00	1.00	1.00	1.00	1.00	1.00	1.00
4	0.68	0.77	0.52	0.49	0.55	0.64	0.59
5	0.79	0.85	0.73	0.92	0.88	0.81	0.88
6	0.78	0.64	0.69	0.69	0.67	0.71	0.67
7	0.80	0.63	0.63	0.62	0.63	0.66	0.60
8	0.78	0.61	0.67	0.63	0.62	0.70	0.65
9	0.71	0.64	0.70	0.64	0.66	0.70	0.66
10	0.70	0.64	0.69	0.64	0.66	0.70	0.66
11	0.75	0.60	0.64	0.62	0.66	0.69	0.66
12	0.70	0.54	0.62	0.61	0.60	0.64	0.64
13	0.74	0.60	0.66	0.65	0.64	0.67	0.64

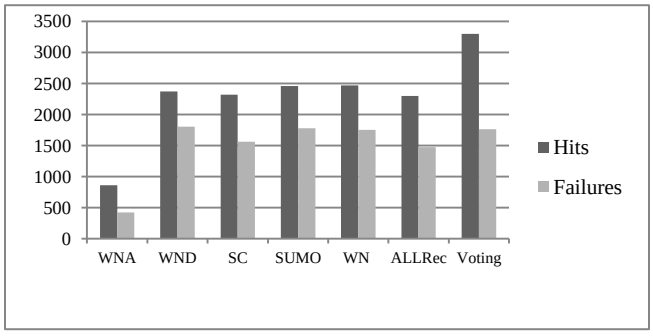

Fig 1. The Failures and Successes from each resource.

Continuing our analysis, we can see in Table 4 that our voting technique gets the greatest number of *UPNE* (0.562), and also (see Fig 1) a greatest number of successes. However, *WNA* exhibits the best relation comparing number of successes against number of failures, getting a better Accuracy (0.662). However, the voting surpasses *WNA* in about 2376 successes and exhibit a good Accuracy (0.646).

A resume of Average Precision for the 13 datasets is shown in Table 3. Only upon datasets four and five than *WND* and *SUMO*, respectively, they obtain better values;

WNA gets the maximum values of *AP*. However, we already knew the problem of low recall of this resource.

According to our judgment, the encouraging results of the voting technique (see Fig 1 and Table 4) it is due to the fact that is capable to take a better decision analyzing the verdict of all of the resources. As we can see in Table 3, all the resources have quite similar deportment, but also a complementary one. This, can be seen watching the behavior of *ALLRec*; excluding *WNA*, its results are better that each one of the isolated resources.

Table 4. Experiment results.

	WNA	***WND***	***SC***	***SUMO***	***WN***	***ALLRec***	**Voting**
Unequal Polarity and Non-Entailment (*UPNE*)	476	1733	1474	**1801**	1724	1409	1752
Unequal Polarity and Entailment (*UPE*)	426	1809	1565	**1816**	1751	1485	1755

Average Precision (*AP*)	**0.745**	0.678	0.684	0.675	0.690	0.725	0.678

7. Conclusion and future works

To our knowledge, this work represents the first attempt to discover the influence of sentiment polarity in the Recognition of Textual Entailment. We conducted an experiment with various datasets from the RTE task; showing that it is possible to detect -with an acceptable precision- the entailment and non-entailment relation, just analyzing the polarity of the text-hypothesis pair.

It is helpful to improve the method for calculating polarity with some kind of semantic analysis, in order to increase its precision. We accomplished a voting decision that he improved the calculation of polarity and it permitted us to get a good precision detecting non-entailment.

The resources as *WNA*, *SUMO* and the method *ALLRec*, seem to be very important for this task. It is urgent the taxonomic of *WNA*, because it is his weak point.

As a final remark, we observe that several resources are better for detecting non-entailment and others for entailment, so it is necessary to tackling this problem from a multidimensional point of view.

As further works, we propose to use this analysis as a new feature for a machine learning system.

Abstract— *This paper investigates the usage of a sentence simplification module that aims at improving automatically generated summaries built from a collection of texts. We describe an experiment with human subjects, that was conducted to assess the actual impact of sentence simplification in enhancing the summary quality. Motivated by those results, we present an automatic sentence simplification module that removes, from a sentence, specific sentential constructions that do not add critical information to the general message of that sentence. The rationale is that sentence simplification not only removes expendable information, but also makes room in a summary for further relevant data.*

Keywords: Multi-document summarization, sentence simplification, text simplification

1. Introduction

Text simplification is a NLP task that aims at making a text shorter and more readable, by simplifying its sentences structurally, into shorter and simpler sentences, while preserving the meaning and the information of the original sentence as much as possible. This task can be addressed in three ways: lexical, syntactic and discourse simplification. Lexical simplification involves replacing infrequent words by their simpler synonyms. To perform syntactic simplification, a linguistic representation of the text is produced as a tree-structure over which transformations are made [1]. Discourse simplification is concerned with maintaining coherence and cohesion of the simplified text: while syntactic simplification is applied to one sentence at a time, discourse simplification considers the interactions across sentences.

In order to improve the quality of the summary delivered to the end user, we discuss the inclusion of a syntactic simplification module within an extractive summarization system for Portuguese. Sentences are simplified after summarization to produce highly informative summaries.

Previous works ([2] and [3]) have focused mainly on syntactic simplification. Several types of structures are removed from a sentence based on rules induced using an annotated aligned corpus of complex and simplified texts. These structures include, for instance, passages delimited by punctuation, subordination and coordinating conjunctions, relative pronouns and boundaries of clauses and phrases. Closer to our work is the work of [4], in which simplification is used to improve content selection in a summarization system, that is, before summarizing. It is a syntactic simplification system, that uses hand-crafted rules which specify relations between simplified sentences.

A text usually contains passages that seek to explain or qualify other phrases, by providing background information about entities, or relating those entities to the discourse. These passages are parenthetical phrases. Appositions are a specific type of parentheticals, composed by a noun phrase that describes, details or modifies its antecedent (also a noun phrase). This type of phrases often add no crucial content to the correct comprehension of the sentence. Thus, we intend to remove those passages affecting the content expressed in the text to be summarized as less as possible.

The following examples present two sentences, from which parenthetical and apposition phrases (in bold) were removed, creating the corresponding simplified sentences.

Parenthetical phrase removal:

ORIGINAL SENTENCE:

Vilaça não duvidou declarar que Jones Bule ***(como ele chamava ao inglês)*** *fizera do Ramalhete "um museu".*

"Vilaça was the first to declare that "Jones Bule" **(as he called the Englishman)** had made of Ramalhete "a veritable museum"."

SIMPLIFIED SENTENCE:

Vilaça não duvidou declarar que Jones Bule fizera do Ramalhete "um museu".

"Vilaça was the first to declare that "Jones Bule" had made of Ramalhete "a veritable museum"."

Apposition phrase removal:

ORIGINAL SENTENCE:

Em 1858, Monsenhor Buccarini, ***Núncio de Sua Santidade,*** *visitara-o com ideia de instalar lá a Nunciatura.*

"In 1858, Monsignor Buccarini**, the Papal Nuncio,** had visited it with a view to establishing his residence there."

SIMPLIFIED SENTENCE:

Em 1858, Monsenhor Buccarini visitara-o com ideia de instalar lá a Nunciatura.

"In 1858, Monsignor Buccarini had visited it with a view to establishing his residence there."

To assess the possible improvements that simplification may bring to a summary, we performed a test with language experts, by asking them to rate simplified summaries over summaries whose sentences had not been simplified. The experts stated that simplification actually improves the final summary, since it allows the creation of a more simpler and incisive text, preserving at the same time the information to be conveyed. Based on these conclusions, we developed an automatic sentence simplification system that is included in a multi-document summarization system.

This paper is organized as follows: Section 2 describes the manual experiments; Section 3 describes the simplification system; Section 4 presents an evaluation of the summarization system with and without the simplification module; and, finally, in Section 5, some conclusions are drawn.

2. Manual Experiment

Experiments with human experts were made to assess whether text simplification improves the quality of a summary. Source texts were randomly selected from *TeMário* corpus [5]. Automatic summaries were build using GistSumm [6], a single-document summarizer for Portuguese (the only one available on-line). These summaries have a compression rate of 50%, since texts with a higher compression rate will not have enough material to work with. Then, simplified summaries were constructed by hand, from the automatic summaries, by removing parenthetical and apposition phrases from their sentences. This procedure was manually performed and aimed at simulating the process an automatic text simplification tool would execute.

In the first experiment, three language experts[1] were asked to perform two different tasks, in which they considered different texts (the source texts, the automatic and the simplified summaries). Also, they were invited to comment not only the tasks, but also the overall quality of the summaries. This experiment was based on two goals, Goal#1 and Goal#2, which will be pursued in two different tasks, Task#1 and Task#2, respectively. The two tasks, their goals and their evaluation are described in the following sections.

2.1 Task#1

This task aimed at verifying whether the simplified summary was a good summary for the original text (without taking into account the automatic summary). In order to perform this task, five texts, one from each section of the corpus (Special, World, Opinion, International, Politics) were selected. Experts were given the same five texts and their respective simplified summaries. Afterwards, they rated (0, bad – 5, very good) the simplified summaries concerning the original texts.

[1]Three researchers on Language Technology, graduated in linguistics.

Goal#1:

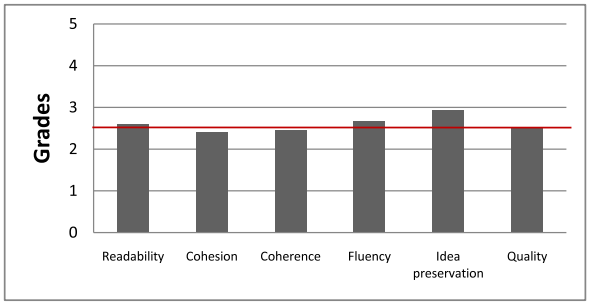
Confront the original text with a simplified summary, in order to assess the summary's quality.

Task#1:

Rate the **simplified summary** over the **original text**, concerning:
1. Readability (0 – 5);
2. Cohesion (0 – 5);
3. Coherence (0 – 5);
4. Fluency (0 – 5);
5. Original text idea preservation (0 – 5);
6. Overall quality (0 – 5);

Results are illustrated in Figure 1. By observing the graph, we can conclude that by having a low but positive grade (2.53) the *overall quality* of the summaries is acceptable. It is important to note that the best parameter is the *original text idea preservation* (2.93). Thus, we can infer that even though the simplified summary has less content, it does not mean that it does not maintain enough information conveyed by the original text. However, the way the information is presented is not the best, meaning the *fluency* (2.67) and the *readability* (2.6) of the text can be improved. The worst evaluated parameters are *coherence* (2.47) and *cohesion* (2.4). According to the experts, the sentence selection causes a lack of cohesion in the overall text. Since sentences seem disconnected and not linked with each other, text coherence is also compromised.

Fig. 1: Simplified summaries features.



2.2 Task#2

This task aimed to confront both summaries to verify if the simplified summary, though with less content, can still convey the same information within the automatic one. It comprises two phases. In PHASE I, the simplified summary is rated vis a vis the automatic summary, considering the same set of features used in Task#1. PHASE II seeks to understand if the simplification process would not remove information that is relevant to the overall understanding of

the text. Thus, experts have answered a survey that compares the automatic and the simplified summaries.

Goal#2:

Compare an automatic summary with a simplified summary in order to assess the simplified summaries quality.

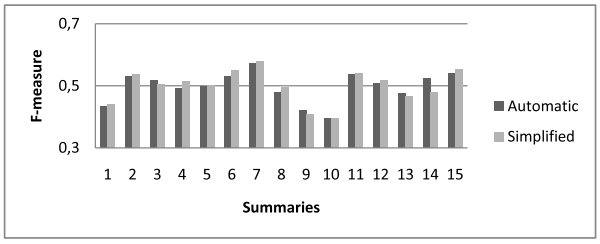
Task#2:

PHASE I: Rate the **simplified summary**.
1. Readability (0 – 5);
2. Cohesion (0 – 5);
3. Coherence (0 – 5);
4. Fluency (0 – 5);
5. Original text idea preservation (0 – 5);
6. Overall quality (0 – 5);

PHASE II: Answer the following questions by comparing the **simplified summary** with the **automatic summary**:
1. Which of the summaries is the best?
2. Consider that the simplified summary was built over the automatic one, by removing expressions considered unnecessary:
2.1. Were the removed expressions necessary?
2.2. Are there any expressions that you consider that should not have been removed?
2.3. Does the sentences context remain the same?
2.4. Does the simplified summary preserve the same idea of the original one?
2.5. Can the simplified summary replace the automatic one without losing information?
3. Other comments.

Before giving the two types of summaries to be evaluated by the human experts, both summaries were compared using ROUGE [7]. The graph in Figure 2 shows the f-measure values for all the 15 summaries used in this experiment. There is a slightly difference between them, as the average of the f-measure values for both automatic summaries (0.49752) and simplified summaries (0.49826) confirms.

Fig. 2: ROUGE f-measure values for automatic and simplified summaries.

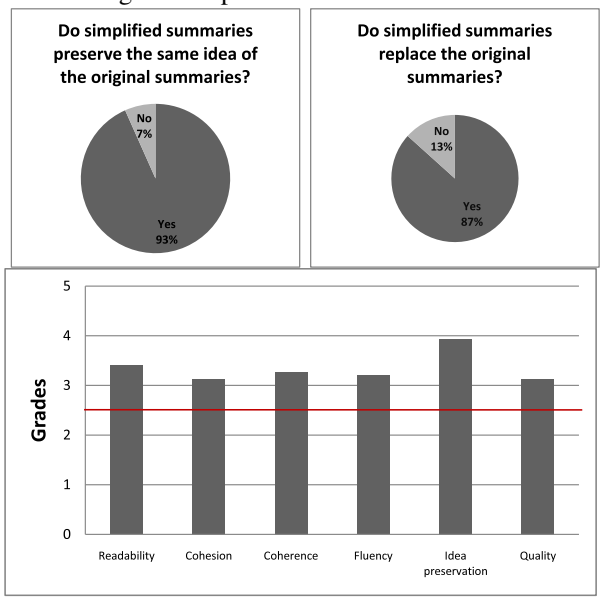


By comparing the graph in Figure 2 with the results in Figure 3, we can conclude that ROUGE does not reflect all the modifications performed in the simplified summaries, evidencing the need for manual evaluation. Nevertheless, it is a very useful tool to perform evaluation during system development, as metrics are obtained automatically.

To actually execute Task#2, each of the three experts was given five different texts. One text from each section of the corpus. Thus, we evaluated 15 texts, 3 from each section. This way, different sorts of texts were tested. Despite all of them being news texts, different sections may have different vocabulary and different writing styles. In PHASE I, experts did not have access to the original texts, so their conclusions were only based in the information contained in both summaries. Still, the automatic summary, by being longer and by having more content, should be expected to have more information than the simplified summary.

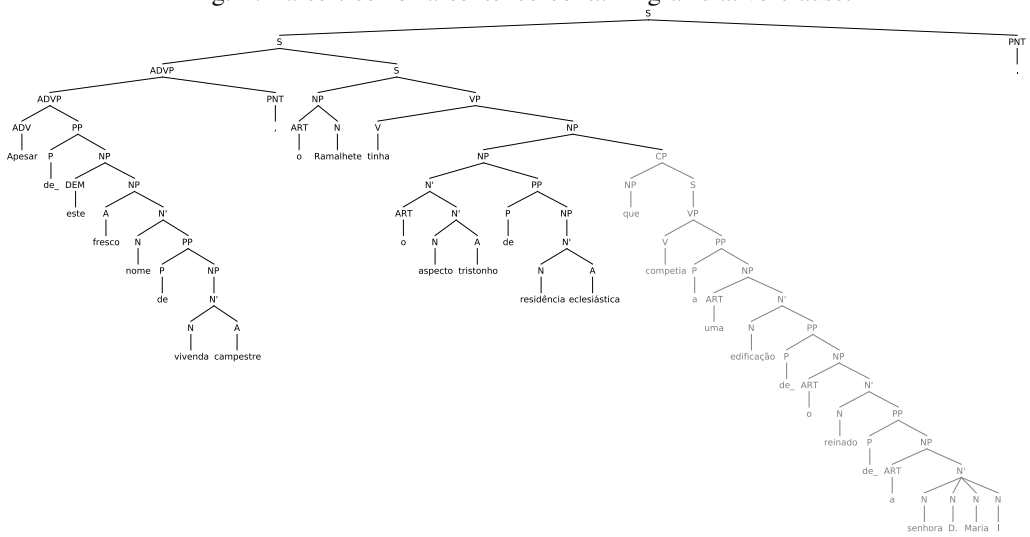
Figure 3 presents the answers given by the experts to the survey.

Fig. 3: Simplified summaries features.



The answers to question 1. were not conclusive, since, as experts observed, the differences between automatic and simplified summaries are minimal. However, they definitely stated that simplified summaries can replace the non-simplified ones, which means that no relevant information is being missed. Thus, the information that was removed is not essential for the comprehension of the text. In addition, experts reported that the simplified summaries were simpler than the automatic ones. Also, they stated that the majority of the removed expressions were not necessary to the comprehension of the text content. Finally, they mentioned that, mainly when long parenthetical information is removed, text readability is improved.

Fig. 4: Parse tree for a sentence containing a relative clause.



Since very similar texts were being compared, an improvement in the overall quantitative grades was expected. Nevertheless, the *original text idea preservation* was still the best feature (3.93), which lead to the fact that the information removed was indeed not essential in the summary. Moreover, this removal did not have a significant impact on text *readability* (3.4), seeing that the simplified text remains readable despite the modifications. This is not only reflected in the text *coherence* (3.27), *cohesion* (3.2), and *fluency* (3.13), but mainly in the text *overall quality* (3.13).

With this experiment, we can conclude that the simplified summaries preserve the original text idea. Also, the relevant information conveyed by the original text is maintained, allowing at the same time an optimization of the summary compression rate.

3. Simplifier

Based on the promising conclusions driven from the manual experiments, this task has been performed automatically. The simplifier is a module integrated in a multi-document summarization system, which produces generic summaries from a collection of texts in Portuguese, from any domain. After selecting the relevant content to be part of the summary, the chosen sentences are simplified to produce highly informative summaries. A detailed description of this summarizer can be found in [8].

The simplifier receives a set of sentences and retrieves them simplified. It includes two main phases, analysis and transformation, which are described in the next sections.

3.1 Analysis

The analysis phase aims to identify in each sentence the expressions which are candidate for removal. Three types of structures are recognized: (1) relative clauses; (2) parentheticals – explanatory or qualifying phrases; and (3) appositions – specific type of parentheticals, composed by a noun phrase that describes, details or modifies its antecedent (also a noun phrase). These phrases are candidates to removal, since they may introduce extra information whose removal does not affect the information eventually conveyed too much.

In order to identify the removable passages, a constituency parser for Portuguese [9] is used to build the sentence parse tree. Then, for each sentence, relative clauses, parentheticals and appositions are retrieved.

The following sentence contains a **relative clause**:

Apesar deste fresco nome de vivenda campestre, o Ramalhete tinha o aspecto tristonho de residência eclesiástica que competia a uma edificação do reinado da senhora D. Maria I.

"Despite that fresh green name worthy of some rural retreat, Ramalhete, as befitted a building dating from the reign of Queen Maria I, had the gloomy appearance of an ecclesiastical residence."

S *Apesar deste fresco nome de vivenda campestre, o Ramalhete tinha o aspecto tristonho de residência eclesiástica.*

"Despite that fresh green name worthy of some rural retreat, Ramalhete had the gloomy appearance of an ecclesiastical residence."

CP *que competia a uma edificação do reinado da senhora D. Maria I*

"as befitted a building dating from the reign of Queen Maria I"

Figure 4 illustrates the sentence parse tree in which both clauses are identified.

The first clause is the main one (starting in the top node *S* in the parse tree), and the second one is the subordinate relative clause (starting in the top node *CP* in the parse tree). Subtrees starting with the tag `CP` (complementizer phrase) are stored to be processed later.

Fig. 5: Parse tree for a sentence containing an apposition phrase.

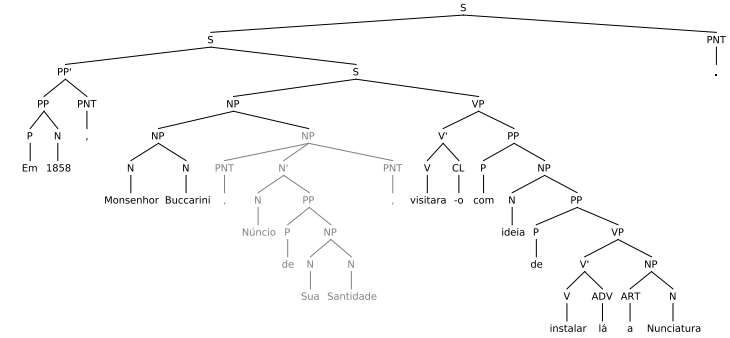


Fig. 6: Parse tree for a sentence containing a parenthetical phrase.

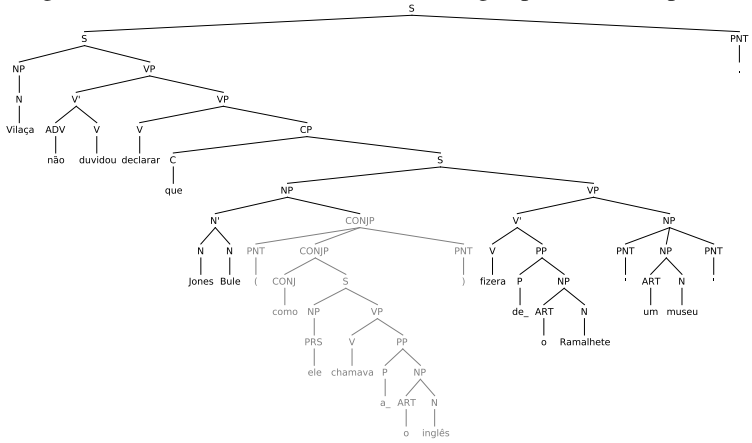

Appositions (specific type of parentheticals) are noun phrases, enclosed by commas or dashes, that define, describe or modify their antecedent which is also a noun phrase. Figure 5 depicts the parse tree for the following sentence, which includes an apposition:

Em 1858, Monsenhor Buccarini, ***Núncio de Sua Santidade,*** *visitara-o com ideia de instalar lá a Nunciatura.*

"In 1858, Monsignor Buccarini**, the Papal Nuncio,** had visited it with a view to establishing his residence there."

Considering the sentence parse tree, subtrees that start with the tags `NP` (noun phrase) or `AP` (adjective phrase), and whose leftmost child is a dash or a comma and whose rightmost child is a matching dash or comma or a period, are defined as appositions.

Parentheticals are phrases, enclosed either by parenthesis, or by commas or dashes, that explain or qualify other information being expressed. Consider the following sentence containing a parenthetical phrase:

Vilaça não duvidou declarar que Jones Bule ***(como ele chamava ao inglês)*** *fizera do Ramalhete "um museu".*

"Vilaça was the first to declare that "Jones Bule" **(as he called the Englishman)** had made of Ramalhete "a veritable museum"."

Figure 6 illustrates the parse tree for this sentence. In the parse tree, parentheticals are defined by a node, represented by any tag, which leftmost child is the opening punctuation token and its rightmost child is a closing punctuation token of the same type.

3.2 Transformation

The transformation phase aims to decide which of the phrases, retrieved in the analysis phase, can be removed without impacting on the sentence's overall informativity. Consider the following sentence:

Na conferência de líderes de ontem, a primeira da nova sessão, que a vice-presidente da bancada do PS, Ana Catarina Mendes, disse esperar que fique marcada pela 'governabilidade', ficou estabelecido que a execução orçamental será o tema central da Comissão Permanente.

"At yesterday's Leaders' Conference, the first of the new session which PS' delegation vice-president, Ana Catarina Mendes, said to hope it would be remembered by 'governability', it was settled that budget execution will be the main subject of the Standing Committee."

This sentence for instance has three removal candidates: a relative clause – *"que a vice-presidente da bancada do PS, Ana Catarina Mendes, disse esperar que fique marcada pela 'governabilidade'"*; and two appositions – *"a primeira da nova sessão"* and *"Ana Catarina Mendes"*.

For each sentence, the algorithm first considers the relative clauses, then the apposition phrases and finally the parenthetical ones. In order to obtain the new sentence, the parse tree of the original sentence is traversed until the index of the first leaf of the phrase to be removed is found. Also, the index of the last leaf of the phrase is gathered. Then, the parent node of these leaves is retrieved and the subtree is removed. The new sentence is then created without the subtree representing the phrase removed.

Afterwards, the simplification score is computed for both the main sentence and the new sentence. It is important to note that the simplifier is part of a text summarization system. This system computes the scores of the words composing the collection of sentences submitted as input, in order to select the most relevant sentences within that collection. Thus, the simplifier uses the simplification score to compare simplified sentences. This score is computed as the sum of each word score[2] composing the sentence divided by the total number of words of the sentence.

$$simplificationScore_{sentence} = \frac{\sum_{word \in sentence} score_{word}}{totalWords_{sentence}}$$

Considering the previous sentence and its removal candidates, the new sentences obtained along their simplification scores are shown in Table 1.

Table 1: Candidates to replacement.

	Candidate sentences	Score
1	*Na conferência de líderes de ontem, a primeira da nova sessão, que a vice-presidente da bancada do PS, Ana Catarina Mendes, disse esperar que fique marcada pela 'governabilidade', ficou estabelecido que a execução orçamental será o tema central da Comissão Permanente.* "At yesterday's Leaders' Conference, the first of the new session which PS' delegation vice-president, Ana Catarina Mendes, said to hope it would be remembered by 'governability', it was settled that budget execution will be the main subject of the Standing Committee."	0.01045
2	*Na conferência de líderes de ontem, a primeira da nova sessão, ficou estabelecido que a execução orçamental será o tema central da Comissão Permanente.* "At yesterday's Leaders' Conference, the first of the new session, it was settled that budget execution will be the main subject of the Standing Committee."	0.01615
3	*Na conferência de líderes de ontem, ficou estabelecido que a execução orçamental será o tema central da Comissão Permanente.* "At yesterday's Leaders' Conference, it was settled that budget execution will be the main subject of the Standing Committee."	0.01926

The first sentence in the Table is the original sentence and its simplification score is also compared with the ones of the simplified sentences. As the algorithm first considers the relative clauses, none of the simplified sentences contain the relative clause (*que a vice-presidente da bancada do PS, Ana Catarina Mendes, disse esperar que fique marcada pela 'governabilidade'*). Thus, the second simplified sentence was built by eliminating the relative clause. The third one is obtained by removing not only the relative clause, but also the first apposition referred (*a primeira da nova sessão*). The other apposition (*Ana Catarina Mendes*) is never considered since it is included in the relative clause. Owing that the third simplified sentence has the highest simplification score, it is the one selected to replace the original sentence in the final summary.

The same algorithm is executed for all the sentences which are candidates to be in the summary, ensuring the creation of a concise and highly informative text.

4. Evaluation

In order to perform evaluation, the *CSTNews* corpora [10], an annotated corpus composed of texts in Portuguese, was used. It contains 50 sets of news texts from several domains, for a total of 140 documents, 2,247 sentences, and 47,350 words. Each set contains, on average, 3 documents, which address the same subject, and an ideal summary (built manually). Ideal summaries have an average of 137 words, resulting in an average compression rate of 85%.

First, for each set of *CSTNews*, two types of summaries were created using our summarizer: simplified and non-simplified summaries. Simplified summaries are built by executing the whole summarization process. Otherwise, non-simplified ones are created without running the simplification module. In addition, summaries were generated using `GistSumm`[3] to serve as a baseline for our work. Summaries were built using a compression rate of 85% (average compression rate of the ideal summaries), meaning that the summary contains 15% of the words of the set of texts.

Afterwards, ROUGE [7] was used to derive precision, recall and f-measure metrics for the automatic summaries. ROUGE-L (longest common subsequence) was the metric selected, since it identifies the common subsequences between two sequences. This is a fairer metric compared to the original ROUGE-N metric, due to the fact that the simplification process introduces gaps in the extracted sentences. These gaps would not be taken into account when using a metric that considers co-occurring matches. Table 2 presents the results obtained.

Table 2: ROUGE-L evaluation metrics.

	GistSumm	Non-simplified	Simplified
Precision	0.3847	0.4276	0.4364
Recall	0.4362	0.4854	0.4942
F-Measure	0.4040	0.4492	0.4585

[2]The word score is the `tf-idf` score of the word considering the collection of texts to be summarized.

[3]Despite being a single-document summarizer, `GistSumm` also builds multi-document summaries by means of an option in its interface.

The complete summarization process has an overall better performance than the baseline considered, since both results with simplified and non-simplified summaries overcome the results obtained by `GistSumm`. The recall values obtained by our summarizer are very encouraging. These values indicate that there is a higher density of words that are both in the automatic summaries and in the ideal summaries. Retrieving the most relevant information in a sentence by discarding the less relevant data ensures that the summary indeed contains the most important information conveyed. This is a direct result of the simplification process. The precision values, by being identical, suggest that all summaries cover nearly the same topics. Intuitively, the precision values for the simplified summaries should decrease, since less in-sequence matches are likely to be found between them and the ideal summaries. When computing the f-measure value, by combining both precision and recall, we can confirm that both simplified and non-simplified summaries are better than `GistSumm` summaries.

Finally, note that the simplified summaries achieve better results than the non-simplified summaries. Despite being small, this difference between both summaries is very interesting. Yet, the simplification process is reflected in the evaluation of the summaries, implying that a simplification process, containing more sophisticated rules, can indeed be expected to help produce even better summaries.

5. Conclusions

This paper presents a text simplification system which is part of a text summarization system. The simplification system is focused on improving the summarization output, by simplifying the sentences composing the summaries. Our premise is that simplified sentences contain as much information as needed, helping to create more informative texts.

As manual experiments have hinted out, the simplification system is a huge contribution to the summarizer. Three main reasons lead to the decision of applying simplification after summarization: (1) this way, no relevant information is excluded before selecting the sentences to include in the summary, once all the computation regarding each original sentence has been done; (2) the simplification algorithm described does not remove the identified structures without constraints, since we aim to ensure that no crucial content is deleted from the sentence; (3) during the compression process, it is possible to add more relevant content to the summary that was not being considered in the initial list of sentence candidates.

Considering that most of the experiments have been done for the English language, we intended to prove that simplification actually improves summarization of texts in Portuguese, by using a corpora of Portuguese texts in all the experiments made.

***Abstract*-- We present six distinct English-language sentence paraphrasing techniques as transforms: *Active-to-Passive, Diction, Nodebox, Phrase, Simplify* and *Pivot translation*. We describe the basic algorithm for each and score them on precision and recall using 50 random sentences from project Tatoeba [1]. Our aim is to use these techniques for style transformation.**

Keywords: Computational Stylistics, Style Processcing, Natural Langauge Processing, Machine Learning, Computational Linguistics

1 INTRODUCTION

Statistical style transformation refers to an automatic method of rewriting text such that the information content remains the same, but the style of writing changes. Manual style transformation has been done successfully in the past [2]. In the absence of a precise universally accepted nomenclature and litmus test for different writing styles in natural languages, we define style as choice of expression [3] such as that often associated with an author. As the authorship attribution literature has shown, there are distinguishable style markers that can be used to successfully classify works by different authors [4][5] and hence also isolate their "style". Our approach uses this type of classification as a litmus test for achieving style transformation. This was done by Juola [6] already to evaluate manual style obfuscation cases.

Our model requires sentence level paraphrases to be continuously generated by modules (called transforms) and scored based on a greedy algorithm. Whichever paraphrased sentence would move the entire text statistically closest to the target style, that sentence is adopted and becomes part of the new text, but it could still be subject to further substitutions.

2 TRANSFORMS

The transforms are implemented as Python classes. They use various techniques such as typed dependency reformulation [7] or web-based validation [8] to produce a grammatical and synonymous sentence to the one they were passed in. All the implementation and most of the algorithms come from the authors, but external resources have been used quite extensively as stated below. We briefly describe each transforms.

2.1 Active to Passive transform (A2P)

Example: *The boy kicked the ball. => The ball was kicked by the boy.*

This transform converts an active voice sentence into its passive form. We encode 20 highly general rules in terms of parts-of-speech for basic active voice and equivalent passive voice cases [9][10]. The initial rules are mutated to produce 120 rules, adding variations to handle particles, adverbs and complex noun phrases. The input sentence is parsed into chunks using the Link Grammar Parser and compared with all the patterns in the database, and if matched, converted accordingly. Various NLP techniques are used to ensure plurals, pronouns and subject/verb agreement.

2.2 Diction Transform

Example: *The fact is, in the majority of cases, X is defined as an unknown. => Usually X is an unknown.*

This transforms employs a large number of rules for substituting wordiness and "bad style" phrases with their equivalent. The data sources are:

1. 655 rules from GNU *Diction* v. 1.11, itself based on *Elements of Style* [11].
2. 658 "wordiness" rules from Steve Hanov (Stevehanov.ca) partially based on William Zinsser's *On Writing Well.*
3. 409 word/alternative pairs from *The A to Z of alternative words* by the Plain English Campaign.

The rules are applied as straight string substitutions. Many of the rules had to be modified manually by the authors to remove "hints" and discussion originally designed to be examined by users of word editing programs. Some generic suggestions with no clear substitution suggestions were removed altogether from the original set of rules.

2.3 Nodebox transform

Example: *We recieved 6533 boxes. => We received thousands of boxes.*

This transform is based on the Nodebox Linguistics package [12]. It performs two tasks in particular: First, it

changes a set of unambiguous misspelled words, to their correct equivalents. Second, it converts Arabic numerical symbols modifying certain noun phrases into English approximation phrases.

2.4 Phrase replacement transform (Phrase)

Example: *I wanted to be with you alone => I desired to be with you only.*

This transform replaces phrases (defined as one or more consecutive words) with synonyms. It uses the Stanford Part of Speech Tagger to label each token in the phrase, and then uses Word Net to find synonyms for each non-overlapping phrase matching the POS in the input sentence.

For each phrase, this transform determines all the synsets of the same sense using *jcn* distance [13] to do Word Sense Disambiguation (WSD). The remaining candidates are ranked using two criteria: probability of co-occurrence with other words in the same sentence in the Microsoft BING N-Gram database (all bigrams and trigrams crawled by BING search engine) [14], and the probability of co-occurrence with other words in the same sentence in the target corpus. If the latter is not available, then only the search engine data is used.

Once a suitable candidate is chosen, NLP tools are used to produce the correct inflection before actual substitution. Heavy use of NLTK NLP tools [15] was made for this transform. The following figure summarizes the major steps in this transform and external tools used to accomplish them.

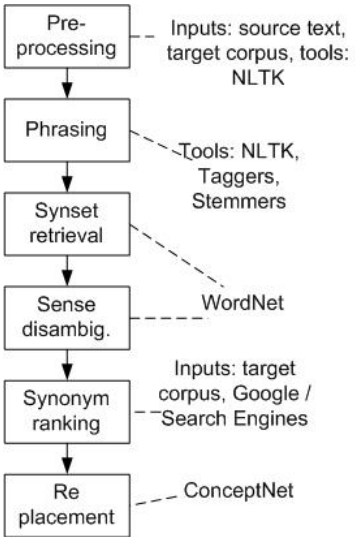

Figure 1. Phrase Transform

2.5 Simplify transform

Example: *I love Luna who is very cute and who is my pet. => I love Luna. Luna is very cute. Luna is my Pet.*

This transform aims to simplify sentences on several criteria, possibly producing more than one sentence as a result. It is written by Advaith Siddharthan [7] mostly in Perl, using the Stanford parser and the RASP toolkit. Two additional rules and a Python wrapper are written by the authors to integrate it into our evaluation system.

Simplify produces typed dependency trees for each sentence and then runs its user-modifiable rules to match patterns and adjust the final word order which could result in more than one sentence. It examines conjunctions and anaphora and looks for independent clauses that can be separated into their own sentences.

2.6 Pivot translation transform

Example: *I like to play Tennis. => I enjoy playing Tennis.*

This transform performs statistical translation by pivot: It translates an English sentence into another language and then translates the result back to English. The idea is that automatic translation tools usually produce valid but slightly modified sentences. A translation from English into another language and back to English could provide a valid semantic variation of the original with sufficient quality. Because of the high likelihood that the very same string is retuned, this transform accepts an ordered list of languages to try one at a time until a response different than the input is found.

As the back-end statistical translator, it supports Yahoo/Babelfish, Google Translator, and Microsoft Translator. We found the Microsoft product to be the most suitable for several reasons and we used it for this project.

3 METHODOLOGY

Fifty random English sentences are selected from the project Tatoeba [1] corpus, and passed on to each transform. Then each of the transforms produces responses consisting of zero, one or more paraphrased sentences for each of the input sentences. Some transforms such as *Phrase*, can produce more than one alternative paraphrase. Others such as *Diction* are highly specialized applying to few random sentences. We produce 381 paraphrases for the original 50 sentences. Each of these is scored on the scale of 0 to 3 by three separate human judges based on the following criteria.

Table 1. Evaluation criteria

Code	Criteria
3	Sentence is modified, preserves original meaning and original level of grammaticality.
2	Sentence is unmodified, or barely modified with very minor changes, or modified and the result is "acceptable" but not great.
1	Sentence is modified and the result is not acceptable.
0	No response, machine error or incomprehensible response.

4 RESULTS AND CONCLUDING REMARKS

Before the *Pivot translation* transform can be evaluated, we must decide which of the supported languages to use and how many languages to translate to before returning to English. Through a separate process using human 2 judges, we evaluate over 900 sentences using translation by pivot, and determined an ordered set of 8 languages (out of a total of 32 supported by Microsoft Translator) to use for the translation transform. In order of decreased effectiveness, they are: Czech, Swedish, Danish, Vietnamese, Norwegian, Dutch, Portuguese, and Spanish.

In addition, we generate three baseline translation "tours" (multiple language translations before returning to English) for comparison purposes. Tour1 is English->French->Spanish->German->English. Trou2 is English->Danish->Portuguese->Swedish->Vietnamese->English. TourR consists of English and four random languages.

All 381 paraphrases are scored for precision (majority score of the 3 judges). We derive the relevant precision and recall statistics as follows.

- *"recall" is calculated by counting the number of sentences for which the transform had a response (other than the input), divided by the total number of sentences, 50.*
- *"precision" is the average of all the (0-3) scores given by human evaluators to any response of the transform, across all sentences.*
- *"F-measure" is defined as* $F = \frac{2*(precision*recall)}{precision+recall}$

Table 2. Transform experiment evaluation results in terms of precision, recall and F-measure

Transform	Recall (%)	Precision (%)	F-measure
A2P	10	80	0.178
Diction	4	100	0.077
Nodebox	20	87	0.325
Phrase	100	82	0.903
Simplify	7.6	78	0.138
Translation	74	83	0.782
Tour 1	88	63	0.733
Tour 2	78	70	0.738
Tour R	88	58	0.702

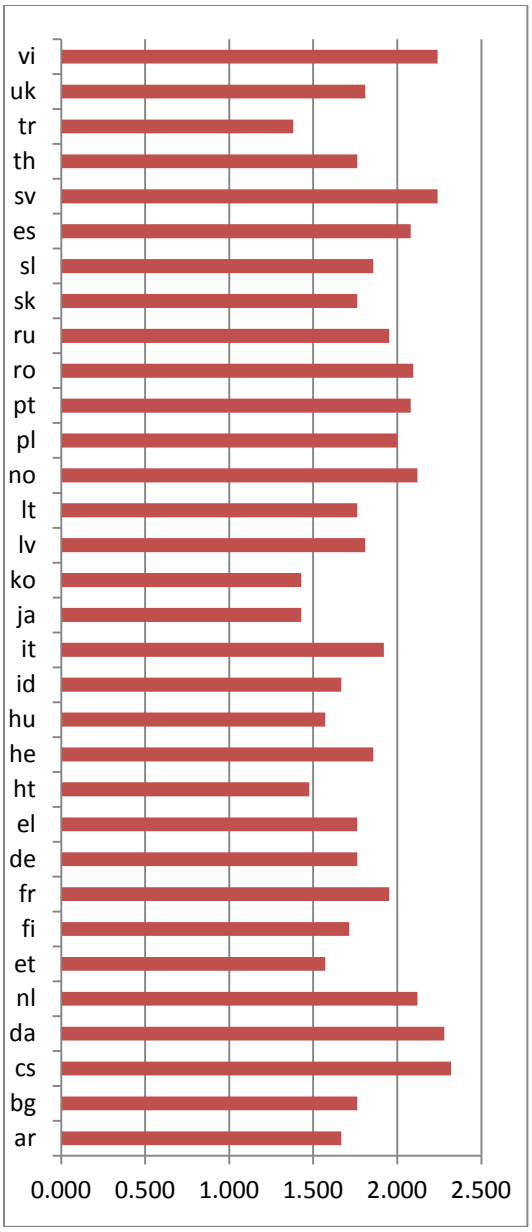

Figure 2. Microsoft translator language performance

As observed from Fig. 3, the transforms can be generally divided into two groups: high precision and high recall. The transforms in the high precision group have unsurprisingly low recall. This is because the patterns they generally seek are very specific, such as the "wordiness" phrases in *Diction*. The high recall group has more general pattern matching. Every sentence contains at least one word that would have a synonym in Word Net. Almost every sentence would have at least one translated paraphrase from some language.

We find that Phrase has the highest F-measure. But the real goal for our work is not to find a single approach, but to combine the power of different approaches to get a super-

transform of increased recall and precision. We are pursuing future work in this area.

Table 3. Microsoft Translator supported language codes (ISO 639-2)

Code	Language	Code	Language	Code	Language
ar	Arabic	he	Hebrew	ro	Romanian
bg	Bulgarian	hu	Hungarian	ru	Russian
cs	Czech	id	Indonesian	sk	Slovak
da	Danish	it	Italian	sl	Slovenian
nl	Dutch	ja	Japanese	es	Spanish
et	Estonian	ko	Korean	sv	Swedish
fi	Finnish	lv	Latvian	th	Thai
fr	French	lt	Lithuanian	tr	Turkish
de	German	no	Norwegian	uk	Ukrainian
el	Greek	pl	Polish	vi	Vietnamese
ht	Haitian	pt	Portuguese

Quantity and Degree Assessment in an RDF-based Semantic Language

Igor Boguslavsky
Universidad Politécnica de Madrid, Spain / Institute for Information Transmission Problems, Russian Academy of Sciences, Moscow, Russia

Abstract - *This paper introduces a semantic language developed with the objective to be used in a semantic analyzer based on linguistic and world knowledge. Linguistic knowledge is provided by a Combinatorial Dictionary and several sets of rules. Extra-linguistic information is stored in an Ontology. The meaning of the text is represented by means of a series of RDF-type triples of the form* predicate(subject, object). *Semantic analyzer is one of the options of the multifunctional ETAP-3 linguistic processor. The analyzer can be used for Information Extraction and Question Answering. We describe semantic representation of expressions that provide an assessment of the number of objects involved and/or give a quantitative evaluation of different types of attributes. We focus on the following aspects: 1) parametric and non-parametric attributes; 2) gradable and non-gradable attributes; 3) ontological representation of different classes of attributes; 4) absolute and relative quantitative assessment; 5) punctual and interval quantitative assessment; 6) intervals with precise and fuzzy boundaries.*

Keywords: knowledge representation, semantic analysis, ontology, RDF languages, gradable attributes

1 Semantic Analysis and Semantic Structure

The semantic language described in this paper is used in a semantic analyzer under development in the Institute for Information Transmission Problems of the Russian Academy of Sciences and in the Madrid Polytechnic University. A distinctive feature of this analyzer is that the semantic representation is based on both linguistic and world knowledge. In many aspects our approach is similar to that of Ontological Semantics (Nirenburg, Raskin 2004) but the linguistic framework is substantially different. For more details about the analyzer, the reader is referred to Boguslavsky et al. 2010 and Boguslavsky 2011.

The source of linguistic information is the knowledge base of the ETAP-3 linguistic processor. World knowledge is contained in the Ontology and in the Fact Repository. Semantic representation is constructed in two steps. First, all the sentences of the text sentence are independently of one another transformed into their Backbone Semantic Structures (BSemS), which reflect the meaning directly conveyed in the sentence. Second, BSemSs are enriched by means of the Ontology and the Fact Repository and converted to Enhanced Semantic Structures (EnSemS). As an example, we will show BSemS and EnSemS of a short text (1). The working language of the analyzer is Russian, but for readers' convenience we provide an English translation of the text:

(1) *On October, 8 "Zenit" Football Club had a first friendly match in the tournament, which is taking place in Spain's La Manga. The pupils of Luciano Spaletti lost 0:1 to the Warsaw Club "Polonia".*

Step 1: BSemS construction.

BSemS of the first sentence: *On October, 8 "Zenit" Football Club had a first friendly match in the tournament, which is taking place in Spain's La Manga.*

(2)
```
hasTime(Match-01,DateTimeDescription-01)
hasMonth(DateTimeDescription-01, 2)
hasDay(DateTimeDescription-01, 8)
hasCategory(Match-01, friendly)
isPartOf(Match-01, Tournament-01)
hasParticipant(Match-01, Team-01)
hasName(Team-01, Zenit)
hasSportDiscipline(Team-01, football)
hasLocation(Tournament-01, La Manga)
hasLocation(La Manga, Spain)
```

As is usual in Artificial Intelligence, instances of classes are supplied with unique numerical identifiers. In order not to distract the reader's attention, from now on, we will omit these identifiers, if only they are not needed to distinguish between different instances.

It should be stressed that many of the classes referred to in the BSemS have many more property slots in the Ontology, but these slots are not represented in this BSemS, since the text does not provide data for filling them.

BSemS of the second sentence: *The pupils of Luciano Spaletti lost 0:1 to the Warsaw Club "Polonia".*

(3)
```
hasWinner(WinEvent, Team-02)
hasLoser(WinEvent, Team-03)
inContest(WinEvent, SportEvent)
inContest(MatchScore, SportEvent)
hasValue1(MatchScore,1)
hasValue2(MatchScore,0)
hasName(Team-02, Polonia)
represents(Team-02, Warsaw)
hasCoach(Team-03, Luciano Spalletti)
```

The second sentence was analyzed independently of the first one, and the two teams mentioned (the winner and the loser) received new identifiers – `Team-02` and `Team-03`. These teams are referred to in the text in different ways. One of them is called by its name (`Polonia`), and the only thing that is communicated about the second one is the name of its coach (`Luciano Spaletti`). The result of the match is conveyed by means of two propositions: the first one says that one of the teams defeated the other (by means of the predicate `WinEvent`), and the second one gives the score (the predicate is `MatchScore`). In order to show that both propositions refer to the same match, the `inContest` slot of both predicates is filled by the same match (`SportEvent`).

Step 2: Enhancement of BSems.

The main tasks that are solved at this stage are coreference resolution (i.e. determination of phrases that refer to the same entity) and filling of the slots for which the fillers have not yet been found. The information used to solve these tasks can be taken from the Ontology and the Fact Repository, which contains, among other things, semantic structures of previous sentences of the text processed. In particular, the Ontology should contain all the information available about the individuals. In our example, the Ontology disposes of the following information about the Zenit team:

```
hasName(Team-00, Zenit)
hasSportDiscipline(Team-00, football)
hasCoach(Team-00, Luciano Spalletti)
```

Based on this information, we can identify `Team-01` from the first sentence, whose name is `Zenit`, with `Team-03` from the second one, since its coach is `Luciano Spaletti`.

Semantic links between the sentences in the text are implicit. In EnSemS they should be restored wherever possible. We will show how it can be done in our example. There are several considerations that allow us to infer some implicit information. The first sentence of (1) tells us that a match has taken place. The second sentence gives information about a result of a match. The two sentences belong to the same text and, moreover, one of them directly follows the other one. They share at least one participant (`Zenit`) and there are no textual indications of the topic shift. Therefore, one can conclude that both sentences are describing the same match. That means that in the EnSemS we should identify `Match` from the first sentence with `SportEvent`, to which `WinEvent` and `MatchScore` are linked in the second sentence. As a result, EnSemS of (1) looks like (4) (elements introduced during the SemS extension are printed in bold face and underlined):

(4)
```
hasTime(Match, DateTimeDescription)
hasMonth(DateTimeDescription, 2)
hasDay(DateTimeDescription, 8)
hasCategory(Match, friendly)
isPartOf(Match, Tournament)
hasParticipant(Match, Team-01)
hasName(Team-01, Zenit)
hasCoach(Team-01, Luciano Spaletti)
hasSportDiscipline(Team-01, football)
hasLocation(Tournament, La Manga)
hasLocation(La Manga, Spain)
hasWinner(WinEvent, Team-02)
hasLoser(WinEvent, Team-01)
inContest(WinEvent, Match-01)
inContest(MatchScore, Match-01)
hasValue1(MatchScore, 1)
hasValue2(MatchScore, 0)
hasName(Team-02, Polonia)
represents(Team-02, Warsaw)
```

Semantic structures (2)-(4) have already given some idea of the semantic language used for representing the meaning of the texts. Below, we will concentrate on one important fragment of this language, namely the one dealing with quantitative assessment of different types of objects.

Quantitative assessment is mostly made by means of gradable attributes. We will discuss these attributes in section 2, and the values they ascribe to objects - in section 3.

2 Gradable attributes

As mentioned above, prototypically, quantitative assessment of an object is made by means of gradable attributes. Properties that they ascribe to the objects can be compared in terms of "more/less". For example, `Price` and `Intelligence` are gradable, because one bicycle can be more expensive than another one, and one person can be more

intelligent than another. Very often, they characterize an object by assigning it a numerical value (e.g. *a price of 100 Euros*). However, not all the attributes that assign a value to their object are gradable, and not all gradable attributes assign a value to their object. Let us explain this.

We will refer to the attributes that assign some definite value to their object as p a r a m e t e r s . The parameters and their values can be quantitative or not. Values of quantitative parameters, such as `Price`, `Height`, `Speed`, `Temperature`, etc. are located on a scale and are prototypically expressed by numerical expressions consisting of a numeral and a measurement unit: *the height of 15 meters*, *the speed of 180 km/hour*, *the temperature of 50 degrees Celsius.*

Non-quantitative parameters have values that are not located on a scale and are not expressed by means of a numerical expression. Typical examples of non-quantitative parameters are `Name`, `Nationality`, `Address`, `Color`, `Form`, etc. For example, the parameter of `Nationality` has values `French`, `Russian`, `Malay`, etc.

All the parameters, quantitative or not, have a sufficiently homogenous and compact range of values. The kind of entities that can serve as values of a parameter is always restricted. An important linguistic property of parameters is their behavior in *what*-questions. Any word denoting a parameter can be used in a *what*-question, and this question is always interpreted as a request for the parameter's value. When somebody asks *What is her name?* it is quite obvious what kind of entity is expected as an answer. Cf. a dialogue in which the answer does not belong to the class of parameter values and therefore does not directly satisfy the information need of the interrogator: *What is his name? - ??An unusual one*. Not all attributes are like this. Such attributes as `Beauty` or `Intelligence` do not presuppose a set of homogeneous values. Therefore, they are not parameters.

On the other hand, `Beauty` and `Intelligence` are gradable attributes, in the sense that different objects may have these properties to different extents – see above.

However, gradability of this property does not only manifest itself in comparative contexts, as is the case of (5):

(5) *Lucy is more intelligent than Mary.*

When we simply say that Lucy is intelligent, we ascribe to Lucy a high degree of intelligence, in a similar way as we ascribe to her a high degree of height, when we say that she is tall.

However, there is also an important difference between such attributes as `Height` on the one hand, and `Intelligence`, on the other. We showed above that `Height` is a parameter, and `Intelligence` is not. `Height` is a two-place predicate, which assigns to its object a value on a well-defined scale, while `Intelligence` is a one-place predicate. It does not assign any definite value to its object, but instead it has degrees.

We would like to capture the similarity between the attributes of the `Height` class and the `Intelligence` class, and on the other hand, take into account the difference between them. We adopted the following solution. Our ontology contains the class of `Parameters` with two subclasses: `GradableParameters` (like `Price`) and `Non-gradableParameters` (like `Name`). All the parameters have a `hasValue` slot. On the other hand, there is a class `GradableAttributes`. One of its subclasses is `GradableParameters` (which at the same time belongs to the `Parameters` class), and another one is `QualitativeAttributes`, which contains attributes of the `Intelligence` type. Gradable parameters have values located on a corresponding scale. Qualitative attributes do not have values but have a `hasDegree` slot instead. Specific behavior of parameters is accounted for by means of the `Parameters` class and its `hasValue` slot. For example, interpretation of the *what*-questions asked of parameters implies filling of the `hasValue` slot. How the quantification of qualitative attributes is assured is seen in SemS (5a), which represents the meaning of (5):

(5a) `hasSubject(Intelligence-01, Lucy)`
`hasDegree(Intelligence-01, var-01)`
`hasSubject(Intelligence-02, Mary)`
`hasDegree(Intelligence-02, var-02)`
`more(var-01, var-02)`

3 Values of gradable attributes

As stated in the previous section, parameters and qualitative attributes are both gradable but in a slightly different way. Although they have different slots for quantitative elements (`hasValue` and `hasDegree`), for simplicity's sake we will speak about values in both cases.

3.1 Numerical expressions

As for quantitative parameters, their values are compound numerical expressions. They are formed by a numeral and a measurement unit. Such expressions are represented by a series of two-place predicates that express a corresponding measure, such as `LinearMeasure`, `CurrencyMeasure`, `DurationMeasure`, etc.

(6) *3 meters*

(6a) `hasUnit(LinearMeasure, meter)`
`hasUnitQuantity(LinearMeasure, 3)`

(7) *20 euros 45 cents*

(7a) `hasUnit(CurrencyMeasure, euro)`
`hasUnitQuantity(CurrencyMeasure, 20,45)`

(8) *3 liters (of wine)*

(8a) `hasUnit(Amount, liter)`
`hasUnitQuantity(Amount, 3)`

(9) *3 glasses (of wine)*

(9a) `hasUnit(Amount, glass)`
`hasUnitQuantity(Amount, 3)`

A special case is temporal expressions, which are often presented in natural languages by several measurement units of different granularity, as in (10). We chose not to reduce them to a single unit (for example, a second), but to preserve the internal structure of the expression, in order to match the way humans are conceptualizing time:

(10) *3 years 2 months 5 days 10 hours and 25 minutes*

(10a) `hasYears(DurationMeasure, 3)`
`hasMonths(DurationMeasure, 2)`
`hasDays(DurationMeasure, 5)`
`hasHours(DurationMeasure, 10)`
`hasMinutes(DurationMeasure, 25)`

Another special case is a quantitative parameter which may do without a measurement unit. It is quantity, e.g. *5 books*. Besides the peculiarity of lacking a unit, this parameter has another one. It does not apply to single objects but only to collections of objects. When we say *5 books*, we don't say anything about any single book, but describe quantitatively a whole set of books. Therefore, multiple objects are represented by sets (as in Nirenburg, Raskin 2004), and sets may have a `Cardinality` parameter:

(11) *50 books*

(11a) `hasElementType(Set, Book)`
`hasSubject(Cardinality, Set)`
`hasValue(Cardinality, 50)`

There exist parameters whose value is not constituted by a single numerical expression. The state of a sport match at a given moment is characterized by the parameter of `Score`, which is a pair of numbers, e.g. `3:1`. Another example of a complex parameter value is coordinates on the Earth surface, which is a combination of two independent parameters – latitude and longitude, each of which is usually rendered by a triple of numbers – degrees, minutes and seconds.

3.2 Brief typology of quantitative assessment.

We will distinguish between two major types of quantitative assessment – absolute and relative assessment. Relative assessment, in its turn, will be divided into two subclasses: assessment with respect to the whole and with respect to the norm. In each of these three classes, the value can denote either a point on the scale, or an interval. In the latter case, the interval can have either exact or fuzzy boundaries. Below, we will illustrate all these classes.

A. Absolute assessment.

A.1 Punctual absolute assessment.

(12) *The ticket costs 20 euros*

(12a) `hasSubject(Cost, Ticket)`
`hasValue(Cost, CurrencyMeasure)`
`hasUnit(CurrencyMeasure, euro)`
`hasUnitQuantity(CurrencyMeasure, 20)`

(13) *The boy is 4 feet tall*

(13a) `hasSubject(Height, Boy)`
`hasValue(Height, LinearMeasure)`
`hasUnit(LinearMeasure, foot)`
`hasUnitQuantity(LinearMeasure, 4)`

A.2 Interval absolute assessment.

When a quantitative expression is characterized by an interval, its boundaries can be either exact or fuzzy. The difference between exact and fuzzy boundaries is manifested in inferences one can make. If it is claimed that the number of students is in the exact interval [100,150], then this claim is definitely false if in fact there are 98 or 151 students. If the interval is fuzzy, then such an inference cannot be made. The distinction between exact and fuzzy intervals is relevant for representing the meaning of many natural language words and phrases. An interval with exact boundaries is illustrated in (14), and one with fuzzy boundaries – in (15).

(14) *Only children from 5 to 8 years old are admitted to the class.*

(14a) `hasObject(Admit, Child)`
`hasSubject(Age, Child)`
`hasValue(Age, DurationMeasure)`
`hasYears(DurationMeasure, Interval)`
`from(Interval, 5)`
`to(Interval, 8)`

(15) *About 10 to 15 students will come to the meeting.*

(15a) `hasAgent(Come, Set)`
`hasElementType(Set, Student)`
`hasSubject(Cardinality, Set)`
`hasValue(Cardinality, FuzzyInterval)`
`from(FuzzyInterval, 10)`
`to(FuzzyInterval, 15)`

The word *several* is one of those natural language elements whose meaning cannot be rendered in exact terms. According to Longman English Dictionary *several* means 'a number of people or things that is more than a few but not a lot'. COBUILD dictionary gives a similar definition: 'imprecise

number of people or things that is not large but is greater than two'. Such definitions, obviously, cannot be used directly. However, this word has a clear enough meaning, which is rather specific. On the one hand, it refers to concrete numbers, as opposed to such words as *many* or *few*. It is impossible to give a number, however approximate it might be, denoting *many* or *few*. It is obviously different in different situations. As for *several*, the situation is different. Most of our informants say that the number referred to by *several* is an integer which is greater than or equal to 3 but less than 9. On the other hand, the upper boundary is not rigid. Some people feel that perhaps 8 is too many to count as several. Other people agree to accept even as many as 10. One could of course ignore this vagueness and describe *several* as any quantity expressed by an integer greater than or equal to 3 but smaller than 9. However, if we wish to approximate meanings expressed by natural language words (and we do), we should find a way to account for such an important property of natural language semantics as uncertainty, which is obviously manifested in the meaning of *several*. Our proposal is to describe *several* as a fuzzy interval between 3 and 8:

(16) *several books*

(16a)
```
hasElementType(Set, Book)
hasSubject(Cardinality, Set)
hasValue(Cardinality, FuzzyInterval)
from(FuzzyInterval, 3)
to(FuzzyInterval, 8)
```

Similarly, one could characterize approximate quantities such as *about 80* as fuzzy intervals with identical lower and upper boundaries:

(17) *about 80 people*

(17a)
```
hasElementType(Set, Person)
hasSubject(Cardinality, Set)
hasValue(Cardinality, FuzzyInterval)
from(FuzzyInterval, 80)
to(FuzzyInterval, 80)
```

B. Relative Assessment.

There are two varieties of relative assessment: the assessment with respect to the whole and with respect to the norm. In both cases, it can be punctual or interval, as in case of the punctual assessment above, and the interval boundaries can be both exact and fuzzy.

B.1 Relative Assessment with respect to the whole.

To make this kind of assessment, we introduce a predicate `FormsPartOf`, whose first argument (subject) corresponds to the quantity being assessed, the second argument (object) – to the whole with respect to which the assessment is made, and the third argument (value) characterizes the relation between the two.

B.1.1 Punctual assessment

(18) *half of the population*

(18a)
```
hasSubject(FormsPartOf, Set)
hasObject(FormsPartOf, Population)
hasValue(FormsPartOf, 0.5)
```

B.1.2 Interval Assessment.

Interval with exact boundaries:

(19) *From 13% to 15% of the population*

(19a)
```
hasSubject(FormsPartOf, Set)
hasObject(FormsPartOf, Population)
hasValue(FormsPartOf, Interval)
from(Interval, 0.13)
to(Interval, 0.15)
```

Interval with fuzzy boundaries:

(20) *about 13% - 15% of the population*

(20a)
```
hasSubject(FormsPartOf, Set)
hasObject(FormsPartOf, Population)
hasValue(FormsPartOf, FuzzyInterval)
from(FuzzyInterval, 0.13)
to(FuzzyInterval, 0.15)
```

B.2 Relative assessment with respect to the norm.

In natural languages there are many words that express a value of a gradable attribute, but do so in an imprecise, fuzzy way. For example, a stone can be characterized as big. We understand that the adjective *big* places the stone somewhere on the scale of size, but we don't know this position exactly. The only thing that the lexical meaning of *big* tells us is that the size of the stone is above the norm. This idea has long been adopted in linguistics. What exactly the norm is in each particular case is beyond the competence of lexical semantics and is determined by the context and encyclopedic knowledge. What is big for a child may be not so for an adult. A big cat is much smaller than a small horse. However, it is not enough only to state that *big* is above the norm. *Enormous* is also above the norm, but to a different extent. There are series of words and phrases that refer to the same scale but denote different points, or rather, different areas, on that scale. *Never, seldom, sometimes, from time to time, often, very often, always* – all these words correspond to different degrees on the frequency scale. A convenient way of representing the meaning of such words has been proposed within the Ontological semantics approach. All the words that express a value of a gradable attribute are assigned a point or a range in

the interval between 0 and 1. For example, the meaning of *hot* is represented as the range [0.75–1] on the scale of temperature (Nirenburg, Raskin 2004: 206).We adopt this idea in principle, but realize it in a different way.

We introduce a predicate RelativeToNorm with 4 arguments:

- `hasSubject`: what is assessed
- `hasObject`: which parameter of the Subject is assessed
- `hasValue`: what value is assigned
- `normFor`: the norm for what kind of entities is used as a reference (the fourth argument will be illustrated below in (25))

As in previous cases of assessment, the value slot can be filled both by a point and an interval in the range [0,1].

B.2.1 Punctual assessment

(21) *false solution* (limit point on the scale of Correctness)

(21a)
```
hasSubject(RelativeToNorm, Solution)
hasObject(RelativeToNorm, Correctness)
hasValue(RelativeToNorm, 0)
```

(22) *brilliant answer* (limit point on the scale of Quality)

(22a)
```
hasSubject(RelativeToNorm, Answer)
hasObject(RelativeToNorm, Quality)
hasValue(RelativeToNorm, 1)
```

B.2.2 Interval assessment

Interval assessment with exact boundaries does not seem to be possible. Fuzzy boundaries, on the contrary, are very wide spread.

(23) *a tall boy*

(23a)
```
hasSubject(RelativeToNorm, Boy)
hasObject(RelativeToNorm, Height)
hasValue(RelativeToNorm, FuzzyInterval)
from(FuzzyInterval, 0.6)
to(FuzzyInterval, 0.8)
```

(24) *a very tall boy*

(24a)
```
hasSubject(RelativeToNorm, Boy)
hasObject(RelativeToNorm, Height)
hasValue(RelativeToNorm, FuzzyInterval)
from(FuzzyInterval, 0.8)
to(FuzzyInterval, 0.9)
```

As one can easily see from (23) – (24), the difference between a tall boy and a very tall boy is manifested in different intervals on the scale of `Height`: [0.6, 0.8] in the first case and [0.8, 0.9] in the second case.

(25) *John is short for a basketball player*

(25a)
```
hasSubject(RelativeToNorm, John)
hasObject(RelativeToNorm, Height)
hasValue(RelativeToNorm, FuzzyInterval-01)
from(FuzzyInterval, 0.2)
to(FuzzyInterval, 0.4)
normFor(RelativeToNorm, BasketballPlayer)
```

(26) *story of average length*

(26a)
```
hasSubject(RelativeToNorm,Story)
hasObject(RelativeToNorm,Length)
hasValue(RelativeToNorm,FuzzyInterval)
from(FuzzyInterval, 0.4)
to(FuzzyInterval, 0.6)
```

(27) *negligibly few resources*

(27a)
```
hasSubject(RelativeToNorm, Resource)
hasObject(RelativeToNorm, Amount)
hasValue(RelativeToNorm, FuzzyInterval)
from(FuzzyInterval, 0.1)
to(FuzzyInterval, 0.2)
```

Now, it is not difficult to represent the difference between three related constructions: (28) *John solved **many problems,*** (29) *John solved **many of the problems***, and (30) *John solved **most of the problems***. Sentence (28) simply says that the number of the problems John solved is large. This is done by means of the `RelativeToNorm` predicate. It should be stressed that in this context the set of the problems John solved is interpreted as the set of **all the problems** that John solved. This meaning is rendered by a special attribute – isComplete.

(28) *John solved many problems*

(28a)
```
hasAgent(Solve, John)
hasObject(Solve, Set)
hasElement(Set, Problem)
hasSubject(RelativeToNorm, Set)
isComplete(Set)
hasObject(RelativeToNorm, Cardinality)
```

```
hasValue(RelativeToNorm,
FuzzyInterval)
from(FuzzyInterval, 0.6)
to(FuzzyInterval, 0.8)
```

Sentence (29) evaluates the proportion between two sets: some set of problems and its subset that John solved. What *many* claims here is that the second set is a large part of the first one. It is difficult to define precisely what part of the whole qualifies as large. However, what is certain is that it cannot necessarily be more than a half. It is quite possible that many of the problems have been solved and at the same time many of the problems remained unsolved. Consequently, the beginning of the large-part interval should be less than 0.5. On the other hand, a large part of something can easily be more than a half. To express this, one needs to introduce these two sets of problems and evaluate their correlation by means of `FormsPartOf`:

(29) *John solved many of the problems.*

(29a)
```
hasElement(Set-01, Problem)
hasProperSubset(Set01, Set-02)
hasAgent(Solve, John)
hasObject(Solve, Set-02)
isComplete(Set-02)
hasSubject(FormsPartOf,Set-02)
hasObject(FormsPartOf, Set-01)
hasValue(FormsPartOf,FuzzyInterval)
from(FuzzyInterval, 0.3)
to(FuzzyInterval, 0.7)
```

Sentence (30) is similar to (29) in that it compares the set of the problems that John solved and the overall set of problems. What it adds to (29) is the idea that the number of solved problems is larger than half of the whole number of problems. One of the ways to convey this meaning is to change the value of the `FormsPartOf` predicate .

(30) *John solved most of the problems.*

(30a)
```
hasElement(Set-01, Problem)
hasProperSubset(Set01, Set-02)
hasAgent(Solve, John)
hasObject(Solve, Set-02)
isComplete(Set-02)
hasSubject(FormsPartOf, Set-02)
hasObject(FormsPartOf, Set-01)
hasValue(FormsPartOf,
FuzzyInterval)
from(FuzzyInterval, 0.55)
to(FuzzyInterval, 0.9)
```

4 Conclusions

We presented a semantic language intended for performing semantic analysis and representing the meaning of NL texts. Semantic analysis is knowledge-intensive and uses two major sources of knowledge: linguistic knowledge incorporated in the combinatorial dictionary and rules of the ETAP-3 Linguistic Processor, and world knowledge stored in the Ontology and Fact Store. At the moment of writing, the Ontology is under construction. In developing it, we take into account various existing ontologies, such as SUMO, Ontological Semantics Ontology, and PROTON, but in many cases take our own solutions. The semantic language in which semantic structures of sentences are formulated consists of RDF-type triples `predicate(subject, object)`. In this paper, we show how this language represents information on quantity and degree assessment.

Technological peculiarity of knowledge extraction for logical-analytical systems

Igor P. Kuznetsov, Elena B. Kozerenko, Mikhail M. Charnine
Institute for Informatics Problems of the Russian Academy of Sciences, Moscow, Russia

Abstract *The paper is dedicated to constructing of the new classes of expert and logical-analytical systems, based on the knowledge structures. For this the means of knowledge representation (the extended semantic networks - ESN) and the tools of their processing (the language of logical programming DEKL) have been designed. They have been used as basis for creating the new technologies, which provide the following functions: the automatic extraction of the knowledge from natural language texts, forming the Knowledge Base and the solution of the most complex problems of the logical-analytical processing by transformation and comparison of the knowledge structures. On this basis many intellectual systems for different applications have been designed.*

Keywords semantics, natural language, linguistic processor, knowledge extraction, named entities

1 Introduction

The present significance of named entities extraction pertains to the growing amount of information available in unstructured form [1-20]. The existing Internet largely consists of unstructured documents. Knowledge contained within these documents can be made more accessible for machine processing by means of transformation into relational form. An intelligent processing is proposed to transform unstructured data into something that can be reasoned with [2,5,11,13]. A typical application of entities extraction is to scan a set of documents written in a natural language and populate a database with the information extracted. More prospective approach consists of using Knowledge Base. It proposes the development of new technology including the extraction of knowledge structures and organization of their processing in Knowledge Base [3,4,6].

The distinctive features of our technology are as follows:

1. Extraction from the texts of knowledge structures (not only separate named entities) that represent the links of named entities and their participation in actions and events.

2. For the knowledge extraction the unique semantic-oriented language processors (LP) are designed. Processor LP provides the deep analysis of NL-texts and revealing set of objects together with their structures.

3. Processor LP is controlled by the linguistic knowledge, which are declarative structures (on extended semantic networks - ESN) and which provide the quick tuning of LP to subject area and language - Russian and English.

4. Linguistic knowledge consists of the rules, which provide the high degree of selectivity in the entities extraction and elimination of collisions during their application. Rules provide the minimization of noise and losses, that is the high degree of completeness and accuracy.

5. The knowledge structures and means of their processing (intellectual language DEKL) were designed as the united tools, oriented at the tasks of linguistic analysis, semantic search, logical-analytical processing and the expert solutions. Using this tools considerably facilitates the development of applied intellectual systems.

Technology of knowledge structure extraction and processing have been used for construction of new classes of analytical systems [3,7,12]: "Criminal", "Analytic", "AntiTerror", "Resume" etc. [http://IpiranLogos.com/en/Systems/].

2 Knowledge Structures

2.1 Named Entities

In our technologies Named Entities (NE) are extracted from the documents on Natural Language (NL) and presented in the Knowledge Base (KB) as the fragments of the extended semantic network (ESN). The arguments of fragments are the collections of normalized words, numbers and signs, which reflect essence NE and indicate to its type. For example, the fragment

FIO(IVANOV,IVAN,IVANOVICH,1957/1+)

represents the person *Ivanov Ivan Ivanovich 1957* year of birth. The entity type is indicated by the constant FIO. Every fragment has a unique code (sign "1+"), which corresponds to all information of the fragment and which may be on the argument places of other fragments (sign 1-). It is the main difference of the concept "*fragment"* from the classical concept "*predicate"*. The network ESN consists of the set of fragments. Their order is arbitrary.

In our systems more than 40 types of NE are extracted from NL-texts. Their quantity depends on the subject area and the tasks of users. Let us note that in KB some NE can be constitutional components of others. Connections between NE may be complicated [1,6,14].

2.2 Type of entities and links for extraction

The set of the entities to be extracted depends on the tasks of a user. At the same time the quality of a linguistic processor is determined by the possibilities for knowledge extraction. The linguistic processors "Criminal", "Analytic" and ''Semantix" support more than 40 types of semantic entities which can be extracted automatically. Some examples of basic entities types and connections extracted by the these processors are given below:

• persons (by family name, given name and patronymic - FNP) with their role features (criminal, victim);
• the verbal description of the persons, their distinctive signs;
• address, posting information attributes;
• date(s) mentioned;
• weapon with its special features;
• telephone numbers, faxes, e-mails with their subsequent standardization;
• the means of transport with the indication of the vehicle type, its state number, color and other attributes;
• passport data and other documents with their attributes;
• explosives and narcotic substances;
• organizations, positions;
• quantitative characteristics (how many persons or other objects participated in an event);
• the numbers of accounts, sums of money with the indication of the currency type;
• terrorist groups and organizations;
• participants of terrorist groups with the indication of their roles (leader, head of, etc.);
• the armed forces, assigned for antiterrorist combat (Military Force);
• event (criminal, terrorist, biographical, and so on) with the indication of the information objects participation in them;
• time and the place of events.

Standard entities (names, dates, addresses, types of weapons and others) are reduced to one standard form. The identification of entities is performed taking into account brief designations (for example, separate surnames, patronymics, Initials), anaphoric references (indicative and personal pronouns, for example, this person, it...) definitions and explanations (for example, the *mayor of Moscow Sabyanin* is identified with the subsequent words *mayor*, *Sabyanin*). An important task is the identification of entities in the entire text, the use for these purposes of indicative pronouns, brief names, anaphoric references.

2.3 Connections between the entities and participation in actions

Connections and relations between NE, extracted from the NL-texts, can be very diverse. They depend on entity types. For example, one person can be connected with another by relative and friendly relations, and also by the place of living, area of interests and so on. Actions frequently are connected with the time and the place. There can be reason-consequence and other connections between actions. In such a way the complex structures are created. For their formalization special tools of knowledge representation have been designed.

Actions usually are expressed in NL-texts by the tensed verb forms, nonfinite verb forms, e.g. verbal nouns, participial and adverbial constructions, gerunds. The actions are also NE, components of which can be another NE. For example, there can be those, who participate in action, or entities, on which the action is directed. Moreover, some actions may be components of others. For many applications the actions are also the significant information which requires formalization. Because the system is oriented at the deep analysis of text constructions, it extracts all actions and events with NE.

Example of action extracting by the System "Semantix" is shown on fig.1 [http://IpiranLogos/en/Semantix/].

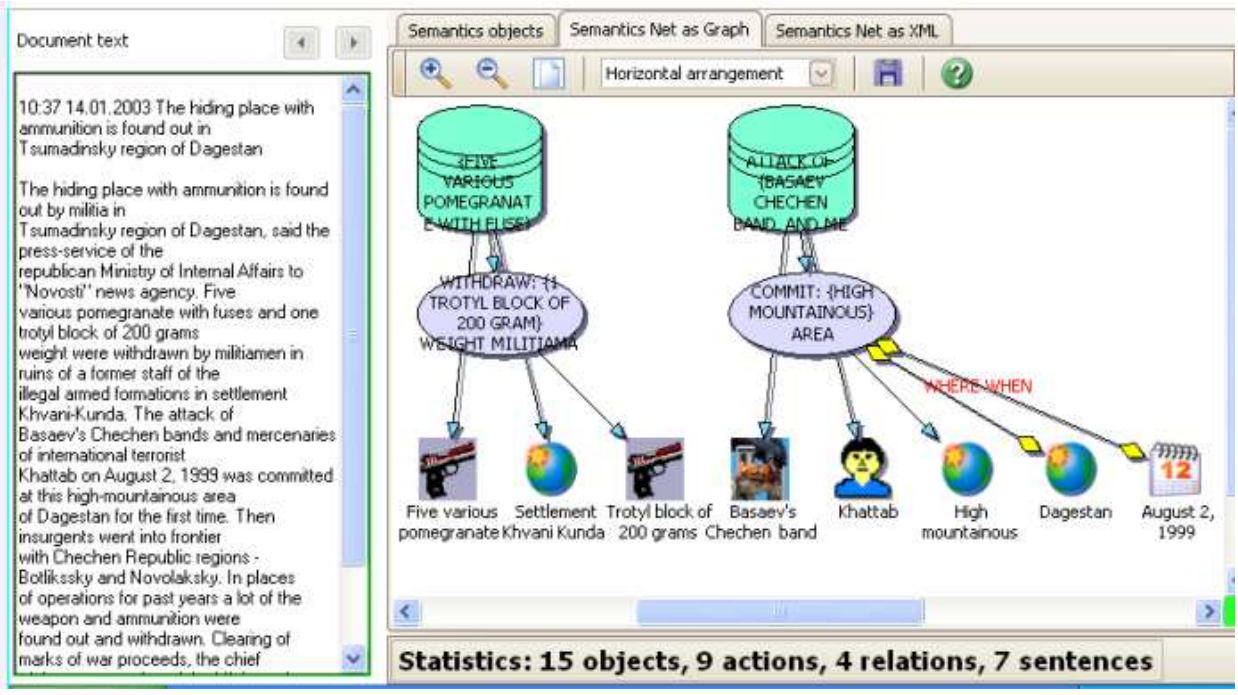

Fig.1 Example of extracted actions with entities

2.4 Meaningful portrait of a document

It is the formal representation of entities (NE), their properties and the connections, extracted from the text of the document. Such portraits are the structures of knowledge. As means of formalization in our technologies we use the extended semantic networks (ESN). Formalization is achieved automatically by the semantics-oriented linguistic processor, which analyzes the texts of NL-documents and transforms them into knowledge structures [3,10].

A set of meaningful portraits (together with index files) comprise the Knowledge Base (KB) where various types are provided of semantic search and logical-analytical functions by comparison and transformation of knowledge structures. We design the technology which provides the processing in the KB distributed within the net of computers.

The Example of text (with number 22 from file e1-02-98.TXT) :

12:16 27.12.2002 In the Chechen Republic one of leaders of bands the Arabian mercenary Abu-Tarik is destroyed. As have informed the Ministry of Foreign Affairs of the Chechen Republic, Chechen special militia destroy the insurgent in settlement Starye Atagi of Groznensky region. In one of the houses there were found the hiding place with three sub-machine guns.

On some data, Abu-Tarik was involved in murder of Salikhov's family in Starye Atagi in this year.

Meaningful portrait of the text:

DOC_(22, "1-02-98.TXT","SUMMARY; " /0+) 0-(ENG)
DATE_(DEC.,~27,12,HOUR,16,MINUTE/1+)
CRIM_GROUP(1,LEADER,OF,BAND,ARABIAN,MERCENARY/2+)
FIO("ABU - TARIK"," "," "," "/3+)
DESTROY(2-,3-/4+) 4-(22,ACT_)
PLACE_(CHECHEN,REPUBLIC/5+)
WHERE(4-,5-)
ORGANIZATION_(MINISTRY,OF,FOREIGN,AFFAIRS,OF,CHECHEN,
REPUBLIC/6+)
INFORM(6-/7+) 7-(22,ACT_)
FORCE_(SPECIAL,MILITIA/8+)
DESTROY(CHECHEN,8-,INSURGENT/9+) 9-(22,ACT_)
PLACE_(SETTLEMENT,STARYE,ATAGI,OF,GROZNENSKY,REGION/10+)
WHERE(9-,10-)
WEAPON_("SUB ",MACHINE,GUN/11+)
FIND(1,HOUSE,HIDE,PLACE,3,11-/12+) 12-(22,ACT_)
PLACE_(STARYE,ATAGI/13+)
INVOLVE(3-,MURDER,SALIKHOV,FAMILY,13-,YEAR/14+) 14-(22,ACT_)

SENTENCE_(22,1-/15+) 15-(1,1,19)
SENTENCE_(22,4-/16+) 16-(1,20,114)
SENTENCE_(22,7-,9-/17+) 17-(2,115,288)
SENTENCE_(22,12-/18+) 18-(5,289,376)
SENTENCE_(22,ON,SOME,DATA,14-/19+) 19-(6,377,476)

A meaningful portrait consists of the elementary fragments, arguments of which are words in the normal form (it is necessary for the search and processing). Each elementary fragment has its unique code, which is written in the form of the number with the sign + and is separated by a slash line. For example, in the fragment FIO("ABU - TARIK"," "," "," "/3+) the sign "3+" is its code (but "3-" is the reference to it). Fragments DOK_(22, "1-02-98.TXT", "SUMMARY; " /0+) 0-(ENG) indicate that the meaningful portrait is built on the basis of the English-language text of document with number 22 of the file of 1-02-98.TXT", which was processed as the summary of the incidents (linguistic knowledge depends on this). The following fragments present date DATE_(…/1+), criminal group CRIM_GROUP(…/2+), person's surname (name and patronymic) FIO(… /3+) and so forth. The signs "0+","0-" and "1+", "1-" and "2+", "2-" and "3+", "3-", … are the codes of the fragments, with the aid of which their connections and relations are assigned. Actions are represented in the form of fragments of the type DESTROY(2-,3-/4+) 4-(22,ACT_), where it is represented as "*criminal group* (CRIM_GROUP with code "2+") *and person* (FIO with code "3+")*, are destroyed*". With the aid of it is the fragment 4-(22, ACT_) indicates that the first fragment is DESTROY(…./4+) presents the action and relates to the document with the number 22. Fragments PLACE_(CHECHEN,REPUBLIC/5+) WHERE(4-,5-)

indicate the place of this action (WHERE). Fragments ORGANIZATION_(…/6+) INFORM(6-/7+) 7-(22,ACT_) represent that "*organization ... was informed*".

The fragments PREDL_(...), which correspond to the sentences play the special role. They are filled up with the words, which did not enter into the named entities (in this example they are absent), or with the codes of entities themselves. To these fragments the indicators of their position in the text are added. For example, the fragment SENTENCE_(22,7-,9-/17+) 17-(2,115,288) represents the fact that the objects with codes "7-" (corresponding to the action "*inform*"), "9-" (corresponding the action "*destroy"* are located in the sentence, which begins from the 2nd line of the text of the document and they occupy the place from the 115-th to the 228-th byte. These means of positioning are necessary for the work of the reverse linguistic processor.

A set of meaningful portraits of documents are organized in the Knowledge Base. Logical reference is provided with the aid of the rules IF… THEN (productions) of the language DECL, which are the basis for decision of logical-analytical tasks.

3 Semantic-oriented linguistic processor

Semantics-oriented linguistic processor comprises the following components.

3.1 The component of *lexical and morphological analysis* (LMA)

It extracts words and sentences from the text, performs lemmatization of words (normal form establishment) and constructs the semantic network presenting the space structure of text (SpST), which reflects the sequence of words, their basic features, beginnings of sentences and the presence of space character lines. The component LMA uses a two-level general ontology and a special collection of subject dictionaries (the dictionary of countries, regions of Russia, names, forms of weapons, and other items specific for the supported domains). The component performs semantic grouping of the words and assigns them additional semantic attributes [9].

3.2 The component of *syntactic-semantic analysis* (SSA)

It converts one semantic network (SN) into another which represents the semantic structure of text (SemST) the, i.e., the relevant semantic entities and their connections [6,12]. The SemST is called the meaningful portrait of document. It comprises knowledge structures of the knowledge base which serves the basis for implementing different forms of semantic search : the search by features and connections, the search for the entities connected at different levels, the search for similar persons and incidents, the search by distinctive characteristics (with the use of ontology).

The component SSA is controlled by the linguistic knowledge (LK), which determines the process of text analysis. LK includes the special contextual rules which ensure the high degree of selectivity with the extraction of entities and connections [http://www.ipiranlogos.com/english/topics/topic3-e.htm].

The functions of this component are the following:
- Extraction of entities from the flow of NL documents: persons, organizations, actions, their place and time, and many other relevant types of entities.
- The establishment of connections between entities. For example, persons are connected with organizations (PLACE_OF_WORK), by addresses (LIVES, REGISTERED). Or figurants of criminal events are connected with such entities as the type of weapon, drugs (TO HAVE).
- The analysis of finite and nonfinite verbal forms with the identification of the participation of entities in the appropriate actions. For example, one figurant gave the drugs to another figurant, and this is the fact linking them.
- The establishment of the connections of actions with the place and time (where and when some action or event occurred).
- The analysis of the reason-consequence and temporary connections between actions and events.

3.3 *Expert system* component (ES)

On the basis of semantic networks the new knowledge pieces are constructed in the form of additional fragments (ESN). For example, the component ES extracts the field of a person's activity (in accordance with the assigned classifier) from the text of resume for each autobiography. The person's experience in his field is evaluated. The correlation of a criminal incident to the specific type is accomplished with the analysis of the criminal actions of ES: the following facts are revealed - the nature of crime, the method of its accomplishment, the instrument of crime, and so forth (in accordance with the classifiers of the criminal police).

3.4 *Reverse linguistic processor* which converts the meaningful portrait of document (semantic network) into the texts on NL.

3.5 *Base of linguistic and expert knowledge* (KB)

It contains the rules of the text analysis and expert solutions in the internal representation. They determine the work of the linguistic processor. Our logical-analytical systems have several such bases, which are activated depending on subject areas and user tasks.

Fig.2 presents the example of extracted named entities (without links). The actions are the kind of entities (significant objects).

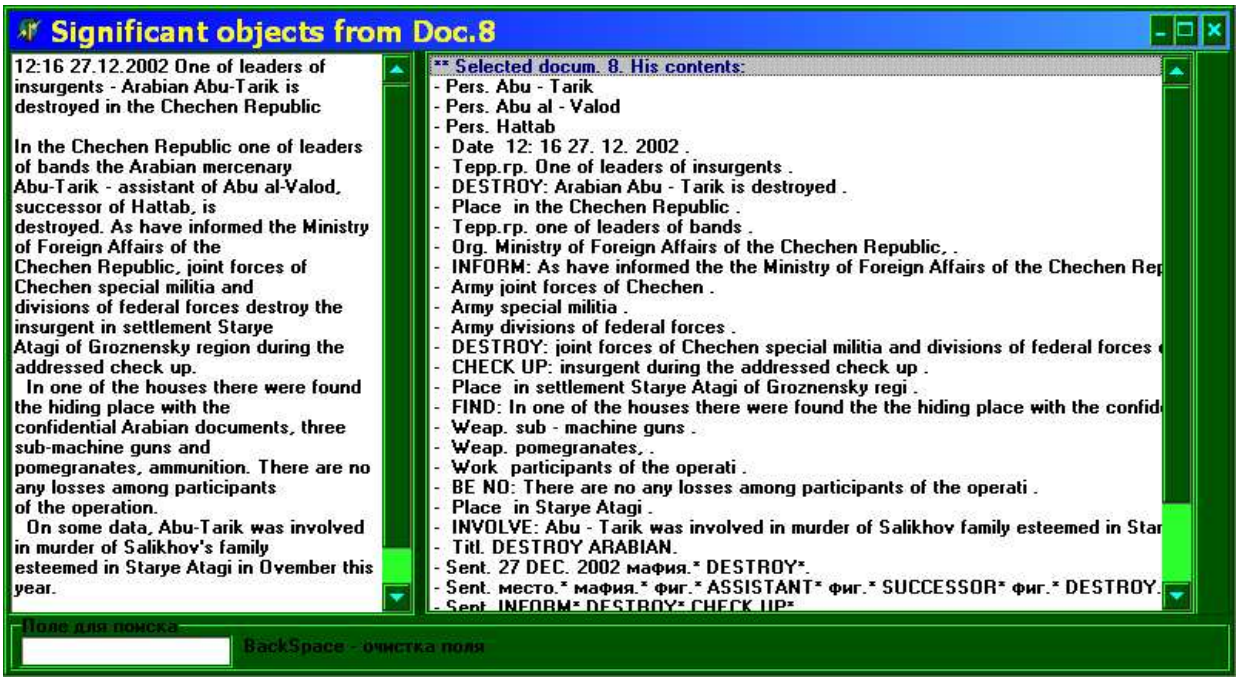

Fig.2. Example of extracted named entities

4 Logical analytical tasks

4.1 Semantic search

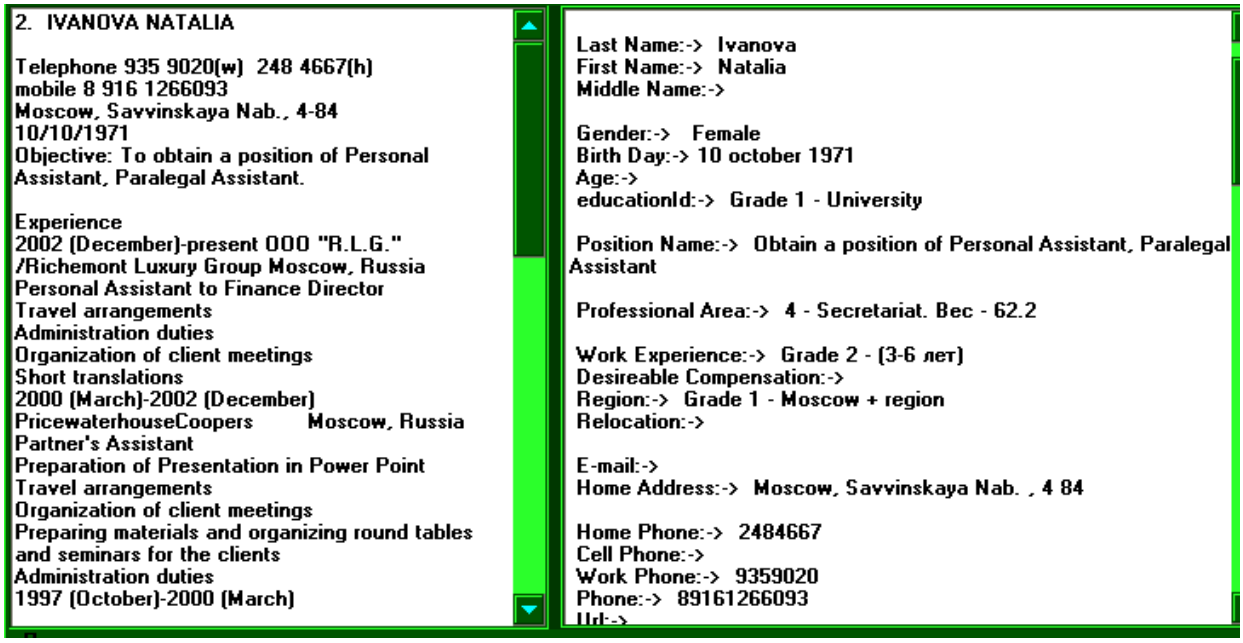
Semantic search is based on comparison the meaningful portrait of question and information in Knowledge Base (KB). Our technologies realize various types of semantic search [http://ipiranlogos.com/en/Technologies/]:
- Search for similar entities: persons, addresses, etc.,
- Search for links (e.g. search for anonymous persons based on their word portrait),
- Search for the entities from different documents based on the indirect links.
- Answer to free questions in natural language.

4.2 Tasks of criminal police

System "Criminal" is based on the documents, which enter from different sources: the summary of incidents, explanatory and official notes, the notebooks of figurants (criminal persons), accusatory conclusions and other. By analysis of the documents the Knowledge Base (KB) automatically is formed [http://ipiranlogos.com/en/Criminal/]. Structures in KB are the basis to achieve (by methods of structural processing) the solution of the logical-analytical problems:
- the search for similar incidents and figurants according to the information in KB;
- the search for figurants by verbal portrait;
- retrieval for information on question in NL (Russian);
- the explanation of the search results;
- analysis and mapping the connections between the figurants;
- the estimation of the degree of the participation of figurants in the incident;
- the ordering figurants according to the degree of their criminal activity;
- the discovery of the organized criminal groups;
- statistical processing of information to estimate the dynamics of the criminal processes in time.

4.3 Tasks of recruit agency

Many services, which deal with the flows of text information, must decide the problem of their formalization: the need for representation in those forms, which are accepted in these services and within the framework which this information is used [http://ipiranlogos.com/en/Resume/]. For example, the important task of many recruit agencies is connected with automatic processing of autobiographical data, claim for the work of the persons (resumes, written in the arbitrary form - on NL) with the extraction of all necessary data of these persons and the forming of the computer depositories (sites, KB, tables), which provide the necessary search. The entities extracting and automatic transformation is shown on Fig. 3.

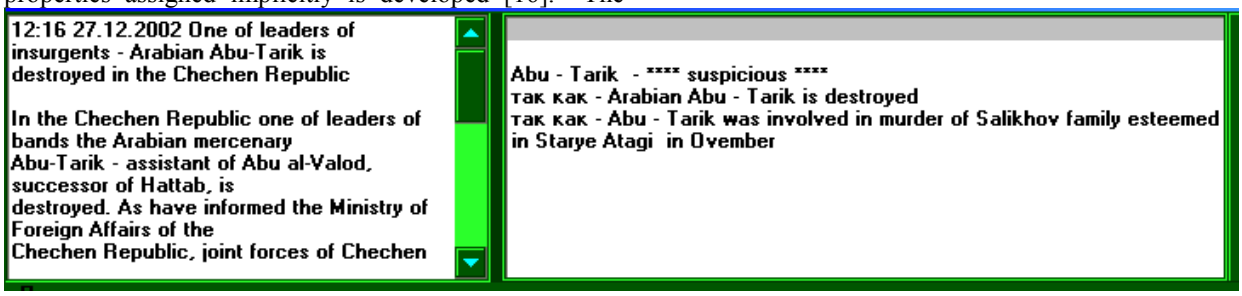


4.4 Expert systems

Expert systems on the basis of the analysis of meaningful portraits of document refer this document to the specific category (item of the classifier). In our systems two types of shells for the expert systems have been realized. The first is based on the weight coefficients of the words which correspond to the specific category. The second one is based on the presence of words in the named entities. Fig. 3 shows some examples. The "Professional area" (Secretariat – 62.2) was formed by the first type of expert system, "Region" (Moscow) was formed by second type.

4.5 Determination of the role functions of the entities

The technology of the determination of the new entities properties assigned implicitly is developed [16]. The procedure of this determination based on the analysis of the knowledge structures is proposed. The task of the determination of the role functions of entities (persons, organizations and others) on the base of their descriptions is examined as the field of application. This task in general form includes all possible "estimations", "descriptions". For example, the estimation of the stability of an enterprise (according to the information from the Internet), descriptions of political figures (positive or negative depending on the statements about them in the press), the estimation of the quality of article (on the statements of users), etc. Frequently it is not said directly: this is bad, but this is good. As a rule, in the texts (NL) the events and situations are described in which one or another information object participated. On their basis the estimation is done which is often represented in the form of the new property of entities (NE). The example of determination and argumentation of role function of persons is shown on Fig. 4.



5 Conclusion

The proposed technologies were used for construction of several intellectual analytical systems: "Criminal", "Analytic", "AntiTerror", "Monument" and others. The distinctive features of these systems are as follows: automatic extraction of knowledge structures from texts (Russian, English) and forming the Knowledge Base which is used for realization of logical-analytical functions [13]. The ESN apparatus provides powerful representational possibilities for describing all levels of natural language, including the level of deep semantic structures, and cross-lingual correspondences.

The implemented linguistic processors were created on the basis of this approach which made it possible to manufacture design solutions for the basic problems of extracting meaningful knowledge from the texts in natural languages (Russian and English).

Abstract – *This paper discusses the formal representation and lexical acquisition strategies of antonyms. The methodologies and toolbox of Ontological Semantic Technology (OST) are introduced as a framework. A brief outline of the technology and antonym taxonomies is followed by a discussion of how common and recalcitrant cases of antonyms can be represented and acquired, along with illustrations through pertinent examples.*

Keywords: computational lexicon, antonyms, language engineering, ontological semantics, structural semantics

1 Introduction

The relation of antonymy is a commonly used approach to express a key meaning relation between certain word pairs and word sets—or fields—in particular in structural semantics. The purpose here has been to enable a description of meaning without having to actually analyze that meaning, that is, relate senses to each other systemically and label that relationship rather than having to give senses meaningful descriptions in and of themselves.

Providing meaningful descriptions requires an exhaustive and interrelated system, like the ontology underlying the present approach. This ontology is not just a taxonomy and cannot afford to be selective in where it draws lines of distinction, but has to do it across the senses of the lexicon of a language. In other words, the types of antonymy must be systematically related to each other as part of the ontology. The present approach integrates the advantages and insights of the selective contrastive approach afforded by existing research on antonyms and combines it with the exhaustive, descriptive, systematic apparatus of interrelated concepts for meaning representation of ontological semantic technology (OST).

1.1 The semantics of antonyms

While extensive research exists on the semantics and classification of antonyms, the computational aspects of representing and acquiring antonymy received little attention in the literature on computational linguistics. This section will present a brief outline of the semantics of antonyms and their taxonomy.

In general, the concept of antonymy is based on dichotomization. [Murphy 2003, 183] points to binarity as the fundamental conceptualization mechanism underlying antonymy, discussing the tendency to construe of taxonomically similar entities in sets of two, so that triplets like *solid/liquid/gas* would further bifurcate into *solid/liquid*, *liquid/gas*, and *gas/solid*. Section 2.5 will discuss how the binarity principle of antonymy formation could inform antonymy acquisition within OST.

Not least since Sapir (1944), a major division of antonyms into non-gradable and gradable has been made [cf. Riemer 2010, Murphy 2003, Lyons 1977], which can be exemplified on the antonym pairs *dead-alive* (non-gradable) and *light-dark* (gradable; e.g., X is lighter/darker than Y). Further subdivisions, often orthogonal, have been proposed based on linguistic-semantic as well as logical properties. These will be discussed in more detail in relation to their acquisition and detection in section 2. Overall, the group of non-gradable antonyms is an eclectic set exhibiting significant variation at both syntactic and semantic levels, including culture- and context-based variation, which presents significant challenges even for a semi-automatic acquisition system.

Several publications exist that attempt to account for the human acquisition of antonyms by capitalizing on the tendency of antonyms to co-occur in structurally similar sentences with higher than random consistency. [Justeson and Katz 1991] build on the hypothesis introduced in [Charles and Miller 1989] that adjectival antonym pairing is largely informed by statistical co-occurrence within same sentences. Based on the list of 55 antonym pairs frequency-tested on the Brown corpus, [Justeson and Katz 1991] established that an adjectival antonym pair on average co-occurs

once in every 15 sentence in syntactically recurring constructions, which, it is concluded, provides substantial training for antonymous associations. [Fellbaum 1995] and [Jones 2002] have explored syntactic contexts for co-occurring antonym pairs, and [Jones 2006] extended the approach to spoken English. The statistical line of research presented above turns out to be of interest to OST in that it supplies a verifiable list of commonly occurring antonym pairs, which can guide the selection of proper surface word forms during semi-automatic antonym acquisition.

1.2 Ontological Semantic Technology

Ontological Semantic Technology has received extensive coverage [Nirenburg and Raskin 2004, etc.] and substantial research and development has been carried out in a number of academic and commercial projects.

The lexicon entry template below illustrates the structure of lexical entries in the OST lexicon, specific to every language handled and separate from the core resource, the ontology (for a detailed review see Nirenburg and Raskin 2004, Petrenko 2010, for a sketch of the system architecture see Fig. 1):

```
(head-entry
    (sense-1, 2, 3…
        (cat(n/v/adj/pro/prep))
        (synonyms "")
        (anno
            (def "")
            (comments "acquisition time stamp or other
                notes")
            (ex "")
        )
        (syn-struc(
            (root($var0))(cat(n/v/adj/pro/prep))
            (subject/object((root($var#))(cat(np/vp/s))))
        )
        (sem-struc
            (root-concept
                (property(value(^$var#
                (restricted-to(default/sem(concept)))))))
        )
    )
)
```

The entry begins with a part-of-speech classification, a listing of synonyms (if any), and an annotation zone for human consumption. This annotation includes a definition, an example sentence, and comments (if any) for lexicon acquirers and maintainers to quickly grasp which sense of the word is intended to be represented, as well as any syntactic peculiarities or open issues to be handled later.

This is followed by a syntactic description of the behavior of this sense in relation to other elements that will be found in its syntactic environment when the sense is used (syn-struc).

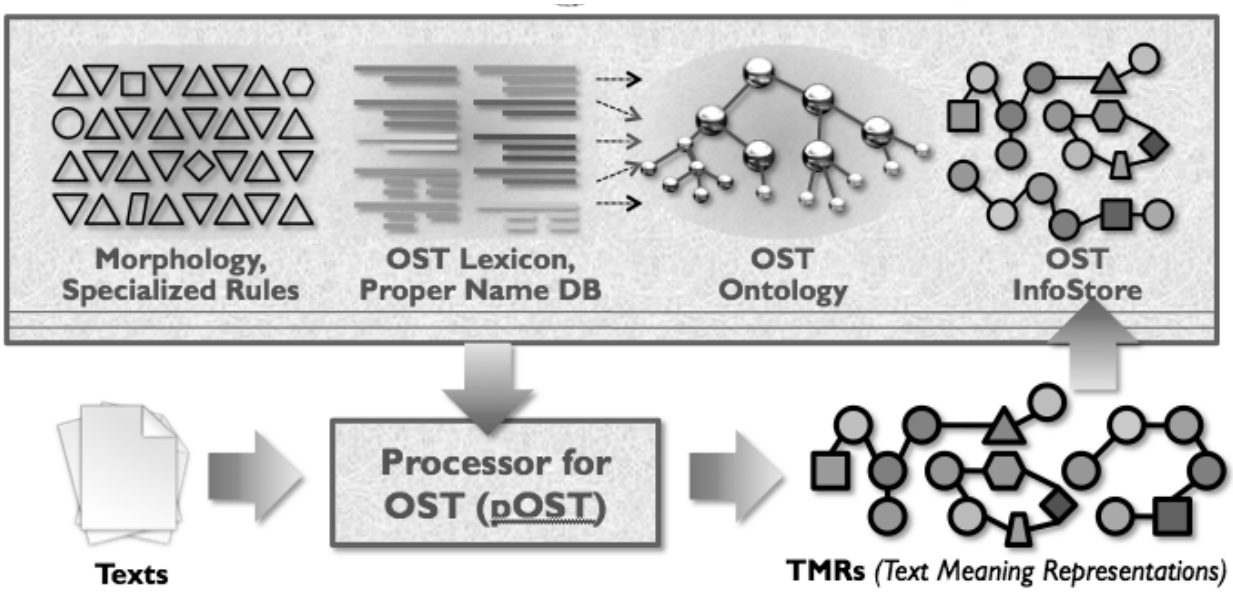

Figure 1: OST Architecture

The main information that the sense entry contributes to the OST system for text processing is in the semantic description (sem-struc). In most cases, a concept from the ontology will form the root of the semantic description, usually further refined by specifying additional constraints about certain properties of the root concept. In addition, mappings via the syn-struc to senses of other words found in the sentence can be made. For example, commonly

the syntactic subject of a sentence is mapped to the semantic role of agent.

The ontology on which the sem-strucs are based is a lattice of concepts that are interrelated as mutual property fillers. At the top level it distinguishes objects, events, and properties; objects and events are further distinguished into physical, mental, and social subtypes; properties are distinguished into attributes and relations; etc (see Fig. 2). In previous applications, the ontologies contained 5-7,000 concepts with 15-20,000 unique properties, which, by inheritance, are multiplied into 69-90,000 "facts" across the ontology.

As has hopefully become clear even from this rather cursory overview, the acquisition and maintenance of resources is the crucial effort in OST. Therefore it is guided by a set of tools that facilitate this effort by the use of templates, propagation of similar senses, formal consistency, and semantic consistency, mainly against the constraints of the ontology. For detailed accounts of methodological, practical, and computational aspects of lexicon acquisition see [Taylor et al. 2010, Petrenko 2010, Raskin and Nirenburg 1995, and Raskin et al. 2010].

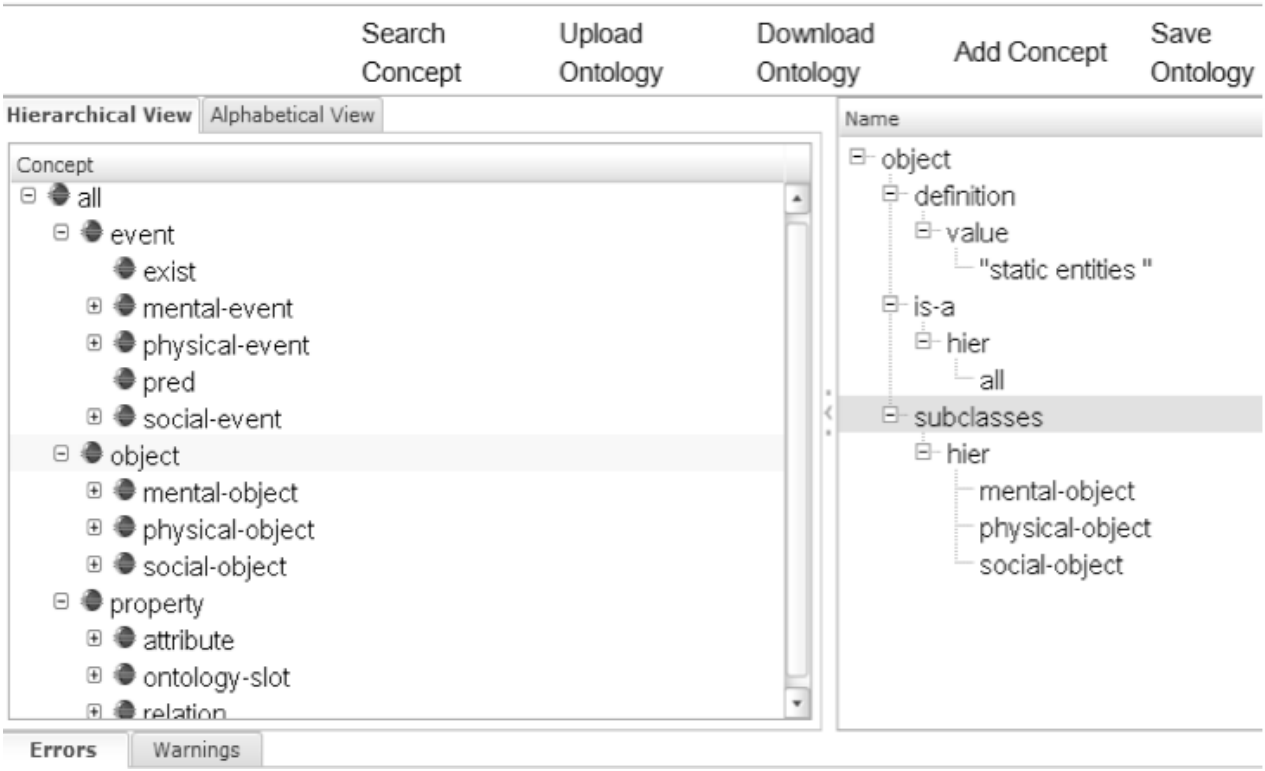

Figure 2: Top Level of the Ontology

Simplifying the exact process for the sake of brevity, in processing language the analyzer module will build representations of the text clause by clause from the building blocks found in the sem-struc. The information in the sem-strucs of every possible sense of a word is checked for compatibility with those of all senses of all other words in the clause by constraint matching, which also happens with the help of the information in the syn-struc. Finally, the combination of senses of all words in the clause that has the best matching of all constraints is chosen as the text-meaning representation of that clause to be stored in the InfoStore resource (see Fig. 1).

2 Antonyms in Ontological Semantic Technology

This section outlines representation formalisms and acquisition strategies for various types of antonyms.

2.1 Non-gradable antonyms

Lexical items with non-scalar semantics do not have a unified representation, and there are engineering considerations against having one in the static resources. For a scalable knowledge-based and domain-independent natural language processing system, explicit preference of otherwise unmarked

ontological concepts and properties representing a non-gradable pair like *alive-dead* (e.g. LIVE vs. LIVE(EPISTEMIC(0))), if implemented consistently, would lead to an unnecessary bias in extracting conceptual relations from input. While it would therefore be undesirable to accommodate the core antonym detection functionality in the static resources, and this functionality being one of the procedural, algorithmic components of an OST application, the ontology with its large descriptive thesaurus provides a comprehensive way to capture non-gradable antonym pairs.

Among the most common formats representing non-gradable antonym pairs are contrastive concept pairs, property fillers, and mutually exclusive facet values. An example below illustrates how a "male-female" pair can be captured via two contrastive literal fillers or values of the GENDER property.

```
(male-adj1
    (cat(adj))
    (anno(def "of male gender")
        (ex "a male suspect was arrested"))
    (syn-struc((root($var0))
        (cat(adj))(np((root($var1))(cat(np))))))
    (syn-struc1
        ((subject((root($var1))(cat(np))))
        (root(be))(cat(v))
        (directobject((root($var0))(cat(adj))))))
    (sem-struc(^$var1(gender(sem(male))))))

(female-adj1
    (cat(adj))
    (anno(def "of female gender")
        (ex "a female suspect was arrested"))
    ...
    (sem-struc(^$var1(gender(sem(female))))))
```

The representation above captures the contrastive gender properties as mutually exclusive values of the non-scalar attribute GENDER. An alternative representation could conceptualize the contrast as that between two full fledged concepts, as per below:

```
(male-adj1
    (cat(adj))
    (anno(def "of male gender")
        (ex "a male suspect was arrested"))
    ...
    (sem-struc(male))

(female-adj1
    (cat(adj))
    (anno(def "of female gender")
        (ex "a female suspect was arrested"))
    ...
    (sem-struc(female))
```

There are procedural implications of attribute value-based representations and concept-based representations. The former seems more intuitive but makes the semantic structure less accessible to a processor as attribute values are seldom used by semantic processing modules.

2.2 Gradable antonyms

An efficient way of representing lexical items with scalar semantics has been introduced in [Raskin and Nirenburg 1995], where the acquisition of scalar adjectives like *good*, *hot*, etc. is acquired by rapid propagation of pertinent values on a single scale (EVALUATION, TEMPERATURE, etc.). Given the scalar nature of gradable antonym pairs a similar approach could be adopted, which involves anchoring both members of an antonym pair in a single scalar attribute and assigning contrastive values:

```
(large-adj1
    (cat(adj))
    (anno(def "largely sized")
        (ex "he carried a large bag"))
    (syn-struc((root($var0))
        (cat(adj))(np((root($var1))(cat(np))))))
    (syn-struc1((subject((root($var1))(cat(np))))
        (root(be))(cat(v))(directobject((root($var0))
        (cat(adj))))))
    (sem-struc(^$var1(size(greater-than(0.8))))))

(small-adj1
    (cat(adj))
    (anno(def "small sized")
        (ex "he carried a large bag"))
    (syn-struc((root($var0))
        (cat(adj))(np((root($var1))(cat(np))))))
    (syn-struc1((subject((root($var1))(cat(np))))
        (root(be))(cat(v))(directobject((root($var0))
        (cat(adj))))))
    (sem-struc(^$var1(size(less-than(0.3))))))
```

[Riemer 2010] and [Murphy 2003] point out the semantic non-comittedness of certain pairs of gradable antonyms. In particular, [Riemer 2010] observes that in the *good-bad* pair, *good* merely posits an evaluation scale and is not committed to a specific value, which is evidenced by the acceptability of the example, "How good was that film? – Really bad." The contrastive member *bad*, on the other hand, is committed, which is in turn illustrated by the oddness of the example, "*How bad was the film? – The film is worse than the TV series, but they are both really good" [Riemer 2010: 138].

A reasonable adjustment to the representation formalism which would be sensitive to semantic non-comittedness of some gradable antonyms could involve postulating an open-ended variable whose value would be calculated contextually. More specifically, a TMR for "How good was the film" could override the default value of >.5 from the lexical entry and posit an open ended variable instead:

TMR: *How good was the film?*
exist
theme *sem* video-file
evaluative *value* $var99

The value of the high-numbered variable isassigned based on the output of higher-level processing modules capable of aggregating contextual data from ambient input segments across sentences or even acress texts in a corpus. In the example above, the ellipsis processing module would establish the co-reference of the EVALUATIVE modality filler in "Really bad.", and since *bad* is uncommitted, its value would override the default value in the previous TMR.

2.3 Autoantonyms

Autoantonymous lexical items have received extensive coverage in [Murphy 2003] and [Riemer 2003]. Unlike uncommitted antonym pairs, which posited both representational and processing challenges, autoantonyms are essentially multi-sense entries representation-wise, and the challenge mainly lies in selecting an appropriate sense at the TMR building stage. Consider, for example, 'sanction-v1' and sanction-v2:

```
(sanction-v1
    (cat(v))
    (anno(def "to allow")(comments "")
        (ex "the court sanctioned investigation into
        bribe allegations in the corporation")
    ...
    (sem-struc(allow
        (
        agent(value(^$var1(restricted-to(human)))))
        (theme(value(^$var2(restricted-to
            (sem(social-event culture-event)))))))))

(sanction-v2
    (cat(v))
    (anno(def "to penalize, impose sanctions
        on")(comments "")(ex "the union
        sanctioned the rogue state for stifling
        political opposition")(synonyms "")
    ...
    (sem-struc(allow(epistemic(0))
        (agent(value(^$var1(restricted-to(human)))))
    (patient(value(^$var2(restricted-to(sem(human
        organization)))))))))
```

A seeming similarity of the two autoantonymous senses is considerably reduced by the different case roles on their restrictions: if the theme of ALLOW is restricted to EVENTS, ALLOW(EPISTEMIC(0)) only requires an animate PATIENT filler.

2.4 Conversives and reversives

The OST framework offers an explicit formalism for representing both conversive and reversive lexical items. For a conversive pair, the order of the same ontological properties is reversed with fillers remaining in situ. For a reversive pair, sibling properties are invoked to capture the opposition. To illustrate, the canonical conversive pair *buy-sell* would receive the following representation:

```
(buy-v1
    (cat(v))
    (anno(def "to purchase")(comments "")
        (ex "he bought a cell phone from a friend")
    ...
    (sem-struc(buy
        (agent(value(^$var1(restricted-to(human)))))
        (theme(value(^$var2(restricted-to
        (sem(artifact food information)))))))
            (source(value(^$var3
                (restricted-to(sem(human)))))))))

(sell-v1
    (cat(v))
    (anno(def "to exchange for money")
        (comments "")
        (ex "he sold his cell phone to a friend")
    ...
    (sem-struc(buy
        (source(value(^$var1
            (restricted-to(human)))))
        (theme(value(^$var2(restricted-to
            (sem(artifact food information)))))))
        (agent(value(^$var3
            (restricted-to(sem(human)))))))))
```

A reversive pair "enter-leave" would receive the following representation:

```
(enter-v1
    (cat(v))
    (anno(def "to move into a structure")(comments
        "")(ex "he entered the room") (synonyms "")
    ...
    (sem-struc(move
        (agent(value(^$var1(restricted-to(human)))))
```

```
(end-location(value(^$var2
    (restricted-to(sem(artifact/building/
        landscape-object)))))))))

(leave-v1
    (cat(v))
    (anno(def "to exit a structure")(comments "")
        (ex "he left the room") (synonyms "")
    ...
    (sem-struc(move
        (agent(value(^$var1(restricted-to(human)))))
        (start-location(value(^$var2
            (restricted-to(sem(artifact/building/
                landscape-object)))))))))
```

The sibling case roles END-LOCATION and START-LOCATION are invoked to capture the reversion.

Given the multitude of ontological levels and sibling concepts, automating the acquisition of conversives and reversives is problematic. Section 2.5 will discuss additional issues and considerations regarding antonym acquisition.

2.5 Acquisition of antonyms in Ontological Semantic Technology

This section will discuss a preliminary strategy for automating the acquisition of a limited set of gradable and all gradable antonyms in OST. The strategy will allow for semi-automatic acquisition of antonyms from manually acquired senses.

A number of intrinsic parameters of many non-gradable antonyms make their automatic acquisition problematic and, in some cases, unjustified. As pointed in [Murphy 2003], the semantic motivation for relating many non-gradable antonyms is arbitrary, as well as culture- and context-sensitive. [Murphy 2003: 173] discusses the cross-cultural and contextual variation of antonyms of taste for the word *sweet* with *sweet-pungent* being preferred in Japanese, *sweet-sour* in English in neutral contexts, and *sweet-salty* (when describing snack food), *sweet-bitter* (chocolate), *sweet-dry* (wine), etc. While the OST knowledge resources provide for recognition and semantic representation of such context-sensitive antonyms, their acquisition would lead to unjustified idiosyncrasies and thus bias the text processor at the TMR building and reasoning levels. An additional consideration exists against automatic representation of those non-gradable antonyms whose semantic structure contains head concepts with multiple siblings. This leaves the machine with the uncertainty as to which sibling filler would constitute antonymy; in these cases the machine would over-generate, and there would be no scalable way to eliminate false positives. To illustrate, multiple sibling fillers of the attribute HAS-COLOR exist, many of which are culturally contrastive (e.g. *black-white*), while others are context-sensitive (e.g. *black-red* when describing a roulette wheel), and there are no *a priori* intrinsic linguistic clues for the machine to use to capture those pairs.

Among non-gradable antonyms, only cases like *male-female*, whose semantics involves selection from a set of two property fillers, lend themselves to acquisition and can be incorporated into the general semi-automatic acquisition strategy described below.

The antonym-acquisition strategy takes advantage of the representational potential of OST's knowledge resources, morphological regularities in antonym formation, the available lists of high-frequency antonym pairs and, available tagged corpora.

The general steps of the strategy are outlined below:

1) **Base antonym type detection**: Based on its semantic structure, the type of the base antonym is determined automatically. Senses whose semantic structure posits a concept in the set of two siblings, or a property with a set of two sibling fillers are non-gradable senses whose semantic structure contains a scalar attribute. are gradable, other cases are eliminated.

2) **Semantic derivation**: Depending on the base antonym type, a respective rule is applied to derive an appropriate semantic structure.

The following semantic derivation rules can be formulated for each base antonym type:

For non-gradable antonyms:

(1) (sem-struc(concept)) → (sem-struc(sibling-concept))

(2) (sem-struc(concept(facet(filler)))) → (sem-struc(concept(facet(sibling-filler))))

For gradable antonyms:

(3) (sem-struc(attribute(facet(literal-filler-a)))) → (sem-struc(attribute(facet(literal-filler-b[with a and be being the only literal fillers of that attribute))))

Rules (1-2) select an alternate sibling for the head concept or filler, and rule (3) reverses the value of the scalar attribute of the base antonym. The part of speech and syntactic structure of both pair members remain the same.

3) **Form derivation:** Morphological rules are applied to the base antonym to form a new sense by adding commonly used affixes. The list of regular antonym-forming prefixes and suffixes is based on [Justeson and Katz 1991] and, with minor additions, includes the following: [a-, ab-, an-, dis-, il-, im-, in-, un-,

non-, anti-, counter-, -less.] At this stage, the set is recursively applied to the base antonym form with each affix attached at a time. All the resulting forms are then passed to the form verification procedure.

4) **Form verification**: The core objective of this procedure is to assign an acceptable word form to an already instantiated sense template. The legitimacy of the newly derived word checked against a tagged corpus (e.g. Brown corpus) and the antonym list developed in [Justeson and Katz 1991] (referred to as JK list) containing 57 pairs of antonyms of higher than random frequency. The JK list comprises a set of 35 antonymous adjectival pairs tested in [Deese 1964] and an additional set of 22 pairs tested in [Justeson and Katz 1991.] The procedure takes all morphological derivates from procedure (3) as input. If none of the candidate forms returns a match in the tagged corpora, the JK list, as well as online and offline lists of antonyms are taken advantage of. The output of the procedure essentially completes the antonym acquisition cycle: the antonym has been derived semantically, syntactically, and lexically. If no match is returned from the available corpora, the acquisition cycle is aborted.

5) **Rapid propagation**: Once a legitimate antonym has been confirmed, its synonyms are assigned an identical sense template, thus facilitating acquisition. The application of this procedure is largely dictated by the general grain size of lexical coverage. Finer-grained applications may require a more thorough representation capturing purely preferential differences between, say, the more standard *big-little* and the less acceptable *large-little*. More generic applications may allow for antonymy to be established between all members of each pair. Procedurally, steps similar to rapid propagation outlined in [Nirenburg and Raskin 1995, 2004] are taken, when the syntactic and semantic structures of a fully derived sense get propagated across a large set of similar entries. A similar procedure was also deployed in [Petrenko 2011] in relation to deriving synonyms of semi-automatically acquired deverbal senses.

As an illustration of the antonym acquisition strategy, a selected pair *cold-hot* with contrastive TEMPERATURE values is discussed below with each procedure described in detail. Procedure (1) will determine the base antonym *cold* as gradable:

```
(cold-adj1
    (cat(adj))
    (anno(def "having a low temperature")
        (ex "he stepped in the cold water"))
    (syn-struc((root($var0))
        (cat(adj))(np((root($var1))(cat(np))))))
    (syn-struc1((subject((root($var1))(cat(np))))
        (root(be))(cat(v))(directobject((root($var0))
            (cat(adj))))))
    (sem-struc(^$var1(temperature(less-than(0.3)))
)))
```

Based on the output of procedure (1), semantic derivation rule (3) for gradable antonyms of procedure (2) will be called, which will return the following semantic structure:

(sem-struc(^$var1(temperature(greater-than(0.8))))

None of the word forms (**acold, *abcold, *ancold, *discold, *ilcold, *imcold, *incold, *uncold, *noncold, *anticold, *countercold, *coldless*) generated morphologically via procedure (4) will match the existing corpora, so the system will have to resort to existing corpora of antonyms including the JK list. The JK list will return a match "hot" for "cold", whose sem-struc, if acquired earlier, will match the template derived in procedure (1). After the *cold-hot* antonym pair has been derived, synonyms will be looked up in available online and offline corpora:

cold-adj1: [arctic, frigid, gelid, glacial, icy, polar, bleak, cutting, raw-chilly, parky, crisp, frosty, nipping, nippy, snappy, frigorific, frore, frosty, rimed, rimy, heatless, ice-cold, refrigerant, refrigerating, refrigerated, shivery, stone-cold, unheated, unwarmed]

hot-adj1: [baking, baking hot, blistering, blistery, calefacient, warming, calefactory, calefactive, calorifacient, calorific, fervent, fervid, fiery, igneous, heatable, heated, heated up, het, het up, hottish, overheated, red-hot, scorching, sizzling, sultry, stifling, sulfurous, sulphurous, sweltering, sweltry, thermal, torrid, tropical, tropic, white, white-hot]

Under the generic, coarse-grained functionality assumption, the instantiated templates for *cold* and *hot* will be propagated among all members of the retrieved sets. The acquirer will be offered an option of manually approving each built sense. Finer-grained acquisition would introduce additional demarcation criteria (stylistic preferential, etc.) and thus substantially increase the amount of manual effort.

4 Conclusion

This paper has presented a first account—descriptive and procedural—of antonyms within Ontological Semantic Technology. We first outlined, based on

relevant literature, the pertinent properties and major types of antonyms which directly resonate with the descriptive potential and computational goals of OST applications. We then discussed how non-gradable and gradable antonyms are represented within OST, how non-comittedness, auto-antonymy, reversion and conversion can be captured with OST formalisms. We concluded the paper by introducing a general strategy for semi-automatic acquisition of a limited set of non-gradable and all gradable antonyms in the OST lexicon, which takes advantage of manually acquired base senses, rich ontological and lexical knowledge resources, and relies on existing corpora.

Abstract - *In an increasingly diverse cross-cultural environment, individuals and organizations are constantly interacting with foreign cultures, which require perceptiveness and adaptability. Cultural intelligence appears as an emerging application in cross-cultural activities. Researches on this domain provide a new perspective and a promising means of intercultural conflicts and obstacles reduction. However, these researches rely mainly on questionnaires to find solutions to the cultural intelligence problems in cross-culture settings. Up until now, no research on cultural intelligence has been empirically computerized. The traditional computational techniques cannot treat cultural intelligence soft data to help individuals and organizations in solving intercultural problems. This research aims to create a new cultural intelligence model based on an innovative breed of AI technologies, and implemented in an expert system called CIES. The purpose of CIES is to support ordinary people when making culturally intelligent decisions and to improve their cultural skills when facing various authentic situations.*

Keywords: Cultural Intelligence; Soft-Computing; Expert System; Hybrid System

1 Introduction

In the context of the environment of globalization, multicultural communication and exchanges are part of today's world reality. Individuals and organizations are required to make culturally-intelligent decisions and to show their competence in culturally diverse workplaces. When confronted with cultural diversity, some individuals and organizations are able to adapt successfully to the new cultural environment, while others are not. What is the decisive factor for these opposing responses? How can good decisions be made in culturally-diverse environments? What skills can be improved to enable cultural adaptation?

In recent years, researchers have shown great interest in globalization and intercultural management. Cultural intelligence has, therefore, been presented as a new phenomenon in order to answer the above questions. Organizational psychology and human resource management have paid great attention to cultural intelligence since its introduction. These fields of study have yielded valuable results that apply to the real cultural world. However, most current studies related to cultural intelligence do not focus on the computational aspects. Moreover, a great deal of cross-cultural knowledge is expressed as 'soft data,' such as, "*this culture is more masculine*", "*that person is highly confident*". Effectively dealing with these natural linguistic variables is beyond the scope of traditional computer technology.

The new AI technologies provide us with a means for coping with these incomplete, vague and ambiguous terms that are often used in the cultural domain. This research attempts to offer effective solutions to the problems mentioned above. These solutions mainly rely on a new computational model of cultural intelligence implemented in a system called the CIES (Cultural Intelligence Expert System). This system has integrated the cultural intelligence knowledge of experts and has the potential to achieve better performance than human experts. The CIES is considered as highly intelligent due to its wealth of knowledge, openness, scalability, flexibility, adaptability, and capability to self-learn. Such a system has three goals: 1) to assist individuals and organizations in their decision-making processes involving cultural affairs; 2) to assist people in improving their use of a specific form of intelligence based on their capacity to understand, to reason correctly, and to adapt to culturally diversified situations [1]; and 3) to facilitate the work of researchers and to better equip them in their studies of cultural intelligence.

2 Cultural Intelligence and its dimensions

In the research literature, cultural intelligence has been referred to using the acronym CQ. Researchers have different opinions regarding the concept of CQ. Earley and Ang presented CQ as a reflection of people's ability to collect and to process information, to form judgments, and to implement effective measures in order to adapt to a new cultural context [2]. Earley and Mosakowski redefined CQ as the ability of managers to deal effectively with different cultures [3]. They suggested that CQ is a complementary intelligence form,

which may explain its capacity to adapt and face diversity, as well as to operate in a new cultural setting. Peterson interpreted CQ in terms of its operation [4]. He believes the concept of CQ is compatible with the Hofstede [5] cultural values and their five main dimensions, i.e., individualism versus collectivism, masculinity versus femininity, power distance, uncertainty avoidance, and short and long term orientation. Brislin et al. defined CQ as the level of success people obtain when adapting to another culture [6]. Thomas explained CQ as the ability to interact efficiently with people who are culturally different [7] [8]. Ng et al. presented CQ as the ability to be effective in all cultures [9]. Johnson et al. defined CQ as the ability of an individual to integrate a set of knowledge, skills and personal qualities so as to work successfully with people from different cultures and countries, both at home and abroad [10].

Researchers in the field of culture also use different dimensional structures to measure CQ. Each of these researches is associated with conceptual models. These structures seek to explain the attributes that enable people to develop their abilities in various cultural contexts and, thereafter, to determine how people can improve these capabilities. Earley and Ang [2] presented the first structure of CQ which integrates the following three dimensions: cognition, motivation and behaviour. While Thomas agrees with Earley and Ang that there are three dimensions to CQ [8], he does not share their point of view regarding what these three dimensions should be. He, therefore, advocated another tridimensional structure. His belief is founded on the theory of Ting-Toomey [11], which states that the structure of CQ should be based on the skills required for intercultural communication, that is to say, knowledge, vigilance and behaviour. Vigilance acts as a bridge connecting knowledge and behaviour, which is the key to CQ. Tan [12] believes that CQ has three main components: 1) strategic thinking about culture; 2) dynamics and persistence; and 3) specific behaviours. Tan stressed the importance of behavior as being essential to CQ. If the results of the first two parts are not converted into action, CQ is meaningless. Ang and Van Dyne [1] suggested a four-dimensional CQ structure. This structure is based on the general intelligence structure of Sternberg and Detterman [13]. Ang et al. used the framework of Sternberg, which divides CQ into metacognitive CQ, cognitive CQ, motivational CQ and behavioral CQ. This structure has been widely used in the following cultural researches and studies.

3 CIES architecture

We believe that the diverse structures of CQ should be considered collectively in order to integrate the elements necessary to respond the cultural knowledge acquired. Therefore, we build the CQ architecture. It is based on the specific CQ four-dimensional structure of Ang and Van Dyne [1]. The architecture is noteworthy because we use the four CQ dimensions as integrated and interdependent entities. It represents a comprehensive overview of the multi-aspects of the researches on CQ.

The architecture of CIES uses both the symbolic and connectionist approaches of AI. The architecture respects the cognitive concepts of Ang and Van Dyne [1] regarding the theories of global CQ, it also includes other important aspects, for example, Hofstede's theory of five cultural dimensions [5]. The architecture also relies on engineering concepts in its solutions when designing and implementing software. It offers learning mechanisms which emulate human intelligence.

In total, the architecture has an eleven-step cognitive process. It recognizes cross-cultural business-related information in natural language from its environment by using its cognitive cycle. The following describes these steps. These steps correspond to the numbers inside the rectangles in Fig.1.

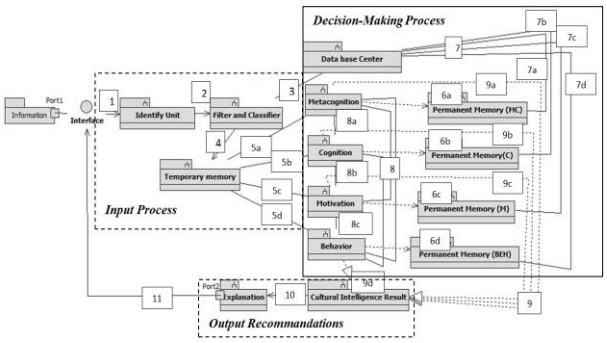

Figure 1. Architecture of CIES

Step 1: A cultural information in natural language, expressing a problem, and a question or a requirement of the user, is inputted through the user interface. This information enters the *Identify* module. This module identifies the information to determine what the user requires.

Step 2: The cultural information goes to the *Filter and Classifier* module. In this module, the information is classified and filtered from what is not useful for cultural analysis in the following steps.

Step 3: To perform this classification, the module has an associated relationship with the *Cultural Intelligence Database Center*, which has all the necessary data that the system needs, such as countries, religions, languages, and laws.

Step 4: The classified cultural data are ready to be sent to the *Temporary Memory* module. This module keeps

the data temporarily and, at the same time, interacts with the other modules.

Step5: The 5a-*Metacognitive* module, 5b-*Congnitive* module, 5c-*Motiviational* module and 5d-*Behavioral* module collect the cultural data belonging to them in the temporary memory.

Step 6: Each module depends on the consultation of its own *Permanent Memory*. These permanent memory modules are 6a for metacognition, 6b for cognition, 6c for motivation and 6d for behavior. Each permanent memory represents a complete and specific cultural database that is used by its associated module to analyze the cultural information stored in the *Temporary Memory*.

Step 7: 7a, 7b, 7c and 7d analyze the cultural information. If data are missing, permanent memories modules go to the *Cultural Intelligence Database Center* to assist in the cultural analysis of the respective modules.

Step 8: After the analysis is completed in each module, the four modules must interact with each other so that each module can adjust its cultural decision. This interaction gives a complete and effective decision before continuing to the next step.

Step 9: Following the interaction between the modules of the different CQ dimensions, the four modules in steps 9a, 9b, 9c and 9d send their final cultural decisions to the *Cultural Intelligence Result* module. In this module, the decisions of these four modules are generalized and offer significant cultural information to the user.

Step 10: The *Explanation* module justifies and explains in detail, using natural language understandable to the user, why these decisions were presented.

Step 11: The explanations are sent to the *User interface*.

4 Choices of AI techniques

CQ generally has two types of data: the first type is associated to "hard" computing; which uses numbers, or crisp values; the second type is associated with "soft" computing, which operates with uncertain, incomplete and imprecise soft data. The second type is presented in a way that reflects human thinking. When we introduce the cultural concept to cross-cultural activities, we usually use soft values represented by words rather than crisp numbers. The traditional technique, or "hard" computing, is based on Boolean logic, so it cannot treat cultural soft data. In order to enable computers to emulate humans' way of thinking and to model a human-like understanding of words in decision-making, we use a neuro-fuzzy soft-computing technique to design the CIES. This soft computing technique is capable of dealing with uncertain, imprecise and incomplete cultural soft data.

This hybrid neuro-fuzzy soft-computing technique makes use of the advantages and power of fuzzy logic and the artificial neural network (ANN). Fuzzy logic and the ANN are complementary paradigms: 1) The fuzzy logic technique is used for three reasons. First, the CQ concepts are described in natural language containing ambiguous and imprecise linguistic variables, such as "*this person has low motivation*" and "*that project is highly risky because of this religion.*" Second, fuzzy logic is well-suited to modeling human decision-making processes when dealing with "soft criteria." These processes are based on common sense and may contain vague and ambiguous terms [15]. Third, fuzzy logic provides a wide range of cultural expressions that can be understood by computers. 2) ANN: Although the fuzzy logic technique has the ability and the means to understand natural language, it offers no mechanism for automatic rule acquisition and adjustment. The ANN offers learning mechanisms in an uncertain, incomplete and imprecise cultural setting, which emulates human intelligence. It presents viable solutions for processing incomplete and imprecise cultural information. The ANN can manage the new cultural data input and the generalization of acquired knowledge. The hybrid neuro-fuzzy technique represents the essence of our soft computing model.

5 Inference engine of the system

5.1 Creating fuzzy sets

All the fuzzy sets come from the CQ domain. A practical approach to form CQ fuzzy sets is used in our system. The fuzzy sets define the sets on the universe of discourse. For example, when X is the universe of discourse of metacognition, and its elements are denoted as *x*, the fuzzy set *Metacognition (MC)* is part of the universe *X*, and is defined by the function $\mu MC(x)$ as a function of membership in the set *Metacognition*. This equation is expressed as: $\mu MC(x): X \rightarrow [0,1]$. For every element *x* of universe *X*, the membership function $\mu MC(x)$ equals the degree to which *x* is an element of set *Metacognition*. This degree, having a value between 0 and 1, represents the level of membership of element *x* to set *Metacognition*.

5.2 Linguistic variables and fuzzy rules

The idea of linguistic variables is one basis of the fuzzy set theory. A linguistic variable is a fuzzy variable. For example, when we say "the CQ is high," it means that the linguistic variable of CQ takes the linguistic value high. Thus, our cultural linguistic variables are used in fuzzy rules in the system. For example:

Rule 1:

IF Metacognition is high AND Cognition is high AND Motivation is high AND behavior is high

THEN CQ is high

The operations of cultural fuzzy sets used in our CIES are the *Intersection* and *Union*. For example, the fuzzy operation used to create the *Intersection* of two cultural fuzzy sets A and B is as follows:

$$\mu A \cap B(x) = min[\mu A(x), \mu B(x)] = \mu A(x) \cap \mu B(x), where\ x\ \in \mathrm{X} \quad (1)$$

The operation to form the fuzzy *Union* of two cultural fuzzy sets A and B is as follows:

$$\mu A \cup B(x) = max[\mu A(x), \mu B(x)] = \mu A(x) \cup \mu B(x), where\ x \in X \quad (2)$$

The CIES uses a technique called the fuzzy inference method by Mamdani [16]. Fig.2 illustrates in the CIES an example of the application of a technique called Mamdani fuzzy inference method by using triangular sets. We define that the fuzzy system as having four CQ inputs: metacognition, cognition, motivation, and behavior, and as having one output: CQ. For example, input metacognition is 7.95, cognition is 3.31, motivation is 3.41 and behavior is 2.38, inferenced by six fuzzy sets rules 1,2,3,4,5 and 6; output CQ is the result from six rules 1,2,3,4,5 and 6.

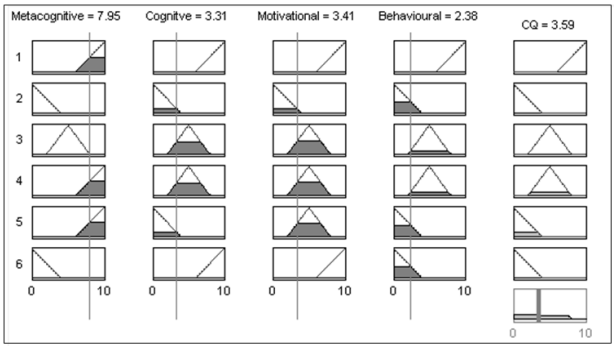

Figure 2. Example of the Fuzzy Inference System of Mamdani Using Triangular Sets in CIES

The CIES neuro-fuzzy system is similar to a multilayer neural network. Fig.3 shows the CIES neuro-fuzzy system that corresponds to the fuzzy inference model shown in Fig.2. It is represented with a neural network composed of five layers in the CIES. It has four dimensions of CQ input layer and CQ output layer, and three hidden layers that represent membership functions and CQ fuzzy rules. Each layer of the neuro-fuzzy inference model of CIES in the cross-cultural application is associated with a particular step in Mamdani fuzzy inference process. The four inputs are: metacognition (MC), cognition (C), motivation (M) and behavior (BEH), and has one output: CQ

Layer 1 - Input: No calculation is made at this layer. Each neuron corresponds to an input cultural variable. These input values are transmitted directly to the next layer.

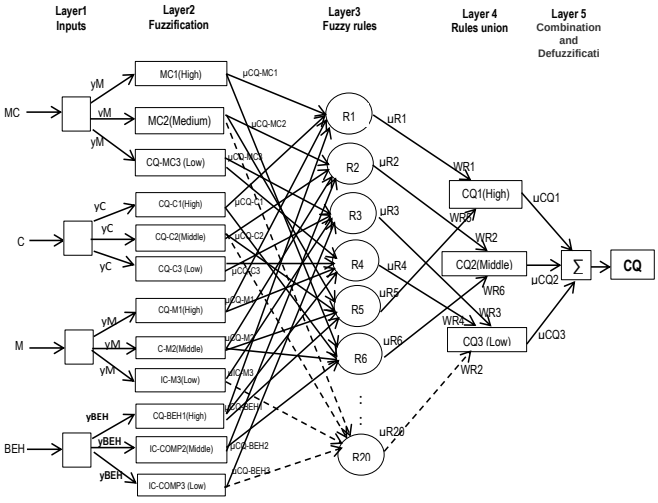

Figure 3. Soft-Computing Model of CQ

Layer 2 - Fuzzification: Each neuron corresponds to a cultural linguistic label (e.g., high, medium and low) associated with one of the input cultural variables in layer 1. In other words, the connection of the output, which represents the inclusion value, specifies the degree to which the four input cultural values belong to the neuron's fuzzy set. The connection is computed at this layer.

Layer 3 - Fuzzy Rule: The output of a neuron at level 3 is the cultural fuzzy rules. Each neuron corresponds to one cultural fuzzy rule. The cultural fuzzy rule neurons receive inputs from the layer 2 (fuzzification neurons), which represent cultural fuzzy sets. For example, neuron R1 represents cultural Rule 1 and receives input from the neurons MC1 (*Metacognition High*) and C1 (*Cognition High*). The weights (WR1 to WR20) between layers 3 and 4 are the normalized degree of confidence of the corresponding cultural fuzzy rules. These weights are adjusted when the system is trained.

Layer 4 - Rule Unions (or consequence): This neuron has two main tasks: 1) to combine the new precedent of cultural rules, and 2) to determine the output level (high, medium and low). The output level belongs to the cultural linguistic variables. For example, *μR1*, *μR5* are the inputs of *CQ1 High*, and $\mu CQ1^{(4)}$ is the output of the neuron *CQ1 High*.

Layer 5 - Combination and Defuzzification: This neuron combines all the consequential rules and computes the crisp output after defuzzification. The composition method "sum-product" [17] is used. It computes the outputs of the membership functions defined by the weighted average of their centroids. We

apply, in this case, the triangle calculation in our neuro-fuzzy system; which is the simplest calculation of the fuzzy set as shown in Fig.4:

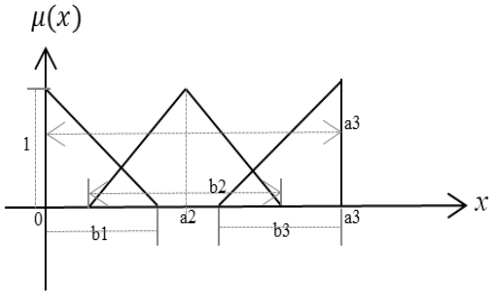

Figure 4. General Cultural Intelligence Fuzzy Sets

Where a2 is the center and a3 is the end of the triangle. b1, b2 and b3 are the widths of fuzzy sets which correspond with *CQ 3 (Low), CQ2 (Medium)* and *CQ1 (High).* The calculation formula of weighted average of the centroids of the clipped three CQ fuzzy sets CQ High (CQH), CQ Medium (CQM) and CQ Low (CQL) are calculated as:

$$y\,CQ = \frac{\frac{1}{3}b_1^2\mu CQH + a_2 b_2 \mu CQM + \left(a_3 - \frac{2}{3}b_3\right)b_3\mu CQL}{b_1\mu CQH + b_2\mu CQM + b_3\mu CQL} \quad (3)$$

5.3 Supervised and unsupervised learning

The soft-computing model can easily be modified by changing, adding or subtracting CQ rules through two main types of learning occurring in the CIES neuro-fuzzy network: supervised learning and unsupervised learning. The supervised learning is the type of training where the neuro-fuzzy network is provided with desired outputs to improve its performance. We provide to the system the fully processed external CQ experts' data, required for the supervised learning. These data are processed user cases. Each user case contains the original input cultural data, and the output data provided by cultural experts, that CIES is expected to produce. The CIES compares actual output with the cultural experts' data from the training case. If the actual output is different from the data given by experts in the training case, the CIES weights are modified. The back propagation algorithm is used in the CIES. The signal difference at the output of neuron *n* at sequence *s* is calculated as showed in equation (4). We increase sequence *s* by one, and repeat the process until the preset difference criterion is satisfied.

$$D_n(s) = y_{e,n}(s) - y_n(s) \quad (4)$$

Where $y_{e,n}(s)$ is the cultural experts' data of neuron *n* at sequence *s*, the CQ rules for updating weights at the output layer are defined in equation (5) as:

$$W_{mn}(s+1) = W_{mn}(s) + \Delta W_{mn}(s) \quad (5)$$

$\Delta W_{mn}(s)$ represents the weight correction. We use a forward procedure method to update CQ rules' weight W_{mn}. Fig. 5 shows an example of the result where CIES trains weights from bad rules to the desired CQ rules.

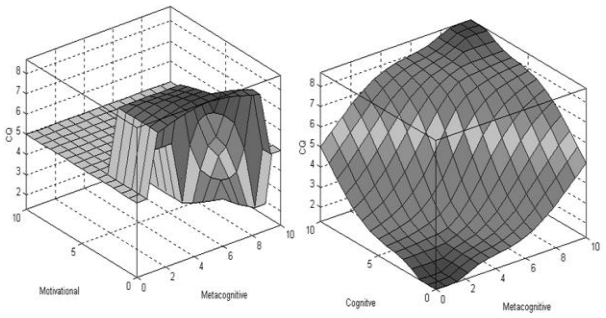

Figure 5. An Exemple of Supervised Learning

In contrast to supervised learning, with unsupervised learning in CIES, the neuro-fuzzy network is trained without desired output. The unsupervised learning does not require external cultural experts' data. During the learning process, the CIES receives a number of different original input user cases, find relationships in these cases and build new rules based on these cases used. The CQ rules for updating weights at the output layer are calculated in the equation (6). The equation (6) shows how the CIES changes the CQ rules weights, between a pair of neurons in the unsupervised learning process, through multiplication of input and output signals.

$$W_{mn}(s+1) = W_{mn}(s) + \alpha y_n(s) x_m(s) \quad (6)$$

$\Delta W_{mn}(s) = \alpha y_n(s) x_m(s)$ represents the weight correction by Hebbian algorithm [18] in CIES, α being the learning rate parameter.

6 Data acquisition and the application domains

Christine Kon et al. [19], Ang, Van Dyne et al. [20], and Ang et al. [1] developed a self-evaluation questionnaire with 20 items measuring CQ. This questionnaire was used to collect data for studies on the capabilities of the test subjects regarding their cultural adaptation capacity. This questionnaire is generally divided into four sections: CQ metacognitive CQ, cognitive CQ, motivational CQ and behavioral CQ. For example, one of the items is "*I am conscious of the cultural knowledge I use when I interacting with people with different cultural backgrounds.*" Linn Van Dyne et al. [21] developed a version of the questionnaire from the point of view of an observer. It is also based on the 20 items of Ang et al. [1] which measure the CQ of individuals. The questionnaire was adapted from each

item of the self-evaluation questionnaire to reflect the assessment made by an observer rather than the trainee himself. For example, the item of the questionnaire mentioned above changes from: "*I am conscious of the cultural knowledge I use when…*" to "*This person is conscious of cultural knowledge he / she uses when ....*"

As explained by Linn Van Dyne et al. [21], these questionnaires also allow for the effective assessment of CQ in practical applications. Among other potential applications, we can identify three application domains covered in our system. They are *Business Activities*, *Expatriates Assignments* and *Training*. Thus, we adapted the self-evaluation questionnaire of Ang et al. [1], and the observer questionnaire by Linn Van Dyne et al. [21], in order to measure CQ for these three application domains. By collecting the data from these two questionnaires, first, the data can be prepared and be used in our neuro-fuzzy network future training. Second, the user or organisations' expatriate's assignments can be evaluated so that proper training can be offered by CIES.

7 Implementing the CIES

We would like the CIES to be capable of acquiring, extracting and analyzing the new knowledge of the cultural experts. First, it should be able to: 1) express knowledge in a form that is easily understood by the users, and 2) deal with simple requests in natural language rather than programming language. Second, the CIES should consist of an efficient team of cultural experts who are able to make decisions and provide explanations in the decision-making process in culturally diverse settings. Hence, we integrated the neuro-fuzzy soft-computing model into an expert system. It relies on the functional «*consciousness*» mechanism for much of its operation [14]. Its modules communicate and offer information to each other. Fig. 6 shows the system structure of the CIES. This structure includes four main modules:

1) *The CQ knowledge base* is represented by the trained neuro-fuzzy network. This module contains CQ knowledge that is useful for solving CQ problems. The soft-computing technique used in this module makes the system able to reason and learn in an uncertain, incomplete and imprecise CQ setting. It supports all the cultural decision-making steps in the system. This module connects with three different units which are *New Data, Training Data* and the *Cultural Intelligence Database Center*. New Data include users' requests for solving a given problem that involves some cultural affairs. *Training Data* are a set of training examples. They are used for training the neuro-fuzzy network during the learning phase. The *Cultural Intelligence Database Center* mostly contributes to the knowledge gathered from data about different cultural aspects which has been collected from different countries.

2) The Cultural Intelligence Rules examines the CQ knowledge base and produces neuronal rules which are implicitly «buried» in the CIES network.

3) The Inference Engine is the core of the CIES. It controls the flow of cultural information in the system, and initiates inference reasoning from the knowledge base in the *Cultural Intelligence model*. It also concludes when the system has reached a decision.

4) *The Explanation* clarifies to the user why and how CIES achieved the specific cultural results. These explanations include analysis, advice, conclusion, and more required facts for deeper reasoning.

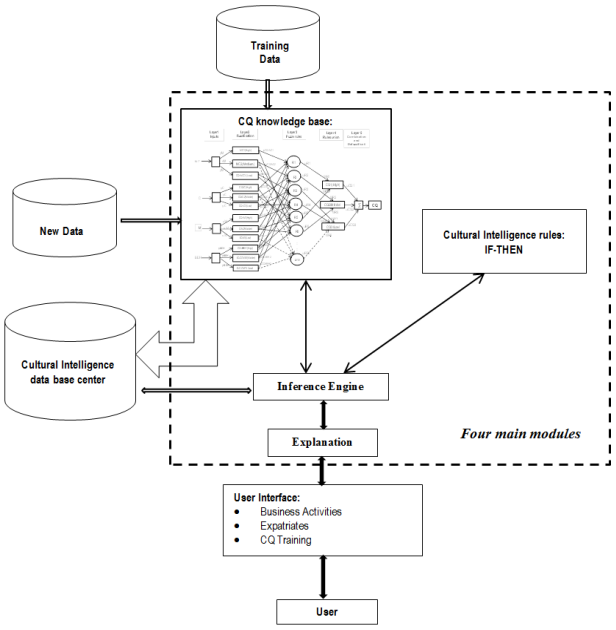

Figure 6. Structure of CIES

7.1 CIES for decisions making

The CIES possesses generic CQ, that is not specific to a particular culture (such as USA or China etc.). The system shows great capabilities of cultural adaptation by modeling the human decision-making process in situations characterized by cultural diversity. Furthermore, because of its elaborated cultural schemas and analytical abilities, the CIES can help users to identify and understand key issues in cultural judgment and decisions making, giving them the corresponding explanations.

For example, Fig.7 and Fig.8 present an output of the *Business Activity* application domain of how the CIES can help a user to make a decision, by taking into consideration his/her inputted request. The CIES prototype system follows the decision-making cycle process shown in Fig.1. The input data are specific

cross-cultural questions in the natural language of the users. The system provides two outputs as an answer to the question. Output1 (Fig.7), gives a general decision to answer the question asked by the user.

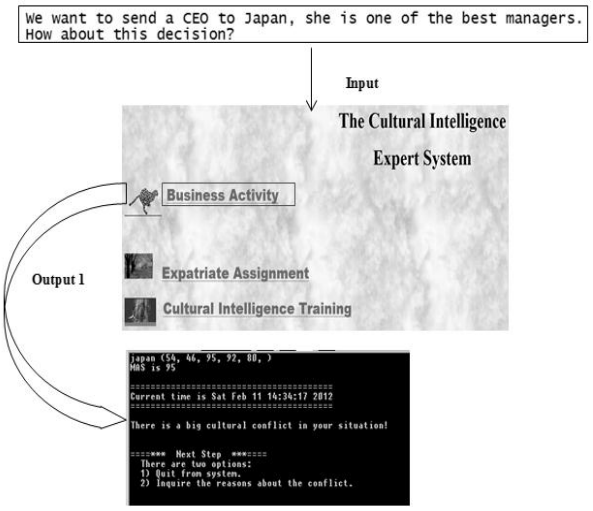

Figure 7. Business Activity in CIES Prototype (Output 1)

Output2 (Fig.8), gives more detailed explanations to clarify to the user why the system reached this decision.

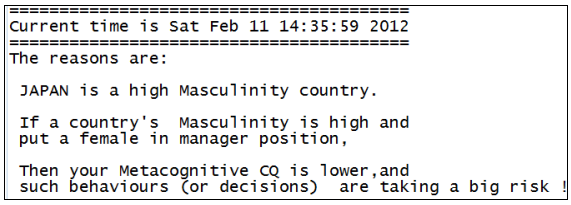

Figure 8. Business Activity in CIES Prototype (Output 2)

7.2 CIES for training

The CIES could be used in self-awareness training programs. The system provides important insights about personal capabilities and information on the user's own CQ in cultural diversity situations. Users can get two evaluations (self or observer [1] [19] [20] [21]) on the 20-itemed questionnaires so as to compare their results. Organizations could also use CIES (both self and observer evaluations) to evaluate or train, for expatriate purposes, employees who may be well-adapted. The CIES serves as an efficient team of top CQ tutors who work constantly with individuals or organizations wanting to have cross-cultural recommendations and insights on how to increase their efficiency in culturally-diverse settings. Fig.9, Fig.10 and Fig.11 present one part of the results of the self-evaluation questionnaire of a user in the CIES prototype. The CIES provides different feedback to a user receiving a high score (8>), than it does to a user receiving a low score (6<). In addition, it accordingly gives useful suggestions for personal self-development as required. This process permits the CIES to evaluate users so as to identify their problems in the CQ domain. The CIES next offers a tailored course to users based on the results of the evaluation. Moreover, during the training course, the system uses natural language to communicate with users in order to provide them a stress-free and friendly learning environment.

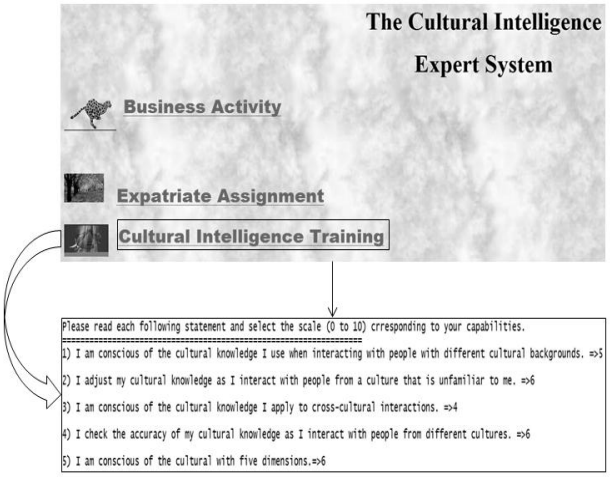

Figure 9. CIES Prototype for Traning (Self-Evalution Questionnaire)

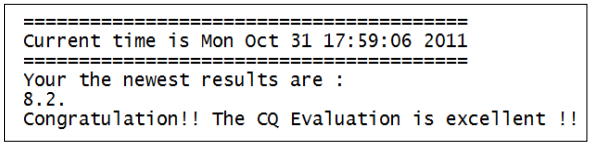

Figure 10. CIES Prototype (Output1: high score 8>)

Output 2 (Fig.11), gives useful suggestions for self-improvement to the user, when CQ is required.

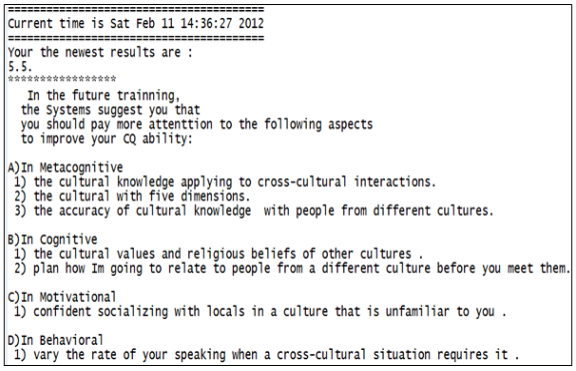

Figure 11. CIES Prototype (Output 2: low score 6<)

Three cultural experts have validated our computational CQ model, as well as that of the CIES prototype system. This validation ultimately reflects the consistency between the real world and the artificial CIES system. The CIES prototype system was tested on one hundred people. Based on the results of the validation, the cultural experts compared the CIES

results with their own. These experts concluded that the cross-cultural business decisions recommended by CIES are similar to the ones suggested by a human expert.

8 Some interesting features of CIES

First, due to the powerful designed functions and the CQ capabilities in CIES, the CIES could evaluate users and expatriates employees along with providing them specific cultural recommendations by using its knowledge to train people to improve their CQ skills, in addition, it could be used as a CQ decision-making support system to help individuals and organizations take cultural decisions in cross cultural activities. The CIES is also able to adapt dynamically to the CQ capacity of users. Second, this system is open in the sense that it can provide a standard interface that can facilitate further development. Third, the CIES is extensible, both in terms of the system concept model and the implementation of the system. Fourth, this system has the potential to work as an extended cultural and cognitive agent which could integrate into another existing intelligent system.

9 Conclusion

CQ is the human ability to capture and reason appropriately in culturally diverse settings. CQ can be measured with four dimensions. Thus, we built a CQ computational model based on a soft-computing technique so as to integrate these dimensions and embody an expert system called the CIES. This paper shows how the CIES can be used as a "culturally aware" system. The research captures the essence of culture and addresses culture from the perspective of the intelligence of an individuals or organizations wanting to develop their ability to adapt to various cultures. The CIES enables users to be more efficient and "intelligent" as they develop their cultural skills. The CIES acts as an intelligent cultural expert assistant which helps individuals or organizations to make better decisions in cross-culture activities, and it enables users to solve cultural problems that would otherwise have to be solved by cultural experts.

The contribution of our research is, first and foremost, to fill the gap between CQ and AI. Second, it improves the application of CQ theories in the field of cognition. The research focuses on modeling four CQ dimensions that are interdependent and integrated. As a result, the theories are complete, efficient, and precise in their applications. Third, we brought to the field of AI the computerization of CQ. As a result, new research topics and directions relevant to this research have arisen, and the range of computational intelligence possibilities has been expanded. Fourth, our research is groundbreaking as it simplifies the work of the researchers by freeing them from heavy, complex and repetitive tasks, normally carried out manually in CQ studies. The algorithms and techniques used in this research may offer some enlightenment as they can be applied to other research domains to improve model designs and system performances.

A System for Qualitative Spatio-Temporal Reasoning*

Michael J. Almeida
Mathematics & Computer Science, Fayetteville State University, Fayetteville, NC, USA

Abstract - *The ability to reason about the spatial relationships between objects in the environment is a core requirement of mobile robots and many other types of intelligent systems. However, since objects frequently change their location, the representation of spatial location critically depends on time. Thus, what is really required is spatio-temporal reasoning. This paper presents a unified system for qualitative spatio-temporal reasoning consisting of representations for spatio-temporal knowledge and a spatio-temporal inference system to manipulate those representations. Following Almeida [2], we treat spatial relations as event types incorporating the interval-based temporal ontology of Allen [1] and the region-based spatial ontology of Randell, Cui & Cohn [13]. Our basic reasoning system is essentially an extension of the temporal reasoning system of Allen [1]. Critical to the success of this system is the ability to create and reason with maximal temporal intersections.*

Keywords: spatio-temporal reasoning, motion event, temporal intersection

1 Introduction

The ability to reason about the spatial relationships between objects in the environment is a core requirement of mobile robots and many other types of intelligent systems. However, since objects frequently change their location, the representation of spatial location critically depends on time. Thus, what is really required is spatio-temporal reasoning. This paper presents a unified system for qualitative spatio-temporal reasoning consisting of representations for spatio-temporal knowledge and a spatio-temporal inference system to manipulate those representations.

Our system makes use of an event-based representation for the changing locations of objects, adapted from the proposal of Almeida [2]. Event-based representations incorporate a concept for an *event*, the spatio-temporal particular described by the proposition [12]. For example, in "I saw the vase on the table", what I saw was the *state* (a type of event) of the vase being on the table. In other words, a spatial state is a configuration of objects in certain relationships at a particular time. Thus, events, unlike propositions, can be seen and can have causes and effects.

The event-centered style of representation that forms the basis of our approach is a development of Davidson's [5] original proposal, and is based on the following three premises. First, that *events* understood as concrete spatio-temporal particulars constitute a part of the ontology of the human conceptual system. Second, that many sentences make an implicit reference to an event even when they lack an explicit event-referring expression. And third, that the other entities referred to in the sentence are related to this implicit event assertionally rather than structurally, that is, the links between the event and the entities that play roles in that event are in the form of propositions. These propositions are most often composed of two-place predicates with the first argument being the event. So the event is the "center" around which the other entities of the sentence are arranged. Thus, "Shem kicked Shaun" would have a representation something like: inst(e1, kicking) $\wedge$ agent(e1, Shem) $\wedge$ object(e1, Shawn), where e1 is a Skolem constant representing a particular kicking of Shaun by Shem event.

2 Temporal and spatial ontology

For our temporal ontology we are using the popular interval-based representation of Allen [1]. In this system there are thirteen pairwise disjoint and collectively exhaustive relations that can hold between two nonpoint intervals of time. These are: before (b), after (bi), meets (m), met-by (mi), overlaps (o), overlapped-by (oi), starts (s), started-by (si), during (d), contains (di), finishes (f), finished-by (fi) and equals (=).

In order to represent indefinite information, the temporal relationship (tRel) between two intervals is allowed to be an arbitrary disjunction of the basic relations. Temporal relations sets (tRelSets) are used to express these disjunctions. For example, the temporal relation set [m,o,s] between intervals t1 and t2 represents the disjunction, (t1 meets t2) $\vee$ (t1 overlaps t2) $\vee$ (t1 starts t2). Therefore, if the temporal relation set between time t1 and time t2 is the disjunction [m,o,s] then this would be represented by the formula: tRel(t1, [m,o,s], t2). Networks where the vertices represent intervals and the arcs can be labeled with arbitrary subsets of the basic relations are called *interval algebra* (IA) networks [15].

For the representation of space we are using the region-based system of Randell, Cui & Cohn [13]. Their system is the spatial analog of Allen's interval-based temporal system in

* supported by NSF Award CNS-0959958

that it presupposes there are only extended (non-point) regions of space. The eight basic relations between regions of space are disconnected (dc), externally-connected (ec), partially-overlaps (po), equals (eq), tangential-proper-part (tpp), nontangential-proper-part (ntpp), tangential-proper-part-inverse (tppi), and nontangential-proper-part-inverse (ntppi). These relations are also pairwise disjoint and collectively exhaustive.

Again, in order to represent indefinite information, the spatial relationship (sRelState) between two regions is allowed to be a disjunction of the basic relations. Spatial relation sets (sRelSets) are used to express these disjunctions. For example, the spatial relation set [ec,dc] between regions l1 and l2 represents the disjunction, (l1 ec l2) ∨ (l1 dc l2). Since spatial relationships, unlike temporal relationships, are relative to time, we represent them as events, as described in the next section.

3 Representing spatial relationships

In a temporal network, each pair of times is always related by exactly one (possibly ambiguous) temporal relationship. On the other hand, since spatial relationships hold only for specific periods of time, pairs of spatial regions may be related by any number of spatial relationships. It is because of this essential difference between temporal and spatial information that we use event-based representations for spatial information.

The two principal representations used for locating objects spatially are:

(1) The *position* of an object at an instant or granule of time is the region of space occupied by that object at that moment of time [8]. Objects are assigned positions for intervals of time by *be-pos* states as follows:

inst(Event, be-pos) ∧ theme(Event, Object)
  ∧ holdsFor(Event, Time) ∧ loc(Event, Position)

This formula states that *Event* is a be-pos event where *Position* gives the spatial position of *Object* for each moment of *Time* that *Event* holds for. (*holdsFor* is one of four possible event-time connectors discussed in Section 5.) Note that, in general, what we are calling *positions* are really sequences of positions indexed by instants or granules of time. Thus, these "positions" are essentially the same as paths, which are discussed in Section 6.

(2) Spatial relationships between positions are given by *sRel* states as follows:

inst(Event, sRel) ∧ rels(Event, SRelSet)
  ∧ holdsFor(Event, Time) ∧ arg1(Event, Position1)
  ∧ arg2(Event, Position2)

This formula states that *Event* is an sRel state relating *Position1* to *Position2* by *SRelSet* for the interval *Time*. Again the "positions" being related are actually sequences of positions indexed by time, so that for each instance or granule of time in *Time*, *Position1* is spatially related to *Position2* by *SRelSet*.

As a simple example, to represent a scene in which a ball is in a box which in turn is in a room, we would use a combination of be-pos and sRel states as follows.

% A room has a position. (a be-pos state)
inst(e1, be-pos) ∧ theme(e1, room1) ∧ holdsFor(e1, t1)
  ∧ loc(e1, l1)
% A box has a position. (a be-pos state)
inst(e3, be-pos) ∧ theme(e3, box1) ∧ holdsFor(e3, t3)
  ∧ loc(e3, l3)
% The box is in the room. (an sRel state)
inst(e6, sRel) ∧ rels(e6, [tpp, ntpp]) ∧ holdsFor(e6, t6)
  ∧ arg1(e6, l3) ∧ arg2(e6, l1)
% A ball has a position. (a be-pos state)
inst(e4, be-pos) ∧ theme(e4, ball1) ∧ holdsFor(e4, t4)
  ∧ loc(e4, l4)
% The ball is in the box. (an sRel state)
inst(e7, sRel) ∧ rels(e7, [tpp, ntpp]) ∧ holdsFor(e7, t7)
  ∧ arg1(e7, l4) ∧ arg2(e7, l3)

One way we can show that these spatial events all hold simultaneously is by asserting that some interval t0 is during all of their times:
tRel(t0, [s,d,f,=], t1)
tRel(t0, [s,d,f,=], t3)
tRel(t0, [s,d,f,=], t4)
tRel(t0, [s,d,f,=], t6)
tRel(t0, [s,d,f,=], t7)

Running the reasoner on this example, two new sRel states are inferred:
inst(e8, sRel) ∧ rels(e8,[dc,ec,po,tpp,tppi,ntpp,ntppi,eq])
  ∧ holdsFor(e8, ∩(t4,t1)) ∧ arg1(e8, l4) ∧ arg2(e8, 11)
inst(e9, sRel) ∧ rels(e9, [tpp,ntpp])
  ∧ holdsFor(e9, ∩(t7,t6)) ∧ arg1(e9, l4) ∧ arg2(e9, l1)

The first inferred state, e8, relates l4 (the position of the ball) to l1 (the position of the room) for the interval ∩(t4,t1), i.e., the temporal intersection of t4 and t1. This is not a very informative relationship because it is ambiguous over all the spatial relations. It simply says that the ball and the room exist at the same time and therefore have some spatial relationship. The second inferred state, e9, is much more informative. It also relates the position of the ball to the position of the room, but here the relation set is [tpp, ntpp], that is, *inside-of*. This time the interval is ∩(t7,t6). In other words, we have inferred that the ball was in the room for the intersection of the time the ball was in the box (t7) and the time the box was in the room (t6).

4 Maximal temporal intersections

Temporal intersections are formed from pairs of overlapping times. Two intervals t1 and t2 overlap iff tRelSet(t1,t2) ⊆ [o,oi,s,si,d,di,f,fi,=]. If t1 and t2 overlap, then their *maximal temporal intersection* is denoted by ∩(t1,t2).

The intervals t1 and t2 are called the *components* of the intersection. Maximal temporal intersections play a central role in spatio-temporal reasoning because as the longest interval shared by two overlapping intervals they are unique. This uniqueness means that any other interval that is contained in both component intervals will be a subinterval of the maximal intersection. As will be described below, this uniqueness allows us to determine whether newly inferred spatial relations are nonredundant, that is, that they tell us something that we don't already know.

Although temporal intersections in our system always have exactly two components, there is no loss of generality since the components themselves may be intersections. For example, ∩(t1,∩(t2,t3)) denotes the intersection of three intervals: t1, t2 and t3. Of course this means that there may be many formulas, e.g., ∩(t2,∩(t1,t3)), that denote the same interval. Even the intersection ∩(t1,t2) can be rewritten as ∩(t2,t1). However, in our system, once one of these intersections has been created, all equivalent formulas are automatically matched to that first formula, which can be shared by multiple events.

When in the process of spatio-temporal inference a new maximal intersection is created, that interval is added to the temporal network in two steps. In the first step, the procedure *connectIntersectToComponents* uses Table 1 to determine how to temporally relate the intersection time to its two components. The entries in the table state that if A has relation Rel to B then ∩(A,B) has relation RelA to A and ∩(A,B) has relation RelB to B.

```
Procedure connectIntersectToComponents(∩(A,B))
tRelSet ← getTRelSet(A, B)
tRelSetA ← []
tRelSetB ← []
for each r1 ∈ tRelSet do
  getTable1Values(r1,RelA, RelB)
  tRelSetA ← tRelSetA ∪ RelA
  tRelSetB ← tRelSetB ∪ RelB
add tRel(∩(A,B), tRelSetA, A) to tNetwork
add tRel(∩(A,B), tRelSetB, B) to tNetwork
```

Table 1. Relation of ∩(A,B) to A and B

Rel	RelA	RelB
o	f	s
oi	s	f
s	=	s
si	s	=
d	=	d
di	d	=
f	=	f
fi	f	=
=	=	=

In the second step, the intersection is related to the rest of the intervals in the temporal network. We use a set of tables to determine the relation of ∩(A,B) to each interval C, given that A has relation Rel1 to C and B has relation Rel2 to C. There is one table for each possible relation between A and B, a total of nine in all. Table 2 is the table for the case where A strictly overlaps (o) B. (Unfortunately, there is not enough room to show all of the tables here.) Blank entries in these tables mark relations that are not possible. For example, given that A [o] B, A [m,o] C and B [di,=] C, from the four ordered pairs derived from [m,o] and [di,=], we infer that ∩(A,B) [m,o,s] C.

In general, the temporal relation sets determined by these tables are less ambiguous than those generated simply by Allen's [1] temporal inferencing algorithm, i.e., path consistency, and this extra precision turns out to be very useful.

Table 2. Relation of ∩(A,B) to C given A o B and A Rel1 C and B Rel2 C

A o B		B Rel2 C												
A Rel1 C		**b**	**bi**	**m**	**mi**	**o**	**oi**	**s**	**si**	**d**	**di**	**f**	**fi**	**=**
	b	b		b		b					b		b	
	bi		bi											
	m					m					m		m	
	mi		bi											
	o					o	d	s	s	d	o	d	o	s
	oi		bi		mi		oi							
	s						d			d		d		
	si		bi		mi		oi							
	d						d			d		d		
	di		bi		mi		oi		si		di			
	f						f							
	fi						f		=		fi			
	=						f							

5 Event-time connectors

An effective way of representing the aspectual information of events, such as their beginnings and endings, is to connect events to their times in different ways. For example, Almeida [3] proposes the following four *event-time connectors* (ETCs):

1. holdsAt(E,T) – event E holds for all of interval T, with E starting at the beginning of T and E ending at the end of T.
2. initiatesAt(E,T) – event E comes into existence at the start of interval T and holds for all of T, but doesn't necessarily end at the end of T.
3. terminatesAt(E,T) – event E holds for all of interval T, going out of existence at the end of T, but doesn't necessarily start at the beginning of T.
4. holdsFor(E,T) – event E holds for all of time T, but doesn't necessarily start at the beginning of T or end at the end of T.

The following implications hold between these four connectors:

1. holdsAt(F,T) => initiatesAt(F,T)
2. holdsAt(F,T) => terminatesAt(F,T)
3. initiatesAt(F,T) => holdsFor(F,T)
4. terminatesAt(F,T) => holdsFor(F,T)

Clearly, *holdsFor* is the most ambiguous, and *holdsAt* is the least ambiguous, of these relationships. (Note that these ETCs are related to, but different from, the similarly named relations used in the *event calculus* [11].)

The *findETC* procedure determines the event-time connector to be used for a newly inferred event, given the event-time connectors (ETC1 and ETC2) of its two component events and the temporal relations set (tRelSet) that relates the times of those two components.

```
Procedure findETC(ETC1, ETC2, tRelSet)
if initiates(ETC1, ETC2, tRelSet)
then if terminates(ETC1,ETC2, tRelSet)
      then return holdsAt
      else return initiatesAt
else if terminates(ETC1, ETC2, tRelSet)
     then return terminatesAT
     else return holdsFor

Procedure initiates(ETC1, ETC2, tRelSet)
return (ETC1 ∈ [holdsAt, initiatesAt]
        ∧ tRelSet ⊆ [s,d,f,oi,si,=])
     ∨ (ETC2 ∈ [holdsAt, initiatesAt]
        ∧ tRelSet ⊆ [o,s,si,di,fi,=])

Procedure terminates(ETC1, ETC2, tRelSet)
return (ETC1 ∈ [holdsAt, terminatesAt]
        ∧ tRelSet ⊆ [o,s,d,f,fi,=])
     ∨ (ETC2 ∈ [holdsAt, terminatesAt]
        ∧ tRelSet ⊆ [f,oi,si,di,fi,=])
```

If the ETC of an event is changed, that change may propagate to all the events of which it is a component, and so on, recursively, but it does not affect temporal relationships.

6 Incompatible events

Incompatible events are those which cannot hold simultaneously. These sets of events can be an important source of constraints on both temporal relationships and ETCs in that (1) incompatible events cannot temporally overlap one another in any way, and (2) if two incompatible events temporally *meet* (m), the first is constrained to terminate, and the second to initiate, at the point where they meet.

In general, incompatiblity of events is a matter of world knowledge. However, since the RCC8 spatial relations are pairwise dijoint, different sRel events relating the same objects by disjoint spatial relation sets will be incompatible with one another since no (classical) object can be in two different places at once.

7 Representing motion events

Motion events contain spatial paths as part of their meaning. The defining properties of *paths* are (1) regions on a path may be visited repeatedly, as can happen in, for example, running around a circular track, and (2) paths are given lengths using purely spatial measures, e.g., five miles. Therefore, paths cannot be understood simply as the join or the sum of the instantaneous positions of the event, nor are they understood as four-dimensional spatio-temporal objects. Instead, we treat paths as sequences of positions, each indexed by a point or granule of time.

Motion is always relative to some frame of reference, so, for example, the event of walking down the aisle of a moving airplane has a different path depending on whether we use the airplane or the earth as the frame of reference. However, our current system assumes a uniform frame of reference for all motion events, so we omit the reference frame role from our representations.

Jackendoff [10] proposes a classification of paths as they are expressed by prepositional phrases. All of these paths are oriented according to reference objects or places. There are three major types depending on the nature of the path's relationship to its reference object: *bounded paths, directions* and *routes.* In this paper, we will only consider bounded paths. An example of a sentence describing a motion event with a bounded path is "John walked from the house to the store". Bounded paths include *source paths,* in which the reference object occupies the initial position in the path, and *goal paths,* in which the reference object occupies the final position in the path. Source path expressions usually use the preposition *from,* as in "from the house", and goal path expressions often use *to,* as in "to the store". Conceptual analyses of bounded paths can be found in [7], [4] and [2].

Following is an example of how we represent motion events with bounded paths, in this case the sentence "The robot moved from outside the box to inside the box", where "outside the box" is the source and "inside the box" is the goal.

```
% A robot has a position. (a be-pos state)
inst(e1, be-pos) ∧ theme(e1, robot1) ∧ holdsFor(e1, t1)
  ∧ loc(e1, l1)
% The box has a position. (a be-pos state)
inst(e3, be-pos) ∧ theme(e3, box1) ∧ holdsFor(e3, t3)
  ∧ loc(e3, l3)
% The robot moved from the start to the end of path p1 over
% time t4. (a motion event)
inst(e4, moving) ∧ agent(e4, robot1) ∧ holdsAt(e4, t4)
  ∧ path(e4, p1).
% The time of the move is during t1 and t3.
tRel(t4, [s,d,f,=], t1).
tRel(t4, [s,d,f,=], t3).
% The position of the robot is given by p1 over time t4.
% (an sRel state)
inst(e5, sRel) ∧ rels(e5, [eq]) ∧ holdsFor(e5, t4)
  ∧ arg1(e5, l1) ∧ arg2(e5, p1)
% The path of the robot starts away from (disconnected from)
% the box. (an sRel State)
inst(e6, sRel) ∧ rels(e6, [dc]) ∧ terminatesAt(e6, t6)
  ∧ arg1(e6, p1) ∧ arg2(e6, l3).
% The time of the move is started by (the end of) the time
%  when the robot is away from the box.
tRel(t4, [si], t6).
% The path of the robot ends inside the box. (an sRel state)
inst(e7, sRel) ∧ rels(e7, [tpp, ntpp]) ∧ initiatesAt(e7, t7).
  ∧ arg1(e7, p1) ∧ arg2(e7, l3).
% The time of the move is finished by (the start of) the time
% when the robot is inside the box.
tRel(t4, [fi], t7).
```

The assumption of *continuity of motion* [7] would allow the system to infer that in the time between the robot being disconnected from the box and its being inside the box, the robot's position was at one time externally-connected to the position of the box, then it partially-overlapped the position of the box, and then it was a tangential-proper-part of the position of the box.

8 Temporal reasoning

Now that our basic set of representations has been described, we can look first at temporal and then spatio-temporal inference. The algorithm that forms the basis for both our temporal and spatio-temporal reasoners is *path consistency* (or 3-consistency), which was first suggested for maintaining knowledge about temporal intervals by Allen [1]. The version of this algorithm we use is from Shoham [14]. This form of inference is not optimal in that it does not give us the most precise results possible from the data. Instead it gives us an approximation to the optimal result, one which is possibly more ambiguous than the optimal result. However, this approach is reasonably accurate and efficient and so is widely used.

The principal variables for the temporal reasoner are: (1) *tNetwork* - the temporal network, which is globally accessable, (2) *tList* – a list of times, and (3) *tQueue* – a list of ordered pairs of times $\{(i, j) : i \neq j\}$.

In the following procedures, *tRelSet(i,j)* is the set of temporal relations (a disjunction) holding between times i and j, and *tTable(i, j)* is the (i, j)'th entry in Allen's [1] transitivity table.

```
Procedure propagateTimeConstraints(tQueue, tList)
repeat until tQueue is empty
 remove any (i, j) from TQueue
connectTIntersectNodeToC(i, j)
   for each interval k ∈ tList with k ≠ i, j do
        tRelSet(k, j) ← tRelSet(k, j) ∩
          timeConstraints(tRelSet(k,i), tRelSet(i,j))
        if tRelSet(k, j) changed then add (k, j) to tQueue
        tRelSet(i, k) ← tRelSet(i, k) ∩
          timeConstraints(tRels(i,j), tRels(j,k))
         if tRelSet(i,k) changed then add (i, k) to tQueue
```

```
Procedure timeConstraints(tRelSet1, tRelSet2)
tRelSet ← empty
for each r1 ∈ tRelSet1 and r2 ∈ tRelSet2 do
  tRels ← tRels ∪ tTable(r1,r2)
return tRelSet
```

The *tInference* procedure processes the entire temporal network. This should only be necessary when the network is first being established, unless a major change is made.

```
Procedure tInference()
tList ← makeTList()
tQueue ← {(i,j) : i, j ∈ tList ∧ i ≠ j}
propagateTimeConstraints(tQueue, tList)
```

The following procedures are used to make various types of additions to the temporal network. The *addNewTime* procedure (given in [1]) is used to add to the network a single new time i that is to be connected to exactly one pre-existing time j using tRelSetIJ. *propagateTimeConstraints* is called with tQueue consisting of only one pair {(i,j)} and the complete tList including i.

```
Procedure addNewTime(i, tRelSetIJ, j)
tList ← makeTList()
tList ← addToTList(i, tList)
addTRelToTNetwork(i, tRelSetIJ, j)
propagateTimeConstraints({(i, j)}, tList)
```

processNewTime is used to add a new time i which is connected to a set tNodes of pre-existing times. This procedure is primarily used to add temporal intersections, as will be described in the discussion of the spatio-temporal reasoner.

```
Procedure processNewTime(i, tNodes)
tList ← makeTList()
tList ← addToTList(i, tList)
tQueue ← {(i,j) : j ∈ tNodes}
propagateTimeConstraints(tQueue, tList)
```

9 Spatio-temporal reasoning

Our spatio-temporal reasoner is essentially an extension of the temporal reasoner described above. In a temporal network, each pair of times is always related by exactly one (possibly ambiguous) temporal relationship. On the other hand, since spatial relationships hold only for specific periods of time, pairs of spatial regions may be related by any number of spatial relationship states. This is responsible for the difference between temporal and spatio-temporal inference.

The principal variables for the spatio-temporal reasoner are: (1) *stNetwork* - the spatio-temporal network, which is globally accessable, (2) *sList* – a list of spatial positions, and (3) *sQueue* – a list of ordered pairs of positions.

As with the temporal reasoner, the core of the algorithm consists of two path consistency procedures, *propagateSpaceConstraints* and *spaceConstraints*. The basic process is that for as long as there are triplets of spatial relationships that haven't been tried yet, do:

(1) Given any three different spatial regions k, i and j where a spatial relation Ski holds between positions k and i, and a spatial relation Sij holds between positions i and j, a transitive spatial relationship event based on Ski and Sij will be inferred between positions k and j only if timeOf(Ski) and timeOf(Sij) overlap, that is, there is a nonempty intersection interval during which both Ski and Sij hold. A new sRel event with relation set Ski will therefore hold for the interval ∩(time(Ski), time(Sij)).

(2) If a new sRel event is proposed, it has to be merged into the set of sRel states, stateList(k,j), that already exist. If the new state subsumes, i.e., makes redundant, any preexisting states, they are deleted from stNetwork. If the new state is subsumed by an already existing state, then the new state is discarded, otherwise it is added to the stNetwork and the pair of positions it relates is added to sQueue.

```
Procedure propagateSpaceConstraints(sQueue, sList, tList)
repeat until sQueue is empty
  remove any (i,j) from sQueue
  for each k ∈ sList with k ≠ i, j do
    stateList(k,i) ← all sRel states relating k to i
    stateList(i,j) ← all sRel states relating i to j
    stateList(k,j) ← all sRel states relating k to j
    for each stateIJ in stateList(i,j) do
      for each stateKI ∈ stateList(k,i) do
        if timeOf(stateKI) overlaps timeOf(stateIJ)
        then stateKJ ← proposeNewSRel(stateKI,
                stateIJ, tList)
         mergeSRelIntoSet(stateKJ, stateList(k,j))
         if stateKJ not redundant
              then sQueue ← add (k,j) to sQueue
      for each stateJK ∈ stateList(j,k) do
        if timeOf(stateJK) overlaps timeOf(stateIJ)
        then stateIK ← proposeNewSRel(stateIJ,
                stateJK, tList)
         mergeSRelIntoSet(stateIK, stateList(k,i))
         if stateIK not redundant
              then sQueue ← add (i,k) to sQueue

Procedure spaceConstraints(sRelSet1, sRelSet2)
sRelSet ← empty
for each r1 ∈ sRelSet1 and r2 ∈ sRelSet2 do
  sRelSet ← sRelSet ∪ sTable(r1,r2)
return sRelSet
```

Whenever a new sRel state is inferred, its time interval will always be an intersection of two previously existing times. This intersection must always be checked to see if it already exists. If so, it is already fully connected to the temporal network, if not, it must first be connected to its components using Table 1, then it must be connected to all the other time intervals in the system using Table 2, as described in section 4.

```
Procedure proposeNewSRel(State1, State2, tList)
sRels ← spaceConstraints(sRelSetOf(State1),
          sRelSetOf(State2))
newTime ← makeTIntersect(timeOf(State1),
          timeOf(State2))
if newTime not in tList then
    connectIntersectToComponents(newTime)
    connectIntersectUsingTable2(newTime, tList)
    processNewTime(newTime,
          [timeOf(State1), timeOf(State2)])
return makeNewSRel(newTime,sRels,arg1Of(State1),
          arg2Of(State2))
```

A spatial relation state S1 relating positions k and j is redundant if there already exists a spatial relation state S2 relating k and j such that timeOf(S2) contains timeOf(S1) and sRelsOf(S2) is a subset of sRelsOf(S1). If S1 is redundant it is simply discarded. If it is not redundant, then we still need to check to see if it renders any other spatial relation state redundant. If so, the redundant relation states must be deleted from the network. The procedure *mergeSRelIntoSet* describes this process.

```
Procedure mergeSRelIntoSet(S1, StateList)
for each S2 in StateList do
  if time(S1) during time(S2) ∧ rels(S1) ⊇ rels(S2)
  then return S1 is redundant
  else if time(S2) during time(S1) ∧ rels(S2) ⊇ rels(S1)
      then delete S2 from stNetwork
```

The following two procedures start spatio-temporal inference. *stInference* runs inference on the complete stNetwork, while *addNewSNode* is used to add a single new sRelState to the network. *sInference* should only be run when the stNetwork is being first established or if there are major changes.

```
Procedure stInference()
tInference()
sList ← makeSList()
sQueue ← {(i,j) : i, j ∈ sList ∧ i ≠ j}
```

propagateSpaceConstraints(sQueue, sList)

addNewSNode is used to add a single new sRel state to the network connecting positions i and j with the relation set sRelsIJ and the time *newTime*. *addNewSNode* triggers spatio-temporal inference but only on the newly related positions, so it is very efficient.

Procedure addNewSRel(i, sRelsIJ, j, newTime)
sList ← makeSList()
makeNewSRel(newTime, sRels, i, j)
propagateSpaceConstraints({(i,j)}, sList)

10 Conclusions & future work

In this paper we have described the current state of our system for qualitative spatio-temporal reasoning. The system consists of (1) a spatio-temporal reasoner based on an extension of the path consistency algorithm to allow inference of new spatial events, (2) procedures to connect the maximal temporal intersections that are the times of these new events into the temporal network, and (3) procedures to create and update the event-time connectors that relate these events to their times. The system as described in this paper has been implemented in Prolog as part of a mobile robotics project, but we are still experimenting with the most effective ways of combining these components together.

We have three immediate goals for the future expansion of this system. (1) We need to expand the coverage of the spatial representational system by incorporating locative functions, that is, functions from regions of space to regions of space. [10], [9] and [13] contain many examples of such functions. (2) As described in the discussion of the spatio-temporal reasoner, newly inferred transitive spatial relationship states have times which are temporal intersections. So far, this is the only part of the system that combines time intervals. Aside from the inference of these states, temporal intersections and unions seem to be primarily useful in spatial question-answering. For this reason, we plan to add the ability to infer intersections and unions of temporal intervals at query-time. (3) So far, the temporal component of the system is purely interval-based. We plan to introduce a granularity into the temporal representation that is suitable for a mobile robot.

Modeling Crowd Evacuation from Indoor Spaces

Pejman Kamkarian[1], **Henry Hexmoor**[2]

Abstract - *A crowd in an emergency situation located inside a public space, they will evacuate from that space. Crowd evacuation is a dynamic process which relies to a variety of environmental factors, as well as crowd specifications itself. To help people out of danger, rapidly and safety, we need to have a previous plan for any public space, which is obtained by collecting information of crowd evacuation in different situations, for that space. Simulating a public space virtually, helps us to study on crowd evacuation, in terms of considering all possible kinds of behaviors that are as symptoms of evacuation during emergencies. Using such strategy, keeps any possible injuries limited to the virtual simulated environment and hence we are able to study on real events with no cost of occurring any damages. This paper demonstrates application of optimized Imperialist Competition Algorithm to exit doors of indoor spaces to find the best possible locations for them, and also to estimate the minimum required width for each door in order to be able to evacuate a crowd out of risk in a reasonable time, and with the most possible safety.*

1 Introduction

In the developed countries, people spend most of their lives in indoor spaces. Often, large groups of people are gathered at the same location for leisure or work purposes. We consider these groups as crowds. Generally, a crowd is defined as a set of agents as particles who are gathered at one physical location to share or follow some common activities [9]. If a life threatening emergency such as fire or earth quake occurs, there should be efficient and reliable ways available for people to rapidly evacuate buildings. Evacuation becomes more complicated when observing to increase number of people inside space, or increasing the time that occupants need to remain at the location. Derived from safety concerns in indoor spaces, there is a force to evacuate that people toward exit openings. This has best been modeled in terms of a game among members of a crowd [8], Game theoretic modeling and analysis as well as a extensively validated fire evacuation simulator are reported from a finish research center [8]. We will focus more closely on characteristics of a crowd in the context of an emergency that requires evacuation. Although each group has a shared set of goals among its members, individuals do not necessarily decide on sharing similar actions. This is especially true when they encounter dangerous situations such as fire. In such cases, because of fear and natural instinct for survival, individuals will take separate, individualistic actions to address their own needs for survival. They will not follow group patterns for action selection. This is similar to what one can expect when a crowd of people is running away from source of danger (e.g., a fire) towards a safe place [11].

The idea of evacuating a crowd is not limited to humans and it pertains to all other types of animals. The safest exit doors should be able to evacuate not only humans but all kinds of animals that might be present in indoor spaces. This urges us to consider appropriate designs for exit doors. Buildings must adhere to an acceptance standard to be able to evacuate people who are inside it in an emergency. In most cases, such standards must account for combinations of exit doors including stairs and ladders. Emergency evacuation conditions of a crowd and abstraction of the real crowds are modeled by [13], [1]. The required number of exit doors will vary based on the size and architecture of each environment. One of the most important considerations about locating exit doors is having evacuation rate for public space. The goal is to evacuate most number of people in least amount of time. Lacking such strategy leads us having serious problems in emergency situations, even if exit doors themselves are built and located in safe and reliable positions. To make this clear, we point to stampeding events, which are one of the most common occurrences during an emergency. A stampede can occur due to human reaction to unexpected sets of events. People will herd and push each other in competition to reach the exit doors. People who are in emergencies often behave irrationally, largely based on reactions to the information available to them at the time. For instance, studies of evacuations in fires such as in [12], and in [4], indicate that people tend to leave gathering venues through the original pathways they entered. This holds even people have better solutions in terms of availability of closer, more accessible exit doors. This can be seen as irrational behavior. In fire, the smoke and heat in fires create limited visibility, which may cause people to seek escape through an exit door that they already know exists if they are unfamiliar with other possible choices.

To study and simulation crowd, macroscopic models are computationally less expensive because they consider less detailed interactions among people and with their environment. Instead, mathematical models are used to describe crowd movements as liquid flows [5], [6], [7].

2 An Overview of Environmental and Exit Door Features

As one of the most important steps to studying, designing and locating exit doors, we have to consider salient attributes that can directly or indirectly affect exit doors designs. In the following we outline several of these key attributes. Specifications of attributes for people present inside the public space, such as their health status, or their age range will lead to a better and safer selection of exit doors in terms of design and location for each. In case of considering only human beings in our environment, we can use particle systems that were proposed in [2], to simulate human behaviors. Based on particle swarms theory, each agent is considered to be a particle, augmented with a state and a feedback function to dominate its behavior. All agents' behaviors constitute the whole system's performance. Particle systems are also used for modeling the motion of groups with significant models of physics [2], [3]. Considering the number of individuals leads having a more accurate estimation. As an important factor, it should be taken into account while deciding widths and locations for exit door. As we pointed in previous examples, absence of these attributes was the main reasons for injuries and deaths. The width of exit doors should be determined relative to the proportion of the crowd. Time is another important attribute that should be accounted while designing and locating exit doors. On the other hand, exit doors should be able to service evacuation of the crowd through them in the minimum possible time. This will reduce the number of people who may potentially lose their lives due to breathing poisoned air, or stampeding of herding behavior.

3 Imperialist Competition Algorithm (ICA)

The Imperialism competitive algorithm is a natural inspiration method, which can solve variety types of optimization processes. It classifies as an evolutionary algorithm that relies on collecting a set of candidates random solutions, called initial countries. At the beginning, each country may have a different size of population, based on its features. A few such countries that have the most power among are called empires. After forming empires, all remaining countries, are called colonies. As a strategy, each empire, tries to extend its power and royalty of its government beyond its territory by trying to absorb and control the weaker countries as its colonies. At the end of initialization process, all colonies with their populations are divided among imperialists based on their powers. The total power of each empire, defines based on the power of the imperialist country itself, as well as the total powers of respective colonies. In other terms, this model obtains the amount power of each empire by adding the imperialist country itself and the mean power of its colonies in percentage. In the beginning of competition process, all colonies start moving toward their relevant imperialism country. In other hand, the imperialistic competition begins among all existing empires by increasing their power that earns by stimulating to take control on more colonies. During the process, any empire that is not able to increase and developing its power, or preventing losing its colonies, will be replaced [10], and hence eliminates from the competition.

4 Application of Optimized ICA

Based on ICA, the solution consists of many different sections. In order to focus on crowd evacuation, as well as people inside a public space, and exit doors, many sections are optimized to meet our research project requirements. At first glance, the examined space is classified to have three different kinds of components: *exit doors*, *obstacles*, and *people* present inside. The obstacles themselves can be categorized into two different groups. The first group includes the ones that are installed inside the public place, based on a previous plan. The second group may be formed accidentally, during emergencies, such as smoke, debris, and the wall or ceil parts that can block the whole, or a part of environment. Each exit door, represent a country. By initializing, they can have a population gathered around them. The people inside the space are considered as the population. Based on each person's distance from each exit door, as well as the velocity that each one may has based on some physical body features, they are classified to belong to the nearest exit door at the beginning. For instance, the equation $\{ed_1, ed_2 ed_3\ ,\ldots, ed_{N_{var}}\}$, denotes a group of exit doors, where each *'ed'*, represents a separate door. Each exit door, measures with a floating point number, which indicates the cost of it. The cost of each exit door, determines by the total number of people who are belong to that door. In the public space, the walls that have any unblocked exit door on them called a valid region. A collection of an exit door with its population is called a zone. The size of each zone might vary based on the size of that particular exit door as well as the total number of population that belongs to that door. Each person inside the space, as an entity, has a speed to reach to its designated exit door. At the beginning of the process, the initial cost for each exit door is captured by $Init\ Cost(ed_1) = Init\ Cost(ed_2) = \cdots = Init\ Cost(ed_n) = m$, where *'m'* is the initial value of each exit door as initial. The velocity of population is showed by $(p_n) = f(p_n) = f(sw_n) + f(bd_n)$, where *'p'* represents as a person inside the public space. To find the best possible exit door for each person, we use the following equation: $\{p_n \in ed_n\} \equiv \{\max(Velocity_{p_n}), \min(Distance_{ed_n})\}$. On the other hand, dependencies for each exit door are measured and determines by evaluating the maximum speed and the minimum distance from each exit door. After the initialization phase, we may have many different valid regions. Each valid region may have many exit doors. Each exit door as an empire, has a zone including population as its colonies, belong to that door. At the beginning of the process, we consider any separator walls that divide the interior area from the exterior, as a valid region. As initial locations of exit doors, based on the potential crowd inside space, each valid region may have one or more exits in same distances from one another. Each exit door has an initial width that will be determined based on

the number of people that gather around it. We note this initial width as γ. For example γ_i is the width of i^{th} exit door. Assuming crowd forms randomly inside the space, the application classifies each person as a colony to be dependent to the nearest exit as its calling an empire. To increase accuracy and also accounting for possible symptoms that crowd may have while emergencies, initially, we considered having a number of people as colony to choose their exit door as empire randomly regardless of distance. This may occur in the real world, for some reason, such as smoke covers the air and hence limited the vision site of people inside public space that leads choosing an inefficient exit door as the best solution to evacuate through.

When the process starts, people move toward the nearest exits to which they belong. If a person reaches and crosses through any exit door, it is removed from the process of evacuation. Hence that exit door as an empire loses that person as a colony. This reduces empire's power consequently. Based on the capacity and status of each exit door to evacuate people at each moment, and also with respect to other exit doors, exits as empires, they will try to raise their power by absorbing other colonies of people, from any other zones, into their own zones. In the real world, when an exit door has more capacity to evacuate people than those people around it, the other people who are currently trying to evacuate toward other exits might change their exit door, to the one with the least risk and lower number of people around it. As another reason to change the zones by people inside, we can address formation of unwanted obstacles, such as smoke or debris that are symptoms of emergencies. In case of presence of obstacles between a person and his chosen exit door, he tries to find the shortest path to turn around toward the exit. If there are other exit doors located closer to such a person changing the zone belongs to that exit door might be the best option for that person to choose. In other terms, this is a way for empires to increase their power. The following figure 1 shows a person, and an obstacle, which is located between him and his zone.

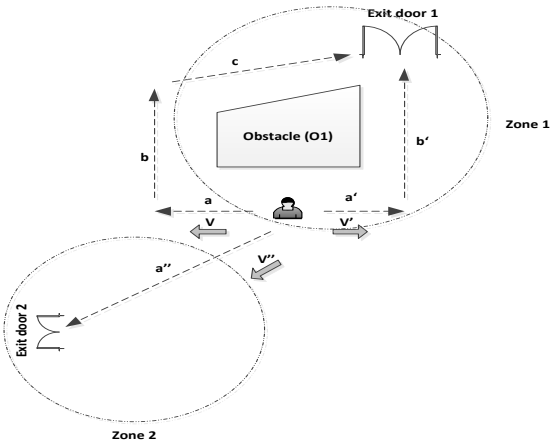

Figure 1. A person as a particle and an obstacle located between him and his optimal exit door with another exit door as an alternative to change the zone

Figure 1 shows obstacle O_1 forms during an emergency situation. The routes to reach the current optimal exit door are based on the following equations: $V = a + b + c$, $V' = a' + b'$. If there was another exit say exit door 2, located at a close distance of such person, the distance from it is calculated based on $V'' = a''$. Considering that exit is capable to accept more people to evacuate, Figure 2 is a decision flowchart which may apply to a particle as a person, in order to continue staying at the current zone, or changing it to the exit door 2.

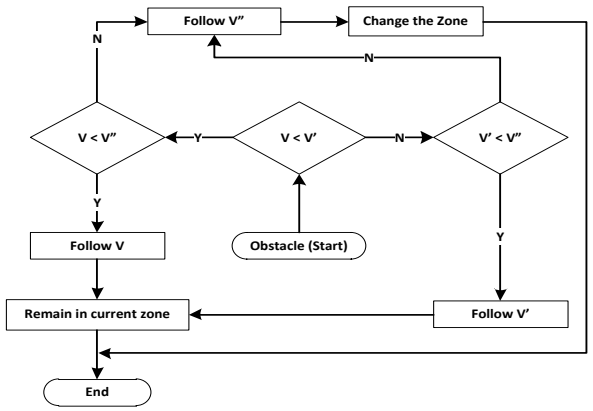

Figure 2. Decision flowchart to decide about to staying or leaving zones

We can consider other kinds of objects, between particles and exit doors at any time as obstacles. For example, any other person, or group of people who are located at any positions between any person and his optimal exit door can be classified as obstacles. In such cases, following the decision flowchart to decide about to staying or leaving zones by people as particle is essential. The process of evacuation continues until all particles as people evacuate through available exit doors. Based on the number of people who could evacuate successfully, using equation 1, the application determines the best possible width of each exit.

$$W_i = \left\lfloor \frac{\sum Pop_i}{\sum S_i} \right\rfloor \times \partial \ (in) \qquad (1)$$

Here W_i is the suggested width obtained from experiment cycle for exit door, i. S_i is the number of people who changed their zones during the experiment for any reasons. ∂ is a constant that can be vary based on the examined public space and the native architecture standards. Here we assumed $\partial = 10$, as the default value. Each exit door, based on its status during the experiment, may have a different W. based on this value, the amount that should be added to each exit, obtains. To increase the accuracy, we can repeat the experiment until the W became either minimum

or very close to its previous value in last experiment. At the end of process, the total amount of value that should be added to each exits, determines by equation 2.

$$C_i = \sum W_i + \gamma_i \quad (2)$$

C_i is the total optimized amount in inches that should be added to exit door i. γ_i is the first initialization value that i^{th} exit door had at the beginning of the first period of experiments, and W_i is the total value that earned during experimental processes.

5 Conclusions

This paper has explored the implementation and adaption of the optimized imperialist competitive algorithm to a sample indoor layout to demonstrate a solution for locating the best exit doors. The results of our implemented system are applied to prototypical scenarios has demonstrated that the location of each exit door in an indoor space can affect significantly in terms of evacuating the crowd out of danger in emergency situations. Future work will account for complex floor plans. We will also relax our assumption about traps so we can add to realism of evacuation chaos with unexpected clutter and debris.

Abstract *- The previous researches of GPS positioning for navigation all focus on performing preliminary GPS data ranging error filtering by Kalman filter first and then calibration with the map matching method. However, this approach requires the accuracy of the GIS map. This paper proposes a GPS data calibration technique for navigation which entirely depends on human behavior to further calibrate GPS data from Kalman filter without map information under any unprepared environment. The study adopts the context-aware approach to fully explore user's behavior and rectify GPS data from Kalman filter accordingly. The presented method is coined as Perceptive GPS (PGPS). It starts with extracting user's feature data from Kalman filtered GPS data to classify his current state. Newton Markov Model (NMM) is then introduced from Hidden Markov Model to capture the user's motion state. Based on NMM, PGPS technique records the GPS carrier's behavior into a Transition Probability Matrix (TPM). This TPM is then used to infer the behavior of the GPS carrier from the online received GPS data and calibrate GPS carrier's position accordingly. Finally, a series of experiments to validate PGPS technique are conducted and fully discussed at the end of the paper.*

Keywords: Augmented Reality, Context aware, Hidden Markov Model, Entropy.

1. Introduction

The GPS navigation system in the market is composed by positional signal module, geographic information system(GIS) and user interface module[1]. The legacy GPS systems use the map matching technique to calibrate GPS data during navigation. The map matching approach always tries to fit the GPS data to a road that has shortest perpendicular distance. However, when there are two nearby parallel roads, the map matching approach will hop between these two roads so as to cause the serious cognitive disorder. Furthermore, owning to human cognitive errors caused by those traditional 2D map guiding, the live-view GPS navigation system has been proposed and also attracts much attention[2]. The live-view GPS navigation system adopts Mobile Augmented Reality(MAR) technology to overlay directional arrow on the live-view image to provide intuitive navigational information. Due to the lack of 2D map display, the map matching technique does not apply to live-view GPS navigation system. Along with the rapid evolvement of silicon technology in recent years, most of mobile devices, such as smartphone, nowadays are often equipped with camera, wireless network, the Global Positioning System (GPS) receiver and a variety of sensors. Such smart mobile devices allow users to interactively perceive their environmental information, such as location, personal ID, temporal or spatial information. Hence, it is a booming trend in the recent years to employ smart mobile device as a platform for developing the live-view GPS navigation system. For example, Wikitude Drive[3], AVIC-VH09[4] and Route 66 Maps+[5] systems are three well-known systems which have released their demo videos in YouTube.

However, since such built-in GPS receiver is susceptible to the environmental interferences, most of MAR applications utilize auxiliary equipment such as inertial sensors to calibrate GPS ranging error. One of the earliest MAR navigation applications that used GPS as a positional sensor was Touring Machine[6]. To get the accurate signals in urban street canyons, it redesigned vessel-based GPS receiver with a bulky wearable computer.

Fong et al.[7] in 2008 applied Differential GPS Carrier Phase technique to meet high accuracy requirements. They proposed a relative position measurement technique from GPS carrier phases of two GPS receivers, one is stationary and the other is mobile, for high precision positioning toward outdoor MAR applications. Such differential GPS carrier phase technique required at least a three-dimensional coordinates of reference receiver to stay fixed on a known control point. Therefore, the practicability of this approach is still not adopted by most of the mobile augmented reality systems applications yet.

Most existing commercial GPS navigation systems are still restricted by the inaccuracy of built-in GPS chip and employ Map matching algorithm[8] to solve GPS ranging error problem. For live-view GPS navigation system, because 2D electronic map is unable to be displayed on the screen, the Map matching algorithm becomes worthless to calibrate GPS data. We must rely on the cognitive user's behaviors to calibrate ranging error during live-view GPS navigation process.

In this paper, the technique has been proposed[2] to perceive user's behaviors for live-view GPS navigation system. We explore the context-aware approach to perceive user's behavior to calibrate the GPS ranging error accordingly and the presented algorithm is named as Perceptive GPS (called PGPS thereafter). PGPS extracts user's feature data from the received GPS data to classify his current state. The modeling method of PGPS is then introduced to infer a plausible motion state of the user. This perceived motion state is then cross-referenced with the classified current state to

reduce the possible noise and accumulative error of hardware sensors, further to correct GPS data error accordingly.

2. Related Works

Context-aware technique is originated from Pervasive Computing to deal with understanding user's behavior from the sensed environmental data and to provide proper service to the users accordingly. The so-called Context composes of "Con" and "Text". "Con" stands for connection and "Text" is related to user's surrounding information. Such data depict information of the user's states, including identification, spatial and temporal information, activities and others. In other words, a context-aware system is capable to extract and interpret context data from sensors to infer proper services for the users. The greatest challenge of designing such a system is the complexity of collecting, extracting, and reasoning the contextual data.

The previous context-aware studies regarding modeling and reasoning user's behavior from GPS data can be classified into time-series model and state-space model. Time-series model is based on the past temporal GPS raw data to profile human behaviors. For example, in 2004, Patterson et al.[9] utilized joint conditional probabilities between GPS data of user historical footprint and the terrain geometry of physical environment to predict user's transport behaviors and then infer the user's location. Different from time-series model, which is usually limited by the past finite GPS data and complicated environmental information to infer, the state-space model classifies GPS data into abstract state space to model the user's behavior and then to infer his location. The advantage of state-space model in this approach can reason user's behavior without being influenced by the fixed length of temporal sequence. It can easily couple with inertial effect to dramatically reduce the computational complexity. For example, Patterson et al.[10] applies state-space model to GPS data collected from the GPS receiver carried by animals to observe the animal behaviors. This research proves that it is feasible to perceive and model state space of animal behaviors through GPS data.

Most state-space model studies are based on environmental types to predict subject's motion state. Liao et al [11] applies hierarchical Dynamic Bayes Network(DBN) or Conditional random fields(CRF) to GPS data from different vehicles to infer their respective transport models. Due to the lack of speed and acceleration, this method is only feasible to monotonous or long-distance moving behaviors. In order to discuss more complicated motion states, the spatial conceptual maps[12] applies geometric relationship of physical environment to the state-space model to solve GPS data error problems. However, these studies did not use user's real-time motion states as the predictive basis; therefore, they can not be applied to an unprepared environment.

All these models discussed above were built on the assumption of a known or prepared environment. Further, since GPS receiver is susceptible to environmental interference the efficiency of user's state space model will be easily affected by an unknown or unprepared environment and lead the inaccuracy of GPS positioning. Hence, previous researches also require the accuracy of GIS map. The goal of this research attempts to perceive user's behavior from GPS data alone without specifically observing user's behaviors. In other words, this research treats GPS receiver as a sensor to acquire user's behavior and further to amend filtered GPS data accordingly. To achieve this goal, context-aware[13] technique is employed to explore the received NMEA 0183 formatted GPS data and to perceive GPS carrier's behavior accordingly. Since GPS data represents the snapshot of momentum changes of carrier, we can use Newton's Laws of Motion[14] to interpret GPS data. Therefore, an enhanced HMM by integrating Newton's Laws of Motion, coined Newton Markov Model(NMM), is proposed to reason user behavior from GPS data. The GPS carrier's behaviors in different environments are then captured into the Transition Probability Matrix (TPM) of NMM. This TPM is later used to perceive carrier's online motion status and further effectively amend the GPS data. This approach is named as Perceptive GPS (PGPS) method.

3. Rational of PGPS

In order to perform the context aware computation on commercially available GPS module, the context of the GPS carrier has to be decided first. While the context is a sequence of data that represents the states of behavior of GPS carrier, the context should be derived from GPS data. However, GPS data itself contain multiple dimensions of information, such as altitude, longitude, latitude and course etc., not all of them can be used for state reasoning directly. Because the goal is to perceive the behavior of GPS carrier from the received GPS data, the selected context has to contain spatial and temporal information of the GPS carrier. Furthermore, the context of GPS data has to be capable to highlight the motion of the carrier without being interfered by the environment. Under such prerequisite, the feature data for behavior aware computation is further extracted from GPS data. Therefore, the first issue of this research is to decide what the contexts hidden in GPS data are and how to extract them into the required feature data? The next question then focuses on how to classify the feature data into liable state that represents the behavior of GPS carrier? When the meaningful states are well defined, the subsequent issue is how to create the model of behavior of GPS carrier from the classified states? Importantly, in order not to be influenced by the discrepancy of different environments, this model must be in line with the innate characteristic of the GPS carrier so that the intention of GPS carrier can be captured. After the model is built, the final question is how to use the model to infer carrier behavior and amend GPS error data interactively?

To solve the above four issues, two phases, which are learning and perception phases, and five executing stages, i.e. feature extraction, state classification, learning, perception and amendment stages, as shown in Figure 1, are designed. Feature extraction stage extracts GPS carrier's feature of

motion from GPS data such as speed over ground(SOG), position and course over ground(COG) information. The extracted feature data include user's displacement, velocity change, and the course difference between two consecutive GPS data. Based on the momentum changes, the state classification stage then uses feature data to classify GPS carrier's behavior into pre-defined modeling states. The classified state is coined as the current state(CS) of GPS carrier.

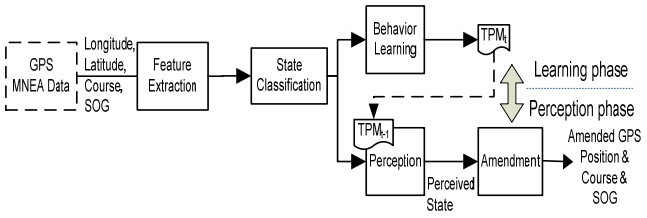

Fig. 1. PGPS process diagram

Perception needs to know the past history of the GPS carrier. The proposed technique is composed of learning phase and perception phase to perform the online perception. During the learning phase, outputs of state classification are analyzed by Newton's Laws of Motion to compute the state transition probability among modeled states. These state transition probabilities are then collected into a Transition Probability Matrix (TPM) to represent the habitual behavior of the user on that period of time. In other words, the value of TPM is filled in the form of momentum change of user's motion. This TPM then becomes inference foundation of the perception phase when the user performs online perception next time. Hence, in order to distinguish TPMs between the learning phase and the perception phase, subscript t of TPM_t represents new TPM derived from the current learning phase while subscript *t-1* of TPM_{t-1} denotes TPM from the previous learning phase. In short, during the online perception, new TPM, i.e. TPM_t, is interactively built to record user's current habitual behavior and previous TPM, i.e. TPM_{t-1}, is used to forecast the most likely current status of the user, called the perceived state(PS). Finally, the amendment stage fine-tunes of the GPS positional and course data are based on the differences between PS and CS. Detail description of each stage layout is displayed at the following sessions.

3.1 Feature Data Extraction

Among GPS sentence functional formats, NMEA 0183[15] is the most widely used standard nowadays. NMEA 0183 format regulates longitude, latitude, speed, UTC time, orientation, and satellite information, and so on into more than ten different sentences. Among these sentences, GPRMC, GPGGA, GPGSA, and GPGSV are four sentences that contain important contextual information of GPS carrier, as shown in Table 1, to capture its snapshot behavior.

Table 1. The context data from NMEA 0183

Course over ground	PDOP	SNR	Visible satellites
UTC time	latitude	longitude	Velocity over ground

Since each GPS data is the snapshot of GPS receiver at an instant of time, the study assumes that the GPS carrier is a rigid body and the sequence of received GPS data is the trajectory of GPS carrier. Under the assumption of Newton's motion physics, this study applied Newton's second Law of Motion, $F = d(mv)/dt$, to calculate the momentum of GPS carrier and to analyze the motion of GPS carrier accordingly. Based upon Newton's second Law of Motion, the momentum change is induced by the displacement, velocity change and course difference. Since the location information embedded in GPS data is denoted in latitude and longitude, Haversine formula[16] is adopted to compute the displacement Δx. Subsequently, the displacement (Δx), the velocity difference (Δv) and the course difference ($\Delta\theta$) of two consecutive GPS data are extracted as the feature data to detect the behavior change of GPS carrier.

3.2 State Classification

After the feature data are extracted, they can be used to estimate current state of GPS carrier. The question is how the GPS carrier's behaviour is classified from the above feature data? Newton's second Law of Motion tells us that the momentum change may be caused by the alteration of mass or the variation of velocity. Under the assumption that the GPS carrier is a rigid body and its mass is fixed, the momentum change is dominated by the variation of velocity. Consequently, Δv should be the first element to classify GPS carrier's behaviour from the received GPS data. Further, there is no doubt that the ranging error of GPS data is indeed embedded in the value of displacement Δx which naturally becomes the second classification key. Finally, the difference of course, $\Delta\theta$, then turns into the last component for classification. Hence, with the help of Newton's Laws of Motion, the computed feature data Δv, Δx, $\Delta\theta$ can classify GPS carrier's behaviour into 7 reasonable states: stationary(S_s), linear cruise(S_{lc}), linear acceleration(S_{la}), linear deceleration(S_{ld}), veering cruise(S_{vc}), veering acceleration(S_{va}), and veering deceleration states(S_{vd}). In other words, based upon Newton's Laws of Motion, this research assumes that the behaviour of GPS carrier can be modelled by the set $\mathbf{S} = \{S_s, S_{la}, S_{lc}, S_{ld}, S_{va}, S_{vc}, S_{vd}\}$. In order to accommodate the innate ranging errors reside in GPS signal, three threshold values, $\alpha_v, \alpha_x, \alpha_\theta$, of feature data Δv, Δx, $\Delta\theta$, respectively, are assigned for state classification. However, although the classification rules are derived from Newton's Laws of Motion, due to the GPS data ranging error, some classified states are against the law of nature and, hence, are collectively called Group X. Table 2 summarizes the above classification rules and the result of classification.

To further model the behaviour of GPS carrier by states in **S**, the Markov model is applied to Table 2 to deduce a state transition diagram as shown in Fig. 2 and it is named Newton Markov Model (NMM) thereafter. To facilitate the following discussion, the state sequence of a GPS carrier is expressed as $\{S_i\}$, with i indicates a discrete instance of time and $S_i \in \mathbf{S}$.

In Fig. 2, each node represents a state of the GPS carrier and the dotted line denotes the state transition probability between states. This dotted line is further formulated by the equation $P(S_t = j \mid S_{t-1} = i)$ to indicate the probability of state transition from state i at time t-1 to state j at time t. For example, $P(S_t = S_{la} \mid S_{t-1} = S_{la})$ represents the probability of the state S_{la} at time t-1 transition to the state S_{la} at time t.

Table 2. Summary of classification rules under valid value of Δv

$\Delta\vartheta$ & Δx & Δv	$\lvert\Delta v\rvert < \alpha_v$	$\Delta v > \alpha_v$	$\Delta v < -\alpha_v$
$\lvert\Delta\theta\rvert \le \alpha_\theta$ & $\lvert\Delta x\rvert < \alpha_x$	Group 0 (Stationary state)	Group X (Unclassified state)	Group X (Unclassified state)
$\lvert\Delta\theta\rvert \le \alpha_\theta$ & $\lvert\Delta x_t - \Delta x_{t-1}\rvert = \alpha_x$	Group 1 (Linear cruise state)	Group X (Unclassified state)	Group X (Unclassified state)
$\lvert\Delta\theta\rvert \le \alpha_\theta$ & $\lvert\Delta x_t - \Delta x_{t-1}\rvert > \alpha_x$	Group X (Unclassified state)	Group 2 (Linear acceleration state)	Group 3 (Linear deceleration state)
$\lvert\Delta\theta\rvert > \alpha_\theta$ & $\lvert\Delta x_t - \Delta x_{t-1}\rvert = \alpha_x$	Group 4 (Veering cruise state)	Group X (Unclassified state)	Group X (Unclassified state)
$\lvert\Delta\theta\rvert > \alpha_\theta$ & $\lvert\Delta x_t - \Delta x_{t-1}\rvert > \alpha_x$	Group X (Unclassified state)	Group 5 (Veering acceleration state)	Group 6 (Veering acceleration state)
$\lvert\Delta\theta\rvert > \alpha_\theta$ & $\lvert\Delta x\rvert \le \alpha_x$	Group 0 (Stationary state)	Group X (Unclassified state)	Group X (Unclassified state)

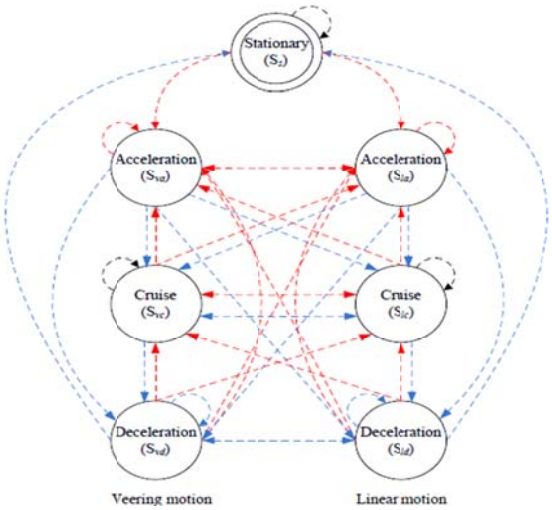

Fig. 2. Newton Markov Model

3.3 Behavior Learning

Most human will take the same habitual reaction under the similar environment. For example, when veering, at the beginning, most people would slow down, then turn, and finally to accelerate progress. To deal with the unpredictable user's behaviour under an unprepared environment is a critical issue of this study. This study takes Hidden Markov Model and Maximum Entropy to capture the uncertainty in motion behaviour modelling. If the observable GPS data sequence follows Newton Markov model, we can employ the principle of Hidden Markov Model to learn use's behaviour into a transition probability matrix(TPM) and apply Maximum Entropy to resolve the ambiguity in dynamic learning problem.

There are three canonical problems associated with HMM[17]. Since the study of inferring GPS carrier's behaviour from its past habitual behaviour is confirmed as the second canonical problem of HMM, this paper utilizes the approach of the second problem to compute the TPM of NMM. According to the state classification stage, GPS carrier can be one of 7 modelled states at any instant of time. Since GPS carrier can transit fom one state to any of 7 states at the next instant of time, we can capture its behavior by a 7X7 probability matrix. This 7 by 7 probability matrix is TPM that represents the habitual behavior of GPS receiver. Given A_{ij}(t) to denote the transition probability from state i to state j at a discrete time t, TPM can be formulated by Eq.(1).

$$\mathrm{TPM} = [P(S_t = j \mid S_{t-1} = i)]_{N\times N} = \left[A_{i,j}(t)\right]_{N\times N} \quad (1)$$

where $A_{ij}(t) = P(S_t = j \mid S_{t-1} = i)$ and N is the numbers of states. N is equal to 7 in this paper.

Therefore, if $A_{ij}(t)$ can be pre-learned, the current reasonable state of GPS carrier can then be inferred from its previous state and TPM. TPMs, which are computed from temporal sequences, represent the habitual behaviour of GPS receiver.

From the information theoretic perspective, the complexity of motion state can be related to the positioning accuracy and subsequently entropy.[18] The entropy is then becomes a good choice for quantifying the complexity of motion state. Everyone has his unique characteristics; and even for the same person, his first action would be positively different from the second movement without any accounts. Since different temporal motion state sequences may represent different behaviours, different temporal motion state sequences would derive different TPMs. The paper defines the entropy, H_t, as the absolute difference between two consecutive TPM_t and TPM_{t+1}. That is, the entropy of the system is shown as in Eq.(2).

$$H_t = \lvert TPM_{t+1} - TPM_t \rvert = \sqrt{\sum_{\forall i,j} \left(A_{i,j}^{t+1} - A_{i,j}^{t}\right)^2} \quad (2)$$

where $A_{i,j}^{t}$ indicates the possibility of state i transforming to state j in observation sequence O_t.

The continous entropy can be peceived as the changes of user's behavior. In other words, we can employ the maximum entropy to the optimal learning stratgey to perceive a stable user behavior. As the learning process continues, more TPMs will be derived from the received GPS data sequences. Therefore, we further define Eq. (3) to compute the average behaviours of GPS carrier among m consecutive observable GPS data sequences after received t^{th} sequences.

$$\psi_m(t) = \frac{1}{m}\sum_{i=0}^{i=m-1} H_{t+i} \quad (3)$$

Therefore, given ε as a tolerance value, $\psi_m(t) < \varepsilon$, when ε approaches zero, implies that the system is approaching a local stabilized behaviour with threshold ε during m consecutive training sequences. At this moment, the computed TPM is then

called a stable TPM. The stable TPM of the system can help to predict whether the user's behaviour is stable or not.

3.4 Behavior Perception

The stable TPM becomes the criteria to predict the optimal current state during online perception phase. This prediction is conducted by finding a maximum transition probability over all possible current states from a known previous state. To further increase the accuracy of prediction, this paper exercises previous two consecutive states *i, j* to compute the most possible current state *k.* Hence, the stable TPM derived from the learning phase will be in the form of a three-dimensional state transition matrix as shown in (4).

$$\mathrm{TPM} = [P(S_t = k \mid S_{t-2} = i \,\&\, S_{t-1} = j)]_{N\times N} = \left[A_{i,j,k}(t)\right]_{N\times N\times N} \quad (4)$$

As a result, Eq. (5) is the formula to obtain the maximum probability of current state from a stable TPM. Namely, Eq. (5) gives the maximum value among $A_{i,j,k}$ for all k with previous two consecutive state *i,* state *j*.

$$P(S_k \mid TPM, S_i, S_j) = \underset{given\ i,j}{\arg\max}\{A_{i,j,k}\ \forall k\} \quad (5)$$

The state computed from Eq. (5) is then compared with the current state, CS, derived from the state classification stage to detect if a GPS ranging error is occurred or not. That is, the predicted state, PS, computed from Eq. (5) gives the most likely current state based upon stable TPM, whereas the state classified from Table 2 is the possible current state according to the received GPS data**.** Hence, the comparison between these two states from two different sources can give the clue to detect GPS ranging error. Although Eq. (5) allows us to use the past experiences recorded in TPM to infer the most likely current state, yet, this computation still has some problems. For example, when $A_{i,j,k}$ is 0 or the computed maximum probability is not an unique value, the computed state would become ambiguous. Furthermore, when the perceived state, PS, from Eq. (5) is not the same as the current state, CS, from Table 2, there is no absolute conclusion on whether it means the received GPS data has ranging error or the GPS carrier is changing its habitual behaviour.

After conducting a series of experiments, the above problems can be summarized into the subsequent four possible scenarios. First, the GPS signal has the ranging errors caused by the environmental effects. The second case is that, GPS carrier is changing from one state into another during activity. The third scenario which we suppose it could be the prediction of current state is incorrect. The final situation is the habitual behaviour of GPS carrier has changed. Hence, the solutions to these four cases are discussed as below.

(1) When GPS signal has the ranging errors caused by the environmental effects, the received GPS data will not follow Newton's Laws of Motion. Hence, the received GPS data have to be amended according to the perceived state; so that it can be used to infer the following state with the stable TPM.

(2) The second case is that the GPS carrier is currently changing its state during activity. Since stable TPM records the inertial behaviour of GPS carrier, the original inertia may also be changed when the GPS carrier is switching from one state into another. In this case, the perceived state from Eq. (5) is wrong. In order to distinguish this case from the first case, a mechanism is designed to detect the change of inertial status of GPS carrier. Since the inertia has the characteristics of continuity, a posture threshold parameter, β_{pt} , is designed to count the number of consecutive state change. That is, $\beta_{pt} = \beta_{pt} + 1$ when the perceived state from Eq. (5) is continuously different from the classified state by Table 2. An inertial threshold φ is further defined for each GPS carrier so that when $\beta_{pt} > \varphi$, it implies that the GPS receiver is changing its state. The system will then believe that the state of GPS receiver has changed, and trust the classified state from the received GPS data as the accurate current state. If $\beta_{pt} \le \varphi$, we assume the system is in the first scenario and amend GPS data accordingly.

(3) The third situation is the perceived state computed from Eq. (5) is inaccurate. Since the maximum possibility inferred from Eq. (5) maybe 0 or not an unique value, it implies the state transition from the previous state to current one is undecided or there are more than one possibilities of such transition exist. Under such circumstances, the perceived state thus will become distrusted and another approach is required to verify the accuracy of online received GPS data. Hence, a cross reference scheme between two consecutive feature data sets is designed to achieve this goal. If the difference between two consecutive feature data sets is within the range of predefined threshold, the classified current state from online received GPS data is then accepted. Otherwise, the previous perceived state is trusted based upon the inertial principle.

(4) The final case is the change of habitual behaviour of GPS carrier. Different habitual behaviours will produce respective TPMs for online behaviour inference. Hence, the corresponded stable TPM for state inference and thresholds for state classification are switched for further state perception process.

3.5 Amendment

The data amendment approach is related to the geographical system. When a GPS error is detected, Dead Reckoning[19] is adopted to estimate current position based upon its previous position and reasonable state. However, since the received GPS data is in latitude and longitude format, this estimation must meet the Earth's geographical property. Consequently, the tangent line formula is used to evaluate the current position of GPS carrier as follows.

According to the tangent line formula, assuming that there are three consecutive GPS location data, A(λ_A, φ_A), B(λ_B, φ_B), C(λ_C, φ_C), where λ is longitude data, φ is latitude information. Based on the principle of inertial and tangent line formula, we can calculate the predicted location D from tangent line formula as following Eq.(6),

$$D_x = C_x + r(\lambda_B - \lambda_A)$$
$$D_y = C_y + r(\varphi_B - \varphi_A) \quad (6)$$

Besides, the veering angle, Φ, of the GPS carrier can also be estimated by Dead Reckoning formula as shown in Eq.(7).

$$\Phi = \arcsin\left(\frac{\varphi_B - \varphi_A}{\sqrt{(\varphi_B - \varphi_A)^2 + (\lambda_B - \lambda_A)^2}}\right) \quad (7)$$

Finally, to avoid effect from the accumulated error, the same Dead reckoning principle is also used if fine-tuning of GPS data is required.

4. Experiments and Results

The Implementation of PGPS is coded in java language on the Android-based smartphone. In specific, the smartphone used is HTC Hero model which is equipped with Sirf III GPS module. In order to acquire more reliable GPS data, the study applies some pre-screening steps during the initialization stage. Since GPS receiver employs a three-dimensional position computation, Phatak et al.[20] stated that there must be at least four satellites visible before the received GPS data becomes useful to compute the position of the GPS carrier. Furthermore, SNR of each satellite must exceed 30 dB [21] to derive the accurate positioning. Hence, the total SNR value should be more than 120 dB to let the received GPS data become useful for positioning. In addition, Lin et.al [22] shows that the proper PDOP value should be less than 20 during the initialization phase thereinafter.

Since the goal is to perceive the behaviour of a GPS carrier, it must have a proper framework to learn the habitual behaviour of GPS carrier before beginning to infer the behaviour of GPS carrier interactively. As a result, several questions are raised to validate the PGPS approach. Among them, the first question is if such learning framework and the perceived algorithm are applicable to GPS carriers with different momentum natures? In other words, Eq.(2) and Eq.(3) are used to calculate the stable habitual behaviour of GPS carrier. Nevertheless, the habitual behaviour of a GPS carrier will not be the same at all time. In terms of the principle of momentum, the inertial momentum will vary with the habitual behaviour and will become locally stabilized for different ranges of speed. Hence, the first question can be re-phrased as if Eq.(2) and Eq.(3) can actually capture local stable habitual behaviour of GPS carrier? The next question is if PGPS effective enough to filter out ranging error? To answer these two questions, a series of experiments are conducted to verify the presented PGPS methodology as presented in the following sections.

4.1 Entropy of Momentum

The first experiment is to verify whether Eq.(2) and Eq.(3) can capture different local habitual behaviours of the same GPS carrier? This experiment tries to calculate various entropies of the same GPS carrier under different velocity ranges that represent diverse momentums. During this experiment, the subject carries a GPS receiver and walks in the park with different speeds, including 2m/s~6m/s, 1m/s~3m/s, 0m/s~1m/s and 0m/s, to derive different GPS data learning sequences. Afterwards, the entropies for these four GPS learning sequences are then computed by Eq.(2) and Eq.(3), individually. The results are shown in the sub-graphs of Fig. 3. The vertical axis of Fig. 3 is the mean value of entropy by Eq.(3) and the horizontal axis is different segment length of the learning sequence. The result of this experiment shows that the mean entropy (i.e. vertical axis) of all four velocity ranges can be converged to a specific value after certain length of learning segments. Because the minimum learning segment length of this experiment was set up at 20, this experiment reveals that the carrier with higher velocity (momentum) will require longer length of learning segment to obtain stable TPM.

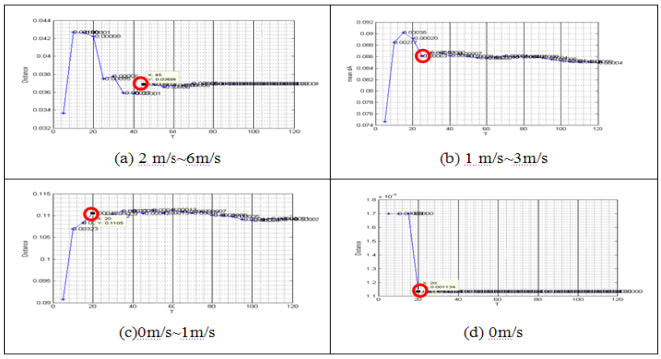

Fig. 3. Entropies in different velocity ranges.

4.2 Effectiveness of the PGPS

As depicted in Fig. 4, we chose a linear path (red line) from A to B as the base line for this experiment. A student was then asked to hold a smartphone and walk from point A to point B to log resulted PGPS data sequence. For the control group, this student repeated the same path with a notebook that is plugged in with a high-precision external GPS receiver to log GPS data sequence between points A and B.

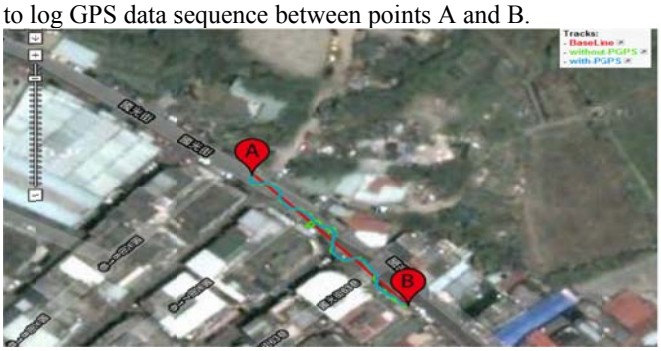

Fig. 4. The measurement scenario

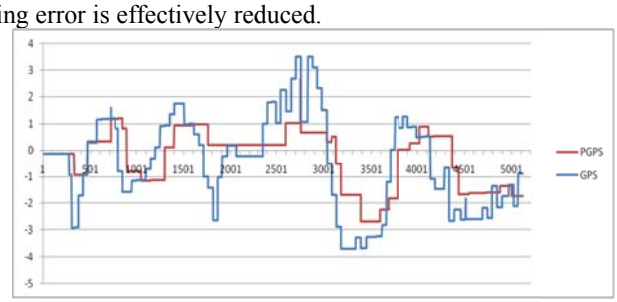
In order to display the effectiveness of PGPS on reducing ranging error, Fig. 5 shows the histogram after screening out eight significantly large ranging error points. The unit of the vertical axis in Fig. 5 is meter and the red line is the result of logged PGPS while the blue line is the logged GPS data from notebook with a high-precision external GPS receiver. We can notice the largest ranging error of the red line is reduced to 4m while the blue line is 8m. This experiment shows that GPS ranging error is effectively reduced.



Histogram (second)

Fig. 5. The result of with PGPS and without PGPS

5. Conclusion and Future work

The paper presents an approach, called PGPS, to interactively infer the behavior of GPS carrier by utilizing the trajectory of received GPS data. Although the GPS signals are vulnerable to the environmental effects, the behavior pattern still exists in the context of the received GPS data. PGPS is a novel approach that adopts GPS data as the feature evidence of behavior state. The presented GPS calibration technique doesn't require either any high cost ground base station assistance, nor any expensive auxiliary peripherals and complex GIS system. The PGPS methodology combines Newton's Law of Motion with context awareness technique to improve the accuracy of GPS positioning. During the learning phase, PGPS applies Newton's Law of Motion to extract the GPS data to learn the behavior feature of GPS carrier. The Newton Markov Model is then defined accordingly to model the habitual behavior of GPS carrier. In accordance with the theory of Hidden Markov Model, PGPS then computes the stable TPM to capture the habitual behavior of GPS carrier. Hence, this study proposes a perceived algorithm that uses stable TPM to reason carrier's behavior online. Moreover, the posture threshold is further elaborated to detect the behavior change of GPS carrier.

The most important application of PGPS method is the live-view GPS navigation system, which needs the accurate position information for object registration during navigation. For example, OmniGuider[2] is a real world browser that can provide you the right information at the right time and right place. PGPS not only can provide an accurate behavior perception to solve the ranging errors; but also could conquer the registration problems of the mobile augmented reality system. In all, PGPS could support the precise longitude and latitude information for the user to perform point of interest (POI) navigation application.[23]

Towards Automated Scheduling in the Oil Industry: Modeling Safety Constraints

Bård Henning Tvedt[1], **Marc Bezem**[2]

Abstract— *Maintenance schedules in the oil industry often consist of several subschedules originating in different organizational units. Even if these subschedules are locally feasible, overall feasibility can be difficult to verify by the mainly manual scheduling procedures used today. One important cross-cutting concern of large-scale scheduling is safety. Scheduling problems in the oil industry are characterized by a large number of absolute safety constraints. As a step towards automatic scheduling, we formalize the safety constraints surrounding heavy lifting. These constraints are interesting since they form an extension of the well-known jobshop model with cumulative resources. We discuss novel strategies for dealing with these safety constraints and demonstrate their usefulness on a set of benchmarks.*

Keywords: automated scheduling, constraint programming, safety constraints

1. Motivation

An oil and gas operator's objectives are to minimize the number of hazardous situations, minimizing the environmental footprint and maximize production. Meeting these, sometimes conflicting, targets is a complicated and challenging task, and meticulous preparations in the form of planning and scheduling are done within all disciplines. These include drilling & completion, reservoir & production and operations & maintenance.

The particular scheduling conditions depend on the location and age of a field, and on the discipline in question. At an offshore platform, for instance, maintenance activities are to be performed in a relatively small, enclosed space. In contrast, on a land-based field a great many maintenance activities are scheduled across vast areas. Even though the particulars of the problems can be different, several aspects are common for most scheduling problems in the industry. These aspects include:

- size – the number of activities can be in the range from hundreds to several thousands;
- complexity – the large number of constraints to be satisfied makes the (manual) generation of a feasible schedule difficult;
- dynamics – the operating conditions are continuously changing, and the dependencies on weather, logistic and equipment failure *will* disrupt schedules.

Today's scheduling routines are naturally shaped by these aspects. The size of the problem has traditionally been reduced by splitting the problem into several discipline- or department-related subproblems. Each separate problem becomes easier to solve, but the interdependencies between them are lost. The resulting schedules may therefore be unfeasible right from the start, and conflict resolution requires good communication between several departments and companies.

Even though the size of the subproblems has been reduced, there is no guarantee that the same applies for the complexity. Several of the considerations taken into account are based on the local scheduler's extensive knowledge of the problem, and not on formalized constraints. There is widespread belief that many of these considerations and best practices are difficult to implement in a solving strategy. This perception may be correct, but has not been properly tested.

Another implication of size and complexity is the quantification of the schedules' quality with respect to one or several objectives. If it is already difficult to ensure the overall feasibility of one schedule, how should several schedule suggestions be compared to determine the best solution?

The dynamics of the problem is a considerable challenge during execution of a schedule. Unforeseen events *will* occur. Due to the limited time available to reorganize a disrupted schedule, the simple strategy of postponing activities is often applied. Such a strategy can be combined with scheduling initially with slack in order to make room for some distortion. This might work well if the schedule experiences the 'right amount' of distortion during execution. On the other hand, if the execution is smooth resources become idle and new tasks must be prioritized and assigned on the fly. Anyway, there is no guarantee that distortions larger then the induced slack cannot occur. In such cases the schedule is rendered unfeasible and must be rescheduled.

The challenges mentioned above can be met by applying automated scheduling algorithms providing a consistent strategy for generating feasible schedule suggestions. To fully utilize the existing potential, several of the considerations made by schedulers must be turned into formal constraints. Some of these can be modeled and solved by well-known scheduling techniques. Others, for example, safety constraints, must be handled by tailor-made techniques as discussed in this paper. The expected benefits are greater

control and overview of safety issues, better prioritizing of activities, reduced idle time of resources, improved regularity of operations and, consequently, increased production.

2. Problem description

Our main focus in this paper is the domain of operations and maintenance. The problem definition has been simplified as much as possible while still keeping industry-specific characteristics such as absolute safety constraints. More common scheduling elements like cumulative resources and dependency constraints are included to provide real-world resemblance. The solution objective is to minimize the *makespan*, the total completion time of all activities to be scheduled. This particular objective aims at efficiency, but the techniques developed can be applied to other objectives as well.

The problem is set at an imaginary oil-platform subdivided into a set of locations. Equipment in need of maintenance is randomly distributed across the platform, and various maintenance activities are to be scheduled. The activities come with a given set of resource requirements and potential dependencies on other activities. All activities require a crew to perform them and a location to be performed at. In addition some activities require a crane because heavy lifting is involved. The crew and crane resources are scarce, meaning that they are in limited supply.

Thus far the problem classifies as a 'Resource-Constrained Project Scheduling Problem' [1, RCPSP], which is described by:

- a set of resources with given capacities;
- a set of non-interruptible activities of given processing times;
- a network of precedence constraints between the activities;
- the amount of resources required by the activities.

Even though the RCPSP description is adequate for a wide range of scheduling problems, there are several additional constraints, typical for the oil-industry as well as for other large-scale industrial settings, which do not fit into this framework. Our objective when generating a set of problem instances was to ensure that formalized examples of industry-related constraints were involved. One such example is the safety situation surrounding dangerous work, like for instance heavy lifting. Currently such schedule information is taken into account manually by the schedulers. By carefully formalizing the safety constraints we get a well-defined problem description for automation.

A solution $S(P)$ to a problem instance P is a schedule in which (1) all activities have been assigned a start time and (2) all activities requiring a crane have been assigned a crane and (3) all constraints are satisfied. Here (2) in combination with the safety constraints among (3) goes beyond the RCPSP framework. The reason is that the safety constraints are dynamic in the sense that they come into effect only *after* a crane has been assigned to an activity.

In the following paragraphs we will take a detailed look at the problem instances described in the above setting.

2.1 Notation and Terminology

A problem instance P consists of activities to be performed, resources needed to perform activities and constraints representing limitations between activities and resource use. We distinguish between *decision variables*, given *constants* and *derived variables*. An example of a decision variable is the starting time of an activity Act_i denoted $v_{sta}(Act_i)$. An activity's duration is assumed to be fixed and therefore a constant denoted $c_{dur}(Act_i)$. Finally, there are derived variables like an activity's end time, which is the sum of its start time and duration, given by $w_{end}(Act_i)$. Formally, $w_{end}(Act_i) = v_{sta}(Act_i) + c_{dur}(Act_i)$. For real objects like activities and resources we use abbreviatons starting with a capital letter.

2.2 Resources

A *location* $Loc_l \in Locs = \{Loc_1, \ldots, Loc_L\}$ is the place where activities are being executed. Even though the locations are viewed as resources there are no restrictions on the number of ordinary activities that can be performed simultaneously on a location. However, when dangerous work like heavy lifting is performed, the location is made inaccessible to all other activities. In that case we say that a *safety zone* has been established, consisting of both the location of the activity and the location of the crane. How to deal with safety zones is an important part of the different models and solution strategies discussed in Section 3.

The *crews* are responsible for executing the activities. A crew is denoted $Crew_j \in Crews = \{Crew_1, \ldots, Crew_J\}$. The resource demand is taken to be one for whole the duration of the activity. A crew can therefore simultaneously work on the same number of activities as its capacity. It is not possible to pool resources to reduce the duration of an activity.

A *crane* $Crane_k \in Cranes = \{Crane_1, \ldots, Crane_K\}$ is a potential resource for activities. Some of the activities need a crane, and all problem instances contain a small number of cranes. The cranes are *unary resources* meaning that they can only perform one activity at the time. An activity requiring a crane does not specify a particular crane, but simply that it needs a crane. A feasible solution must therefore assign one crane to all activities requiring crane from the set of cranes available. This makes the set of cranes an alternative resource [2].

Cranes have a location $c_{loc}(Crane_k) \in Locs$, and each location can only have one crane. Due to the hazardous nature of heavy lifting, crane usage is surrounded by safety zones. These safety zones are established both at the crane's own location and at the location where the activity requiring

the crane is performed. The safety zones established will therefore vary according to which crane is assigned to which activity.

2.3 Activities

An *activity* $Act_i \in Acts = \{Act_1, \ldots, Act_I\}$ comes with a start variable, a constant duration and resource requirements. Initially the domain of the start variable is $v_{sta}(Act_i) \in [0, c_{hor}(P))$, where the horizon, indicating the schedule's maximum completion time, is given as $c_{hor}(P) = \sum_i c_{dur}(Act_i)$.

Every activity Act_i requires a crew $c_{crw}(Act_i) \in Crews$ to perform it, and a location $c_{loc}(Act_i) \in Locs$ to be performed at. Every activity uses one single member of a crew and it is not possible to pool resources to reduce the duration. Some (but not all) activities require a crane, which is expressed by a boolean constant $c_{crn}(Act_i)$. In that case there is also a decision variable $v_{crn}(Act_i) \in Cranes$.

In addition to resource requirements an activity can depend on other activities, meaning that it cannot start before these other activities are finished. This is called *precedence* in the RCPSP framework.

2.4 Constraints

Dependencies between activities are common in the industry. A maintenance activity can, for instance, be dependent on both the delivery of spare parts and raising of scaffolding to ensure access to the area in question. The relation stating that activity $Act_{i'}$ depends on activity Act_i is expressed by the following constraint:

$$w_{end}(Act_i) \leq v_{sta}(Act_{i'}) \tag{1}$$

A *cumulative resource constraint* applies to every crew, ensuring that the total resource consumption is not exceeding the crew's capacity. It is expressed by:

$$\begin{aligned} \forall t, j : \sharp\{Act_i \mid t \in [v_{sta}(Act_i), w_{end}(Act_i)) \wedge \\ c_{crw}(Act_i) = Crew_j\} \leq c_{cap}(Crew_j) \end{aligned} \tag{2}$$

where $c_{cap}(Crew_j)$ is the capacity of the j-th crew.

Cranes are unique individuals and therefore modeled as a set of unary resources. The *mutual exclusion constraint* states that two activities cannot be executed simultaneously when they are assigned the same crane. We prepare by defining the temporal predicate *overlap* expressing that two activities are overlapping in time:

$$\begin{aligned} &overlap(Act_i, Act_{i'}) \equiv \\ &\exists t : \; v_{sta}(Act_i), v_{sta}(Act_{i'}) \leq t < w_{end}(Act_i), w_{end}(Act_{i'}) \end{aligned} \tag{3}$$

The mutual exclusion of crane usage then becomes:

$$\begin{aligned} \forall i, i' \neq i : v_{crn}(Act_i) = v_{crn}(Act_{i'}) \rightarrow \\ \neg overlap(Act_i, Act_{i'}) \end{aligned} \tag{4}$$

for all activities requiring crane.

Now come what we call the *safety constraints*. They are expressed in terms of the location of the activity requiring a crane and of the location of the crane chosen. The first location is known in advance, while the second is dependent on the decision as to which crane to use. The fact that the temporal constraints in (6) below depend on the crane decisions made is interesting because of the added complexity this induces. Although there may be different ways of formalizing such a constraint, it appears to be a real extension of the simple job-shop model with cumulative constraints.

Safety constraints shutting out use of the location of an activity requiring crane are:

$$\begin{aligned} \forall i, i' \neq i : \; c_{crn}(Act_i) \wedge c_{loc}(Act_i) = c_{loc}(Act_{i'}) \\ \rightarrow \neg overlap(Act_i, Act_{i'}) \end{aligned} \tag{5}$$

while safety constraints shutting out use of the crane location itself are given by:

$$\begin{aligned} \forall i,i' \neq i, j : (v_{crn}(Act_i) = Crane_j \wedge \\ c_{loc}(Act_{i'}) = c_{loc}(Crane_j)) \rightarrow \neg overlap(Act_i, Act_{i'}) \end{aligned} \tag{6}$$

2.5 Objective

The objective to minimize makespan $w_{ms}(P)$ or the duration of the schedule is defined by:

$$w_{ms}(P) = \max_i \{w_{end}(Act_i)\} \in [0, c_{hor}(P)] \tag{7}$$

which states that the makespan equals the latest end or completion time in the set of activities.

2.6 Problem instances

The problems are characterized by their sizes determined by the total number of activities, $\#Acts \in \{50, 60, 70, 80, 90, 100, 200, 300, 400, 500, 750, 1000\}$, and cranes, $\#Cranes = [2, 3]$. A total of 5 problem instances were generated for each of the 24 problem sizes, summing up to a total of 120 instances.

The problem instances were not necessarily feasible since they were generated by randomly assigning crews to activities, locations to activities, locations to cranes, dependencies between activities, and activities' crane requirements. 12 problem instances contained circular dependencies, and 11 instances had more than one crane at the same location. The total number of instances used is thus 97.

All the problem instances contain 24 locations and 4 crews with capacity $c_{cap}(Crew_j) \in [2, 3]$ drawn at random with a uniform distribution. The domain for the activities' start variables are default $v_{sta}(Act_i) = [0, c_{hor}(P))$, and the constant durations $c_{dur}(Act_i)$ are drawn uniformly at random from the range of $[1, 6]$ time steps. Approximately 20% of the activities are randomly chosen to require a crane, and approximately 10% of the activities is constrained by dependencies to some other activity.

3. Solution strategies

The problem of determining whether a given RCPSP has a solution with makespan smaller than a given deadline is NP-hard [3]. This means that the extended problem with safety constrains is also at least NP-hard. The simplest form of an RCPSP consist of a set of activities with durations and one resource with capacity two (no cranes, no dependencies between the activities). Finding the minimal makespan is then still NP-hard. This problem is sometimes called *multi-processor scheduling* and can also be viewed as binpacking with two bins. Hence finding an optimal, or even a good solution to such problems in polynomial time is by no means guaranteed.

We have experimented with one non-search and two search-based solution strategies. The first solution strategy is our own implementation of a greedy algorithm. A solution is computed as described below in Section 3.3. This strategy does not backtrack, undoing decisions and exploring other possibilities, but it is nevertheless guaranteed to produce a feasible solution.

The second set of solution strategies is implemented in C++ using the Ilog Solver 6.6 [4] and Ilog Scheduler 6.6 [5] libraries. A default search goal Ilog : IloSetTimesForward, which is designed to efficiently schedule activities in a chronological order, is applied to the activities, while the default goal Ilog : IloGenerate is used to assign cranes to activities. This search-based strategy is constrained by a time limit. The search is iterated with an additional constraint requiring that the makespan of the new solution is less than the current solution, and terminates when it fails to improve on the solution within the time limit. This strategy is applied to two different ways of modeling the safety constraints.

First theoretical lower and upper bounds for the makespans are calculated.

3.1 Theoretical lower bound for makespan

A theoretical lower bound is calculated based on the resource availability for the most constrained crew. The resulting solutions may not be feasible for the entire problem, but are packed tightly for the crew utilizing every crew hour.

$$c_{load}(Crew_j) = \sum_{c_{crw}(Act_i)=Crew_j} c_{dur}(Act_i) \tag{8}$$

$$c_{relload}(Crew_j) = \frac{c_{load}(Crew_j)}{c_{cap}(Crew_j)} \tag{9}$$

$$c_{lb,ms}(P) = \max_j\{c_{relload}(Crew_j)\} \tag{10}$$

3.2 Theoretical upper bound for makespan

A theoretical upper bound for the makespan is

$$c_{ub,ms}(P) = c_{hor}(P) = \sum_i c_{dur}(Act_i) \tag{11}$$

where all activities are executed one after the other. Feasibility of such a schedule requires a linear order of all activities which complies with all temporal dependencies. Finding such an order will be discussed in the next section. Executing all activities one after the other clearly respects all resource and safety constraints.

3.3 Non-search based (greedy) strategy

The first approach that can be expected to give some results is a so-called greedy algorithm. A characteristic of such an algorithm is that it schedules the activities one by one, always taking the earliest time-slot and first crane (if required) such that all constraints are satisfied. Clearly, one has to respect precedence to get a feasible solution and strong heuristics are required to avoid the worst schedules. This is in some sense the classical approach avoiding search: efficient generation of inefficient schedules. Thus the greedy strategy serves very well as a reference method by which the quality of other methods can be measured. Note that the greedy strategy is not unlike manual scheduling, the crucial difference being scale as well as quality of the heuristics.

Let us explain one of the heuristics which is often applied. Among the resources, it is often possible to identify the one that is most scarce. In our setting, although the safety constraints are complicating, the cranes are not a scarce resource since only 20% of the activities uses a crane. To identify a scarce resource one has to sum the total duration of all activities using the resource and divide that sum by the resource's capacity, much in the same way as the theoretical lower bound of the makespan is computed in Section 3.1. Having identified the scarcity of the resources in this way, it is often beneficial to schedule activities using a scarce resource first. Of course this should be done in a way compatible with the dependencies.

A first and necessary preparation for a greedy algorithm is that all activities are linearly ordered in a way respecting the dependencies. This is a well-known procedure called 'topological sort' [6] and can be done in time quadratic in the number of activities. Topological sort also detects circular dependencies. If a circularity is detected, then there exist no feasible schedules. From now on we assume that the activities $Act_1, \ldots, Act_I$ are listed such that $i < j$ whenever activity Act_j depends on Act_i. A feasible schedule can then be computed by scheduling each Act_j at the first possible time such that Act_i is finished (if Act_j depends on Act_i), the necessary resource is available and there is a free crane (if Act_j uses a crane), all satisfying the safety and other constraints.

3.4 Search-based strategies

The second approach is based on exhaustive search, and is applied to two variations of the model.

Inferred constraint

Finding good solutions, let alone solving to optimality, turned out to be difficult even for the smallest instances.

The default ILOG Scheduler search strategies have great performance, but they struggle to find feasible solutions due to the non-chronological elements induced by the decision-dependent safety constraints. In other words, assigning a crane to an activity can be made impossible by decisions taken long ago in the search. To reduce the effect of the non-chronological elements, implicit model information has been made explicit through an additional constraint. The model is expanded with a *cumulative resource constraint* for cranes:

$$\forall t: \ \sharp\{Act_i \mid t \in [v_{sta}(Act_i), w_{end}(Act_i)) \wedge c_{crn}(Act_i)\} \leq c_{cap}(Cranes) \quad (12)$$

where $c_{cap}(Cranes)$ equals the number of cranes. It is important to stress that this 'inferred' constraint (12) is a logical consequence of mutual exclusion of crane usage, constraint (4). As such it does not change the problem in any way. Despite being redundant, (12) improved the performance of Ilog dramatically. The search strategy assigns start times to activities before cranes are assigned. The inferred cumulative constraint ensures that the crane capacity is never exceeded.

Overconstrained model

The overconstrained model expresses all the safety constraints as non-conditional a priori constraints: the conditional constraint (6) is strengthened to (13) below. More precisely, instead of closing only the location of the crane used, we close *all* crane locations when *some* crane is used. In addition, of course the location of the activity requiring the crane is closed. This 'overconstraines' the model to a conventional RCPSP model, and the best possible makespans could go up. As such it is an interesting variant that allows one to analyse the effect of the dynamic safety constraints, both on the difficulty of solving the problem and on the quality of the solutions. This effect can be expected to depend on cranes being the most scarce resource or not.

The safety constraints in the original model expressed in constraint (6) are replaced by:

$$\forall i, i' \neq i : c_{crn}(Act_i) \wedge c_{loc}(Act_{i'}) \in C_{loc} \cup \{c_{loc}(Act_i)\} \rightarrow \neg overlap(Act_i, Act_{i'}) \quad (13)$$

where $C_{loc} = \{c_{loc}(Crane_j) \mid Crane_j \in Cranes\}$. Notice that it is only activities and not cranes that are influenced. Instead of forcing a solution to use one crane it encourages to use several cranes simultaneously. It is in other words not the same as setting the crane capacity to one.

4. Results and Evaluation

The theoretical upper and lower bounds provide the range for the makespan. Due to the way instances are generated and the nature of the bounds, this range is as expected. The durations are drawn uniformly at random from [1, 6], so with mean $\bar{c}_{dur}(Act_i) = 3,5$ units of time. The expected upper bounds are thus approximately 175 and 3500 units of time for 50 and 1000 activities, respectively. The mean theoretical upper bounds of the problem instances are 170 and 3500 units of time.

Table 1: Relative optimality index w_{rq} for the various models

#Act(#P)	≤ 100 (25)		> 100 (21)	
2 Cranes	w_{rq}	$\%^{(1)}$	w_{rq}	$\%^{(1)}$
Greedy	1.311	100	1.524	100
Inferred	1.068	100	1.063	35
Overconstrained	1.143	100	1.076	100
3 Cranes	w_{rq}	$\%^{(1)}$	w_{rq}	$\%^{(1)}$
#Act(#P)	≤ 100 (28)		> 100 (23)	
Greedy	1.276	100	1.393	100
Inferred	1.017	32	1.000	4
Overconstrained	1.176	100	1.037	91

$^{(1)}$ percentage solved problem instances

Based on four crews with a minimum capacity of two and uniformly assigned at random to activities, the theoretical lower bounds can be expected to be 1/8 of the theoretical upper bounds. For 50 and 1000 activities the expected theoretical lower bounds are approximately 22 and 438, respectively. Indeed the mean values in these problem instances are 23 and 440 units of time.

A feasible solution with makespan equal to the theoretical lower bound may not exist. However, the theoretical lower bound is based on the most constrained crew which is the problem's most constrained resource. It is therefore a sensible benchmark to compare various strategies. A measure of relative optimality w_{rq} is used to evaluate the results from the different strategies and models, given by:

$$w_{rq} = \frac{1}{|\mathcal{P}_{sol}|} \sum_{P \in \mathcal{P}_{sol}} \frac{w_{ms}(P)}{c_{lb,ms}(P)} \quad (14)$$

where $\mathcal{P}_{sol}$ is the set of problem instances solved by each approach. The elements in $\mathcal{P}_{sol}$ differ from strategy to strategy and these averages are therefore not entirely comparable, but they give an indication of the quality of the solutions. The measure w_{rq} does not penalize a strategy or model for failing to find a solution. Robustness is measured by the percentage of solved problem instances. The results are summarized in Table 1.

Our greedy solution strategy produces solutions with makespan on average 37% larger than the theoretical lower bound. When scaling up, some (expected) degradation of w_{rq} can be observed. The greedy strategy mimics a manual scheduling procedure for generating feasible schedules, and the results are believed to be comparable. The greedy algorithm's strength is that it always generates a feasible schedule. It is in fact the only strategy that solves all the problem instances. Apart from that it works in negligeable time (seconds).

The theoretical lower bound and the results of the greedy strategy set the stage for the seach-based strategies. Success means to solve many problem instances with a makespan close to the theoretical lower bound, in any case significantly smaller than the makespan the greedy strategy gives. The search-based strategies are iterated, from the makespan of the first solution found downwards in small steps. The initial bound for the makespan is always $c_{hor}(P)$, the theoretical upper bound. Each iteration the constraint enforcing an upper bound to the makespan is sharpened.

We used time limits of 1, 5 and 15 seconds for instances with $<$100, 100..499, $\geq$500 activities, respectively. Increasing the time limits didn't help very much. The final solution was reached in less than 5 iterations, all solutions are thus in fact produced within 60 seconds.

The inferred model produces the overall best makespans for feasible schedules, approximately 5.5% larger then the theoretical lower bound. On the other hand this model scales poorly and struggles when the instances become larger and more complex. For instances with 3 cranes and $>$100 activities it solves only 1 of the 23 instances, and overall it solves 43% of the problem instances.

Not surprisingly the overconstrained model produces slightly worse make-spans. This indicates that, even though cranes are not a scarce resource, the safety constraints have a clear impact on the results. The obtained makespans are approximately 11.4% larger then the theoretical lower bound. This model is, however, quite robust and 98% of the problem instances are solved.

5. Related and Future Work

The solution strategies applied in this paper are relatively simple, and improvements in quality, robustness and solving time can be expected of more sophisticated strategies. The following ideas are expected to yield improvements.

- The greedy strategy can be randomized such as in GRASP [7]. Initial experiments with randomization show promising results.
- Local search techniques such as in [8] could be further explored. Initial experiments have not shown promising results so far. It seems hard to define the right notion of neighborhood.
- Locations can be viewed as cumulative resources in the following way. The capacity of a location is equal to the total number of activities. An ordinary activity consumes one unit of the resource associated with the location of this activity. Activities using cranes consume the whole capacity of the resource associated with the location as well as of the location of the crane. In this way the safety constraints can be replaced by resource constraints, in combination with cranes as alternative resources. Initial experiments have shown promising results.
- The dynamic structure of the safety constraints could be analysed such as proposed in [9] to obtain better heuristics.

6. Conclusion

This is a preliminary study of the feasibility of automating maintenance scheduling in the oil-industry. The aim of our research was to address some of the challenges related to maintenance scheduling. More precisely, to explore different strategies for handling large and complex problems, in the highly dynamic environment of oil and gas production, in an efficient and coherent way.

The greedy strategy solves all problem instances, regardless of size and complexity, within seconds. The short solving time enables consistent handling of disruptions, caused by for instance unexpected events or delays, through rescheduling. In this manner the dynamics of the problem domain is also taken into account. The greedy algorithm mimics a manual procedure for generating a feasible schedule from scratch. Even though the search-based strategies are not as robust, the one that performed best generates solutions with on average a 20% shorter makespan.

When compared to manually scheduling, we believe our results indicate a great unutilized potential with respect to the feasibility, quality and generation time of schedules, to be exploited by automated scheduling.

Abstract— *The product quality in semiconductor manufacturing is ensured with 100% inspection at each process step; hence inspection tools quickly run out of capacities resulting in the production cycle delays. To best utilize the production and inspection capacities, existing sampling (static, dynamic and smart) strategies are based on the risk and delays. These strategies, however do not guarantee a reliable lot sample that represents a likely yield loss and there is a high risk of moving a bad production lot to next production steps. We present a 3-step yield aware sampling strategy to optimize inspection capacities based on the likely yield loss with the predictive state (PSM) and alarm (PAM) models as: (i) classify potentially suspected lots, (ii) cluster and/or populate suspected lots in the priority queues and (iii) apply last in first out (LIFO) to optimize capacities. This strategy is implemented with two heuristics. We also present a data model with ASCM (Alarm and State Control Management) tool for the multi source data extraction, alignment and pre-processing to support the validation of [PSM, PAM] predictive models.*

Keywords: sampling strategy, tool capacity optimization, yield prediction

1. Introduction

The SI has revolutionized our daily lives with electronic chips that can be found in almost all the equipments around us and follows the slogan smaller, faster and cheaper driven by Moore's law [1]. It postulates that the number of transistors shall double in every 18 to 24 months at reduced cost and power. Since then the SI has kept its pace as per Moore's law by continuously investing in R&D for the new technologies. New equipments are being manufactured to support and keep up with the emerging demands and the pace defined by the Moore's law. The equipments are highly expensive; hence decisions to purchase new production equipments are based on the business strategy and estimated ROI (return on investment). The metrology/inspection tools carry fixed costs and often phase out or need changes to cope up with the new emerging technologies; hence efforts are made to use the capacity optimization strategies to balance the inspection load instead of purchasing new inspection tools.

An electronic product (chip) undergoes the most complex manufacturing process with approximately 200 operations, 1100 steps and 8 weeks of processing. The sequences of operations to manufacture an electronic chip (transistors and interconnections between transistors) are classified as the FEOL (front-end-of-line) and BEOL (back-end-of-line) processes. The transistor acts like an on/off switch and it is a basic building block in the chip manufacturing. The interconnections are the wire networks that connect these transistors to form an electronic circuit. To ensure the product quality, measurement (metrology/inspection) steps are added within the manufacturing flow almost after every manufacturing step. Here we make decisions based on the parametric yield to either scrap or move the wafer to the next step with an objective to stop bad products consuming expensive resources and production capacities while ensuring the product quality. We know that the inspection tools have limited capacities; hence optimal capacity utilization in a high product mix is a key for success. There are some critical steps as well where the delay due to inspection capacity limitation might have a strong impact on the next production step, so these priority products must be inspected before other products in the queue. Till now the proposed inspection capacity optimization strategies (static, dynamic and smart sampling) are based on the risk, delays and tool capacities, however these strategies do not guarantee a reliable lot sample that represent a likely yield loss.

Let us start with an introduction to a generic production process (Fig.1) where lots are processed and controlled at production and inspection tools respectively to avoid bad lots moving to the next steps. The inspection capacities are always less than the production capacities and to balance the difference we have static, dynamic and smart sampling strategies. It can be viewed as a blind strategy with a high risk of skipping bad lots to the next steps whereas in our strategy we empower the control with PSM and PAM models to filter good and bad lots followed by capacity optimization. We argue that for a given product yield e.g. 85% the focus must be on finding and controlling the 15% bad products than inspecting 100% product using blind inspection strategies that do not differentiate between bad/good products. In this paper we present a yield aware sampling methodology that identify the potential inspection lots as good, bad or suspected and then only bad or suspected lots are potentially inspected while skipping the good lots to move to the next production steps. Inspection waiting queues are established

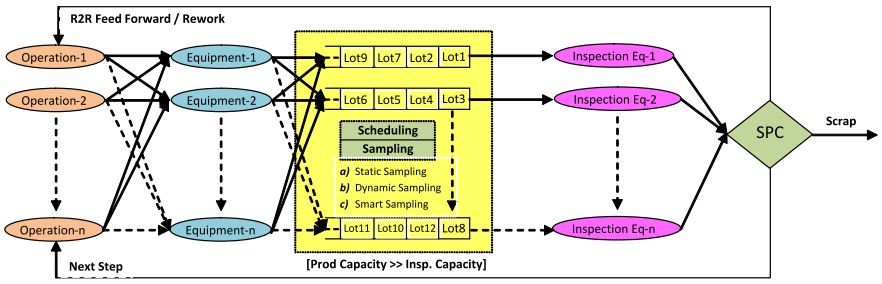

Fig. 1: Generic production process with existing sampling strategies.

and a second level optimization based on LIFO is applied to further save the inspection capacities as (i) inspections lots are clustered based on the product type and process recipe and (ii) if a potential lot results in a bad lot than all lots in the same cluster manufactured before the inspected lots are scarped. The success of this approach depends on the accuracy of learning and classification algorithm for PSM and PAM models. We propose two heuristics, first for the PSM and PAM models and second to cluster the suspected lots and applying queue optimization. A tuning parameter is also provided at the discretion of the user to control the PSM and PAM prediction confidence levels. In order to support the strategy we have also proposed a data model and ASCM tool for data extraction, alignment and pre-processing to support PSM and PAM model validations.

We have divided this paper in 4 sections. Section-1 provides a brief introduction to the semiconductor industry, problem context and the proposed methodology. Section-2 presents the literature review on the existing sampling strategies proposed and being used for capacity optimization. The proposed approach, heuristic algorithms, data model and ASCM tool are presented in the section-3. Finally we conclude this paper with discussion and future perspectives in sections 4 and 5.

2. Literature review

Chip manufacturing has become a complex but expensive production process resulting in process control challenges to find the lots with yield issues before they consume the expensive production resources. Limited inspection tools capacities has a strong impact on the production cycle times, hence an efficient sampling and control strategy is required to optimize the capacities and economic benefits. We have divided our research in two distinct areas as (i) we shall present a historical brief review on the interaction of product quality and process that lead to the emergence of SPC (statistical process control) and process control plans to ensure product quality and (ii) sampling approaches to optimize the inspection tools capacities and dynamic adaption of the process control plans.

The measurement tools are categorized as metrology and inspection tools. The metrology tool physically measures the geometric features and the product follows the SPC based control plan that either scraps the wafer or moves it to next production step. The inspections tools are used to find the defects on the surface of wafer right after the critical production steps to mark the bad chips on the circuit. It is important to understand from where the idea of control and product quality emerged or evolved and what are the latest contributions? The design of an economical control for a production process has always been an interesting research area that was initiated by [2] that lack robust results and require a balance between controls and their costs. [3] proposed a control plan with the concept of skipping by decreasing control frequency as compared to a 100% inspection plan. [4] presented that sampling size and frequency as two levels of controls are the better solution to quickly identify the issues while minimizing the cost of errors. [5] introduced the concept of SPC in the semiconductor industry that served as the basis for an updated control plan. Many approaches have been proposed for an adaptive control as (i) sampling strategy based on the number of wafers passed on metrology tools [6], (ii) updating control plan based on process excursions [7] and (iii) updating control plan based on risk encountered during productions. [8] ,[9] have designed a buffer for control machines taking into account the quality and cycle time expectations and it is the latest contribution in research regarding control plans.

Now we move to the second part of the literature where we shall present the inspection capacity allocation (referred as scheduling) problem in semiconductor industry. Existing strategies are classified as static and dynamic where static sampling [10] selects the same numbers of lots but dynamic sampling [6] select the number of lots for inspection, based on the overall production. Smart sampling is a new approach that sample lots by taking into account the risk associated with production tools, inspection tools capacities and delays to dynamically minimize the wafers at risk [11], [12]. It is a better approach than the static and dynamic strategies. In this strategy, if a lot in the waiting queue is controlled and it passes the inspection step then all lots in the waiting queues, processed before this lot are removed with a belief that they are also good lots. But none of them provide an evidence for a likely yield loss against sampled lots resulting in skipping

the suspected lots to move to the next process steps. We need a yield aware strategy to classify good, bad and suspected lots to reduce the inspection load significantly followed by an optimization strategy that exploit the production resources against limiting inspection tools capacities.

From the above literature, it is evident that the inspection capacity allocation problem is linked with the process control plans in the semiconductor industry. If we commit mistakes like skipping the bad lots to the next production steps as the existing approaches do not provide any evidence of likely yield loss then the consequences are evident in terms of customer dissatisfaction and costs. We argue that our focus should be on the identification of the bad or suspected lots while moving the good lots to the next steps. It shall not only increase the inspection capacities but shall also address critical step implications where the max time between two steps is fixed. Our proposed yield aware 3-step strategy uses the predictions made by the PSM and PAM models. Based on the predictive output combinations lots are either added to the priority inspection queues or moved to the next production steps followed by the capacity optimization.

3. Proposed approach

The proposed 3-step yield aware inspection strategy is presented in Fig.2. In our scenario, equipments are composed of 1...n modules in the parent child relationship. These modules are further classified as critical/non-critical and shared/non-shared elements. All the modules are characterized by meters, alarms and states which are recorded in the databases during the production operations. The alarms are generated at the module level, however based on these alarms the automation system changes the states of the child and parent modules. The changes in the states of the child modules serve as the basis for change in the state of parent modules. It represents the equipment health and such information can accurately predict a likely yield loss in the production induced due to unpredictable equipment behavior. The meter data triggers the preventive maintenance operations; however the module level meter data shall be included in the future to compute the weighted probabilities to weight the state and alarm level predictions. The alarms and states data represents the status of the production process and equipment health respectively; hence we use them to learn predictive alarm [PAM] and state [PSM] models.

In the proposed methodology we have used only the states and alarms data; however the module level meter data shall be included in the future to compute the weighted probabilities to refine the state and alarm level predictions. The first step in the inspection strategy is to classify the good, bad and/or suspected lots. In this step we start with the exploitation of the historical equipment states, alarms and SPC (statistical process control) data from the process, maintenance and alarms databases to build predictive state [PSM] and alarm [PAM] models. These models [PSM, PAM] are then used to classify the new production lots as good and/or bad lots and generate four possible outputs: (i) [good, good], (ii) [good, bad], (iii) [bad, good] and (iv) [bad, bad]. The good production lots [good, good] are moved to the next production steps without metrology and bad lots [bad, bad] undergoes the 100% inspection and their results are used to update the prediction [PAM] and [PSM] models.

The suspected lots [good, bad] or [bad, good] are clustered (2nd step) based on the equipment, product and recipe. It follows by a priority queue allocation algorithms (3rd step) that enter the suspected lot clusters into priority queues for further optimization based on LIFO (last in first out) principal. It states that if a suspected lot defies the prediction upon measurement then all the lots in the same cluster shall be subjected to 100% inspection otherwise the cluster members shall be skipped. The predictive state and alarm models [PSM, PAM] are updated with the feedback against all coherent and incoherent predictions as good and/or bad examples. It provides us an intelligent way to reliably sample only bad or potentially suspected lots followed by priority queuing and optimization for the economic benefits.

The step-1 where we learn the predictive [PSM, PAM] models and classify the new production lots as good, bad or suspected lots, is implemented with a heuristic algorithm as presented in section 3.1. The step-2 and step-3 are presented with a flow chart in section 3.2 that corresponds to the clustering and priority queue optimization.

3.1 Heuristic algorithm for predictive models

The alarms and states data collected from the equipment is not trivial to be used with the existing classification and pattern sequence learning algorithms; hence we have proposed a heuristic algorithm to predict the given wafer W^j as a good or bad. The time required for a production operation vary from 30 minutes to 4 hours and during operation a series of set of equipment states and alarms are generated. It is evident that data collected is a matrix of sets of alarms and states. Our proposed algorithm is simple and is based on probabilistic likely hood with the previous inspections. We start with the presentation of the variables used in the algorithm as under:

The $T^{[Ei]}$ is a tuning parameter and is defined by the user to tight the prediction and it is used to optimize the inspection capacities utilization, if required. For example, if user set its value to 50%, it means that computed likely hood shall be compared with this target prior to [good, bad] predictions. It is also important to note that the historical data shall be used to populate alarms and states matrixes for all equipments; however a confusion matrix [C] shall comprise of duplicated states and alarms sets found in both good and bad matrixes.

Proposed algorithm for the prediction of [PSM, PAM] model is as under. We start with the learning by computing good, bad and confusion matrixes of alarms and states

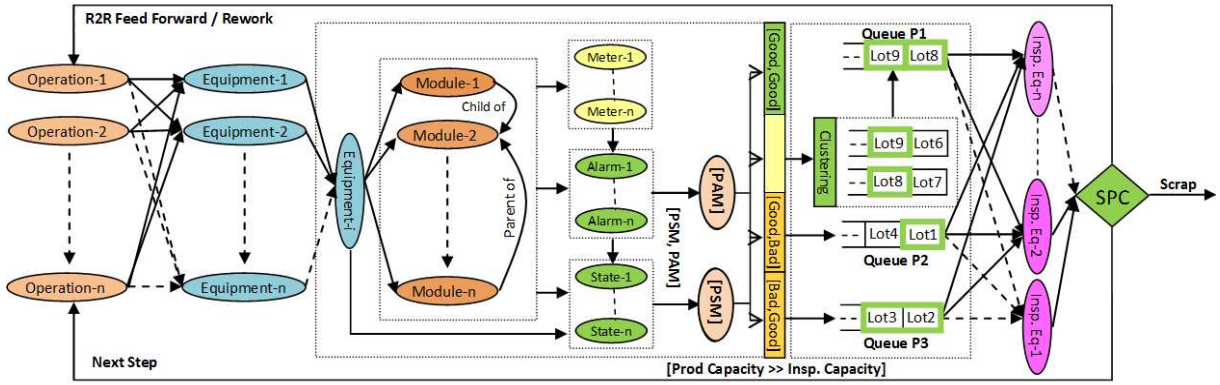

Fig. 2: 3-step methodology with predictive state (PSM) and alarm (PAM) models.

Table 1: Description of variables

Notations and Variables	Description
[G,B,C]:	G→Good, B→Bad, C→Confusion
$[E^i, W^j]$:	E^i → Equipment(i), W^j → Wafer(j)
$M^{[A,S,E^i,W^{i.9}]}_{[G,B,C]}$:	Matrix for alarms and states historical data for equipment E^i
$M^{[A,S,E^i,W^{i.9}]}_{[G,B,C]}(\sum_{j=1}^{n}[a_j, s_j])$:	Matrix for [G,B,C] alarms and states for all equipments and wafers
$M\sum_{j=1}^{n}[a_j, s_j]^{E^i}_{W^j}$:	Matrix for alarms and states sequence for equipment E^i and wafer W^j
$LS_{[G,B,C]}(\sum_{j=1}^{n}[a_j, s_j]^{E^i}_{W^j})$:	Local support for each set of alarms and states in the Matrix for equipment E^i and wafer W^j
$GS^{[A,S,E^i,W^j]}_{[G,B,C]}$:	Global support for alarms and states for equipment E^i and wafer W^j
$T^{[E^i]}$:	Target defined by the user for equipment E^i to be used for model predictions

sequence sets for all equipments as shown in step-1. It shall be used during the computation of the local support. In Step-2, we compute the local support for each set of alarms and states sequence for a given wafer W^j by counting the similar set of alarms or states sequences in [G,B,C] matrixes. This count is divided by the respective count of sequences in [G,B,C] matrixes to get the local support values for each sequence of alarms and states in wafer W^j. Further we compute global support for the wafer W^j by multiplying the local supports computed for each set of alarms and states sequence against [G,B,C] matrixes with the sum of computed local supports. The results are summed at [G,B,C] level for the prediction by comparing it against the $T^{[Ei]}$ in step-4. If the global support is smaller than the $T^{[Ei]}$ then the benefit of doubt is given to the prediction by adding the global support for [C]. Said algorithm for [PSM, PAM] models is presented as under:

Step-1: Compute $M^{[A,S,E^i]}_{[G,B,C]}$ for states and alarms data for each equipment E^i

$$M^{[A,S,E^i]}_{[G,B,C]} = M^{[A,S,E^i,W^{i.9}]}_{[G,B,C]}(\sum_{j=1}^{n}[a_j, s_j]) \quad (1)$$

Step-2: Compute local support for each set of alarms or states sequences for given wafer W^i and equipment E^i

$$LS_{[G,B,C]}(M\sum_{j=1}^{n}[a_j, s_j]^{E^i}_{W^j}) = \text{Count}(M\sum_{j=1}^{n}[a_j, s_j]^{E^i}_{W^j} == M^{[A,S,E^i,W^{i.9}]}_{[G,B,C]}[\sum_{j=1}^{n}[a_j, s_j]])/\text{Count}(M^{[A,S,E^i,W^{i.9}]}_{[G,B,C]}[\sum_{j=1}^{n}[a_j, s_j]]) \quad (2)$$

Step-3: Compute global support for a given equipment E^i and wafer W^j

$$GS^{[A,S,E^i,W^j]}_{[G,B,C]} = \text{Sum}(\text{Sum}(LS_{[G,B,C]}\sum_{j=1}^{n}[a_j, s_j]^{E^i}_{W^j}) * LS_{[G,B,C]}[M\sum_{j=1}^{n}[a_j, s_j]^{E^i}_{W^j}]) \quad (3)$$

Step-4: Predict [PSM,PAM] output for the given Wafer W^j

If $(GS^{[A,S,E^i,W^j]}_{[G]} \geq T^{[E^i]}) \Longrightarrow$ Good

eleseif $(GS^{[A,S,E^i,W^j]}_{[G]} \leq T^{[E^i]}$ AND $(GS^{[A,S,E^i,W^j]}_{[G]} + GS^{[A,S,E^i,W^j]}_{[C]})) \Longrightarrow$ Good

elseIf $(GS^{[A,S,E^i,W^j]}_{[B]} \geq T^{[E^i]}) \Longrightarrow$ Bad

eleseif $(GS^{[A,S,E^i,W^j]}_{[B]} \leq T^{[E^i]}$ AND $(GS^{[A,S,E^i,W^j]}_{[B]} + GS^{[A,S,E^i,W^j]}_{[C]})) \Longrightarrow$ Bad (4)

To demonstrate the said algorithm we present a simple example with [G,B,C] matrixes for alarms data as under (Fig.3):

3.2 Clustering and priority queue allocation

Based on the predictions from [PSM, PAM] models (section 3.1), we follow the 2nd and 3rd step in the proposed yield aware inspection strategy where suspected lots are clustered and added to the priority queues followed by LIFO optimization. It is presented with a simple flow chart (Fig.5). All production lots with prediction combination [PSM'Good and PAM'Good] are simply skipped whereas other lots are populated in the priority queues P1, P2 and P3 where P1>P2>P3. Lots with the combination [PSM'Bad and PAM'Bad] are first clustered based on the similarity of product, technology and recipe followed by the population of last lot from each cluster in P1. If an inspected lot from the P1 validates the model prediction than its respective cluster members are simply scrapped, otherwise each member of the cluster is inspected and the predictive [PSM, PAM] models are updated. In case of difference in model predictions, lots are declared as suspected and are populated in the priority queues P2 [PSM'Good and PAM'Bad] and P3 [PSM'Bad and PAM'Good]. The lots from P2 are sequentially inspected; if it defies the models then all lots processed before the inspected lot in P2 are given the benefit of doubt and are skipped. If a lot inspected from the P3 defies the model then all the respective cluster members are inspected and predictive [PSM, PAM] models are updated for coherences and incoherencies.

It is evident from the above discussion that the [PAM] predictions have higher priority than the [PSM] predictions based on the two facts, (i) child modules influence the states of their parent modules, hence prediction model developed at the module level might have a dual impact and (ii) alarms count and duration result in the change of state of the modules. The states data is an aggregation of the alarms data at module level, hence alarms data provide more low level detailed information with no influence on the alarms of parent modules. Based on these facts in this proposed methodology we have given higher priority to PAM prediction while performing information fusion of modules alarms and states data. The [PSM, PAM] prediction weights shall be defined in the future by including the meter data. The meter data is very critical because the values of the meters initiates the preventive maintenance actions on modules. We believe that it shall play a pivotal role in defining the prediction accuracies of the PAM model. The alarms and resulting prediction shall get more weigh when meter data fall within the distribution of previous preventive maintenance actions.

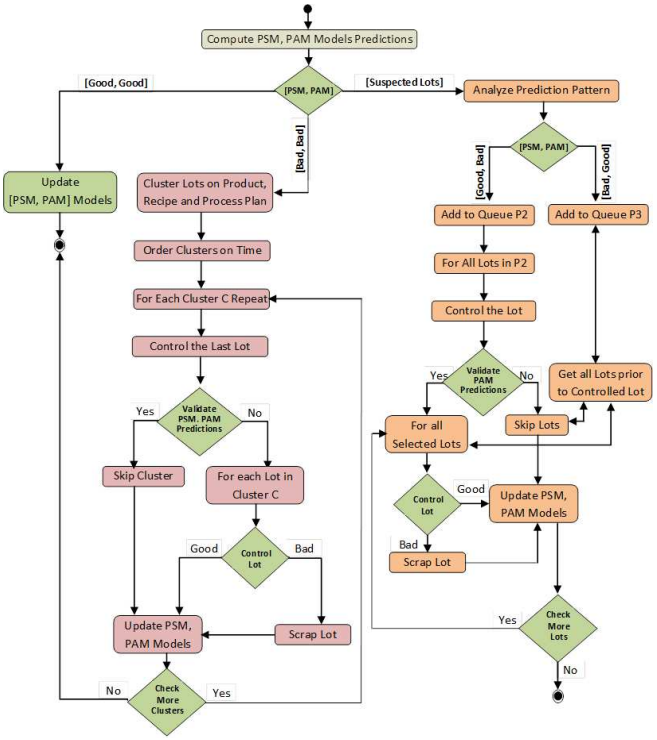

Fig. 5: Flow chart for clustering and queue allocations.

3.3 Data model and ASCM tool for data extraction, alignment and pre-processing

The biggest challenge in building and deploying these PAM and PSM predictive models is the multi-source data extraction, alignment and preprocessing from SPC, maintenance, process and alarms data sources. To facilitate this we have also proposed a data model (Fig.6) with the ASCM (Alarm and State Control Management) tool that allows engineers a quick extraction and alignment of the data.

In this data model the equipments (equipment class) are composed of modules (module class) and every module has a state (state_history class) and alarms (module_alarms class) history. The usage meter data is also available (usagemeter class) but in this paper we have not used this data. The parent-child associations between modules are captured by the parent_child_relation class. A product (product class) is manufactured using multiple lots (lot class) but follows a single process plan (process_plan class). The process plan has multiple operations (process_operation) and each operation can have multiple steps (process_steps). The process

step undergoes different step runs (step_run class) as the production or metrology runs The production step runs are associated with the equipments who have the capability (equipment_capability class) to perform the process steps. This data model is translated into a relational database which is implemented using SQL server to support the ASCM tool.

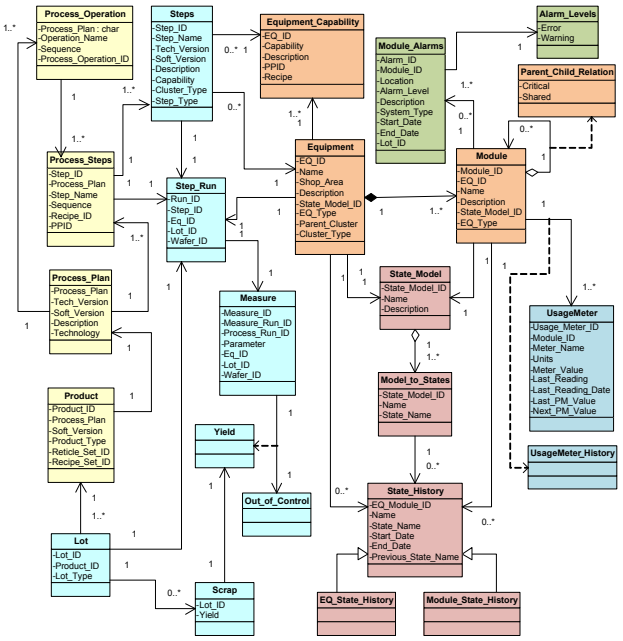

Fig. 6: Data model for extraction, alignment and processing..

A software tool is developed for the R&D engineers to extract data from SPC, maintenance and alarms databases in VB 6.0. The extracted data from different data sources are populated in the database developed as per above data model (Fig.6). Engineers are made capable to analyze and manage the data prior to the extraction for [PSM, PAM] model building. At present the tool is under revisions for the online inclusion of [PAM, PSM] model synchronization and validations. Few interfaces of the developed tools are presented below (Fig.7). This tool provides engineers the facility to analyze the real time state and alarm data at module levels for all the equipments. The states and alarms based pareto analysis result in the identification of insignificant states and alarms which are then put in quarantine to further improve the accurate prediction and classification of the [PSM, PAM] models. This tool also help the engineers to quickly identify best and worst equipments for the data extraction to be used during the [PSM, PAM] learning step.

The first interface provides computed statistics on every equipment being controlled and monitored for the PSM and PAM models. It provides quick information about the best and the worst equipment where the pareto count is based on either number of alarm counts or duration of these alarms. The equipment engineer manages the skipping of non critical alarms which are defined and grouped at the equipment

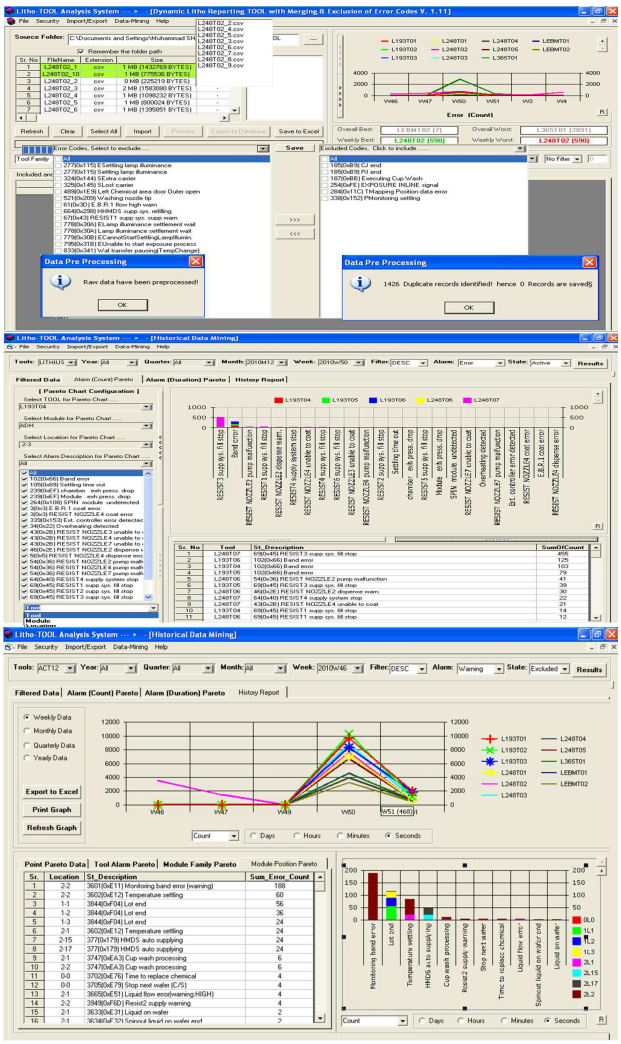

Fig. 7: ASCM Tool for extraction, alignment and pre-processing.

type level. This configuration is updated and further used to filter the unwanted alarms quarantined by the equipment experts. These alarms could easily add up the confusion matrix if not filtered because they have no direct link either with good or bad predictions. The second interface provides the capability to exploit and analyze the alarms data at the equipment and module levels based on the pareto analysis. The third interface provide an option for the point based alarms analysis. All these efforts are put together by the equipment engineers to update the filters list so that accurate and more complete alarms data is extracted to be used for PSM and PAM models.

4. Discussion and conclusions

Existing static, dynamic and smart sampling strategies for inspection are focused on the tool capacity optimization based on risk, delay and capacity. These strategies do not

guarantee the selection of lots with a likely yield loss that can result in serious consequences as if the bad product lots are skipped to the next production steps. These strategies can also be viewed as the blind optimization strategies but risk minimization justifies its adoption in the production line.

Our methodology provides an innovative intelligent sampling strategy that filters the lots as good and suspected lots where suspected lots are further sampled to optimize the inspection tools capacities using clustering and queue allocation algorithm. Our contributions include (i) data model that provide means to extract, align and exploit historical states, alarms and yield data from multiple data sources, (ii) 3-step data mining methodology that generates the PSM and PAM models and (iii) algorithms that perform priority queue allocation and selection of suspected lots for the inspection or its waiver.

We conclude that multi-source information fusion for the prediction models provides an excellent inspection capacity gains in the production line. These gains are very critical because they help us with additional inspection capacities that can be used by the R&D teams to perform more measurements. It is critical because newly emerging spatial variations that often result in increasing costs and lead times, require more measurements to model these variations.The production lots have the highest priority in the production line but unnecessary metrology results in increasing the production cycle times as well. So it is a win-win situation for both production and R&D engineering teams. The required inspection/metrology capacities are spared by reducing unnecessary metrology from the production and they are used by the R&D engineers to improve the technology. It helps us in reducing the production cycle times as well.

It is an important to identify the levels of the PAM and PSM models e.g. product, operation, recipe, equipment or a given technology. We also need to find an optimum policy to test the accuracy of these models based on which the self correction mechanism may be controlled, however in the proposed 3-step methodology, our self correction policy follows the defiance from PAM and PSM predictions. It requires a rigorous analysis on the alarms and states data.

5. Future perspectives

We are validating our methodology with different case studies at the world reputed IDM (integrated device manufacturer) and results shall be published soon. We are also testing our approach with the machine learning based classification and clustering algorithms in comparison with our heuristics. We shall improve our heuristics by adding the capability to compute local support on the partial likely hood with the weighted probability assignments. We believe that it shall improve the performance of our proposed heuristics. Further we are also working to take into account the usage meter data associated with each module in the equipment. The weighted probabilities shall be computed based on the usage meter to take into account the equipment status that can potentially impact the output of the production process.

The proposed approach improves the metrology/inspection tool capacities but makes it difficult to compute the process and machine Cpk and Cmk capabilities. The process capability is an excellent performance indicator to demonstrate the production robustness to the potential customers, however we believe that the newly emerging domain of VM (virtual metrology) shall provide sufficient metrology/inspection information to estimate the Cpk and Cmk indictors. The VM and yield aware metrology/inspection strategy shall help in significantly improving the capacity issues while maintaining the computation of the process and machine (Cpk, Cmk) indicators.

This domain is not yet exploited by the researchers at all and thats why that industrial engineers are using blind optimization strategies to improve the capacities. The semiconductor manufacturing domain is very complex but highly competitive and is characterized by the fastest change in the shortest possible time. The success of the future SI business model heavily depends on their capability to improve the waste of resources from non productive metrology/inspection steps. The machine learning and artificial intelligence are the domains that must come up and take control of these challenges.

Abstract *- Recently, there has been a surge of diverse approaches to investigate leaf vein patterning, covering genetic analyses, pharmacological approaches and theoretical modeling. Genetic and pharmacological approaches remain at this stage insufficient for analyzing the formation of vascular patterns since the molecular mechanisms involved are still unclear. Similarly, theoretical models are not sufficiently constrained, and thus difficult to validate or disprove. Only few exceptions attempted to provide a link between experimental and theoretical studies by implementing different imaging techniques. Visual imaging methods have been lately extensively used in applications that are targeted to understand and analyze physical biological patterns, specifically to classify different leaf species and quantify leaf venation patterns. There is a rich literature on imaging applications in the above field and various techniques have been developed. However, current methods that aimed to provide high precision results, failed to avoid manual intervention and user assistance for the developed software tools. In this paper, we introduce a fully automated imaging approach for extracting spatial vein pattern data from leaf images, such as vein densities but also vein reticulation (loops) sizes and shapes. We applied this method to quantify leaf venation patterns of the first rosette leaf of Arabidopsis thaliana throughout a series of developmental stages. In particular, we characterized the size and shape of vein network reticulations, which enlarge and get split by new veins as a leaf develops. For this purpose, the approach uses imaging techniques in a fully automatic way that enables the user to batch process a high throughput of data without any manual intervention, yet giving highly accurate results.*

Keywords: *fully automation; leaf venation pattern; feature extraction; feature quantification; adaptive thresholding*

1 Introduction

Over the past few years, there has been a resurgence of interest in the leaf vein patterning. Traditional strategies include genetic analyses, pharmacological approaches, and theoretical modeling. Most recently, quantitative studies attempted to provide a link between theoretical and experimental methods. Many quantitative studies of leaf venations patterns have resurged with the sole aim of quantifying the response of plants to changing environments and to breed plants that can respond to such changes. Unfortunately, most of the suggested empirical analyses have failed to provide a quantitative study of the complete leaf vascular network [1],[2]. One major recent approach successfully provided a quantitative study of the complete leaf venation network [3]. The aforementioned approach proposed to quantify vein patterns spatially at the tissue level throughout leaf development. The venation forms a complex network composed of veins of different orders within the leaf tissue. Higher-order veins differentiate within loops that enlarge with the leaf growth. Therefore, quantifying vein patterns spatially at the tissue level in terms of loop shapes and sizes, in addition to vein densities, has brought new insights into patterning mechanisms. It has provided the necessary spatial resolution that was lacking in traditional methods. The procedure developed to extract venation patterns from leaf images consisted of measuring the leaf vascular network parameters by digitizing the vein segments using a user interface: points along each segment were recorded manually leading to a matrix representing all vein segments on the leaf. From the extracted series of vein segments, the topology of the network was calculated allowing the identification of each vein segment and loop. The number and position of branching points and free ending points were also recorded. Finally, the complete venation pattern and leaf outline for each sample was stored in matrix form. Such an approach proved to be efficient on the resolution side. Nevertheless, it is time consuming and painstaking especially when the throughput is high. The approach [3] tried to solve this issue by automatically digitizing veins using unpublished software. Nevertheless, the software was not sufficiently accurate to replace the manual technique described in [3]. Another recent work developed a user-assisted software tool (LEAF GUI) that extracts macroscopic vein structures directly from leaf images [4]. The software tool takes an image of a leaf and, following a series of interactive steps to clean up the image, returns information on the structure of that leaf's vein networks. Structural measurements include the dimensions, position and connectivity of all network veins, in addition to the dimensions, shape and position of all non-vein areas, called areoles. Although the tool is meant to enable users to automatically quantify the geometry of entire leaf networks, it unquestionably needs user assistance and intervention at

several steps of the images preprocessing, and cleaning. Many fully automated image-based algorithms have been in vain proposed for analyzing the leaf venation patterns. For instance, two approaches, one involving scale-space analysis and another including a combination of edge detectors [5], have been implemented to assess the digitization results of 5 test leaf images compared to the results of a manual technique that uses Adobe Photoshop. The main encountered problems were the presence of too many artefacts in the resulting processed images due to inappropriate smoothing and edge detection. Moreover, the scale-space technique was criticized for it resulted in broken venation structures.

Here, we propose a fully automatic approach based on the work described in [3]. Our approach is able to quantify the vein patterns of the first rosette leaf of *Arabidopsis thaliana* by processing 135 images provided by [3], without the need of any user assistance. It also stores the leaf venation pattern for every sample in a matrix, yet giving the same spatial accuracy as with the manual method, while significantly speeding the analysis process. The algorithm is developed in MATLAB and is based on different imaging analysis techniques including noise cleaning, adaptive thresholding, edge detection, and skeletonization.

2 Image analysis and pattern extraction

The image dataset collected for [3] was kindly provided to us by the authors. The available leaves images correspond to patterns of differentiated xylem elements. Fifteen leaves images were captured each day for nine days: from eight to sixteen days after sowing (DAS). The images were stored as jpg into 9 different folders corresponding to each DAS day. However, the algorithm can process any other image format (tif, gif, png, bmp).

Custom programs were developed to obtain quantitative pattern data from the first rosette leaf of Arabidopsis thaliana images using MATLAB. The main goal of our algorithm was speeding up the process of leaf venation pattern extraction while keeping the same spatial accuracy of the manual method [3]. To achieve a practical method that enables high throughput image analysis, it is essential to fully automate the software by avoiding any manual intervention. The main challenge remains the accuracy of the results without requiring any user assistance. Our task was made harder with the presence of noisy images with low contrast and uneven varying illumination resulting from the fact that the images were captured at different harvesting times (Fig. 1a). To resolve these issues, we incorporated different image processing techniques into the algorithm. The main steps performed by our algorithm are described as follows for a given input image: (1) Converting the rgb image into a grayscale image, (2) Performing homomorphic filtering of grayscale image, (3) Denoising and enhancing the grayscale image, (4) Removing border, (5) Thresholding the image, (6) Skeletonizing and processing the image, and (7) Extracting and quantifying the venation pattern features. All the steps do not require any user intervention since they are fully automated. Next we describe in details the overall process that our algorithm performs to process a leaf image and measure characteristic features of the corresponding venation structure.

Step 1: Converting the rgb image into grayscale image

When converting from an rgb image to a grayscale image, the value of each pixel in the resulting image is a single sample that only represents the intensity information. The range of intensities varies from absolute black (0) to absolute white (255).

Step 2: Homomorphic filtering of the image

To better improve the illumination and contrast of the image, homomorphic filtering is applied [6]. An image is a function that is expressed as the product of reflectance and illumination $F(x,y) = I(x,y).R(x,y)$. In order to separate reflectance and illumination, the function can be expressed as a logarithmic function wherein the product of the Fourier transform can be represented as the sum of the illumination and reflectance components $\ln(x,y) = \ln(I(x,y)) + \ln(R(x,y))$. The Fourier transform of the previous equation is $Z(u,v) = F_I(u,v) + F_R(u,v)$. A filter function H(u,v) is applied to the Fourier transformed signal where

$$H(u,v) = (\gamma_H - \gamma_L)[1 - e^{-cD(u,v)^2/Do^2}] + \gamma_L \quad (1)$$

The constant c controls the sharpness of the slope of the filter function as it transitions between γ_H and γ_L, D_0 is the cutoff frequency and D(u,v) is the distance between (u,v) and the frequency origin. H(u,v) is designed such that it tends to decrease the contribution made by low frequencies (illumination, $\gamma_L<1$) and amplify the contribution made by high frequencies (reflectance, $\gamma_H>1$). Next, the resulting function is inverse Fourier transformed. Finally, the inverse exponential operation yields an enhanced image.

Step 3: Denoising and enhancing the image

It is essential to attenuate the presence of background corresponding to the leaf blade and the rest of the image with respect to the foreground represented by the veins. Therefore, applying a denoising technique that cleans the background, which is considered as the unwanted part of the image, is crucial. A non-orthogonal wavelet denoising technique is used here [7]. One of its main characteristics is that it preserves the phase information, which is fundamental to the human visual perception. Also, this technique is capable of determining denoising threshold levels automatically. Nevertheless, the denoising step affects the venation structure for it attenuates the pixels intensities, including the vein pixels. Therefore, enhancing the image contrast is mandatory at this stage of the image processing chain. For this purpose, histogram equalization is applied, where a gray-level transform is used to flatten the histogram of the denoised image. Then, linear contrast stretching is applied to the

Figure 1. Arabidopsis leaf harvested at DAS 16: Processed images corresponding to the 7 automated steps of the leaf image processing

enhanced image where the value in the low end of the resulting histogram is assigned to extreme black (0) and the value at the high end to extreme white (1).

Step 4: Removing border

In order to remove the leaf perimeter, we need first to identify the leaf lamina from the rest of the image. This is achieved by applying global thresholding where pixels with intensities above a certain thereshold are set to 1 (leaf pixels) and pixels with values lower than the threshold are set to 0 (background pixels). The resulting image shows the entire leaf blade in white while the remaining image is black. Next, cropping is applied to the white contour corresponding to the leaf blade perimeter, by applying morphological erosion that uses a disk of n pixel diameter as a structural element. Finally, all the pixels of the eroded white area are preserved in the original image, while the values of the remaining pixels corresponding to the black area are set to 0.

Step 5: Thresholding the image

Thresholding is applied to extract the vein segments of the leaf from the rest of the image. Since leaves harvested on the same day showed uneven illumination in the same image, it was difficult to find a standard value for the threshold value that could be applicable to all images. Thus, adaptive thresholding is used by automatically calculating the

discriminative threshold from the corresponding image histogram. The histogram of any leaf image shows three main gray scale level ranges: a lower one that corresponds to the background of the image, a middle one that corresponds to the leaf blade, and a higher one that corresponds to the leaf veins. Therefore, the higher gray scale level region is of interest for our thresholding. Since the histogram showed additional peaks corresponding to the small variations resulting from high frequency noise, histogram smoothing is performed by applying a weighted averaging filter that acts as a low-pass filter for the histogram. As a result, the smoothed histogram shows three peaks that are separated by two main valley points. The value of the lowest valley point is computed by finding the gray scale level that corresponds to the first local minimum of the histogram function. After excluding the gray scale level values that are lower than the computed valley point, the resulting histogram (consisting now of two peaks) is used to find the optimal threshold separating the gray level values of the leaf blade from the gray level values of the leaf veins. Global thresholding using Otsu's method [8] is thus applied to the new histogram. The final thresholded image represents the venation pattern of the leaf.

Step 6: Skeletonizing and processing the image

Thinning is then performed by skeletonizing the resulting leaf venation structure. Skeletons represent a powerful tool for qualitative shape matching as they can effectively represent both the object shape and its topology. A thinning process is used in our approach to guarantee the condition of obtaining one-pixel thick and connected skeletons. If the skeleton is considered as a connected graph, each vertex can then be labeled as an end point or a branching point. A pixel is defined as an end point if it has a single connected pixel among its 8 neighborhood pixels. A pixel is defined as a branching point if it has more than two connected pixels among its 8 neighborhood pixels. A segment connecting two adjacent vertices is defined as a branch. Skeletonization is followed by image cleaning, which consists of removing unwanted connected blogs below a certain size threshold. For instance, all connected blog regions smaller than 10 pixels are removed.

In order to reinforce our algorithm as a fully automated technique, we need to avoid any broken contour that might result from thresholding and any extraneous spurs that might occurr after skeletonization. A gap filling function was developed to join all the disconnected edges that are supposed to be connected. The function consists of considering all end points of the skeleton and check if they were connected in the original image of the leaf before thresholding by calculating the average intensity of the pixels joining the two end points in the prethresholded image. If the computed value is lower than a preset threshold, the two end point pixels are considered not initially connected and the gap is not filled. If the computed value is higher than the threshold, then the gap between the two end point pixels is filled. This step is followed by cleaning all connected objects that are smaller than the largest connected object (venation structure). This guarantees to clean any other concomitant unwanted leaves or intruders present with the main leaf in the image, which in turn avoids the time-wasting step of manually removing any extraneous features.

On the other hand, extraneous spurs are pruned by considering all branch segments having an end point and a branching point as its vertices. If the branch segment length is smaller than a preset threshold, it is removed.

Step 7: Extracting and quantifying the venation pattern features

Using the known coordinates of the branching points and end points along each vein segment, we could record segment parameters. We could also automatically record the number and position of branching points and free-vein endings. Loops could also be identified by automatically counting the number of closed elements. The latter correspond to elements starting at one node and ending at the same visited node. The area of the blade is computed by finding the area of the white blog resulting from the aforementioned Step 4. As for the length of the venation structure, it is computed by summing the number of pixels of the final processed skeleton.

3 Results and discussion

Software was developed in the lab to extract venation patterns from leaf images. Fig. 1 shows the different images resulting from the processing steps described above. The case of a leaf harvested at DAS 16 was selected on purpose to highlight the efficiency of our algorithm when applied to a complex venation structure. Fig. 2 displays a comparison of the results between the manual and the proposed techniques. The first rosette leaves of Arabidopsis from the [3] data set grew throughout the period analyzed (from 8 to 16 days after sowing), with a decrease in growth rate after 14 days from sowing for both non-automated and automated methods (Fig. 2a). The vein density for each leaf was calculated as the total vein length across the leaf divided by the whole leaf area. The average leaf vein density is shown in Fig. 2b and shows that venation decreases over the period analyzed. The vein density has an obvious decreasing rate starting 12 days after sowing, which is consistent with the results of the non-automated approach. The mean loop number per leaf and the mean segment number per leaf for each day are shown in Figs. 2c, d. Both techniques showed similar plots where loop numbers from day 12 till day 16 and segment numbers from day 13 till day 16 were not significantly different. Free vein ending and branching point densities were calculated as number of free vein endings and branching points per unit leaf area (mm^{-2}) (Figs. 2e,f). Free vein endings showed significant similarities in mean densities of free vein endings between the plots of the non-automated and automated methods. Both techniques showed that free vein ending densities varied considerably between days. We observed comparable results for the

branching point densities where the observed increase in branching point densities between day 8 and day 10 in the automated plot (Fig. 2f) was consistent with the non-automated results.

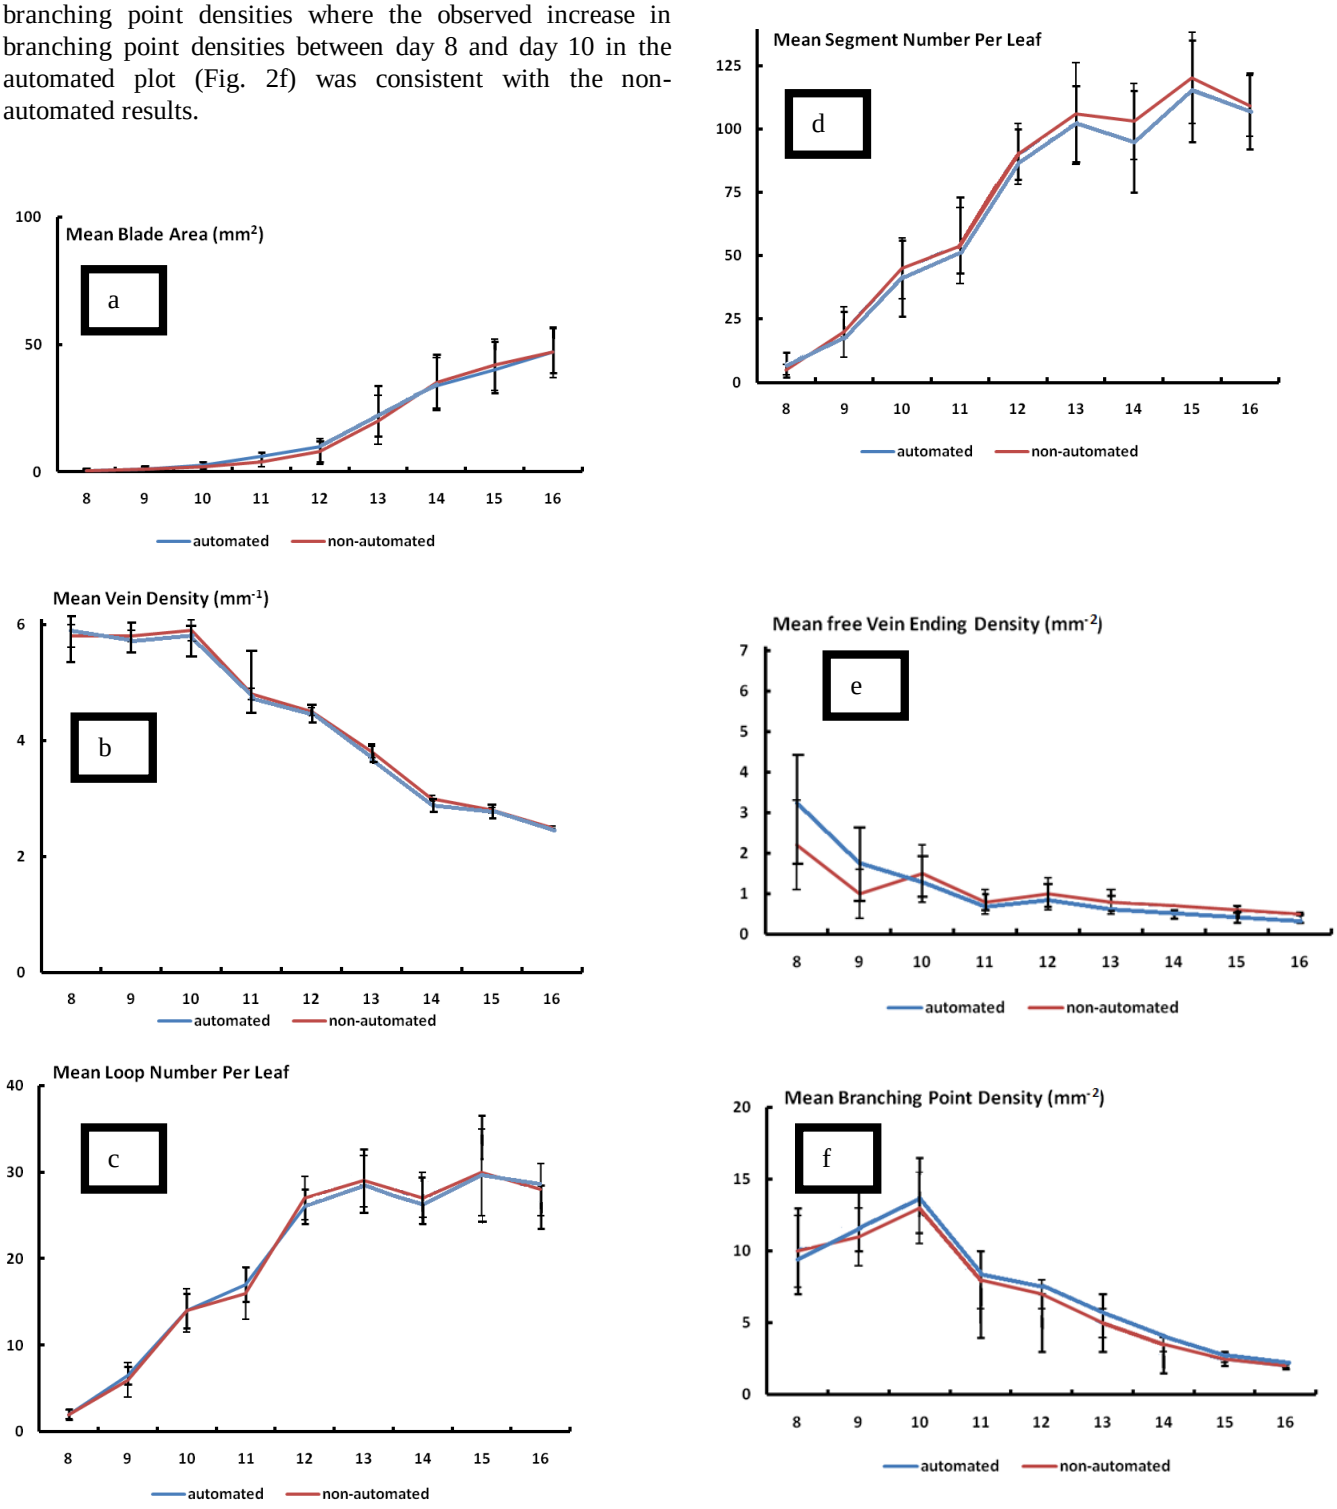

Figure 2. Plots of automated and non-automated temporal analysis of veins patterns in first rosette leaf of Arabidopsis.

4 Conclusions

We developed a method to automatically process and quantify leaf vein patterns using a series of image processing techniques and applied it to the analysis of vein pattern formation during leaf development in the first rosette leaf of Arabidopsis. Our work has the advantage of fully automating the extraction and analysis of leaf venation patterns without any user assistance. Therefore, it speeds up the analysis and allows large scale comparative analyses of vein patterning. To our knowledge, there is no available software that allows for an efficient extraction and analysis of the leaf venation

pattern using fully automated programs. Therefore, our algorithm might be considered a reliable tool that can be used by plant biologists to assess their manual results rapidly and under various conditions.

5 Acknowledgments

We would like to thank Prof. Anne-Gaëlle Rolland-Lagan for kindly providing us with the dataset of the Arabidopsis leaves and for her helpful comments on the draft of this paper.

A Proposed Feature Extraction Method for EEG-based Person Identification

Phuoc Nguyen, Dat Tran, Xu Huang and Dharmendra Sharma
Faculty of Information Sciences and Engineering
University of Canberra, ACT 2601, Australia

Abstract— *We propose in this paper a feature extraction method to extract brain wave features from electroencephalography (EEG) signal. The proposed feature extraction method is based on an assumption that EEG signal could be considered as stationary if the time window is sufficiently short. With this assumption, EEG signal has some similar properties to speech signal and hence a feature extraction method that is currently used to extract speech features can be applied to extract brain wave features from EEG signal. Mel-frequency cepstral coefficients are features extracted and evaluated in EEG-based person identication. Experimental results show that the proposed method could provide very high recognition rate.*

Keywords: EEG, Person Identification, Brain Computer Interface

1. Introduction

Brain Computer Interface (BCI) has been considered as a new communication channel that uses brain activity as reflected by electric, magnetic or hemodynamic brain signals to control external devices such as computers, switches, wheelchairs, or neuroprosthetic extensions [1]. A BCI system can be classified as an invasive or non-invasive BCI according to the way the brain activity is being measured within this BCI. If the sensors used for measurement are placed within the brain, i.e., under the skull, the BCI is said to be invasive. On the contrary, if the measurement sensors are placed outside the head, on the scalp for instance, the BCI is said to be non-invasive [2]. The non-invasive BCI systems avoid health risks and associated ethical concerns. A typical non-invasive BCI system includes the following stages: data acquisition, data pre-processing, feature extraction, classification, device controller and feedback [3].

In invasive BCIs, electrodes or a multiunit electrode array will be placed directly inside the cortex to record electrical potentials for subsequent analysis of the electrocorticogram (ECoG). Brain signals obtained have a superior signal-to-noise ratio, need little user training, and are suitable for replacing or restoring lost motor functions in patients with damaged parts of the neuronal system [3]. Noninvasive BCIs, on the other hand, can use a variety of brain signals as input, for example, electroencephalography (EEG), magnetoencephalography (MEG), functional magnetic resonance imaging (fMRI), and near infrared spectroscopy (NIRS). MEG, fMRI, and NIRS are expensive or bulky, and fMRI and NIRS present long time constants in that they do not measure neural activity directly—relying instead on the hemodynamic coupling between neural activity and regional changes in blood flow—they cannot be deployed as ambulatory or portable BCI systems [4]. As a result, the majority of promising non-invasive BCI systems to date exploit EEG signal, mainly due to its fine temporal resolution, ease of use, portability and low set-up cost.

The use of brain wave patterns for person authentication has been investigated at IDIAP in Switzerland [5]. It has been shown that the brain-wave pattern of every individual is unique and that the EEG can be used for biometric identification [6]. The use of brain wave patterns as a new modality for person authentication has several advantages: 1) it is confidential because it corresponds to a mental task; 2) it is very difficult to mimic because similar mental tasks are person dependent; and 3) it is almost impossible to steal because the brain activity is sensitive to the stress and the mood of the person, an aggressor cannot force the person to reproduce his/her mental pass-phrase [5].

It has been shown that under the same recording condition EEG signals are low intra subject variability and high inter subject variability. In [7], [9], [10], [11] the subjects were asked to image moving hand, finger, foot or tongue while EEG data was recorded. Then the person recognition tasks were performed for each task separately. In [12] the subjects were asked to look at black and white drawings of common objects, extracted from the Snodgrass and Vanderwart picture set, while EEG signals were recording.

As indicated in [2], although numerous pre-processing, feature extraction and classification methods have been proposed and explored for BCI systems, none of them has been identified as the best method for EEG-based BCIs.

We have found that the EEG signal is a slowly time varying signal in the sense that, when examined over a sufficiently short period of time, depending on the signal between 5 and 100 ms, its characteristics are approximately stationary. However over longer periods of time, the signal characteristics are non-stationary. They change to reflect the sequence of different brain activities. Based on this "quasi-stationarity" which is also observed in speech signal, a reasonable brain wave model should have the following components. First, short-time measurements at an interval

of the order of 10 ms are to be made along the pertinent speech dimensions that best carry the relevant information for linguistic or speaker distinction. Second, because of the existence of the quasi-stationary region, the neighbouring short-time measurements on the order of 100 ms need to be simultaneously considered, either as a group of identically and independently distributed observations or as a segment of a non-stationary random process covering two quasi-stationary regions.

Based on this "quasi-stationarity", a feature extraction method that is currently used to extract speech features can be applied to extract brain wave features from EEG signal. In this paper we consider mel-frequency cepstral coefficients (MFCCs) which are the most popular speech features and extract them from EEG signal. We evaluated this feature extraction method in EEG-based person identication using support vector machine (SVM). Experimental results show that the proposed method could provide very high recognition rate.

2. Speech Features

Speech is a time varying signal. In a long period, speech signals are non-stationary but in a short interval between 5 and 100ms, the speech signals are "quasi-stationary", and the articulatory configuration stays nearly constant. Therefore, speech features are extracted for short frames. The sampled waveform is analysed in frames with short window sizes so that the signals are "quasi-stationary". The frames overlap by setting the frame period smaller than the window size. Each frame is then investigated to extract parameters. This process results in a sequence of parameter blocks [19]. source rate and target rate are the number of samples of the wave source and the number of extracted feature vectors, respectively.

In speech signal processing, the window size is typically between 15 ms and 35 ms long with a period of 10 ms. When adapting to EEG signal processing, we multiply the window size by a factor of 10 due to low frequency signal.

We define a frame of speech to be the product of a shifted window with the speech sequence [21]:

$$f_s(n;m) = s(n)w(m-n) \tag{1}$$

where $s(n)$ is the speech signal and $w(m-n)$ is a window of length N ending at sample m.

2.1 Mel-Frequency Cepstral Coefficients

The filterbank models the ability of the human ear to resolves frequencies non-linearly across the audio spectrum and decreases with higher frequencies. The filterbank is an array of band-pass filters that separates the input signal into multiple components. The filters used are triangular and they are equally spaced along the mel-scale defined by [19]:

$$\mathrm{Mel}(f) = 2595\log_{10}(1+\frac{f}{700}) \tag{2}$$

Mel-Frequency Cepstral Coefficients (MFCCs) are calculated from the log filterbank amplitudes m_j using the Discrete Cosine Transform

$$c_i = \sqrt{\frac{2}{N}}\sum_{j=1}^{n} m_j \cos\left(\frac{\pi i}{N}(j-0.5)\right) \tag{3}$$

where N is the number of filterbank channels, c_i are the cepstral coefficients.

2.2 Energy

These features model intensity based on the amplitude. The energy is computed as the average of the signal energy, that is, for speech samples $s(n), n = 1, \ldots, N$, the short-term energy of the speech frame ending at m is [20]

$$E_s(m) = \frac{1}{N}\sum_{n=m-N+1}^{m} f_s(n;m)^2 \tag{4}$$

2.3 Pitch

The pitch signal, or the glottal waveform, is produced from the vibration of the vocal folds. Two common features related to the pitch signal are the pitch frequency and the glottal air velocity [20]. The vibration rate of the vocal folds is the fundamental frequency of the phonation F_0 or pitch frequency. The air velocity through glottis during the vocal fold vibration is the glottal volume velocity. The most popular algorithm for estimating the pitch signal is based on the autocorrelation [20]. At first, the signal is low filtered at 900 Hz and then it is segmented to short-time frames of speech $f_s(n;m)$. Then the nonlinear clipping procedure that prevents the first formant interfering with the pitch is applied to each frame $f_s(n;m)$ giving

$$\hat{f}_s(n;m) = \begin{cases} f_s(n;m) - C_{thr} \text{if } |f_s(n;m)| > C_{thr} \\ 0 \text{if } |f_s(n;m)| < C_{thr} \end{cases} \tag{5}$$

with C_{thr} is about 30% of the maximum value of $f_s(n;m)$. Next the short-term autocorrelation is determined by

$$r_s(\eta;m) = \frac{1}{N}\sum_{n=m-N+1}^{m} \hat{f}_s(n;m)\hat{f}_s(n-\eta;m) \tag{6}$$

where η is the lag. Finally, the pitch frequency of the frame ending at m can be given by

$$\hat{F}_0(m) = \frac{F_s}{N}\mathrm{argmax}_\eta\{|r(\eta;m)|\}_{\eta=N(F_l/F_s)}^{\eta=N(F_h/F_s)} \tag{7}$$

where F_s is the sampling frequency, and F_l, F_h are the lowest and highest perceived pitch frequencies by humans, respectively. Normally, $F_s = 8000$ Hz, $F_l = 50$ Hz, and $F_h = 500$ Hz [20]. The maximum value of the autocorrelation $\max\{|r(\eta;m)|\}_{\eta=N_w(F_l/F_s)}^{\eta=N_w(F_h/F_s)}$ represents the glottal velocity volume.

2.4 Zero Crossing Measure

The number of zero crossings, or number of times the sequence changes sign, is also a useful feature in speech analysis. The short-term zero crossing measure for the N-length interval ending at $n = m$ is given by [21]:

$$Z_s(m) = \frac{1}{2N} \sum_{n=k}^{m} |sign\{s(n)\} - sign\{s(n-1)\}| w(m-n) \tag{8}$$

where $k = m - N + 1$ and

$$\text{sign}\{s(n)\} = \begin{cases} +1 & if \quad s(n) \geq 0 \\ -1 & if \quad s(n) < 0 \end{cases} \tag{9}$$

2.5 Probability of Voicing

Pitch detection has high accuracy for voiced pitch hypotheses but the performance degrades significantly as the signal condition deteriorates. Pitch extraction for telephone speech is more difficult because the fundamental is often weak or missing. Therefore it is more useful to provide F_0 value and probability of voicing at the same time. The hypothesis is that first, voicing decision errors will not be manifested as absent pitch values; second, features such as those describing the shape of the pitch contour are more robust to segmental misalignments; and third, a voicing probability is more appropriate than a "hard" decision of 0 and 1, when used in statistical models [22].

2.6 Jitter and Shimmer

Jitter and shimmer are micro fluctuations in vocal fold frequency and amplitude. They are correlated to rough or hoarse voice quality. The major difference is that shimmer has irregular amplitude at regular frequency while in contrast jitter has irregular frequency at regular amplitude. The wave in the top picture has irregular amplitude at the third peak and the wave in the bottom picture has irregular frequency at the second peak.

Jitter indicates cycle-to-cycle changes of the fundamental frequency and is approximated as the first derivative of the fundamental frequency [23]. These changes are considered as variations of the voice quality.

$$\text{jitter}(n) = \frac{|F_0(n+1) - F_0(n)|}{F_0(n)} \tag{10}$$

where $F_0(n)$ is the fundamental frequency at sample n. Shimmer indicates changes of the energy from one cycle to another.

$$\text{shimmer}(n) = \frac{|\text{en}(n+1) - \text{en}(n)|}{\text{en}(n)} \tag{11}$$

where $\text{en}(n)$ is energy of sample n.

3. Support Vector Machine (SVM)

3.1 Binary Case

Consider the training data $\{x_i, y_i\}$, $i = 1, ..., n$, $x_i \in R^d$, where label $y_i \in \{-1, 1\}$. The support vector machine (SVM) using C-Support Vector Classification (C-SVC) algorithm will find the optimal hyperplane [24]:

$$f(x) = w^T \Phi(x) + b \tag{12}$$

to separate the training data by solving the following optimization problem:

$$\min \frac{1}{2}\|w\|^2 + C \sum_{i=1}^{n} \xi_i \tag{13}$$

subject to

$$y_i \left[w^T \Phi(x_i) + b\right] \geq 1 - \xi_i \text{ and } \xi_i \geq 0 \ , i = 1, ..., n \tag{14}$$

The optimization problem (13) will guarantee to maximize the hyperplane margin while minimizing the cost of error, where $\xi_i, i = 1, ..., n$ are non-negative slack variables introduced to relax the constraints of separable data problems to the constraint (14) of non-separable data problems. For an error to occur the corresponding must exceed unity (see Eq. (14)), so $\sum_i \xi_i$ is an upper bound on the number of training errors. Hence an extra cost $C \sum_i \xi_i$ for errors is added to the objective function where C is a parameter chosen by the user.

The Lagrangian formulation of the primal problem is:

$$L_P = \frac{1}{2}\|w\|^2 + C \sum_i \xi_i - \sum_i \alpha_i \{y_i ({x_i}^T w + b) - 1 + \xi_i\} - \sum_i \mu_i \xi_i \tag{15}$$

We will need the Karush-Kuhn-Tucker conditions for the primal problem to attain the dual problem:

$$L_D = \sum_i \alpha_i - \frac{1}{2} \sum_{i,j} \alpha_i \alpha_j y_i y_j \Phi(x_i)^T \Phi(x_i) \tag{16}$$

subject to

$$\begin{aligned} 0 \leq \alpha_i \leq C \\ \sum_i \alpha_i y_i = 0 \end{aligned} \tag{17}$$

The solution is given by

$$w = \sum_i^{N_S} \alpha_i y_i x_i \tag{18}$$

where N_S is the number of support vectors. Notice that data only appear in the training problem, Eq. (15) and Eq. (16), in the form of dot product and can be replaced by any kernel K

with $K(x_i, x_j) = \Phi(x_i)^T \Phi(x_j)$, Φ is a mapping to map the data to some other (possibly infinite dimensional) Euclidean space. One example is Radial Basis Function (RBF) kernel $K(x_i, x_j) = e^{-\gamma \|\mathbf{x}_i - \mathbf{x}_j\|^2}$

In test phase an SVM is used by computing the sign of

$$f(x) = \sum_{i}^{N_S} \alpha_i y_i \Phi(s_i)^T \Phi(x) + b = \sum_{i}^{N_S} \alpha_i y_i K(s_i, x) + b \tag{19}$$

where s_i is the ith support vector.

3.2 Multi-class Support Vector Machine

The binary SVM classifiers can be combined to handle the multi-class case: One-against-all classification uses one binary SVM for each class to separate their members from other classes, while one-against-one or pairwise classification uses one binary SVM for each pair of classes to separate members of one class from members of the other. In one-against-one approach, there are $n(n-1)/2$ class pairs decision functions were trained. In test phase, the voting stategy was used as follow: each binary classification was considered to be a voting where votes could be cast for all data points x. The final result was the class with maximum number of votes [25].

4. Datasets

The Graz dataset IIIa in the BCI Competition 2005 (Graz IIIa 2005), Graz dataset A (Graz A 2008) and Graz dataset B (Graz B 2008) in the BCI Competition 2008 come from the Department of Medical Informatics, Institute of Biomedical Engineering, Graz University of Technology for motor imagery classification problem in BCI Competition 2005 and 2008 [26], [27], [28]. The Graz IIIa 2005 dataset contains EEG recordings of 3 subjects. Each subject was required to do cued 4 motor imagery task (left hand, right hand, foot, tongue). The recording was made with a 64-channel EEG amplifier from Neuroscan at 250 Hz with time length 7s for each trial. The Graz A 2008 dataset contains EEG recordings of 9 subjects. This dataset use the same cue-based BCI paradigm as the Graz IIIa 2005. Two sessions on different days were recorded for each subject with 288 trials per session. Twenty-two Ag/AgCl electrodes were used and the signals were sampled with 250 Hz and bandpass-filtered between 0.5 Hz and 100 Hz. The Graz B 2008 dataset consists of EEG data from 9 subjects. The subjects paticipated in two sessions contain training data without feedback (screening), and three sessions were recorded with feedback. It consisted of two classes: the motor imagery (MI) of left hand and right hand. Three bipolar recordings (C3, Cz, and C4) were recorded at sampling frequency of 250 Hz.

The dataset searched and downloaded from the web-based de-identified searchable database Australian EEG Database used in this research consists of EEG recordings of 40 patients. The database consists of EEG records recorded at the John Hunter Hospital [29], near University of Newcastle, over an 11-year period. The recordings were downloaded with the search criteria that the recordings come from the both man and women in various age. The recordings were made by 23 electrodes placed on the scalp sampled at 167 Hz for about 20 minutes.

Table 1: Dataset descriptions (#ses: number of sessions, and length: measured in seconds)

Dataset	#subjects	#tasks	#trials	#ses	length
Graz IIIa 2005	3	4	60	1	7
Graz A 2008	9	4	288	2	7.5
Graz B 2008	9	2	120	5	7.5
Australian EEG	40	free	1	1	1200
Alcoholism (large)	20	2	120	1	1
Alcoholism (full)	122	2	120	1	1

The Alcoholism datasets come from a study to examine EEG correlates of genetic predisposition to alcoholism [30]. The datasets contain EEG recordings of control and alcoholic subjects. Each subject was exposed to either a single stimulus (S1) or to two stimuli (S1 and S2) which were pictures of objects chosen from the 1980 Snodgrass and Vanderwart picture set. When two stimuli were shown, they were presented in either a matched condition where S1 was identical to S2 or in a non-matched condition where S1 differed from S2. The 64 electrodes placed on the scalp sampled at 256 Hz for 1 second. The Alcoholism large dataset contains training and test data for 10 alcoholic and 10 control subjects. The Alcoholism full dataset contains 120 trials for 122 subjects. The summary of those datasets is listed in Table 1.

5. Feature Extraction

We used the open-source Emotion and Affect Recognition toolkit's feature extracting backend openSMILE [31] for extracting brain wave features. Each channel is extracted features individually and then features from all channels are merged together. The features include MFCCs, spectral features, energy, pitch (F0), zero crossing rate, probability of voicing, jitter and shimmer and their statistics functionals [32].

The 8 channels selected are C3, Cz, C4, P3, Pz, P4, O1, O2 which are an extension of [9], except for The Graz B 2008 dataset which has only three channels C3, Cz and C4. Because of the resulting high dimensionality the Correlation-based Feature Selection with Sequential Floating Forward Selection is used [33].

Except for the Graz datasets which have separated training and testing sets, the Australian EEG dataset and the Alcoholism datasets used 1/3 for cross validation training and 2/3 for testing. Linear SVM classifiers [25] is trained in 3-folds

cross validation scheme with parameter C ranges from 1 to 1000 in 5 steps.

6. Experimental Results

Person identification rates in test phase are 99% on Graz IIIa 2005, 80.8% on Graz B 2008, 46.24% on Graz A 2008, 92.8% on Alcoholism large and 61.7% on Alcoholism full datasets. Tables 2, 3 and 4 show the confusion matrices for the Graz datasets. Results show high identification rate on Graz IIIa 2005 and Graz B 2008. However it is not high on Graz A 2008. The reasons could be that the data for training is not enough when there is high variation in data (4 imagery tasks), and the training data should come from different sessions in order to have good performance in test phase.

Table 2: Confusion matrix in test phase on Graz dataset IIIa BCI Competition 2005. Identification rate is 99%.

Classified as →	k3b	k6b	l1b
k3b	149	0	0
k6b	0	83	0
l1b	0	3	80

Table 3: Confusion matrix in test phase on Graz data set A, BCI Competition 2008. Identification rate is 46.24%.

B8	4	2	0	6	6	0	0	212	0
B9	0	0	0	2	0	0	0	0	243

Figure 1 shows the identification rate on Australian EEG database using a single channel Cz and 8 channels C3, Cz, C4, P3, Pz, P4, O1 and O2. For a single channel case, the EEG recording length should be at least 7 seconds for the person to be recognizable. The identification rate has a peak of 94% at 15 seconds length then slowly decreases and climbs up again. The use of 8 channels shows stable performance 97% at recording length from 3 to 60 seconds and shows higher performance of 99% at recording length longer than 90 seconds.

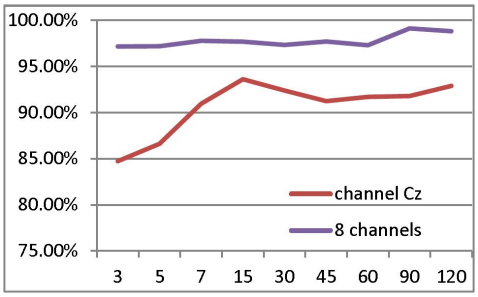

Fig. 1: Identification rate (in %) versus segment length on Australian EEG dataset

Person identification rates on Alcoholic large and Alcoholic full show that a single channel can hardly recognise the subjects. The use of 8 channels have high performance 92.8% in identification of 20 subjects and it can classify 122 subjects.

Table 5: Accuracies on dataset Alcoholic large and Alcoholic full using a single channel Cz and 8 channels C3, Cz, C4, P3, Pz, P4, O1, O2.

	Alcoholic large		Alcoholic full	
	channel Cz	8 channels	channel Cz	8 channels
Cross validation	52.50%	100%	21.87%	99.68%
Test	34.50%	92.83%	18.36%	61.59%

7. Conclusion

We have proposed a speech-based approach to brain wave feature extraction and used the proposed features to identify person. A single channel with appropriate recording time interval can be used in person identification task. The set 8 channels can give very good identification performance. For future investigation, other speech feature extraction methods will be applied to brain wave feature extraction.

A Comparison on How Statistical Tests Deal with Concept Drifts

Paulo M. Gonçalves Jr.[1,2], **Roberto S. M. Barros**[1]
[1]Centro de Informática, Universidade Federal de Pernambuco, Cidade Universitária, 50.740-560, Recife, Brasil
[2]Instituto Federal de Pernambuco, Cidade Universitária, 50.740-540, Recife, Brasil

Abstract— RCD *is a framework proposed to deal with recurring concept drifts. It stores classifiers together with a sample of data used to train them. If a concept drift occurs,* RCD *tests all the stored samples with a sample of actual data, trying to verify if this is a new context or an old one that is recurring. This is performed by a non-parametric multivariate statistical test to make the verification. This paper describes how two statistical tests (*KNN *and Cramer) can distinguish between new and old contexts.* RCD *is tested with several base classifiers, in environments with different rates-of-change values, with gradual and abrupt concept drifts. Results show that* RCD *improves single classifiers accuracy independently of the statistical test used.*

Keywords: Multivariate non-parametric statistical tests, concept drifts, data streams.

1. Introduction

Concept drift is a situation that frequently occurs in data streams environments [1]. One informal definition, as stated by Kolter and Maloof [2], informs that "concept drift occurs when a set of examples has legitimate class labels at one time and has different legitimate labels at another time." Another definition of concept drift describes that, in machine learning, "the term concept refers to the quantity that a learning model is trying to predict, i.e., the variable. Concept drift is the situation in which the statistical properties of the target concept change over time." [3]

Therefore, dealing with concept drift is a task of increasing importance to the areas of data mining and machine learning, as increasing amounts of data are being stored in the form of data streams instead of static databases. Also, it is not very common for data distributions and concepts to keep stable over a long period of time [4], [5].

This paper extends Recurring Concept Drifts (RCD) framework [6] with the implementation of the Cramer multivariate statistical test [7], and shows how it compares to tests using KNN [8]. The performance of the implemented tests were analyzed in terms of accuracy and evaluation time. RCD was tested with several base classifiers in commonly used data sets in the concept drift research area, including abrupt and gradual concept drifts.

The rest of this paper is organized as follows: Section 2 presents approaches to deal with concept drifts, algorithms, and how they work. Section 3 briefly describes how RCD works. Section 4 presents the algorithms used in the comparison, the parameters set, and the data sets used in the tests. Section 5 presents the accuracy, number of detected concept drifts, and evaluation time between RCD and the other algorithms in the selected data sets. Finally, Section 6 presents our conclusions and proposes future work.

2. Background

There are several approaches to handle concept drifts. One is to create a model that adapts its internal structure as instances arrive. CVFDT (Concept-adapting Very Fast Decision Tree) [9] is an example. It extends VFDT [10] to handle concept drifts. VFDT is a decision tree built to deal with data stream and uses a *Hoeffding bound* [11], [12], to decide exactly how many examples are necessary at each node to find the best attribute to test. VFDTc [13] is another proposal, which also extends VFDT with the ability to deal with continuous attributes and the use of naive Bayes classifiers at tree leaves. OcVFDT (One-class Very Fast Decision Tree) [14] is an algorithm to extend VFDT to deal with one-class problems, based on the fact that fully labeled data streams are expensive to obtain. It only deals with discrete attribute values.

Another common approach to deal with concept drifts is to identify when it occurs and create a new classifier. Thus, only classifiers trained on a current concept are maintained. Algorithms that follow this approach work in the following way: each arriving training instance is first evaluated by the base classifier. Internal statistics are updated with the results and two thresholds are computed: a warning level and an error level. As the base classifier makes mistakes, the warning level is reached and instances are stored. If the behavior continues, it will reach the error level, indicating that a concept drift has occurred. At this moment, the base classifier is destroyed and a new base classifier is created and initially trained on the stored instances. On the other hand, if the classifier starts to correctly evaluate instances, this situation is considered a false alarm and stored instances are flushed. Algorithms that follow this approach can work with any type of classifier as they only analyze how the classifier evaluates instances. Proposals that use this approach are DDM (Drift Detection Method) [15], EDDM (Early Drift Detection Method) [16], and ECDD (Exponentially Weighted Moving Average for Concept Drift Detection) [17].

Several proposals try to deal with concept drifts by the use of ensemble classifiers. This approach maintains a collection

of learners and combine their decisions to make an overall decision. To deal with concept drifts, ensemble classifiers must take in account the temporal nature of the data stream.

One of these proposals was the Streaming Ensemble Algorithm (SEA) [18]. It builds separate classifiers, each one trained on a different sequential chunk of data. These classifiers are then combined into a fixed-size ensemble using a heuristic replacement strategy. If there is free space in the ensemble, SEA adds the newly created classifier to the ensemble. If the ensemble is full, the new classifier is only added if it outperforms a stored classifier, substituting it. The performance is measured on the current batch of examples.

The Accuracy Weighted Ensemble (AWE) classifier [19] is another proposal of ensemble classifier. It uses batch classifiers and each one is built in different chunks of data. Classifiers weights are computed based on their expected accuracy in test data. Thus, they proposed to infer the weights by estimating the error rate in the most recent data blocks.

Accuracy Updated Ensemble (AUE) [20] is an enhancement of the AWE classifier. Both use classifier ensembles and associate to them weights that are updated as data arrive. AUE improves AWE in three directions: (a) Instead of batch classifiers, AUE uses on-line classifiers, which adapt to data while they arrive; (b) AUE updates both classifiers and their weights, while AWE only updates the weights; (c) AUE changed the weight computation to avoid situations where no classifier should have precision higher than the stipulated threshold, as in abrupt concept drifting environments, zeroing the weights of all classifiers and no class being predicted.

The Weighted Majority Algorithm (WMA) [21] implements a weighted ensemble classifier, which extends previous work [22] to specifically handle concept drifts. In WMA all the arriving instances are passed to all the classifiers in the ensemble. The initial weight of the classifiers is 1, and, if a classifier makes an error, its weight is reduced by a factor of β if higher than a specified minimum threshold. Then, the classifier is trained. After all the ensemble classifiers have been trained, their weights are normalized.

Dynamic Weighted Majority (DWM) [2] is another example of ensemble classifier. It extends WMA to add and remove classifiers according to the algorithms global and local performance. If the ensemble commits an error, then a classifier is added. If one classifier commits an error, its weight is reduced. If after many examples a classifier continues with a low accuracy, indicated by a low weight, it is removed from the ensemble. This method is general and, in principle, can be used with any classifier.

A common situation regarding concept drifts is its recurrence. It happens when the actual context is similar to a previously seen context. One approach commonly used to treat recurring concept drifts is to store information about the contexts, and continuously identify if actual context is similar to old contexts. If it is so, obtain stored information and use it again, as it is expected that it also represents actual context. Algorithms that use this approach to deal with context recurrence are FLORA [4], Prediction Error Context Switching (PECS) [23], and SPLICE [24].

3. The RCD Framework

The RCD framework, proposed in [6], deals with concept drifts by storing classifiers together with data samples used to train the classifiers. It starts with one single classifier and uses a concept drift detector, like DDM or EDDM for example, to identify the occurrence of a concept drift. While no drift is detected, the arriving instances are used to train the actual classifier and are stored in a FIFO data buffer with fixed length. If the drift detector enters the warning level, RCD stops storing instances in the classifier's buffer and stores them in a new buffer. If the error level is reached, indicating a concept drift, a multivariate non-parametric statistical test is performed to compare the instances obtained in the warning level with the instances associated to each classifier to identify if both samples come from the same data distribution. If not, a new classifier is stored alongside with the instances in the new buffer. If both samples come from the same data distribution, it is considered that this is an old concept that is occurring again. In this situation, the stored classifier is used as the actual classifier.

In [6], besides presenting how RCD works, we also show how RCD deals with concept drifts, comparing it with single and ensemble classifiers in environments with abrupt and gradual concept drifts. Artificial and real world data sets were tested using KNN as statistical test.

In this paper, RCD is tested using different base learners, in four different artificial data sets, with abrupt and gradual concept drift with various rates-of-change, and three real world data sets. One new implemented statistical test, Cramer, is also analyzed. It was based on the implementation of the Cramer package [7] of The R Project for Statistical Computing [25] tool.

RCD was configured with the following parameters: classifiers buffer size (100), test frequency (500), maximum number of classifiers to store (15), concept drift detection method (DDM), and minimum amount of similarity between distributions (0.05). RCD was implemented using of the MOA framework [26]. Instructions on how to download and use RCD can be found at `https://sites.google.com/site/moaextensions/`.

4. Algorithms and Datasets

In this section we present the algorithms used in the tests, their parameters, and information about the data sets.

4.1 Algorithms

Three base learners were used to test RCD: Hoeffding tree with naive Bayes at the leaves [13], naive Bayes, and

Multilayer Perceptron (MLP). From now on we will reference the decision tree as HTNB. We tested each base learner against RCD with KNN and Cramer statistical tests.

The parameters used by HTNB in the experiments are the default values present in the MOA framework: number of instances a leaf should observe between split attempts (200), split criterion to use (information gain), allowable error in split decision (10^{-7}), and threshold below which a split will be forced to break ties (0.05).

The parameters used by MLP in the experiments are the default values present in the WEKA tool [27]: learning rate (0.3), momentum (0.2). Only the number of epochs to train was reduced from 500 to 100 to increase its speed.

The following sections presents the data sets used in the comparison of the framework. The data sets used are well known in the field and have been used in several previous experiments.

4.2 Artificial data sets

We first describe the artificial data sets used to test the algorithms. All these data sets are available through the MOA framework.

4.2.1 Hyperplane

Hyperplane [9] is an artificial data set that simulates concept drifts through a moving hyperplane. A hyperplane in a d dimensional space is the set of points x that satisfies $\sum_{i=1}^{d} w_i x_i = w_0$, where x_i is the i^{th} coordinate of x. Examples where $\sum_{i=1}^{d} w_i x_i \geq w_0$ are classified as positive, and examples where $\sum_{i=1}^{d} w_i x_i < w_0$ are classified as negative. Hyperplanes are used to simulate gradual concept drifts where it is possible to smoothly change the orientation and position of the hyperplane by modifying its weights. It is possible to introduce changes in the data set changing the weight of each attribute $w_i = w_i + d\sigma$, where σ is the chance the direction of change be inverted and d is the amount of change applied to each example.

4.2.2 LED

The LED [28] data set represents the problem of predicting the digit shown by a seven-segment LED display. It is composed of 24 nominal attributes, where 17 are irrelevant, and one nominal class with ten possible values. Noise was added by including a 10% probability of each attribute being inverted. The version of LED used in the experiments is available at MOA that includes concept drifts to the data sets by simply changing the attributes positions. The number of drifting attributes chosen were 1, 3, 5, and 7.

$$(((LED_1 \oplus_{t_0}^{W} LED_3) \oplus_{2t_0}^{W} LED_5) \oplus_{3t_0}^{W} LED_7)$$

4.2.3 SEA

The SEA [18] concepts are commonly used to test abrupt concept drifts. The values of each of its three attributes are in the interval [0,10), but the third one is irrelevant. In each concept, a data point belongs to class 1 if $f_1 + f_2 \leq \theta$, where f_l and f_2 represent the first two features and θ is a threshold value between the two classes. For the experiments, we used the thresholds proposed by [18]: 8, 9, 7, 9.5 to represent four concepts. Noise was inserted by randomly changing the class value of 10% of the instances. In the following tests, SEA concepts are defined as follows:

$$(((SEA_9 \oplus_{t_0}^{W} SEA_8) \oplus_{2t_0}^{W} SEA_7) \oplus_{3t_0}^{W} SEA_{9.5})$$

4.2.4 Random RBF

RBF (Radial Basis Function) [29] creates complex concept drifts that are not straightforward to approximate with a decision tree model. It works as follows: a fixed number of random centroids are generated where each center has a random position, a single standard deviation, a class label and a weight. New examples are generated by selecting a center at random, taking weights into consideration so that centers with higher weight are more likely to be chosen. A random direction is chosen to offset the attribute values from the central point. The length of the displacement is randomly drawn from a Gaussian distribution with standard deviation determined by the chosen centroid. The chosen centroid also determines the class label of the example. This effectively creates a normally distributed hypersphere of examples surrounding each central point with varying densities. Only numeric attributes are generated. Drift is introduced by moving the centroids with constant speed. This speed is initialized by a drift parameter.

4.3 Real data sets

Here we present three real data sets used in the experiments. It is not easy to find large real-world datasets for public benchmarking, especially with substantial concept change. Another problem is that we do not know when drift occurs or if there is any drift at all. The data sets used are: Forest Covertype [30], Poker-Hand [29], and Electricity [15]. They were obtained from the MOA web site, in the following address: `http://moa.cs.waikato.ac.nz/`.

4.3.1 Forest Covertype

This data set contains the forest cover type for 30 x 30 meter cells obtained from US Forest Service (USFS) Region 2 Resource Information System (RIS) data. The goal is to predict the forest cover type from cartographic variables. It contains 581,012 instances and 54 attributes.

4.3.2 Poker Hand

The Poker Hand data set is constituted of five categoric and five numeric attributes plus one categoric class with 10 possible values informing the value of the hand, for example, one pair, two pairs, a sequence, a street flush, etc. It represents the problem of identifying the value of five cards in the Poker game. Bifet [31] describes that "in the Poker hand data set, the cards are not ordered, i.e., a hand can be represented by any permutation, which makes it very hard for propositional learners, especially for linear ones". So, in the experiments, we used a modified version, where the cards are sorted by rank and suit, and duplicates were removed. This data set is composed of 829,201 instances.

4.3.3 Electricity

This data set presents data collected from the Australian New South Wales Electricity Market. In that market, prices vary according to market demand and supply. Prices are set every five minutes and the class label identifies the change of the price related to a moving average of the last 24 hours. The goal of the problem is to predict if the price will increase or decrease. It is composed of 45,312 instances.

5. Empirical Study and Results

The evaluation methodology used in the presented data sets were the Interleaved Test-Then-Train approach. Every example is used for testing the model, then it is used to train it. The accuracy was measured as the final percentage of instances correctly classified over the interleaved evaluation. For the Hyperplane and Random RBF data sets, 10 million instances were generated; for LED and SEA, 1 million instances. The experiments were repeated 10 times. The parameters of these streams are the following:

- RBF(x, v): Random RBF data stream with x centroids moving at speed v.
- HYP(x, v): Hyperplane data stream with x attributes changing at speed v.
- SEA(v): SEA data set, with length of change v.
- LED(v): LED data set, with length of change v.

The chosen evaluation methodology, data sets, and configurations are exactly the same as used in [29], [31]. For the tests, we used an Intel Core i3 330M processor (with two cores and emulating two other), with 4GB of main memory.

Table 1 presents how long each statistical test needs to evaluate samples of sizes varying from 100 to 300 instances. Samples were obtained from the Electricity data set. We can see that the time spent by the Cramer test almost doubles each time the sample size is increased by 50 instances while KNN is less impacted. Comparing both tests, it is clear that KNN is considerably faster than Cramer performing the statistical tests. Thus, considering the data set sizes used in the experiments (1 to 10 million, with 10 repetitions), the buffer size used in RCD was 100 to increase its speed.

Table 1: Evaluation time using statistical tests (in seconds).

	100	150	200	250	300
Cramer	0.413	0.947	1.835	3.263	6.375
KNN	0.003	0.007	0.012	0.017	0.024

Tables 2, 3 and 4 present the average evaluation times in seconds and the accuracy of the HTNB, naive Bayes and MLP base classifiers, respectively. For the artificial data sets, the accuracy also contains the 95% confidence interval. The second column presents the results for the base classifier, the third one, RCD using the Cramer test, and the latter, RCD using the KNN test. The last column of Cramer and KNN presents the average number of drifts detected in all repetitions in the artificial data sets, and the total number of drifts in the real-world data sets. Best results in performance are highlighted in boldface and the values marked by an asterisk (*) represent statistically significant differences between RCD and the base learner.

Analyzing the results presented at Table 2, it is possible to observe that RCD outperformed the HTNB base classifier in the majority of the artificial data sets, independently of the statistical test used. Statistically, RCD had better performance in HYP(10,0.0001), HYP(10,0.001) (when using the KNN statistical test), and in the Random RBF configurations with 50 centroids. In all the other configurations, both algorithms had statistical similar performances.

In the Random RBF configuration without concept drifts, RBF(0,0), all algorithms had exactly the same results. This is an expected result of RCD because, when no concept drift is detected, no statistical test is performed and RCD performs the same as the base learner. In the other RBF data sets with concept drift, the configurations that RCD performed better than the base learner was the ones with 50 centroids. For this data set, the higher the number of moving centroids, the bigger the number of concept drifts. Thus, RCD had better performance exactly in the configurations with higher number of concept drifts while in the configurations with 10 centroids, the ones with lower number of concept drifts, the performances were similar.

It is possible to check the influence of the number of moving centroids compared to the average number of detected concept drifts in each configuration. In the RBF(50,0.001) configuration, using the Cramer test, 17.2 concept drifts were detected, while using KNN there were 15.4 in the ten repetitions. In the RBF(10,0.001) configuration, only 0.4 and 0.3 concept drifts were detected using the Cramer and KNN statistical tests, respectively, in the ten repetitions.

Comparing the usage of the two statistical tests, KNN had a better performance in two data sets: in RBF(50,0.0001), and in the LED data set. In the rest, both statistical tests had comparable performances. Analyzing the number of detected concept drifts, KNN is much more sensible than Cramer. Using KNN, 40,480 concept drifts were detected

while Cramer detected 33,755 in all data sets, considering all repetitions.

Regarding the time spent in the evaluation procedure, as expected, the base learner was faster than the RCD framework. In average, HTNB was approximately 75.41% faster than RCD using the Cramer test and 45.19% using KNN. In 12 out of 13 data sets, KNN was faster than Cramer.

The results presented for the naive Bayes base learner in Table 3, show that, again, the RCD framework had better performance in the majority of the data sets and configurations. Statistically, the results were similar to the ones obtained using the HTNB base learner: RCD also had higher accuracy values in both configurations of Random RBF with 50 centroids and, in this case, in both configurations of the Hyperplane data set. In the other data set configurations, RCD and naive Bayes obtained statistically similar results.

Considering RBF(0,0), two concept drifts occurred in the ten repetitions. The results of the algorithms are practically the same, only differing in the fifth decimal. This is a similar result compared to the same configuration using HTNB: when no concept drift was found, the same results occurred; when only two concept drifts were detected, the accuracy difference was negligible. Again, it is possible to notice that higher number of centroids gives higher number of concept drifts. Using the Cramer test, there were an average of 10.0 concept drifts in RBF(50,0.001) and 5.7 with 10 centroids. The same behavior occurred when using the KNN test: 16.7 and 5.5 concept drifts, respectively.

Comparing the statistical tests, KNN was statistically more accurate than Cramer in HYP(10,0.0001) and in both configurations of Random RBF with 50 centroids. In all other situations, both statistical tests had comparable performances. Comparing the number of detected concept drifts, similar results to the ones using HTNB base learner were obtained. Using KNN, 60,240 concept drifts were detected while Cramer detected 38,985 in all data sets.

Again, the base learner was faster than RCD in evaluating the data sets. The base learner was 2.5 times faster than RCD using the Cramer test, and 72% faster using KNN. The KNN statistical test was faster than the Cramer test in 9 out of 13 data set configurations.

Table 4 presents the results for the MLP base learner. The evaluation results show that, statistically, RCD had higher accuracy values compared to MLP only in RBF(50,0.0001). In all other situations, RCD and MLP had comparable performances, independently of the statistical test used.

In RBF without concept drifts, both versions of RCD performed the same, like when using the other base learners. In the 10 repetitions, only 2 concept drifts were found. These were false positives raised by the drift detector, giving the slightly different results from RCD and MLP. Similarly from the other base learners, RCD was statistically better in RBF(50,0.0001). Again it is possible to verify that the number of centroids has a much higher influence in the number of concept drifts than the speed of change. For example, using the Cramer test, an average of 6.8 concept drifts were identified in the RBF(10,0.001) configuration. Increasing the number of centroids to 50, the number of concept drifts raised to 14.0, while changing the speed of change to 0.0001 augmented the number of concept drifts to 8.0.

Comparing Cramer to KNN, only in the RBF(50,0.0001) configuration the tests had statistical different performances: KNN was better. In all other data sets, they performed similarly. Analyzing the evaluation time, the base learner was again faster. Here, Cramer was faster than KNN in average. While Cramer spent more than two times compared to MLP in the evaluation procedure, KNN was more than three times slower than the base learner. Again, KNN identified more concept drifts than Cramer: 34,348 versus 32,398.

6. Conclusion

This paper presented the implementation of a new multivariate non-parametric statistical test, the Cramer test, in the RCD framework. We compared RCD using two multivariate non-parametric statistical tests (KNN and Cramer) with three

base learners: Hoeffding trees, naive Bayes, and Multilayer Perceptron. The tests were performed in seven data sets: four artificial data sets, with several rates-of-change, and three real world data sets.

The RCD configuration tested presented better performance than the Hoeffding tree base learner with naive Bayes at the leaves in 8 out of 13 possible situations using the Cramer test, in 4 situations the Hoeffding tree performed better, and in 1 situation the performance was similar. Using KNN, RCD has beaten the base learner by 9 to 2. In two situations, the performance was similar. Statistically, in three data set configurations, RCD had a better performance than the base learners considering both statistical tests. In all other situations, the performances were similar.

Using the naive Bayes base learner, the results of RCD are even better considering the Cramer test: of the 13 data set configurations, RCD performed better than naive Bayes in 11. In one situation they performed similarly and in one naive Bayes was better. Using KNN, RCD was better in ten data set configurations and in three the results were similar. Statistically, RCD performed better in four situations: both versions of Hyperplane and Random RBF with 50 centroids.

The results indicate that RCD tends to perform better than the base learners in environments with many concept drifts. This is an expected behavior because RCD stores classifiers and reuses them if actual data is similar to the ones used to build it. In environments without concept drifts, RCD's performance is similar to the base classifier, as the results from the tests shows in the Random RBF(0,0) configuration using the Hoeffding tree as base learner.

Regarding the two statistical tests in the artificial data sets, KNN statistically outperformed Cramer in six situations. In the others, both tests performed similarly. Considering the real data sets, KNN has beaten Cramer by 8 to 1. Results from the experiments clearly show that KNN is better suited for concept drift detection than Cramer.

Considering the evaluation times, as expected, the base learner was faster than using RCD. Comparing the two statistical tests, using the Hoeffding tree and naive Bayes, KNN was faster, while Cramer was faster when using Multilayer Perceptron. In all the tests, KNN was faster than Cramer in 28 situations, while the opposite occurred 11 times.

These results confirmed previous findings that the RCD approach to handle concept drifts is promising and improves single classifiers results when using them as base learners of the framework, independently of the statistical test used.

There was no situation where the base learner had a statistically better performance compared to using RCD in the experiments. Tests using other two base learners, J48 [32] and a pure Hoeffding tree, also had the same results (not presented here due to limitations of space).

6.1 Future Work

Even though RCD is actually highly configurable, as future work, further research might be made to allow the user to choose the best configuration for a specific problem:

- Analyze the influence of the drift detection method, implementing and testing alternatives to DDM and EDDM, like EWMA.
- Create an ensemble classifier based on the individual learners associated with each distribution. As more than one stored classifier can match the actual context, one approach would be to set higher weights to classifiers where their samples return higher confidence levels.
- Implement a pruning strategy different than FIFO and analyze the influence of the number of stored classifiers in terms of accuracy and performance.
- Use the two available statistical tests in conjunction and analyze if they provide better results than their individual use.

A Propositional Family Deontic Logic

Cungen CAO and Yuefei SUI
Key Laboratory of Intelligent Information Processing
Institute of Computing Technology, Chinese Academy of Sciences, Beijing 100190, CHINA

Abstract—*A propositional family deontic logic is introduced, which is a combination of the propositional deontic logic, dynamic logic and ambient logic. A three-layered possible world semantics is given, where a possible world is a set of families which is used to define the semantics for action modality* $[\mathbf{a}]$; *a subpossible world is a family used to define the semantics for family modality* $[\mathbf{m}]$, *and a subsubpossible world is used to define the semantics for the deontic modality* OB. *An axiomatic system of the logic will be given, and the normal form theorem, the soundness theorem and completeness theorem of the axiomatic system will be proved.*

Keywords: Deontic logic, Normative system, Ambient logic, Possible world semantics, Axiomatic system.

1. Introduction

The dynamic logic ([4]) and the propositional deontic logic ([7]) are used to represent the normative systems ([2],[5],[6],[11]). For example, Åotnes, *et al.* ([2]) defined a normative temporal logic for reasoning about normative systems, which is a combination of the computational tree logic and the deontic logic. Herzig, *et al.*([5]) gave a dynamic logic of normative systems, called PDL-PA, in which the normative modalities $\mathbf{A}, \mathbf{P}$ are applied only to the propositional variables with sign $+/-$. This dynamic logic can be taken as a dynamic logic with extra propositional variables.

The propositional family deontic logic is a logic for normative systems, and is a combination of the propositional deontic logic, the dynamic logic and the ambient logic ([3]). The logical language of the logic has three kinds of modalities:

• modality OB in the deontic logic is used to denote the obligation;

• modalities $[\mathbf{a}]$ in the dynamic logic are used to represent the basic actions in/between families, for example, $\mathbf{a}$ may be **birth**, **marry**, **divorce**, where $\mathbf{a}$s are with parameters, and

• modalities $[\mathbf{m}]$ are used to denote families as positions in which propositional variables and obligatory statements are interpreted, where $[\mathbf{m}]$ is used in the ambient logic to denote spatial positions.

Only the obligations considered here are in families, and hence, a formula of form $\mathtt{OB}[\mathbf{m}]\phi$ is not well-defined. Hence, we assume that OB can be applied only to the propositional variables or the negation of the propositional variables. Action modality $[\mathbf{a}]$ changes a family ($\mathbf{a} =$ **birth**), or combines two families ($\mathbf{a} =$ **marry**) or splits a family into two families ($\mathbf{a} =$ **divorce**), and does not change the deontic statements, but can add new deontic statements to the recently-formed families.

The semantics of the propositional family deontic logic is a three-layered possible world semantics, in which

◦ a possible world w is a set of families u, such that an action changes a possible world into another one;

◦ a subpossible world u in a possible world w is a family, such that a family modality $[\mathbf{m}]$ is interpreted to be a subpossible world;

◦ a subsubpossible world z in a subpossible world u is used to interpret modality OB.

For the simplicity, we assume that for any $w \in W$, there is one and only one possible world w' such that w' is accessible from w via modality $\mathbf{a}$; and the interpretation $I_w(\mathbf{m})$ of family name $\mathbf{m}$ is constant with respect to the subpossible world, that is, if w' is accessible from w via some $\mathbf{a}$ then family $I_w(\mathbf{m})$ denoted by $\mathbf{m}$ at possible world w is the same as the one $I_{w'}(\mathbf{m})$ denoted by $\mathbf{m}$ at possible world w'.

We shall build an axiomatic system for the propositional famly deontic logic and prove the normal form theorem, the soundness theorem and the completeness theorem of the propositional family deontic logic.

The paper is organized as follows: the next section gives the basic definitions in the propositional deontic logic; the third section gives the syntax and semantics of the propositional family deontic logic; the fourth section proves the basic theorems on the equivalent formulas and the normal form theorem; the fifth section gives an axiomatic system and proves the soundness theorem and completeness theorem of the logic; the sixth section gives variant family deontic logics; and the last section concludes the whole paper.

2. The deontic logic

This section gives the basic definitions of the propositional deontic logic, its syntax and semantics.

The logical language for the propositional deontic logic consists of the following symbols:

• propositional variables: $p_0, p_1, ...$;
• logical connectives: $\neg, \wedge$;
• the deontic modality: OB; and
• auxiliary symbols: (,).

Formulas are defined inductively as follows:

$$\phi ::= p|\neg\phi_1|\phi_1 \wedge \phi_2|\mathtt{OB}\phi_1.$$

Other deontic modalities are defined:

$$\begin{aligned}
&\texttt{PE}\phi ::= \neg\texttt{OB}\neg\phi\\
&\texttt{IM}\phi ::= \texttt{OB}\neg\phi\\
&\texttt{OM}\phi ::= \neg\texttt{OB}\phi\\
&\texttt{OP}\phi ::= \neg\texttt{OB}\phi \wedge \neg\texttt{OB}\neg\phi.
\end{aligned}$$

The semantics of the propositional deontic logic is the possible world semantics.

A *frame* F is a triple (W, R, D), where

• W is a non-empty set of possible worlds;

• $R \subseteq W \times W$ is the accessibility relation for modality OB, and

• $D \subseteq W$ is a subset such that for any $w \in W$, there is a possible world $w' \in D$ such that $(w, w') \in R$.

A *model* $\mathbf{M}$ is a pair (F, I), where

• F is a frame; and

• I is an interpretation such that for any propositional variable p, $I(p) \subseteq W$.

The satisfaction of formula ϕ at a possible world w, denoted by $\mathbf{M}, w \models \phi$, is defined as follows:[1] $\mathbf{M}, w \models \phi$ iff

$$\begin{cases}
w \in I(p) & \text{if } \phi = p\\
\mathbf{M}, w \not\models \phi_1 & \text{if } \phi = \neg\phi_1\\
\mathbf{M}, w \models \phi_1 \& \mathbf{M}, w \models \phi_2 & \text{if } \phi = \phi_1 \wedge \phi_2\\
\mathbf{A}w'((w, w') \in R \& w' \in D & \\
\quad \Rightarrow \mathbf{M}, w' \models \phi_1) & \text{if } \phi = \texttt{OB}\phi_1
\end{cases}$$

Correspondingly, we have the following

$\mathbf{M}, w \models \texttt{PE}\phi$ iff
$\mathbf{E}w'((w, w') \in R \& w' \in D \& \mathbf{M}, w' \models \phi)$
$\mathbf{M}, w \models \texttt{IM}\phi$ iff
$\mathbf{A}w'((w, w') \in R \& w' \in D \Rightarrow \mathbf{M}, w' \models \neg\phi)$
$\mathbf{M}, w \models \texttt{OM}\phi$ iff
$\mathbf{E}w'((w, w') \in R \& w' \in D \& \mathbf{M}, w' \models \neg\phi)$
$\mathbf{M}, w \models \texttt{OP}\phi$ iff
$\mathbf{E}w'((w, w') \in R \& w' \in D \& \mathbf{M}, w' \models \phi)$
$\& \mathbf{E}w'((w, w') \in R \& w' \in D \& \mathbf{M}, w' \models \neg\phi)$

Axioms:

A1. All tautologies of the propositional logic;

A2. $\texttt{OB}(\phi \to \psi) \to (\texttt{OB}\phi \to \texttt{OB}\psi)$;

A3. $\texttt{OB}\phi \to \neg\texttt{OB}\neg\phi$.

Inference rules:

$$\text{(MP)} \quad \frac{\phi, \phi \to \psi}{\psi}$$

$$\text{(NEC}^{\texttt{OB}}\text{)} \quad \frac{\phi}{\texttt{OB}\phi}.$$

Theorem 2.1([7]). The deontic logic is sound and complete.

□

[1]In syntax, we use $\neg, \wedge, \to, \forall, \exists$ to denote the logical connectives and quantifiers; and in semantics we use $\sim, \&, \Rightarrow, \mathbf{A}, \mathbf{E}$ to denote the corresponding connectives and quantifiers.

3. The family deontic logic

A logic consists of a logical language, syntax, semantics and a deduction system.

The logical language of the family deontic logic contains the following symbols:

• propositional variables: $p_0, p_1, ...$;

• action names: $\mathbf{a}_0, \mathbf{a}_1, ...$; and action modalities: $[\mathbf{a}_0], [\mathbf{a}_1], ...$;

• family names: $\mathbf{m}_0, \mathbf{m}_1, ...$; and family modalities: $[\mathbf{m}_0], [\mathbf{m}_1], ...$;

• the deontic modality: OB, and

• logical connectives: $\neg, \wedge$.

For example,

$\mathbf{a} ::= \mathbf{birth}(x, y) | \mathbf{marry}(x, y) | \mathbf{divorce}(x, y)$,

where x, y are parameters, and $\mathbf{birth}(x, y)$ represents that x gives a birth to y; $\mathbf{marry}(x, y)$ that x marries y, and $\mathbf{divorce}(x, y)$ that x divorces y. Because we consider only the propositional family deontic logic, x, y are taken as parameters, not as variables.

We assume that modality OB is applied only to the atomic formulas or the negation of the atomic formulas; and action modalities and family name modalities $[\mathbf{m}]$ are applied to any formula.

Formulas are defined inductively as follows:

$$\phi ::= p | \texttt{OB}p | \texttt{OB}\neg p | \neg\phi_1 | \phi_1 \wedge \phi_2 | [\mathbf{a}]\phi_1 | [\mathbf{m}]\phi_1.$$

The semantics is a three-layered possible world semantics. Intuitively, we use a possible world to denote a set of families, a subpossible world to denote a family, and a subsubpossible world for the deontic modality.

A *model* $\mathbf{M}$ is a pair (W, R), where

• W is a set of possible worlds such that each possible world $w \in W$ is a submodel $w = (U_w, I_w)$, where

  ◦ U_w is a set of *subpossible worlds* and each subpossible world u is a model $(Z_{w,u}, R^{\texttt{OB}}_{w,u}, I_{w,u})$, where

    ◇ $Z_{w,u}$ is a set of *subsubpossible worlds*;

    ◇ $R^{\texttt{OB}}_{w,u} \subseteq Z^2_{w,u}$ is the accessibility relation for OB in u; and

    ◇ $I_{w,u}$ is an interpretation such that for any propositional variable p, $I_{w,u}(p) \subseteq Z_{w,u}$;

  and for any possible worlds w, w', if $(w, w') \in R_{\mathbf{a}}$ then $U_w \subseteq U_{w'}$, and

  ◦ I_w is an interpretation such that for any family name $\mathbf{m}$, $I_w(\mathbf{m}) \in U_w$.

• for each action name $\mathbf{a}$, $R_{\mathbf{a}} \subseteq W^2$ is the accessibility relation for action modality $[\mathbf{a}]$, such that for any possible world $w \in W$, there is one and only one possible world w' (we use $f_{\mathbf{a}}(w)$ to denote the w') such that

  ◦ $(w, w') \in R_{\mathbf{a}}$, and

  ◦ for any $\mathbf{m}$, if $I_w(\mathbf{m}) \downarrow$ (is defined) then $I_{w'}(\mathbf{m}) \downarrow$, and

$$I_w(\mathbf{m}) = I_{w'}(\mathbf{m}).$$

The last condition ensures that if w' is accessible from w via some action modality $[\mathbf{a}]$, and family $\mathbf{m}$ exists in w then $\mathbf{m}$ exists in w'.

The satisfaction of formula ϕ at a subsubpossible world (w, u, z), denoted by $\mathbf{M}, w, u, z \models \phi$, is defined as follows:

$\mathbf{M}, w, u, z \models \phi$ iff

$$\begin{cases} z \in I_{w,u}(p) & \text{if } \phi = p \\ \mathbf{A}z'((z,z') \in R^{\mathtt{OB}}_{w,u} \\ \quad \Rightarrow \mathbf{M}, w, u, z' \models p) & \text{if } \phi = \mathtt{OB}p \\ \mathbf{A}z'((z,z') \in R^{\mathtt{OB}}_{w,u} \\ \quad \Rightarrow \mathbf{M}, w, u, z' \models \neg p) & \text{if } \phi = \mathtt{OB}\neg p \\ \mathbf{M}, w, u, z \not\models \phi_1 & \text{if } \phi = \neg\phi_1 \\ \mathbf{M}, w, u, z \models \phi_1 \\ \quad \&\mathbf{M}, w, u, z \models \phi_2 & \text{if } \phi = \phi_1 \wedge \phi_2 \\ \mathbf{M}, f_{\mathbf{a}}(w), u, z \models \phi_1 & \text{if } \phi = [\mathbf{a}]\phi_1 \\ \mathbf{M}, w, I_w(\mathbf{m}), z \models \phi_1 & \text{if } \phi = [\mathbf{m}]\phi_1 \end{cases}$$

where z is a subsubpossible world of u, and u is a subpossible world of possible world w.

Remark. For the simplicity, we omit the relation D in the semantics of the propositional deontic logic.

□

A formula ϕ is *valid* in a model $\mathbf{M}$, denoted by $\mathbf{M} \models \phi$, if for any possible world w, subpossible world u of w and subsubpossible world z of $u, \mathbf{M}, w, u, z \models \phi$. ϕ is *valid*, denoted by $\models \phi$, if for any model $\mathbf{M}, \phi$ is valid in $\mathbf{M}$.

4. The normal form

In this section, we discuss the normal form of formulas, just as the disjunctive or conjunctive normal form in the propositional logic. With the normal form and the completeness theorem of the dynamic logic, we can prove the completeness theorem of the propositional family deontic logic.

Proposition 4.1. The following sentences are valid:

$$[\mathbf{a}]\neg\phi \leftrightarrow \neg[\mathbf{a}]\phi$$
$$[\mathbf{a}](\phi \wedge \psi) \leftrightarrow [\mathbf{a}]\phi \wedge [\mathbf{a}]\psi.$$

Proof. It is assumed that for any $w \in W$, there is one and only one $w' \in W$ such that $(w, w') \in R_{\mathbf{a}}$.

$\mathbf{M}, w, u, z \models [\mathbf{a}]\phi$
iff $\mathbf{A}w'((w, w') \in R_{\mathbf{a}} \Rightarrow \mathbf{M}, w', u, z \models \phi$
iff $\mathbf{M}, f_{\mathbf{a}}(w), u, z \models \phi$.

For any model $\mathbf{M}$ and w, u, z,

$\mathbf{M}, w, u, z \models [\mathbf{a}]\neg\phi$
iff $\mathbf{M}, f_{\mathbf{a}}(w), u, z \models \neg\phi$
iff $\mathbf{M}, f_{\mathbf{a}}(w), u, z \not\models \phi$
iff $\mathbf{M}, w, u, z \not\models [\mathbf{a}]\phi$
iff $\mathbf{M}, w, u, z \models \neg[\mathbf{a}]\phi$;
$\mathbf{M}, w, u, z \models [\mathbf{a}](\phi \wedge \psi)$
iff $\mathbf{M}, f_{\mathbf{a}}(w), u, z \models \phi \wedge \psi$
iff $\mathbf{M}, f_{\mathbf{a}}(w), u, z \models \phi \& \mathbf{M}, f_{\mathbf{a}}(w), u, z \models \psi$
iff $\mathbf{M}, w, u, z \models [\mathbf{a}]\phi \& \mathbf{M}, w, u, z \models [\mathbf{a}]\psi$
iff $\mathbf{M}, w, u, z \models [\mathbf{a}]\phi \wedge [\mathbf{a}]\psi$.

□

Proposition 4.2. The following sentences are valid: for any family name $\mathbf{m}$,

$$[\mathbf{m}]\neg\phi \leftrightarrow \neg[\mathbf{m}]\phi$$
$$[\mathbf{m}](\phi \wedge \psi) \leftrightarrow [\mathbf{m}]\phi \wedge [\mathbf{m}]\psi.$$

Proof. For any model $\mathbf{M}$ and w, u, z,

$\mathbf{M}, w, u, z \models [\mathbf{m}]\neg\phi$
iff $\mathbf{M}, w, I_w(\mathbf{m}), z \models \neg\phi$
iff $\mathbf{M}, w, I_w(\mathbf{m}), z\neg \models \phi$
iff $\mathbf{M}, w, u, z\neg \models [\mathbf{m}]\phi$
iff $\mathbf{M}, w, u, z \models \neg[\mathbf{m}]\phi$;
$\mathbf{M}, w, u, z \models [\mathbf{m}](\phi \wedge \psi)$
iff $\mathbf{M}, w, I_w(\mathbf{m}), z \models \phi \wedge \psi$
iff $\mathbf{M}, w, I_w(\mathbf{m}), z \models \phi \& \mathbf{M}, w, I_w(\mathbf{m}), z \models \psi$
iff $\mathbf{M}, w, u, z \models [\mathbf{m}]\phi \& \mathbf{M}, w, u, z \models [\mathbf{m}]\psi$
iff $\mathbf{M}, w, u, z \models [\mathbf{m}]\phi \wedge [\mathbf{m}]\psi$.

□

The normal form of formulas is defined as follows:

$$\begin{aligned} \theta &::= p|\mathtt{OB}p|\mathtt{OB}\neg p; \\ \psi &::= [\alpha_1]\cdots[\alpha_n]\theta|\neg\psi_1|\psi_1 \wedge \psi_2 \end{aligned}$$

where $\alpha ::= \mathbf{m}|\mathbf{a}$. Here, we say that θ and ψ are the formulas in the normal form.

Theorem 4.3. Each formula ϕ is logically equivalent to a formula ψ in the normal form, i.e., $\models \phi \leftrightarrow \psi$.

Proof. By the induction on the structure of formula ϕ and proposition 4.1 and 4.2, we have the theorem.

□

Proposition 4.4. The following formula is valid:

$$[\mathbf{a}][\mathbf{m}]\phi \leftrightarrow [\mathbf{m}][\mathbf{a}]\phi.$$

Proof. For any model $\mathbf{M}$ and w, u, z

$\mathbf{M}, w, u, z \models [\mathbf{a}][\mathbf{m}]\phi$ iff $\mathbf{M}, f_{\mathbf{a}}(w), u, z \models [\mathbf{m}]\phi$
iff $\mathbf{M}, f_{\mathbf{a}}(w), I_{f_{\mathbf{a}}(w)}(\mathbf{m}), z \models \phi$;
$\mathbf{M}, w, u, z \models [\mathbf{m}][\mathbf{a}]\phi$ iff $\mathbf{M}, w, I_w(\mathbf{m}), z \models [\mathbf{a}]\phi$
iff $\mathbf{M}, f_{\mathbf{a}}(w), I_w(\mathbf{m}), z \models \phi$.

Because $(w, f_{\mathbf{a}}(w)) \in R_{\mathbf{a}}, I_{f_{\mathbf{a}}(w)} \supseteq I_w$, i.e.,

$$I_w(\mathbf{m}) = I_{f_{\mathbf{a}}(w)}(\mathbf{m}).$$

Therefore,

$$\mathbf{M}, w, u, z \models [\mathbf{a}][\mathbf{m}]\phi \text{ iff } \mathbf{M}, w, u, z \models [\mathbf{m}][\mathbf{a}]\phi.$$

□

The strong normal form:

$$\begin{aligned} \theta &::= p|\mathtt{OB}p|\mathtt{OB}\neg p; \\ \xi &::= [\mathbf{a}]\theta; \\ \psi &::= [\mathbf{m}_1]\cdots[\mathbf{m}_n]\xi|\neg\psi_1|\psi_1 \wedge \psi_2. \end{aligned}$$

The intuition of the strong normal form is that each family action, such as, **birth**, **marry**, **divorce**, etc., happens in one

family, and a deontic statement is about members in one family.

Theorem 4.5. Each formula ϕ is logically equivalent to a formula ψ in the strong normal form, i.e., $\models \phi \leftrightarrow \psi$.

Proof. By the induction on the structure of formula ϕ. □

5. The soundness and completeness of the propositional family deontic logic

The axiomatic system of the propositional family deontic logic consists the following axioms and inference rules:

Axioms:

All the valid propositional formula
$[\mathbf{m}]\neg\phi \leftrightarrow \neg[\mathbf{m}]\phi$
$[\mathbf{m}](\phi \wedge \psi) \leftrightarrow ([\mathbf{m}]\phi \wedge [\mathbf{m}]\psi)$
$[\mathbf{a}]\neg\phi \leftrightarrow \neg[\mathbf{a}]\phi$
$[\mathbf{a}](\phi \wedge \psi) \leftrightarrow [\mathbf{a}]\phi \wedge [\mathbf{a}]\psi$
$[\mathbf{a}][\mathbf{m}]\phi \leftrightarrow [\mathbf{m}][\mathbf{a}]\phi$.

Inference rules:

$$\text{(MP)}: \quad \frac{\phi, \phi \rightarrow \psi}{\psi}$$

$$\text{(Nec}^{\mathbf{m}}\text{)}: \quad \frac{\phi}{[\mathbf{m}]\phi}$$

$$\text{(Nec}^{\mathbf{a}}\text{)}: \quad \frac{\phi}{[\mathbf{a}]\phi}.$$

Theorem 5.1(The soundness theorem). For any formula ϕ, if $\vdash \phi$ then $\models \phi$.

Proof. By the induction on the length of proofs of ϕ. □

Theorem 5.2(The completeness theorem). For any formula ϕ, if $\models \phi$ then $\vdash \phi$.

Proof. Assume that $\models \phi$. By the normal form theorem, there is a formula ψ in the normal form such that $\models \phi \leftrightarrow \psi$. Therefore, $\models \psi$. By taking ψ as a formula in the propositional logic and the completeness theorem of the propositional logic, $\vdash^1 \psi$, and therefore, $\vdash \phi$, where $\vdash^1$ is the deduction relation in the propositional logic which language contains the following propositional variables:

$$p|[\alpha_1]\cdots[\alpha_n]p|[\alpha_1]\cdots[\alpha_n]\texttt{OB}p|[\alpha_1]\cdots[\alpha_n]\texttt{OB}\neg p,$$

where $\alpha ::= \mathbf{m}|\mathbf{a}$. □

6. The variant family deontic logic

One variant family deontic logic is without restraints on applications of modalities.

Formulas can be defined as follows:

$$\phi :: \quad = \quad p|\texttt{OB}\phi_1|\neg\phi_1|\phi_1 \wedge \phi_2|[\mathbf{a}]\phi_1|[\mathbf{m}]\phi_1.$$

Correspondingly, the semantics is the common possible world semantics.

A model $\mathbf{M}$ is a triple (W, R, I), where

• W is a set of possible worlds;

• for each action name $\mathbf{a}$, $R_{\mathbf{a}} \subseteq W^2$ is the accessibility relation for modality $[\mathbf{a}]$, and $R_{\texttt{OB}} \subseteq W^2$ for modality $\texttt{OB}$, and

• I is an interpretation such that for any propositional variable p, $I(p) \subseteq W$; and for any family name $\mathbf{m}$, $I(\mathbf{m}) \in W$.

Given a model $\mathbf{M}$, for any possible world w, a formula ϕ is satisfied at possible world w, denoted by $\mathbf{M}, w \models \phi$, iff

$$\begin{cases} w \in I(p) & \text{if } \phi = p \\ \mathbf{M}, w \not\models \phi_1 & \text{if } \phi = \neg\phi_1 \\ \mathbf{M}, w \models \phi_1 \& \mathbf{M}, w \models \phi_2 & \text{if } \phi = \phi_1 \wedge \phi_2 \\ \mathbf{A}w'((w, w') \in R_{\texttt{OB}} \Rightarrow \mathbf{M}, w' \models \phi_1) & \text{if } \phi = \texttt{OB}\phi_1 \\ \mathbf{A}w'((w, w') \in R_{\mathbf{a}} \Rightarrow \mathbf{M}, w' \models \phi_1) & \text{if } \phi = [\mathbf{a}]\phi_1 \\ \mathbf{M}, I(\mathbf{m}) \models \phi_1 & \text{if } \phi = [\mathbf{m}]\phi_1 \end{cases}$$

If $\mathbf{a} ::= \textbf{birth}(x, y)|\textbf{marry}(x, y)|\textbf{divorce}(x, y)$ then binary relations for the accessibility relations are not appropriate. In the following, we shall give a model for the family deontic logic, in which

◊ a possible world is a family;

◊ action modality $[\textbf{birth}(x, y)]$ changes a possible world w into a new possible world w'; action modality $[\textbf{marry}(x, y)]$ maps two families w and w_1 into a new family w_2; action modality $[\textbf{divorce}(x, y)]$ maps one family w into two new families w_1 and w_2;

◊ the deontic modality $\texttt{OB}$ is interpreted in a classical way.

Such a model $\mathbf{M}$ is a triple (W, R, I), where

◦ W is a set of possible worlds;

◦ $R_{\texttt{OB}} \subseteq W^2$ is the accessibility relation for the modality $\texttt{OB}$; and

$$R_{\textbf{birth}} : W \rightarrow W,$$
$$R_{\textbf{marry}} : W^2 \rightarrow W,$$
$$R_{\textbf{divorce}} : W \rightarrow W^2$$

are the accessibility relations for modalities $[\textbf{birth}], [\textbf{marry}], [\textbf{divorce}]$, respectively; and

◦ I is an interpretation such that for any propositional variable $p, I(p) \subseteq W$, and for any family name $\mathbf{m}, I(\mathbf{m}) \in W$.

Correspondingly, the modality $[\textbf{divorce}]$ is split into two modalities $[\textbf{divorce}^1]$ and $[\textbf{divorce}^2]$, such that for any possible worlds $w, w_1, w_2 \in W$, if $(w, w_1, w_2) \in R_{\textbf{divorce}}$ then $(w, w_1) \in R_{\textbf{divorce}^1}$ and $(w, w_2) \in R_{\textbf{divorce}^2}$. Hence, if x divorces y in action name **divorce** then $[\textbf{divorce}^1]\phi$ means that ϕ is true in a new family of x, and $[\textbf{divorce}^2]\phi$ means that ϕ is true in a new family of y.

The satisfaction relation is defined as follows: $\mathbf{M}, w \models \phi$

iff

$$\begin{cases} w \in I(p) & \text{if } \phi = p \\ \mathbf{M}, w \not\models \phi_1 & \text{if } \phi = \neg\phi_1 \\ \mathbf{M}, w \models \phi_1 \& \mathbf{M}, w \models \phi_2 & \text{if } \phi = \phi_1 \wedge \phi_2 \\ \mathbf{A}w'((w,w') \in R_{\textbf{birth}} & \\ \quad \Rightarrow \mathbf{M}, w' \models \phi_1 & \text{if } \phi = [\textbf{birth}]\phi_1 \\ \mathbf{A}w_1, w_2((w,w_1,w_2) \in R_{\textbf{marry}} & \\ \quad \Rightarrow \mathbf{M}, w_2 \models \phi_1) & \text{if } \phi = [\textbf{marry}]\phi_1 \\ \mathbf{A}w_1, w_2((w,w_1,w_2) \in R_{\textbf{divorce}} & \\ \quad \Rightarrow \mathbf{M}, w_1 \models \phi_1 & \text{if } \phi = [\textbf{divorce}^1]\phi_1 \\ \mathbf{A}w_1, w_2((w,w_1,w_2) \in R_{\textbf{divorce}} & \\ \quad \Rightarrow \mathbf{M}, w_2 \models \phi_1 & \text{if } \phi = [\textbf{divorce}^2]\phi_1 \\ \mathbf{M}, I(\mathbf{m}) \models \phi_1 & \text{if } \phi = [\mathbf{m}]\phi_1 \\ \mathbf{A}w'((w,w') \in R_{\mathtt{OB}} & \\ \quad \Rightarrow \mathbf{M}, w' \models \phi_1) & \text{if } \phi = \mathtt{OB}\phi_1 \end{cases}$$

For the simplicity of discussion, we assume that for any possible world w,

∘ there is one and only one w' such that $(w,w') \in R_{\textbf{birth}}$; w' is denoted by $f_{\textbf{birth}}(w)$;

∘ there is one and only one pair (w_1,w_2) such that $(w,w_1,w_2) \in R_{\textbf{marry}}$; (w_1,w_2) is denoted by $f_{\textbf{marry}}(w)$; and

∘ there is one and only one pair (w_1,w_2) such that $(w,w_1,w_2) \in R_{\textbf{divorce}}$; (w_1,w_2) is denoted by $f_{\textbf{divorce}}(w)$.

Therefore,

$\mathbf{M}, v, w \models [\textbf{birth}]\phi$ iff $\mathbf{M}, v, f_{\textbf{birth}}(w) \models \phi$
$\mathbf{M}, v, w \models [\textbf{marry}]\phi$ iff $\mathbf{M}, v, \pi_2(f_{\textbf{marry}}(w)) \models \phi$
$\mathbf{M}, v, w \models [\textbf{divorce}^1]\phi$ iff $\mathbf{M}, v, \pi_1(f_{\textbf{divorce}}(w)) \models \phi$
$\mathbf{M}, v, w \models [\textbf{divorce}^2]\phi$ iff $\mathbf{M}, v, \pi_2(f_{\textbf{divorce}}(w)) \models \phi$.

7. Conclusions

The family deontic logic can be used in the normative systems and the common-knowledge representation.

A further work would be to give a less restrictive semantics for the family deontic logic, and in such a semantics, the sound and complete axiomatic system could be given.

Abstract - *According to some authors, design strategies for reverse Supply Chain (SC) are relatively unexplored and underdeveloped. We propose a genetic algorithm (GA) that guides the search for an optimal solution to an NP-hard remanufacturing SC problem. It combines a random solution search with an optimal solution method for solving to optimality an associated LP problem. In this GA, each chromosome is generated into two steps. First is generated the part of the chromosome representing whether the facility is opened or closed. The second part of the chromosome is obtained solving to optimality a LP problem associated to the original problem. The proposed genetic algorithm was coded in GAMS. We report computational results for 11 network instances generated randomly with up to 350 sourcing facilities, 100 candidate sites for locating reprocessing facilities and 40 remanufacturing facilities (350x100x40). Computational results regarding GAP and computing times are promising.*

Keywords: Evolutionary algorithm, sustainable supply chain problem; remanufacturing location problems; integer programming

1 Introduction

The management of product return flows has received increasing attention in the last decade. The efficient waste and product return flows stewardship is concerned with the final destination of products and their components, and what is their impact on the pollution of the air, water and earth besides the costs of treating the disposal in landfill. Notice that by 2013 the total e-waste will reach 73 million metric tons. These products not only need to get back to the supplier, re-use or recycled, some disposal also remain in the earth producing several kind of damages. Several regions and nations set up tighter environmental objectives in a collaborative action to mitigate the potential damage for the economic and also the health of the people. There are specific rules in some regions like UE, where The European Waste Electrical and Electronic Equipment Directive (WEEE) and End of Life Vehicles Directive, (ELV) are encouraging companies in the automotive industry to collaborate with other businesses and organizations in the supply chain to ensure that products can be disassembled and reused, remanufactured, recycled or disposed of safely at the end of their life.

In addition to stronger legal environment restrictions, there are several reasons because an increasing number of companies will be interested into get engaged in sustainable initiatives like the management of reverse flows, going backwards from customers to recovery centers, within their supply chain [1, 2]. Some authors noted that huge monetary values "can be gained by redesigning the reverse supply chain to be faster and reduce costly time delays" [3]. According to the same authors, design strategies for reverse supply chains are relatively unexplored and underdeveloped. Returned products are remanufactured if judged cost-effective. Some firms may treat all product returns as defective. Some returned products may be new and never used; then these products must be returned to the forward flow. In this context, remanufacturing activities are recognized as a main option of recovery in terms of its feasibility and benefits. We study this problem as part of reverse logistics problems. In this paper is addressed the problem of designing a remanufacturing supply chain network and it is proposed a type of genetic algorithm for solving it. The problem is a NP-hard combinatorial optimization problem. For randomly generated test instances of the problem, we analyze the performance of the algorithm in term of computing times and quality of the solution obtained.

This paper makes two primary contributions. First it proposes an evolutionary scheme, combining an optimization method inside of a genetic algorithm scheme for solving a reverse distribution problem. Second, a computational study of the method is performed for problem instances of up to 350 sourcing facilities, 100 candidate sites for locating reprocessing facilities and 40 remanufacturing facilities (350x100x40), concluding regarding the quality of the solution obtained and the computing times. These are the largest instances problems tested so far with evolutionary algorithms.

In the second section, we provide a literature review with a brief introduction to sustainable and reverse supply chain and particularly to the remanufacturing case in connection with reverse logistics. In the third section, we formulate the mathematical model for the problem and propose the genetic algorithm for solving it. In the fourth section, we present experimental results for large sets of networks generated randomly. The last section contains our conclusions.

2 Literature review

Adopting a friendly sustainable management implies a number of changes for companies from the strategy level up to the operational point of view, affecting their people and impacting their business processes and technology. In this regards, in [4] is noted, "the strategic level deals with decisions that have a long-lasting effect on the firm. These include decisions regarding the number, location and capacities of warehouses and manufacturing plants, or the flow of material through the logistics network". They established a clear link between facility location models and strategic decisions of supply chain management (SCM). Supply Chain Management - SCM, and in particular Sustainable Supply Chain Management – SSCM gives a good framework to address sustainable issues. Green supply chain management (GSCM) was emerging in the last few years. This concept covers every stage in manufacturing from the first to the last stage of product life cycle, i.e. from product design to recycle. [5] made a carefully literature review and he shows that a broad frame of reference for Green Supply Chain Management (GSCM) is not adequately developed. As a consequence, the author identifies the need for a "succinct classification to help academicians, researchers and practitioners in understanding integrated GSCM from a wider perspective".

We focus on the remanufacturing network (RMN) and then on reverse supply chain. Here, remanufacturing is defined as one of the recovery methods by which worn-out products or parts are recovered to produce a unit equivalent in quality and performance to the original new product and then can be resold as new products or parts.

2.1 Research on Facility Location Problems for Reverse Supply Chain Design

The problem of locating facilities and allocating customers is not new to the operations research community and covers the key aspects of supply chain design [6]. This problem is one of "the most comprehensive strategic decision problems that need to be optimized for long-term efficient operation of the whole supply chain" [7]. Such as it was observed by [8], some small changes to classical facility location models are quite hard to solve.

In the last few years, mathematical modeling and solution methods for the efficient management of return flows (and/or integrated with forward flows) has been studied in the context of reverse logistics, closed-loop supply chain and sustainable supply chain.

Several authors have studied different aspects of closed-loop supply chain problems, see for example [9-14].

In [2] are discussed the new issues that arise in the context of reverse logistics and reviewed the mathematical models proposed in the literature. In [15] is proposed a generic recovery network model based on the elementary characteristics of return networks identified in [2]. In [16] is proposed a generic mixed integer model for the design of a reverse distribution network including repairing and remanufacturing options simultaneously.

Regarding reverse logistics networks in connection with location problems, in [17] is presented a two-level distribution and waste disposal problem, in which demand for products is met by plants while the waste generated by production is correctly disposed of at waste disposal units. In [18] is described a network for recycling sand from construction waste and proposed a two-level location model to solve the location problem of two types of intermediate facility.

Regarding remanufacturing location models, in [19] is described a small reverse logistics network for the returns, processing, and recovery of discarded copiers. They presented a mixed integer linear programming (MILP) model based on a multi-level uncapacitated warehouse location model. The model was used to determine the locations and capacities of the recovery facilities as well as the transportation links connecting various locations. In [20] is proposed a 0-1 MILP model for a product recall distribution problem. They analyzed the particular case in which the customer returns the product to a retail store and the product is sent to a refurbishing site which will rework the product or dispose it properly. The reverse supply chain is composed of origination, collection and refurbishing sites. With the objective to minimize fixed and distribution costs, the model has to decide which collection sites and which refurbishing sites to open, subject to a limit on the number of collection sites and refurbishing sites that can be opened. In [21] are presented three generic facility location MIP models for the integrated decision making in the design of forward and reverse logistics networks. The formulations are based on the well-known uncapacitated fixed-charge location model and they include the location of used product collection centers and the assignment of product return flows to these centers. In [22] is presented a two-level location problem with three types of facility to be located in a reverse logistics system. They proposed a 0–1 MILP model which simultaneously considers "forward" and "reverse" flows and their mutual interactions. The model has to decide the number and locations of three different types of facilities: producers, remanufacturing centers and intermediate centers.

3 Modeling a remanufacturing supply chain network design problem (RSCP)

In this section we present the MIP model for our problem of designing a sustainable supply chain network. This problem can be categorized as a single product, static, three-echelon, capacitated location model with known demand. The remanufacturing supply chain network consists of three types of members: sourcing facilities (origination sites like a retail store), collection sites and remanufacturing facilities. At the customer levels, there are product demands and used products ready to be recovered, for example call phones. We suppose that customers return products to origination sites like a retail store. At the second layer of the supply chain network, there are reprocessing centers

(collection sites) used only in the reverse channel and they are responsible for activities, such as cleaning, disassembly, checking and sorting, before the returned products are sent back to remanufacturing facilities. At the third layer, remanufacturing facilities accept the checked returns from intermediate facilities and they are responsible for the process of remanufacturing. In this paper we address the backward flow of returns coming from sourcing facilities and going to remanufacturing facilities through reprocessing facilities properly located at pre-defined sites. In such a supply chain network, the reverse flow, from customers through collection sites to remanufacturing facilities is formed by used products, while the other ("forward" flow) from remanufacturing facilities directly to point of sales consists of "new" products.

3.1 RSCP Model

In our model is assumed that the product demands (new ones) and available quantities of used products at the customers are known and deterministic. All returned products (used products) are first shipped back to collection facilities where some of them will be disposed of for various reasons, like poor quality. The checked return-products will then be sent back to remanufacturing facilities, where some of them may still be disposed of. We introduce the following inputs and sets:

I = the set of sourcing facilities at the first layer, indexed by i

J = the set of remanufacturing nodes at the third layer indexed by j

K = the set of candidate reprocessing facility locations at the mid layer, indexed by k

a_i = supply quantity at source location $i \in I$

b_j = demand quantity at remanufacturing location $j \in J$

f_k = fixed cost of locating a mid layer reprocessing facility at candidate site $k \in K$

g_k = management cost at a mid layer reprocessing facility at candidate site $k \in K$

c_{ik} = is the unit cost of delivering products at $k \in K$ from a source facility located in $i \in I$

d_{kj} = is the unit cost of supplying demand $j \in J$ from a mid layer facility located in $k \in K$

u_k = capacity at reprocessing facility location $k \in K$

We consider the following decision variables:

w_k= 1 if we locate a reprocessing facility at candidate site $k \in K$,0 otherwise

x_{ik} = flow from source facility $i \in I$ to reprocessing facility located at $k \in K$

y_{kj} = flow from remanufacturing facility located at $k \in K$ to facility $j \in J$

Following the model proposed in [23], the remanufacturing supply chain design problem (*RSCP*) is defined by:

$$Min \sum_{k \in K} f_k w_k + \sum_{k \in K} \sum_{i \in I} c_{ik} x_{ik} \sum_{k \in K} \sum_{i \in I} g_k x_{ik} + \sum_{k \in K} \sum_{j \in J} d_{kj} y_{kj} \quad (1)$$

Subject to

$$\sum_{i \in I} x_{ik} \leq u_k w_k \qquad \forall k \in K \quad (2)$$

$$\sum_{k \in K} x_{ik} \leq a_i \qquad \forall i \in I \quad (3)$$

$$\sum_{k \in K} y_{kj} \geq b_j \qquad \forall j \in J \quad (4)$$

$$\sum_{i \in I} x_{ik} = \sum_{j \in J} y_{kj} \qquad \forall k \in K \quad (5)$$

$$x_{ik}, y_{kj} \geq 0, \qquad \forall i \in I, \forall j \in J, \forall k \in K \quad (6)$$

$$w_k \in \{0,1\} \qquad \forall k \in K \quad (7)$$

The objective function (1) minimizes the sum of the installation reprocessing facility costs plus the delivering costs from sourcing facilities to reprocessing facilities and from these to remanufacturing facilities. Constraint (2) warranties that supplying at facility $k \in K$ is delivered to a mid layer reprocessing facility already opened. Constraint (3) warranties that all the return products from I is going backward to facility $k \in K$. Constraint (4) warranties that the demand at facility j $\in K$ must be satisfied by reprocessing facilities. Constraint (5) ensures that all the return products arriving to facility k are also delivered to remanufacturing facilities. Constraint (6) is a standard positive constraint. Constraint (7) is a standard binary constraint. This model has $O(n^2)$ continuous variables where $n=max\{|I|, |J|, |K|\}$ and $|K|$ binary variables. The number of constraints is $O(n)$.

Notice that following [24], models like the *RSCP* forget the origin of the products arriving to remanufacturing facilities then we lost the trace of the products. To overcome this point, we can get another formulation introducing triply subscripted variables x_{jkl} to manage the origin to destination product flows and some other changes in parameters, variables and constraints. But this is not the objective of this paper.

3.2 An Evolutionary Scheme

Genetic Algorithms (*GA*) are a type of evolutionary algorithms (*EVA*) used to solve a number of combinatorial optimization problems. See for further details the paper by [25]. An *EVA* is composed by five basic components: (a) a genetic representation of solutions to a problem; (b) a way to create an initial population of solutions; (c) an evaluation function; (d) genetic operators that alter the genetic composition of children during reproduction and (e) values for the parameters [26]. In this section we briefly describe these components and the *GA* implementation for solving the *RSCP* problem.

Typical GA encodes the whole solution for the *RSCP* model as a chromosome, and then applies the above scheme for solving the target problem. We follow a little different approach in this paper.

We can set to 0 or 1 the value of variables w_k $\forall k \in K$, let call them w_k^* . Once you set variables w_k^* we can re-write the *RSCP* model as follow:

$RSCP_R$

$$Min \sum_{k \in K^*} f_k w_k^* + \sum_{i \in I} \sum_{k \in K} c_{ik} x_{ik} + \sum_{k \in K} \sum_{i \in I} g_k x_{ik} + \sum_{k \in K} \sum_{j \in J} d_{kj} y_{kj} \quad (1a)$$

$$Subject\ to:$$

$$\sum_{i \in I} x_{ik} \leq u_k w_k^* \qquad \forall\, k \in K^* \quad (2a)$$

$$(2) - (6)$$

Where, the set K^* contains the facilities already opened, and the variables w_k^* are now coefficients with known values. Constraint (*2a*) continues to ensure that all the sourcing facilities deliver return products to a facility already opened. The rest of constraints remain the same as the original *RSCP* model. Moreover, this associated problem is a linear programming problem.

In our evolutionary scheme, we use a genetic algorithm for guiding the whole process of seeking an optimal solution for the *RSCP* problem. However, part of the chromosome is obtained by solving to optimality the $RSCP_R$ problem. In this way, we use a kind of decomposed genetic algorithm.

The evolutionary scheme is as follows:

1. **Generate** an initial population for the head of the chromosome;
    a. Apply the feasibility procedure to satisfy capacity constraints
    b. Solve to optimality the $RSCP_R$ problem
2. **While** not Finish **do**
    a. Solve to optimality the $RSCP_R$ problem;
    b. Apply selection process;
    c. Do a partial crossover to the head of the individuals;
    d. Generate individuals using the mutation operation;
    e. Apply the feasibility procedure to satisfy capacity constraints
3. **Endwhile**;

Observe that, in step (*1*) we generate each chromosome into two steps. In step *(1a)* is generated the head of the chromosome. This part of the chromosome represents whether the facility is opened or closed as described below. The second part of the chromosome (*1b*), we call tale, is obtained solving the $RSCP_R$ problem to optimality. When it is solved the $RSCP_R$ problem, it is also simultaneously computed the fitness of each chromosome. In step (*2*) the cross-over procedure is applied to the head part of the chromosome, and again, the tale part of the chromosome is obtained solving to optimality the $RSCP_R$ problem. The rest of the steps in the above scheme are similar to a classical GA.

3.3 Representation, Initial Population and Feasible Solutions

In our implementation, each solution (individual) to the problem is coded as a chromosome. In the first part of the chromosome, called head, each gene corresponds to a facility location decision variable, taking value *1* if a facility is open at the mid layer, and zero otherwise. We use a $|K|$ dimensional string to represent facilities located. The rest of the chromosome, called the tale, represents the flows of return products between the sourcing facility and the reprocessing facilities and between the reprocessing facilities and the remanufacturing facilities. As described earlier in this paper, the chromosome´s tale is obtained solving to optimality the $RSCP_R$ problem.

An initial population of 20 individuals is generated randomly. Each gene of the head of the chromosome is generated by a 0-1 uniform probability distribution. For each chromosome of the population we apply a simple feasible solution procedure. This procedure consists in two steps. In the first step we check if the number of facilities already opened is enough to satisfy the entire demand. In the second step, for those chromosomes that do not satisfy the demand, we get a feasible solution to *RSCP* based on the initial chromosome. This procedure is rather simple; it starts open facilities till the demand is satisfied. The population is composed of just feasible solutions. The fitness of a chromosome is calculated by solving simultaneously the $RSCP_R$ problem and using the objective function (*1a*).

3.4 Genetic operators

We use the standard genetic operators. The crossover generates one new individual (chromosome) exchanging the genetic material of two (parental) individuals expecting that "good" solutions can generate "better" ones. One of these individuals is selected randomly from a set of 20 individuals, as described earlier. The other individual is the best one selected from the previous population. We do not limit the number of new chromosomes generated by crossover. In this work crossover probability (*cross_p*) is set to 0.7 (70%) and we perform one-point crossover. In the crossover procedure we generate a random value, if the *cross_p* value is greater than the random value then we pick one individual from the set. We generate another random value between one and the number of potential facility sites for the corresponding layer, i.e, a cut point dividing each individual (parent) into two segments. The child is created by combining the first segment from the first parent and the second segment from the second parent. The mutation operator changes the value of a chromosome with some small probability. In our case, we do not practice mutation, we set this probability to 0.0 (0%) and remain constant through generations of the GA. After the crossover procedure, we check for unfeasible solutions in the population. In the next step we correct this.

3.5 Additional Aspects about the Genetic Algorithm

The selection operator is based on elitist selection, favoring individuals of better fitness value to reproduce more often than the worse ones when generating the new population. In every iteration (generation) the whole population (20 individuals) is ranked in a non-decreasing order of the objective function value, and we select always the best individual. As we described earlier, feasibility of

constraints (2) is verified to every individual at every iteration. In case unfeasibility, a feasible routine is applied to get a 100% of feasible solutions in the population. Considering the optimal procedure we applied inside the genetic algorithm, we work with a reduced population size (20) and with 5 generations (iterations). Nevertheless, the performance in term of quality of the solutions obtained and computing times are promising as described hereafter.

4 Numerical Experiments

In this section we discuss and compare the computational results obtained for the proposed evolutionary algorithm. We analyze the performance of the proposed algorithm regarding computational time to get the solution and the quality of the upper bound obtained.

We implemented the algorithm in *GAMS* and we used *CPLEX* as a subroutine (called from inside *GAMS*) for solving to optimality the $RSCP_R$ problem. All the experiments were developed on a PC with 2Gb RAM and 2.3GHz. In the literature, there are not large data sets available for our problem. We generated randomly 11 test problems following similar methodologies used for well known related supply chain problems [22, 23]. These test problems are data sets corresponding to networks of up to 350 origination sites, 100 candidate sites for locating reprocessing facilities and 40 remanufacturing facilities. The data set for the test problems are given in Table 1 and they are available with the authors. All the transportation costs were generated randomly using a uniform distribution with parameters [1,40]. Management costs were set to 30 for all the instance problems except for the No.1. Instances 7-9 are the same than instances 1-6 except for the value of fixed costs that were obtained multiplying by 10 the fixed costs of instances 1-6. Instances 10 and 11 are the same than instances 8 and 9 but the capacity of each location was increased in 50%. Sourcing units (a_j), capacity of reprocessing facilities (m_k) and capacity of remanufacturing facilities (b_l) are shown in Table 1. To illustrate the size problems, problem instances 5 and 6 involve 27,200 positive variables, 80 binary variables and 500 constraints; and 39,000 positive variables, 100 binary variables and 590 constraints, respectively

In order to compare the performance of the proposed algorithm, we tested it with the test instances generated randomly. We run 5 trials for each test instances. Table 2 and 3 show the results obtained using the algorithm. For each instance problem and trial, the tables show the solution provided by the random phase of the algorithm (z_{ran}), the solution provided by the GA (z_{GA}), the computing times (seconds) and the g*ap* ($100[z_{GA}-z^*]/z^*$) obtained comparing the z_{GA} with the optimal integer value of the objective function (z^*) obtained by *GAMS*. All the gap values were rounded to two decimals. The tables also show the minimum, maximum and average value for each column and each test instance. To illustrate, for problem instance 5 and trial 2, the solution value of the random phase (z_{ran}), the GA solution value (z_{GA}), the computing times and the g*ap* are 2,131,500.0, 2,129,200.0, 74.39 seconds and 0,31% respectively. For the same problem instance, the minimum, maximum and average gap are 0.31%, 0.48% and 0.4% respectively. Observe that, for all the test instances, the maximum average *gap* is 3.65% (#1 instance) and the minimum average *gap* is 0.17% (#2 instance). Regarding computing times, notice that all the test instances were solved in less than 106 seconds.

Table 1: Data set

#	Instance Problems	J	K	L	f_k	a_j	m_k	b_l
1	40x20x15	40	20	15	300	150	400	400
2	100x40x20	100	40	20	500	150	400	750

5 Conclusions

In this paper, we proposed a type of genetic algorithm for solving a remanufacturing sustainable supply chain network design (*RSCP*) problem. This is a NP-hard problem and it addresses the design of a remanufacturing supply network that consists of three types of member i.e., sourcing facilities (sources), reprocessing facilities and remanufacturing facilities. At the customer levels, there are product demands and used products ready to be recovered. At the second level we have reprocessing facilities that receive all the returns coming from the origination facilities. At the last level there are remanufacturing facilities. We need lo locate reprocessing facilities in order to minimize the flow cost from the origination to the remanufacturing facilities. The problem was formulated as a mixed integer 0-1 linear programming problem (*MIP*). The genetic algorithm guides the search for an optimal solution to the *RSCP* problem and it combines a random solution search with an optimal solution method for solving to optimality an associated problem. In this genetic algorithm, each chromosome is generated into two steps. First is generated the head of the chromosome, representing whether the facility is opened or closed. The second part of the chromosome is obtained solving to optimality the $RSCP_R$ problem associated to the original *RSCP* problem. Notice that, when the $RSCP_R$ problem is solved, it is also simultaneously computed the fitness of each chromosome. The proposed genetic algorithm was coded in *GAMS* and tested using 11 test instances generated randomly. Considering the few number of chromosomes and the total number of generations we used, computational results regarding *GAP* and computing times are promising.

***Abstract*—Evolutionary sensor deployment algorithm using the dual population scheme and the multiple overlap measure (ESDA-DPMO) is proposed to solve the full-coverage problem with non-penetrable obstacles. The full-coverage state group (FCSG) and the non-full-coverage state group (NFCSG) find sensor deployment solutions using different fitness functions, mutation operators and selection operators, respectively. Two distinguished search directions keep genetic diversity of sensor deployment solutions and avoid getting stuck in local optimum. In addition, information change between two is well designed for efficient exploration ability. The proposed multiple overlap measure boosts both evolution of FCSG and NFCSG. In the FCSG, by gathering sensors together as much as possible, there is a high probability of reducing redundant sensor without breaking full-coverage state. In contrast, in the NFCSG, by scattering sensors as much as possible to get lower overlap rate, higher coverage rate is obtained using same number of sensors. We perform simulations on 3 virtual maps to verify the proposed ESDA-DPMO as compared to conventional approaches. The results show that the proposed ESDA-DPMO provides full-coverage solutions efficiently.**

I. Introduction

A coverage problem has received much attention in the various research fields, such as such as environmental monitoring, military detection and indoor surveillance in a target area, because coverage can be considered as a measure of the quality of services or tasks [1]–[4]. Whole region of interest should be covered by combination of many sensors to accomplish their own tasks or applications. Although there are given a large number of sensors in a sensor network, inefficient sensor deployments may lead to a low coverage rate and low performance. Thus, the importance of proper sensor deployment strategies for the coverage in the target region cannot be overemphasized.

The evolutionary approach has combined the characteristics of randomized approaches and deterministic approaches. Genetic algorithms(GA) [9], [10], Differential Evolution(DE) [11], Multiobjective approaches [12] and other heuristic optimization methods are adopted to coverage problems. Most algorithms are based on weighted sum approaches among the coverage rate, the overlap rate and the number of deployed sensors. This bottom-up approach may lead to partial-coverage above predefined percentage efficiently. However, it is difficult to provide full-coverage sensor deployment with minimum number of sensors, because these objective functions are highly correlated. In contrast, an evolutionary sensor deployment algorithm (ESDA) [13] uses a top-down approach which gives top priority to full-coverage state solutions. This top-down approach provides efficient full-coverage state solution with minimum number of sensors with well-designed mutation operators and chromosome representations. However, there is some discontinuity at the reduction of sensors while keeping the full-coverage state.

In this paper, The ESDA with dual population structure and multiple overlap measure (ESDA-DPMO) is proposed. Proposed dual population structures keep sensor deployment solutions according to fitness function of each approach respectively. In addition, information change between dual populations are well designed, so excluded individuals in a group are refined slightly and are sent to selection procedure of the other group. Another proposed measure is the multiple overlap measure for the dual population. Multiple overlap measure facilitates the optimization of two groups in dual population, the full-coverage state group (FCSG) and the non-full-coverage state group (NFCSG).

The remainder of this paper is organized as follows. Section II presents the definition of the full-coverage problem with non-penetrable obstacles. Section III explains the chromosome representation and obstacle-avoidance mutation operators of ESDA preliminarily. Section IV describes the proposed ESDA-DPMO in detail and the dual population structures and multiple overlap measure. Section V shows the simulation results among sensor deployment algorithms in various maps. Section VI concludes this paper.

II. Full-coverage Problem with Non-penetrate Obstacles

The purpose of the coverage problem is that the whole target area or target points are covered or monitored by

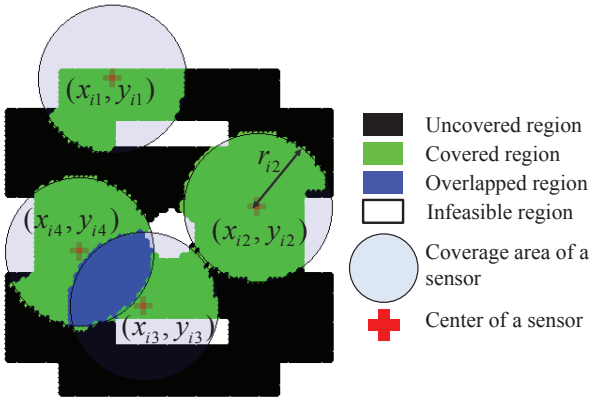

Figure 1. Sensor deployment solution representation.

sensors. A Map and sensors representations are as follows. The detail definition of the problem is defined in [13].

A. Problem Definition

1) Map Representation: A target region is denoted as R. An entire region is divided into a feasible region R_f and an infeasible region R_i. R_f and R_i are excluded.

In the feasible region R_f, sensors can be installed and this region can be covered by sensors within the coverage range. R_f can be divided into 3 subregions. First, an uncovered region R_u is defined as the region that is not covered by any sensors. A covered region R_c is defined as the region that is covered by at least one sensor. An overlapped region R_o is defined as the region that is covered by two or more sensors. In contrast, in the infeasible region R_i, sensors cannot be installed and the sight of a sensor is blocked. Generally, R_i is directly related to an obstacle region.

An entire target region R of an indoor environment is represented as a rectangular composed of a set of sample points $R = \{r_1, r_2, ..., r_{N_e}\}, N_e = W \times L/d^2$, where N_e is the number of samples in the entire region, W is the width of the rectangle including R and L is the length of the rectangular including R, and d is the interval between sample points. For the sake of convenience, we approximate an area-coverage problem into a dense point-coverage problem. The interval between sample points is much smaller than the sensing range of a sensor, the size of the obstacles and the total size of the map.

2) Sensor Representation: A sensor network S is composed of a number of sensors, $S = \{s_1, s_2, ..., s_{N_s}\}$, where s_i denotes ith sensor and N_s represents the number of sensors in the sensor network.

A binary disk model is used as the coverage model of a sensor s in a free space. A sensor s is located on the x, y axis and a feasible sensing range r. The position of the sensor (x, y) is on the target region R. Fig. 1 shows the example of the sensor deployment solution.

In some literature, probabilistic sensor models are often considered [14]. By varying the range of disk, the required number of sensor and the characteristics of sensor deployment can be reflected on the problem. So, the sensor model is not significantly addressed in this paper.

3) Objective Functions: Objective functions of the sensor arrangement problem are given as follows.

- Coverage rate(%) $F_c = 100 \times n(R_c)/n(R_f)$
- Overlap rate(%) $F_o = 100 \times n(R_o)/n(R_f)$
- Number of feasible sensor $N_s = n(S)$

The equivalent function of the coverage rate F_c is defined as uncovered rate $F_u = 100 - F_c(\%)$.

The objectives of the problem are as follows: A full-coverage sensor arrangement is required, $F_c = 100(\%)$. Every sample point is to be covered by the sensors. Minimization of the number of sensors leads to the reduction of overall cost. The other objective is the overlap rate among the sensors. The overlapped region can provide information about redundancy of sensor deployment. This overlap rate can be used differently in the dual population group, and specialized into the multiple overlap measure in Section IV.

III. Evolutionary Sensor Deployment Algorithm

In this section, the ESDA is briefly introduced [13]. The ESDA with obstacle-avoidance mutation operators solves the full-coverage sensor deployment problem. The encoding scheme and the representation on the individuals are introduced. Next, the obstacle-avoidance mutation operators are described.

A. Variable-Length Chromosomes Representations

A population P represents a set of sensor deployment solutions, $P = \{C_1, C_2, ..., C_{N_p}\}$, where N_p is the population size. The population of the ith generation is denoted as P_i, $i = 1, 2, ..., G_{max}$. Each chromosome C in the population P represent a sensor deployment solution including a sensor network S. Each gene g in a chromosome is mapped to a sensor s. A gene g has 3 properties: the position of sensor with respect to X and Y coordinates (x, y) and the radius of the sensing range, r. The variable g_{ij} represents sensor S_j including the location and the radius of the sensor. The variable j is the total number of sensors in the entire region, $i = 1, 2..., N_p$, where N_p is the number of chromosomes in the population P. A population structure is shown in Fig. 2(a).

B. Obstacle-Avoidance Mutation Operators

1) Insertion Mutation: This operator adds a gene into the offspring chromosomes. Physically, a sensor is deployed additionally for covering the uncovered region in the sensor arrangement solution represented by each chromosome. The operation is illustrated in Fig. 2(b). It may improve the coverage rate, but the required number of sensors is increased.

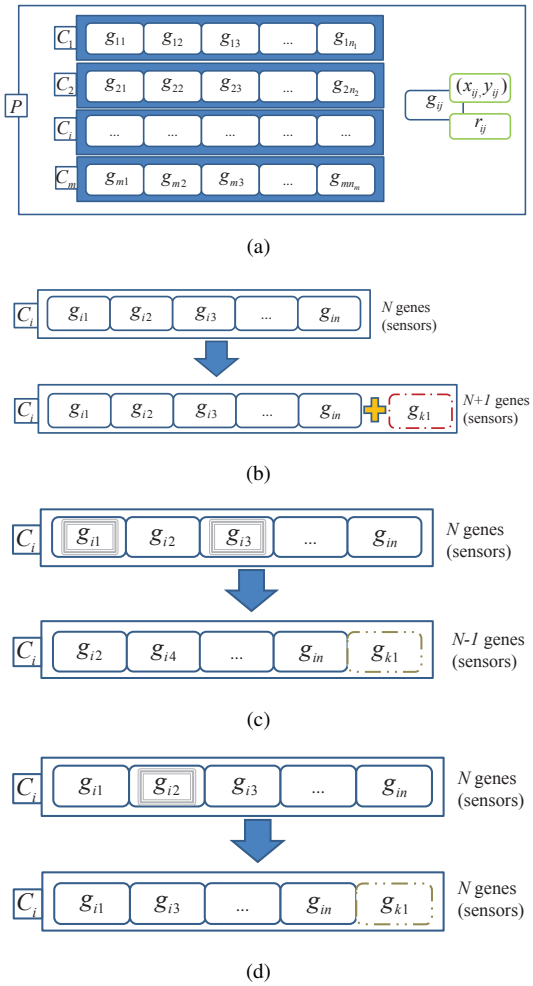

Figure 2. (a) Population, chromosomes, genes representation for sensor deployment solution. (b) Illustration of the operation of insertion mutation operator. (c) Illustration of the operation of fusion mutation operator. (d) Illustration of the operation of substitution mutation operator.

2) Fusion Mutation: If this operator is selected in some chromosome, ESDA selects a gene on the chromosome and finds the gene corresponding to nearest sensor. ESDA tries to merge two genes into a new gene within the square region made by centers of two sensors. If the center of new sensor is on the R_i, this operator applied to two genes is invalid and the substitution mutation is performed. If ESDA checks the validity of this operator successfully, two select genes are deleted and new merged gene is inserted to the chromosome. An example is illustrated in Fig. 2(c). This operator reduces the number of sensors while keeping the full-coverage state as much as possible.

3) Substitution Mutation: This operator moves a randomly selected sensor. A sensor can move towards any direction among 8 directions by at most a half of sensing range within the feasible region. An example is illustrated in Fig. 2(d). This operator has weaker effects because a risk

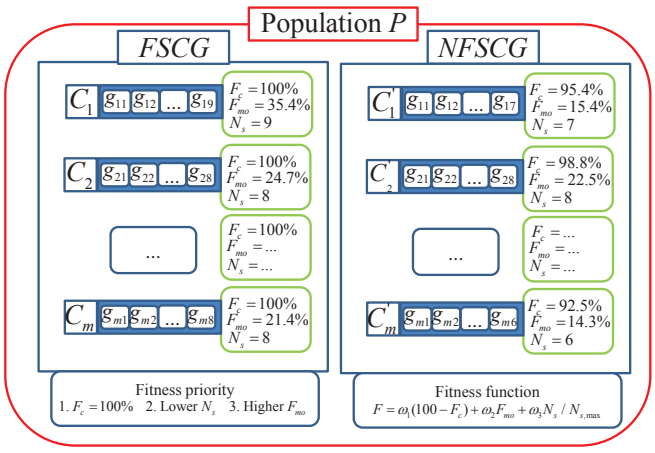

Figure 3. Illustration of ESDA-DPMO population structure.

of failing full-coverage state exists and the overall number of sensors is not reduced. Small amount of exploitation can be performed steadily.

IV. Proposed Dual Population Structure and Multiple Overlap Measure for ESDA

This section introduces ESDA-DPMO for solving the full-coverage sensor node deployment problem. The dual population structure and the multiple overlap measure are also introduced.

A. Dual Population Structure

There are two way of improving deployment solutions. One is that full-coverage solutions are obtained by inserting sensors, and then try to reduce redundant sensor. The other is that the sensors are scattered properly in target region without inserting additional sensors. The former is to keep the full-coverage state solutions in the population as much as possible. In contrast, the latter is to reduce the redundancy of current sensor deployment solutions without changing the number of sensors. In this paper, two population groups are proposed for satisfying both approaches. One is the FCSG for the top-down approach and the other is the NFCSG for the bottom-up approach.

1) Full-Coverage State Group: The fitness function of FCSG is composed of a hierarchical structure. The primary fitness function of FCSG is whether 100% coverage is satisfied or not. Let FG_i be the FCSG of ith generation and let FC_k be the kth individual in the FG_i. If full-coverage state is not satisfied, then the FG_i cannot get higher fitness value in the FG_i regardless of the number of deployed sensors. When there are two solutions with full-coverage state, less number of sensors and higher overlapped rate are compared in turn. Higher overlapped region may lead to gather the sensors as much as possible, thus the probability of eliminating excess sensors are increased.

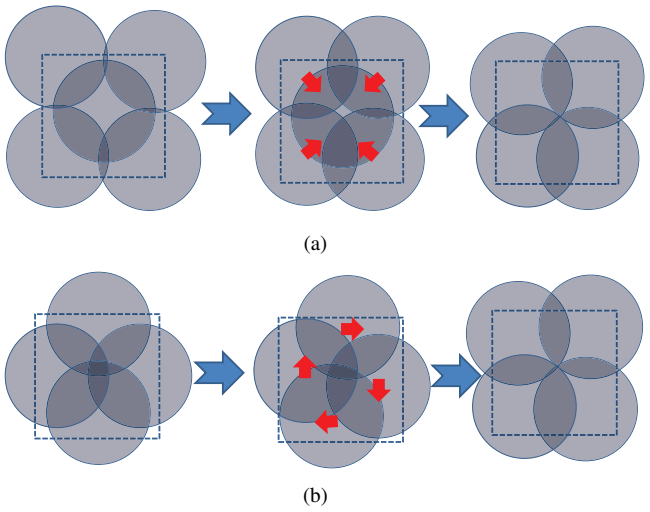

Figure 4. Two full-coverage sensor deployment approach with minimum sensors. (a) A top-down approach. The individual is included in FCSG. (b) A bottom-up approach. The individual is included in NFCSG.

Applied mutation operators are fusion and substitution mutation. Fusion mutation is mainly applied to reduce the number of sensors while keeping the full-coverage state as much as possible. When there is excess number of sensors on some individual and redundancy is appeared, it is highly probable that two sensors are merged into one sensor without breaking the full-coverage state solution. In contrast, the substitution mutation is applied to move a sensor a small amount, thus finding higher overlapped rate solutions. This mutation operator cannot reduce the number of sensor, so the result is not significantly improved compared with fusion mutation.

Selection procedure is defined as follows. After mutation operators are applied to FC in current generation, the generated offspring individuals FC' are checked whether the full-coverage state is satisfied or not. Survived offspring FC'_k are included in the full-coverage offspring group, FO_i. Also, some offspring which satisfy the full-coverage state by inserting sensors from the NFCSG are also included in the FO_i. The parent individuals of FC_{i+1} are selected by the tournament selection among individuals of FO_i and FG_i in the current generation.

FCSG finds full-coverage state solutions using the top-down approach by keeping full-coverage state during all generations.

2) Non-Full-Coverage State Group: NFCSG does not need to keep the full-coverage state. Let NFG_i be the NFCSG of ith generation and let NC_k be the kth individual in the NFG_i. The coverage rate below 100% is allowed and it is possible that the individuals with less number of sensors can be survived in NFCSG. There is no strict hierarchy in the fitness function of the NFCSG. Weighted sum fitness function is used in the NFCSG. Certainly, the coverage rate is most important and the number of sensor is as follows and the overlapped rate is last. The difference compared as FCSG is the overlapped rate. To increase the successful rate of fusion mutation, the higher overlapped rate is demanded in the FCSG, but in the NFCSG, there is no need to use fusion mutation because the full-coverage state is already not satisfied. The coverage rate of individuals in NFCSG is less than 100%, thus the reduction of sensor is not proper to satisfy full-coverage state. The substitution of each sensor is only allowed, and tries to obtain full-coverage state solutions without adding or deleting sensors.

Applied mutation operators are substitution and insert mutation. The substitution mutation is applied to each NC_k, and then NC'_k is generated. To obtain higher coverage rate and lower overlapped rate, the sensors should be scattered properly. Insertion mutation is only applied to generate full-coverage individuals NC''_k for the FO_i as mentioned previously.

Selection procedure is defined as follows. Some individuals FC'_k which are failed to check full-coverage state from the FG_i are included in the non-full-coverage offspring group, NFO_i. Also, all offspring NC' are included in NFO_i. The parent individuals of NFC_{i+1} are selected by the tournament selection among individuals of NFO_i and NFG_i in the current generation.

3) Information change: Tournament selection procedure is applied to each group using different fitness functions. Two groups are independently evolved, but the information change between two groups can increase genetic diversity to avoid getting stuck in the local optimum. In addition, the non-selected individuals are recycled in other group with minor refinement, thus computational cost can be reduced.

B. Multiple Overlap Measure

Multiple overlap measure is proposed in this paper. Multiple overlap measure considers more penalty or advantage in the region which covered by many sensors. Multiple overlap measure facilitates to gather sensors as much as possible in FCSG and to split sensors as much as possible in NFCSG. In the literatures, the overlapped region is defined as the region covered by two or more sensors, thus the influence of multiple sensors are not concerned. However, as the number of sensors is increased in some region, the probability of merging sensors is also increased in FCSG. Also, in the NFCSG, it means that the sensors are not properly scattered in the target region. Multiple overlap measure is defined as follows.

$$F_{mo} = 100 \times n(R_{mo})/n(R_f) \quad (1)$$

$$R_{mo} = \sum((i-1) * R_{o,i}), \qquad i = 2, 3, \ldots \quad (2)$$

If there are only overlapped region by two sensors, then $R_{mo} = R_{o,2} = R_o$. As the number of overlapped sensor is increased at one sample point, the overlapped point is

$FG_0, NFG_0 \leftarrow$ Initialize and evaluate populations

Table I
MAP SETTING

	Optimum N_s	Sample Points $n(R_f)$	Map Size
Map1	11	2753	10mX10m
Map2	26	8010	15mX22.5m
Map3	53	14961	25mX30m

counted as $(i-1) \times R_{o,i}$ points. In the conventional ESDA, $R_o \subset R_c$ and $n(R_o) \leq n(R_c)$ are satisfied, however, in the proposed ESDA-DPMO, $R_{mo} \subset R_c$ is still satisfied, but $n(R_{mo}) \leq n(R_c)$ is not always valid because of count multiplicity of overlapped region by 3 or more sensors.

V. SIMULATION RESULTS

In this section, ESDA-DPMO and other conventional ESDA algorithm are applied to various types of maps.

Table II

Light Blue	4
Purple	5

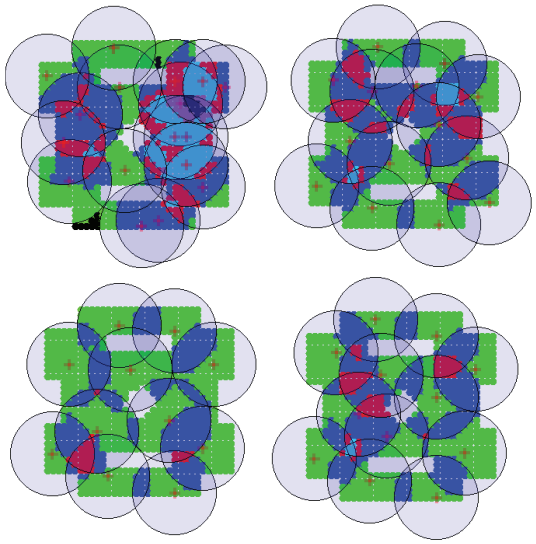

Figure 6. Best sensor deployment results in the Map1. 1st, 100th, 200th and 245th(final) generation from the left-most figure in a clockwise direction.

A. Simulation Conditions

In this simulation, we used the following parameter settings: N_p is fixed at 40 and the number of offspring generated is a half of the N_p; In the FCSG of ESDA-DPMO, the fusion mutation is applied 75% probability and the substitution mutation is applied by 25%. In the NFCSG of ESDA-DPMO, the fusion mutation is excluded and the only substitution mutation is applied all the time. Also, insertion mutation is applied to generate full-coverage state solutions in the NFCSG. Map information is shown in Table I.

$N_{s,max}$ is determined by the average number of sensors from the random deployment until the full-coverage state is satisfied during 10 iterations. Average numbers of evaluation, generation and computation times are average value during 20 independent iterations.

B. Sensor Deployment Results in the Virtual Maps

The number of covered sensor according to color in the figures are described in the Table II. The number of generations and computation times in the 3 virtual maps of each algorithm are shown in Table III. Because the ORRD is deterministic approaches, the deployed number of sensor is mentioned only. Fig. 6, 7 and 8 show the best deployment

results of ESDA-DPMO in the 3 maps according to the number of generations.

1) Convergence Property of ESDA-DPMO: In the Fig. 6, because the sensors are randomly placed, there are a lot of uncovered region and highly overlapped region. When the number of sensors is enough to cover the whole region in the early generations, the redundant sensors are merged or deleted by the fusion mutation on the individuals of the FCSG. In the 100th generations, there are little multiple-overlapped region compared as initial solutions. As the ratio of multiple-overlapped region is decreased, the redundancy of sensor deployment is also increased. It is more difficult to reduce a sensor as the number of sensors approaches into the optimal number. In this situation, the influence of individuals of the NFCSG affects to find less number of sensors while keeping a full-coverage state. The fusion mutation has a risk of breaking the full-coverage state, but, this operation is indispensable to reduce the number of sensors. The NFCSG receives the individuals which loses full-coverage state from the FCSG, and provides new location of sensors to the FCSG. Because the location of sensors using fusion mutation is restricted by the distance between sensors, the diversity of solutions are not enough to reduce even one sensor. In summary, when the excess number of sensors is deployed, the optimization of FCSG leads to delete redundant sensors, and then the NFCSG supports the weakness of FCSG according to lower redundancy when less number of sensors.

2) Comparison with Other Algorithms: First, the simple deployment using GA suffers from the continuous property of weighted sum approaches. To increase the coverage rate, the overlap rate is also increased due to the coverage rate of neighbor sensors. Small variation between the coverage rate and the overlap rate interferes to keep the full-coverage state solutions. Therefore, the computational cost is wasted to find non-full-coverage state solutions. In the Map3, the simple deployment using GA severely suffers from finding the full-coverage state solutions. Certainly, the solutions with higher coverage rate and excess number of sensors can be defeated by the solutions with lower coverage rate and less number of sensors in the complex map. The ESDA-DPMO and the ESDA-ori shows better performance than the simple deployment using GA.

By comparing ESDA-DPMO and ESDA-ori, the ESDA-DPMO shows better performance compared as the ESDA-ori in perspective of the number of generations. It seems that two reasons can be found. One is the existence of multiple

overlap measure in the ESDA-DPMO and the other is the full-coverage state solutions generated by the individuals of the NFCSG help to escape the local optimum more easily. In fact, it seems that it is difficult for the individuals of NFCSG to generate many full-coverage state solutions, but the many solutions with higher coverage rate and less number of sensors near the full-coverage state solutions can be generated and provided. This cooperation of two distinguished population structure may be helpful to get the full-coverage state solutions in the complex environment. Meanwhile, the ESDA-DPMO takes more computational time compared as the ESDA-ori. It seems that the minor refinements to provide full-coverage state solution from the NFCSG to the FCSG requires more time a little bit.

One of the deterministic algorithms, ORRD cannot provide sensor deployment solutions with full-coverage state using minimum number of sensors. These deterministic approaches deploy sensors sequentially in the environment, thus obtaining full-coverage state in the end. However, the number of sensors is not considered at all.

VI. Conclusion

In this paper, evolutionary sensor deployment algorithm using the dual population scheme and the multiple overlap measure is proposed to solve the full-coverage problem with non-penetrable obstacles.

The FCSG and the NFCSG of dual population structure keep genetic diversity of sensor deployment solutions and avoid getting stuck in local optimum. In addition, information change between dual populations lead to less computational cost compared as generating new individuals from scratch. Also, more efficient exploration ability is obtained by combining two different characteristics

The proposed multiple overlap measure boosts both evolution of FCSG and NFCSG. In the FCSG, by gathering sensors together as much as possible, there is a high probability of reducing redundant sensor without breaking full-coverage state. In contrast, in the NFCSG, by scattering sensors as much as possible to get lower overlap rate, higher coverage rate is obtained using same number of sensors.

Compared with conventional ESDA, simple deployment using genetic algorithm and deterministic algorithm, ORRD, the proposed ESDA-DPMO provides full-coverage state solutions with minimum number of sensors using less computational cost.

A Binary Particle Swarm Optimization-based algorithm to Design a Reverse Logistics Network

Ernesto Del R. Santibanez-Gonzalez[1], and Henrique Pacca Luna[2]
[1]Department of Computer Science, Federal University of Ouro Preto, Ouro Preto, MG, Brazil
[2]Computer Science Institute, Federal University of Alagoas, Maceió, AL, Brazil

Abstract - *As recognized by several authors, the design of a reverse logistics network is a complex problem and still relatively unexplored and underdeveloped. We propose a binary particle swarm optimization (BPSO)-based scheme for solving a NP-hard remanufacturing network design problem. The algorithm combines a traditional stochastic search with an optimal solution method for solving to optimality a relaxed LP problem. We divide the swarm into two elementary groups. The first swarm group guides the search for the best location of remanufacturing facilities, while the second group defines the optimal flows between the facilities. We solve to optimality a relaxed LP problem obtained from the original problem and then we project the solution into the swarm space. The algorithm was coded in GAMS and we report computational results for 10 network instances generated randomly with up to 350 sourcing facilities, 100 candidate sites for locating reprocessing facilities and 40 remanufacturing facilities. Computational results regarding gap and computing times are promising.*

Keywords: Evolutionary algorithm ; particle swarm optimization; sustainable supply chain problem; reverse logistics; integer programming

1 Introduction

The management of product return flows has received increasing attention in the last decade. The efficient stewardship of waste and product return flows is concerned with the final destination of products and their components, and what is their impact on the pollution of the air, water and earth besides the costs of treating the disposal in landfill. There are specific rules in some regions like the European Union, where The European Waste Electrical and Electronic Equipment Directive (WEEE) and the End of Life Vehicles Directive, (ELV) are encouraging companies in the automotive industry to collaborate with other businesses and organizations in the supply chain to ensure that products can be disassembled and reused, remanufactured, recycled or disposed of safely at the end of their life.

In addition to stronger legal environmental restrictions, there are several reasons why an increasing number of companies will be interested in becoming engaged in sustainable initiatives such as the management of reverse flows within their supply chain [1,2]. Such as it was noted by some authors [3], huge monetary values 'can be gained by redesigning the reverse supply chain to be faster and reduce costly time delays'. According to the same authors, design strategies for reverse supply chains are relatively unexplored and underdeveloped. Returned products are remanufactured if this strategy is judged to be cost-effective. Some firms could treat all of the product returns as defective. Some returned products may be new and never used; then these products must be returned to the forward flow. Some products that are not reused or remanufactured are sold for scrap or recycling. Remanufactured products are sold in secondary markets for additional revenue, often to a marketing segment that is unwilling or unable to purchase a new product. In this context, remanufacturing activities are recognized as a main option of recovery in terms of their feasibility and benefits. In this paper is addressed the problem of designing a remanufacturing supply chain network and it is proposed a binary particle swarm optimization-based algorithm for solving it. We study this NP-hard combinatorial optimization problem as part of reverse logistics problems.

In the last decades, evolutionary algorithms (EVO) have been widely used as robust techniques for solving a number of hard combinatorial optimization (CO) problems. An EVO is directed by the evolution of a population in the search for an optimum solution to the CO problems. Particle Swarm Optimization (*PSO*) is an evolutionary algorithm that has been applied with success in many areas and appears to be a suitable approach for several optimization problems. Since it has been indicated by some authors, in spite of this technique to have been used by success in many continuous problems, in the discrete or binary version there are still some difficulties [4]. In this paper, for test instances of the problem that were generated randomly, we analyze the performance of the proposed algorithm in term of computing times and quality of the solution obtained.

This paper makes two primary contributions. First, we propose a *PSO*-based scheme, combining an optimization method inside of a *PSO* algorithm scheme for solving a reverse supply chain problem. Second, a computational study of the proposed method is performed for problem instances of up to 350 sourcing facilities, 100 candidate sites for locating reprocessing facilities and 40 remanufacturing facilities (350x100x40), to provide conclusions regarding the quality of the solution obtained and the computing times. These are the largest instances problems tested so far with evolutionary algorithms.

The rest of the paper is organized as follows: In the second section, we provide a literature review with a brief introduction to sustainable and reverse supply chain and with a special emphasis on to the remanufacturing case in connection with reverse logistics. In the third section, we formulate the mathematical model for the problem. In section 4 is proposed the *PSO* algorithm for solving it. In the fifth section, we present experimental results for large sets of networks generated randomly. The last section contains our conclusions.

2 Literature review

The rise of environmental and sustainable concern implies a number of changes for companies from the strategy level to the operational viewpoint, affecting their people and impacting their business processes and technology. In this regard, network design and facility location models are among the important strategic decisions for companies and organizations facing sustainable issues. Supply Chain Management - SCM, and more specifically Sustainable Supply Chain Management – SSCM provide a good framework for addressing sustainable issues. SSCM involves (a) many organizations, (b) many business processes across and within these organizations, and (c) with social, environmental and economic objectives shared by each organization and the entire Supply Chain. Reverse logistics is part of the SSCM and comprises a series of activities to treat returned products until they are properly recovered or disposed of [1]. These activities include collection, cleaning, disassembly, test and sorting, storage, transport, and recovery operations. Regarding recovery operations, we can find a combination of several main recovery options, like reuse, repair, refurbishing, remanufacturing, cannibalization and recycling [5].

There is another type of important logistics network design problem for the specific case of closed-loop supply chains. Typically, the problem of logistics network design is addressed for 'forward' supply chains or reverse supply chains, as in the case that we mentioned previously. When we integrate the forward and reverse supply chains, we obtain a closed system and then there is a new class of problems encompassed by the term closed-loop supply chain management (and design).

In this paper, we focus on the remanufacturing network problem and then on reverse supply chain. Here, remanufacturing is defined as one of the recovery methods by which worn-out products or parts are recovered to produce a unit that is equivalent in quality and performance to the original new product and that can be resold as new products or parts. Because remanufacturing activities are often implemented by the original producer such a network is likely to be a closed-loop system. Remanufacturing activities are recognized as the main option for recovery in terms of feasibility and benefits. It provides firms with a way to master the disposal of their used products, to reduce effectively the costs of production and to save raw materials.

2.1 Research Related to Network Design and Facility Location Models for Reverse and Closed-loop Supply Chain

The facility location is one of the strategic problems being part of a planning process for managing and designing the supply chain network. The problem of locating facilities and allocating customers is not new to the operations research community and covers the key aspects of supply chain design [6]. This problem is one of 'the most comprehensive strategic decision problems that need to be optimized for long-term efficient operation of the whole supply chain' [7]. As it was observed by [8], some small changes to classical facility location models turn these problems quite hard to solve.

In the last few years, mathematical modeling and solution methods for the efficient management of return flows (and/or integrated with forward flows) has been studied in the context of reverse logistics, closed-loop supply chain and sustainable supply chain.

In [9] the research on reverse logistics (and closed-loop supply chain) was classified into three functional areas: Distribution, Inventory and Production and, Supply Chain Scope. Traditional distribution decisions involve the design of network and the location of forward and reverse facilities for the distribution of products and for collecting and reprocessing returned products. In this work we focus on quantitative models for designing closed-loop supply chains, and it concerns the decisions regarding the topological structure of the network, the number of facilities to locate, their locations and capacities and the allocation of product flows between the facilities.

For a review of research on quantitative models for reverse logistics and closed-loop supply chains before 2000, we refer to [9]. [10] did a compilation of the research published on reverse logistics within the period 1995-2005. They studied the topic based on the classification proposed by [9].

As argued by numerous authors, traditional approaches for solving closed-loop (reverse) supply chains network design problems usually formulate large-scale mixed-integer linear programs (MILP) that model potential facility location as binary and product flows as positive variables. Typically, these problems belong to the class of NP-hard combinatorial optimization problems. The integration between forward and reverse flows into closed-loop supply chains networks introduce some modifications to the traditional facility location models and also give rise to some additional complexities.

In chronological order, reverse logistics models are discussed recently, for example, by [11-14]. Almost all the authors proposed MILP models. The majority of solution methods are based on standard commercial packages.

Closed-loop supply chain models are taking into account in [15-19]. Stochastic models in combination with multiobjective function were presented by [20].

Regarding evolutionary algorithms for solving related problems have been studied by: Simulated Annealing [21]; Genetic Algorithm [18], [22], [23]; Memetic Algorithm [24] and Tabu Search [21]. Notice that in [23] were solved problems of up to 15 returning centers, 10 disassembly centers

and 14 processing centers. They did not report computational results regarding time or the quality of the gap obtained. In [21] were solved problems with network of up to 100x40x30 with a maximum computing time (s) of 2,939 and a maximum gap (compared to a lower bound) of 15%.

2.2 Discrete Particle Swarm Optimization Algorithm

PSO is a metaheuristics based on the social behavior and communication of bird's flock and shoal of fishes [25]. *PSO* can be considered as an evolutionary algorithm because its way of exploration via neighborhood of solutions (particles) across a population (swarm) and exploiting the generational information gained. But, it has some divergences from other evolutionary algorithms in such a way that it has no evolutionary operators such as crossover and mutation of genetic methods. *PSO* has the advantage that is ease of use with fewer parameters to adjust. In *PSO*, the potential solutions (particles), move around in a multidimensional search space with a velocity, which is constantly updated by a combination of the particle's own experience, the experience of the particle's neighbors and the experience of the entire swarm. *PSO* has been successfully applied to a wide range of applications [26]. Since *PSO* is developed for continuous optimization problem initially, most existing *PSO* applications are resorting to continuous function value optimization [26, 27]. Recently, a few researches applied *PSO* for solving discrete combinatorial optimization problems (for example: [28, 29]).

3 Mathematical Model for designing a remanufacturing supply chain network (RSCP)

In this section we present the MILP model for the problem of designing a sustainable supply chain network. This problem can be categorized as a single product, static, three-echelon, capacitated location model with known demand. The remanufacturing supply chain network consists of three types of members: sourcing facilities (origination sites like a retail store), collection sites and remanufacturing facilities. At the customer levels, there are product demands and used products ready to be recovered, for example cell phones. We suppose that customers return products to origination sites like a retail store. At the second layer of the supply chain network, there are reprocessing centers (collection sites) used only in the reverse channel and they are responsible for activities, such as cleaning, disassembly, checking and sorting, before the returned products are sent back to remanufacturing facilities. At the third layer, remanufacturing facilities accept the checked returns from intermediate facilities and they are responsible for the process of remanufacturing. In this paper we address the backward flow of returns coming from sourcing facilities and going to remanufacturing facilities through reprocessing facilities properly located at pre-defined sites. In such a supply chain network, the reverse flow, from customers through collection sites to remanufacturing facilities is formed by used products, while the other ("forward" flow) from remanufacturing facilities directly to point of sales consists of "new" products.

3.1 RSCP Model

In our model is assumed that the product demands (new ones) and available quantities of used products at the customers are known and deterministic.

We introduce the following inputs and sets:

I = the set of sourcing facilities at the first layer, indexed by i

J = the set of remanufacturing nodes at the third layer indexed by j

K = the set of candidate reprocessing facility locations at the mid layer, indexed by k

a_i = supply quantity at source location $i \in I$

b_j = demand quantity at remanufacturing location $j \in J$

f_k = fixed cost of locating a mid layer reprocessing facility at candidate site $k \in K$

g_k = management cost at a mid layer reprocessing facility at candidate site $k \in K$

c_{ik} = is the unit cost of delivering products at $k \in K$ from a source facility located in $i \in I$

d_{kj} = is the unit cost of supplying demand $j \in J$ from a mid layer facility located in $k \in K$

u_k = capacity at reprocessing facility location $k \in K$

We consider the following decision variables:

w_k= 1 if we locate a reprocessing facility at candidate site $k \in K$,0 otherwise

x_{ik} = flow from source facility $i \in I$ to reprocessing facility located at $k \in K$

y_{kj} = flow from remanufacturing facility located at $k \in K$ to facility $j \in J$

Following the model proposed by [30], the remanufacturing supply chain design problem (*RSCP*) is defined by:

$$Min \sum_{k \in K} f_k w_k + \sum_{k \in K} \sum_{i \in I} c_{ik} x_{ik} \sum_{k \in K} \sum_{i \in I} g_k x_{ik} + \sum_{k \in K} \sum_{j \in J} d_{kj} y_{kj} \quad (1)$$

Subject to

$$\sum_{i \in I} x_{ik} \leq u_k w_k \qquad \forall k \in K \quad (2)$$

$$\sum_{k \in K} x_{ik} \leq a_i \qquad \forall i \in I \quad (3)$$

$$\sum_{k \in K} y_{kj} \geq b_j \qquad \forall j \in J \quad (4)$$

$$\sum_{i \in I} x_{ik} = \sum_{j \in J} y_{kj} \qquad \forall k \in K \quad (5)$$

$$x_{ik}, y_{kj} \geq 0, \qquad \forall i \in I, \forall j \in J, \forall k \in K \quad (6)$$

$$w_k \in \{0,1\} \qquad \forall k \in K \quad (7)$$

The objective function (1) minimizes the sum of the installation reprocessing facility costs plus the delivering costs

from sourcing facilities to reprocessing facilities and from these to remanufacturing facilities. Constraint (2) warranties that supplying at facility $k \in K$ is delivered to a mid layer reprocessing facility already opened. Constraint (3) warranties that all the return products from I is going backward to facility $k \in K$. Constraint (4) warranties that the demand at facility j $\in$ K must be satisfied by reprocessing facilities. Constraint (5) ensures that all the return products arriving to facility k are also delivered to remanufacturing facilities. Constraint (6) is a standard positive constraint. Constraint (7) is a standard binary constraint. This model has $O(n^2)$ continuous variables where $n=max\{|I|, |J|, |K|\}$ and $|K|$ binary variables. The number of constraints is $O(n)$.

Notice that following [31], models such as the *RSCP* forget the origin of the products arriving to remanufacturing facilities then we lost the trace of the products. To overcome this point, we can get another formulation introducing triply subscripted variables x_{jkl} to manage the origin to destination product flows and some other changes in parameters, variables and constraints. But this is not the objective of this paper.

4 Evolutionary Scheme

Particle Swarm Optimization (*PSO*) is an evolutionary computation method to solve continuous optimization problems. This is an optimization algorithm based on swarm theory where the main idea of a classical *PSO* is to model the flocking of birds flying around a peak in a landscape. In *PSO* the birds are substituted by artificial beings so-called particles and the peak in the landscape is the peak of an objective (fitness) function. The particles of the swarm are flying through the search solution space with a velocity forming flocks around peaks of fitness functions. In a continuous *PSO*, an individual particle's status *i* on the search solution space *D* is characterized by two factors: its position *u* and velocity *v*. The position *u* and velocity *v* of the *ith* particle in the *d*-dimensional search solution space can be represented as:

$$v_{id}^{t+1} = c_1 v_{id}^{t} + c_2 r_1 (p_{id} - u_{id}^{t}) + c_3 r_2 (p_{gd} - u_{id}^{t}) \quad (8)$$

$$u_{id}^{t+1} = u_{id}^{t} + v_{id}^{t+1} \quad (9)$$

Where c_1 is called the inertia weight factor, c_2 and c_3 are constants called acceleration coefficients, r_1 and r_2 are two independent random numbers uniformly distributed in the range of [0, 1], p_{id} corresponding to the personal best objective value of particle *i* obtained so far at time *t*, p_{ig}represents the best particle found so far at time *t*. Equation (8) stands for calculating the new velocity of each particle *i* at time (*t+1*). Equation (9) stands for updating the position of particle *I* at time (*t+1*). Each $v_{id}^{t} \in [-v_{max}, v_{max}]$ and $u_{id}^{t} \in [-x_{max}, x_{max}]$, with v_{max} and x_{max} set by users to control excessive roaming of particles outside the search solution space. Particles fly toward a new position according to (9). The process is repeated until a user-defined stopping criterion is reached.

4.1 The Binary PSO Algorithm

In order to manage discrete optimization problems, in [32] is proposed a binary *PSO* (*BPSO*) algorithm. The difference between a *BPSO* algorithm and traditional *PSO* algorithm is that (9) has been replaced by the following expression:

$$u_{id}^{t+1} = \begin{cases} 1 \; if \; rand(\;\;) < S(v_{id}^{t+1}) \\ 0 \; if \; rand(\;\;) > S(v_{id}^{t+1}) \end{cases} \quad (10)$$

Where *S(.)* is the Sigmoid function and *rand*() is a random number uniformly distributed in the range [0,1]. We use this method in this paper.

Typical *PSO* algorithm encodes the whole solution for the *RSCP* model as a particle, and then applies the traditional algorithm for solving the target problem. We follow a different approach in this paper, taking advantage of the structure of the *RSCP* model.

We can set to 0 or 1 the value of variables $w_k \; \forall k \in K$, let call them w_k^* . Once you set variables w_k^* we can re-write the *RSCP* model as follow:

$RSCP_R$

$$Minimize \sum_{k \in K^*} f_k w_k^* + \sum_{i \in I} \sum_{k \in K} c_{ik} x_{ik} + \sum_{k \in K} \sum_{i \in I} g_k x_{ik} + \sum_{k \in K} \sum_{j \in J} d_{kj} y_{kj} \quad (1a)$$

$Subject\ to$:

$$\sum_{i \in I} x_{ik} \leq u_k w_k^* \qquad \forall k \in K^* \quad (2a)$$

$(2) - (6)$

Where, the set K^* contains the facilities already opened, and the variables w_k^* are now coefficients with known values. Constraint (2a) continues to ensure that all the sourcing facilities deliver return products to a facility already opened. The rest of constraints remain the same as the original *RSCP* model. Moreover, this associated problem is a linear programming problem.

In our evolutionary scheme, we use a *BPSO* algorithm for guiding the whole process of seeking an optimal solution for the *RSCP* problem. However, part of the particle is obtained by solving to optimality the $RSCP_R$ problem. In this way, we use a decomposed *BPSO* algorithm, based into two groups of swarms, one of them guide the overall search for an optimal solution.

4.2 The particle coding method

To find a good coding method corresponding to the optimization problem is the most critical problem [27]. In this paper, the particle's d-dimensional space is divided into two sets u^1 *and* u^2 . The length of each set (vector) respectively corresponds to the number of candidate sites to locate reprocessing facilities $|K|$, the second part represents the solution to the relaxed LP associated.

In the first group of particles, every component of each vector can take only 1 or 0. If the *k*th component of u^1 is equal to 1, then the reprocessing facility at candidate site k must be open, 0 otherwise. The second group of particles represents the

flows of return products between the sourcing facility and the reprocessing facilities and between the reprocessing facilities and the remanufacturing facilities. As described earlier in this paper, this part is obtained solving to optimality the $RSCP_R$ problem.

4.3 The feasibility procedure

The standard *BPSO* algorithm could generate some particles of the first swarm group representing unfeasible solutions. To overcome this problem, for each particle of the first group we apply a simple feasible solution procedure. This procedure consists in two steps. In the first step we check if the number of facilities already opened is enough to satisfy the entire demand. In the second step, for those particles that do not satisfy the demand, we get a feasible solution to *RSCP* based on the initial particle. This procedure is rather simple; it starts open facilities till the demand is satisfied. The swarm is composed of just feasible solutions. The fitness of a particle is calculated by solving simultaneously the $RSCP_R$ problem and using the objective function ($1a$).

4.4 Other considerations

We initialize our algorithm with a size swarm of 20 particles. The maximum number of iterations was also set to 10. We used these setting parameters because initial testing provided good results besides the complexity of the problem addressed in this article. The acceleration coefficient c_2 is set to 2 and c_3 to 1. The inertia coefficient start with a value of 0.9 and it decreases till get 0.4 depending on the number of iterations performed. The initial swarm is composed of just feasible solutions. Each particle of the first group is generated randomly using a uniform distribution in the range [0,1]. Then is applied the binary procedure and after that is applied the feasibility procedure. Regarding the second group of particles, for each particle we solve to optimality the *LP* problem described earlier in this article. The velocity vector v_{id}^t is generated randomly in the range [-4,4] as in the continuous method. At every iteration, the algorithm uses the method of coding described earlier and updates the position vector u_{id}^{t+1} according to (9). The velocity vector v_{id}^t is updated at each iteration according (8). The fitness function is like (1). It is straightforward to calculate its value from. u_{id}^{t+1}. At every iteration we check for updating the best position of a particle and the global best position of the swarm. Notice that we do not explore swarm neighborhood structures, i.e. the way information is distributed among its members.

5 Numerical Experiments

In this section we discuss and compare the computational results obtained by the proposed evolutionary algorithm. Our propose is to analyze the performance of the proposed algorithm regarding computational time to get the solution and the quality of the upper bound (solution) obtained.

We implemented the algorithm in *GAMS* and we used *CPLEX* as a subroutine (called from inside *GAMS*) for solving to optimality the $RSCP_R$ problem. All the experiments were developed on a PC with 4Gb RAM and 2.3GHz. In the literature, there are not large data sets available for our problem. We generated randomly 10 test problems following similar methodologies used for well known related supply chain problems (for example: [15]). These test problems are data sets corresponding to networks of up to 350 origination sites, 100 candidate sites for locating reprocessing facilities and 40 remanufacturing facilities. The data set for the test problems are given in Table 1 and they are available with the authors. All the transportation costs were generated randomly using a uniform distribution with parameters [1,40]. Management costs were set to 30 for all the instance problems except for the No.1. Instances 7 and 8 are the same than instances 4 and 5 respectively except for the value of fixed costs that were obtained multiplying by 10 the fixed costs of instances 4 and 5. Instances 9 and 10 are the same than instances 7 and 8 respectively but the capacity of each location was increased in 50%. Sourcing units (a_j), capacity of reprocessing facilities (m_k) and capacity of remanufacturing facilities (b_l) are shown in Table 1.

Table 1: Data set

#	Instance Problems	J	K	L	f_k	a_j	m_k	b_l
1	40x20x15	40	20	15	300	150	400	400
2	100x40x20	100	40	20	500	150	400	750
3	150x40x20	150	40	20	1000	200	800	1500
4	200x80x20	200	80	20	1000	300	800	3000
5	300x80x40	300	80	40	2000	200	800	1500
6	350x100x40	350	100	40	2000	200	800	1750
7	200x80x20	200	80	20	10000	300	800	3000
8	300x80x40	300	80	40	20000	200	800	1500
9	200x80x20	200	80	20	10000	300	1200	3000
10	300x80x40	300	80	40	20000	200	1200	1500

We run 5 trials for each test instances. Table 2 and 3 show the results obtained using the algorithm. For each instance problem and trial, the tables show the solution provided by the initial random phase of the algorithm (z_{ran}), the solution provided by the BPSO2 algorithm (z_P), the computing times (seconds) and the gap ($100[z^* - z_P]/z^*$) obtained comparing the z_P with the optimal integer value of the objective function (z^*) obtained by *GAMS*. All the *GAP* values were rounded to two decimals. The table also shows the minimum, maximum and average value for each column and each test instance. Observe that, for all the test instances, the maximum average gap is 1.58% (instance #9) and the minimum average gap is 0.04% (instance #2). Regarding computing times, notice that all test instances were solved in less than 58 seconds.

6 Conclusions

In this paper, we proposed a Binary PSO-based scheme for solving a reverse supply chain network design problem. This is a NP-hard problem and was formulated as a mixed integer 0-1 linear programming problem (*MIP*). The algorithm guides the search for an optimal solution to the *RSCP* problem combining a random solution search with optimal solutions generated by solving to optimality an associated problem. The algorithm generates two groups of swarms. First is generated the particles representing whether the facility is opened or closed. The second part of the chromosome is obtained solving to optimality the $RSCP_R$ problem associated to the

original *RSCP* problem. The proposed BPSO algorithm was coded in *GAMS* and tested using 10 test instances generated randomly. Computational results regarding gap and computing times are promising.

Abstract— **In this paper Imperialism Competitive Algorithm (ICA) is proposed to optimal placement of Distribution Generation (DG) in power system. The power distribution generation systems are necessary for consumers to achieve power with less price and best quality. In the other hand, they can help to the active power units in power system networks for system losses reduction, distribution lines, voltage profile improvement. Also, ICA is a global search strategy that uses the socio-political competition among empires as a source of inspiration. The effectiveness of the proposed technique is applied to mat power 30 buses and 57 bus power system. The achieved result shows the robust reaction of the system with DG.**

Keywords: DG, ICA, Losses and Prices.

I. INTRODUCTION

The design and operation of the electricity distribution networks always assumed power flows from higher voltage networks to lower voltage networks. Power injections and power demands that appear at various places in the distribution systems are assumed to be distributing equally between the phases. This assumption is valid for passive networks. However, the connection and operation of significant Distribution Generation (DG) (of varying technologies) alters many network characteristics making the existing assumptions of network design and operation less applicable to distribution networks. The power distribution generation systems are necessary for consumers to achieve power with less price and best quality. In the other hand, they can help to the active power units in power system networks for system losses reduction, distribution lines, voltage profile improvement and etc. The main goal for DG is determining of optimal size and placement of capacitors to be installed and efficient control schemes in the buses of distribution systems [1-4].

The DG sources can classified at four sets; micro DG (5KW to 1MW), small (5KW to 5MW), medium (5MW to 50MW) and large size (50MW to 300MW). Meanwhile, the source for DGs is very widespread so that they contain fuel cells, photo voltaic, hydro turbine, combustion engines, micro turbines and etc [5].

The optimal sizing and placement of DG problem is an attractive research area as publish some papers in this area such as global optimization techniques like genetic algorithms (GA), Harmony Search Algorithm (HAS), Particle Swarm Optimization (PSO) and Evolutionary Programming (EP) techniques have been applied for optimal tuning of DG based restructure schemes. These evolutionary algorithms are heuristic population-based search procedures that incorporate random variation and selection operators. Although, these methods seem to be good methods for the solution of DG parameter optimization problem, however, when the system has a highly epistatic objective function (i.e. where parameters being optimized are highly correlated), and number of parameters to be optimized is large, then they have degraded efficiency to obtain global optimum solution [6]. In order to overcome these drawbacks, in this paper, a strength heuristic algorithm has been presented to determine the optimal sizing capacitor and placement, taking into accounts fixed capacitors as well as potential harmonic interactions (losses, resonance and distortion factors) in the presence of nonlinear loads and DG using ICA. Therefore, for this reasons, ICA algorithm is used to solve DG problem in order to efficiently control the local search and convergence to the global optimum and solution quality. This proposed method has been tested on distorted 34-bus and 57-bus IEEE systems. The

objectives on this method were to minimize power loss in the distorted distribution network having taken the cost of capacitors into account [7-10].

II. DG PROBLEM FORMULATION

The problem is formulated with a objective functions, the real power loss reduction in a distribution system is required for efficient power system operation. The loss in the system can be calculated, given the system operating condition [11].

$$SLOSS = Sij + Sji$$
$$Sloss = \sum_{j=1}^{n} Zj * Ij^2$$
$$PLOSS = real(Sloss) \qquad QLOSS = image(Sloss)$$
$$Sltotal = \sum_{j=1}^{n} Slossj$$
$$INDEX = A * Sltotal + B * \sum_{j=1}^{n} (1 - |Vj|)^2 \quad (1)$$

Where, S_{LOSS}, P_{LOSS} and Q_{LOSS} are power loss, active and reactive power loss for power system network, respectively. The A and B is penalty factor for *INDEX* objective function to voltage profit improvement and minimize total loss. This penalty factors define based operator for minimize loss or modified voltage profile [12]. Also, they are different value for test systems. This problem contains some constrains such as:

(a) Power balance constraint

$$\sum_{DG=1}^{n_{DG}} P_{DG} + \sum_{G=n_{DG}+1}^{n_G} P_G = P_D + P_L \quad (2)$$

(b) Generation and voltage limits constraints

$$P_i^{\min} \le P_i \le P_i^{\max} \qquad i \in 1,2,...,\alpha$$
$$V_i^{\min} \le V_i \le V_i^{\max} \qquad i \in 1,2,...,\alpha \quad (3)$$

The active power transmission loss P_L can be calculated by the network loss formula:

$$P_L = \sum_{i=1}^{n}\sum_{j=1}^{n} A_{ij}(P_i P_j + Q_i Q_j) + B_{ij}(Q_i P_j - P_i Q_j) \quad (4)$$

Where,

$$A_{ij} = \frac{R_{ij}\cos(\delta_i - \delta_j)}{V_i V_j}$$
$$B_{ij} = \frac{R_{ij}\sin(\delta_i - \delta_j)}{V_i V_j} \quad (5)$$

Where, *Pi* and *Qi* are net real and reactive power injection in bus *'i'* respectively, *Rij* is the line resistance between bus *'i'* and *'j'*, *Vi* and δi are the voltage and angle at bus *'i'* respectively.

III. IMPERIALIST COMPETITIVE ALGORITHM

Imperialism is the policy of extending the power and rule of a government beyond its own boundaries. A country may attempt to dominate others by direct rule or by less obvious means such as a control of markets for goods or raw materials. The latter is often called neo-colonialism [13]. ICA is a novel global search heuristic that uses imperialism and imperialistic competition process as a source of inspiration. This algorithm starts with some initial countries. Some of the best countries are selected to be the imperialist states and all the other countries form the colonies of these imperialists. The colonies are divided among the mentioned imperialists based on their power. After dividing all colonies among imperialists and creating the initial empires, these colonies start moving toward their relevant imperialist state. This movement is a simple model of assimilation policy that was pursued by some imperialist states [14]. Figure 1 shows the initial empires. Accordingly, bigger empires have greater number of colonies where weaker ones have less. In this figure, Imperialist 1 has formed the most powerful empire and consequently has the greatest number of colonies.

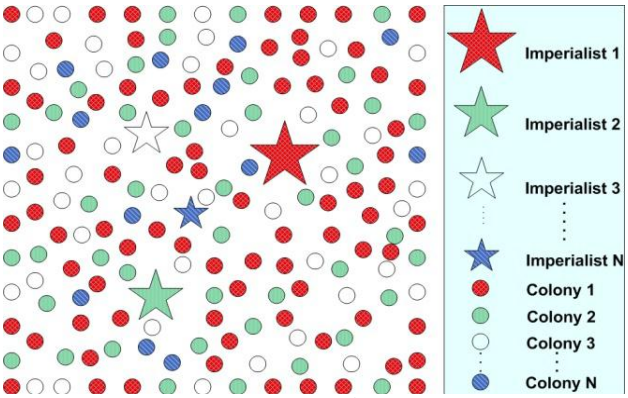

Figure 1. Generation of initial empires

A. Movement of Colonies toward the Imperialist

It is clear that, imperialist countries start to improve their colonies. We have modeled this fact by moving all the colonies toward the imperialist. Figure 2 shows a colony moving toward the imperialist by units. The direction of the movement is shown by the arrow extending from a colony to an imperialist [15]. In this figure x is a random variable with uniform (or any proper) distribution. Then for x we have:

$$x \approx U(0, \beta \times d)$$

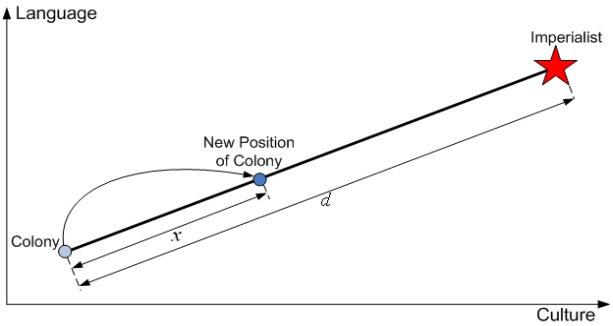

Figure 2. Movement of colonies toward their relevant imperialist

Where d is the distance between the colony and the imperialist state. The condition $\beta > 1$ causes the colonies to get closer to the imperialist state from both sides.

After dividing all colonies among imperialists and creating the initial empires, these colonies start moving toward their relevant imperialist state which is based on assimilation policy [16]. Fig.3 shows the movement of a colony towards the imperialist. In this movement, θ and x are random numbers with uniform distribution as illustrated and d is the distance between colony and the imperialist.

$$x \approx U(0, \beta \times d), \theta \approx U(-\gamma, \gamma) \qquad (6)$$

Where,

β, γ = parameters that modify the area that colonies randomly search around the imperialist.

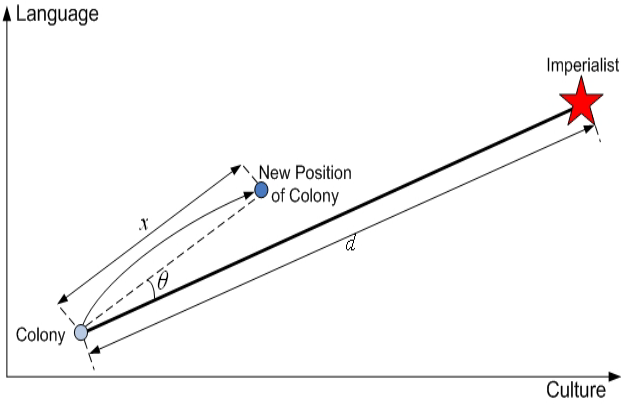

Figure 3. Movement of colonies toward their relevant imperialist in a randomly deviated direction

The total power of an empire depends on both the power of the imperialist country and the power of its colonies. In this algorithm, this fact is modeled by defining the total power of an empire by the power of imperialist state plus a percentage of the mean power of its colonies. Any empire that is not able to succeed in imperialist competition and can not increase its power (or at least prevent decreasing its power) will be eliminated.

The imperialistic competition will gradually result in an increase in the power of great empires and a decrease in the power of weaker ones. Weak empires will lose their power gradually and ultimately they will collapse [15]. The movement of colonies toward their relevant imperialists along with competition among empires and also collapse mechanism will hopefully cause all the countries to converge to a state in which there exist just one empire in the world and all the other countries are its colonies. In this ideal new world colonies have the same position and power as the imperialist. Fig.4 shows a big picture of the modeled imperialistic competition. Based on their total power, in this competition, each of the empires will have a likelihood of taking possession of the mentioned colonies.

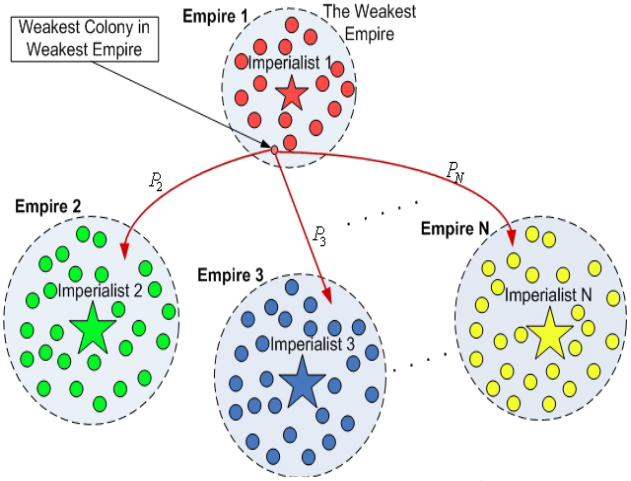

Figure 4. Imperialistic competition: The more powerful an empire is, the more likely it will possess the weakest colony of weakest empire

IV. ICA BASED DG PROBLEM

The ICA technique for solving the optimal placement and capacitor sizing DG problem to minimize the loss may be constructed with the following main stages:

Set power system: Input line and bus data, and bus voltage limits.

Calculate fitness based load flow: Calculate the loss using distribution load flow based on backward-forward sweep.

Initial population: Randomly generates an initial population (array) of particles with random positions and velocities on dimensions in the solution space. Set the iteration counter k = 0. In the other hand, in this step, an initial population based on state variable is generated, randomly. That is formulated as:

$$D = [D_1, D_2, D_3, ..., D_n] \qquad D_i = (d_i^1, d_i^2, ..., d_i^m) \qquad (7)$$

Calculate fitness: For each particle if the bus voltage is within the limits, calculate the total loss. Otherwise, that particle is infeasible. That is formulated as:

min *INDEX*

Updating: update population with ICA explore engine.

Finish: If the iteration number reaches the maximum limit, go to next Step. Otherwise, set iteration index $k = k + 1$, and go back to Step 4.

Results: Print out the optimal solution to the target problem. The best position includes the optimal locations and size of DG or multi-DGs, and the corresponding fitness value representing the minimum total real power loss.

The flowchart of the proposed ICA algorithm is shows in Fig .5.

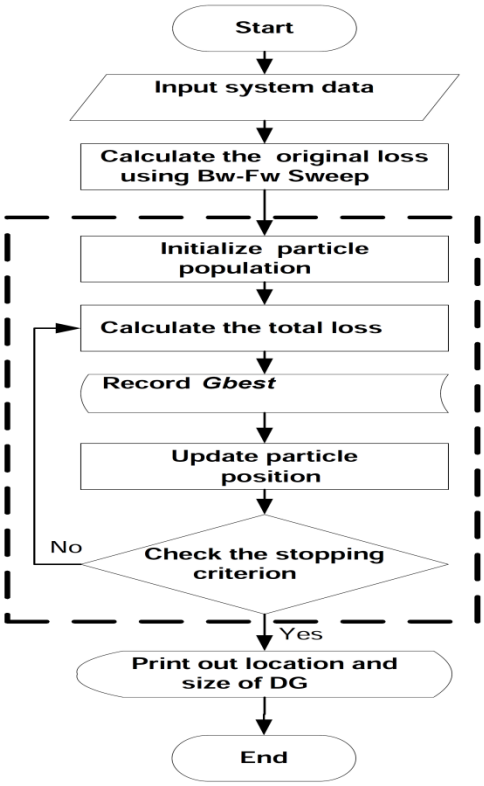

Figure 5. ICADG computational procedure

V. SIMULATION RESULTS

A. *30 and 57 bus Power System*

For the testing of proposed technique two case studies are considered as; mat power 30 and 57 bus power system. For both of the case studies, the DGs are considered with 5-50 MW and 1-10 Mvar. Also the proposed technique considered 5 source of DGs to power systems. Table. 1-2, shows the numerical results of DGs in system.

In the mentioned tables, the active and reactive powers are presented for 5 optimized buses. Fig. 6-7, shows the system response with 5 sources and without sources. It is clear that by increasing the number of DGs in power system, the stability, losses decreasing and improving of voltage profile will be appropriate.

The presented figures show the losses and voltage of active and reactive power in proposed case studies.

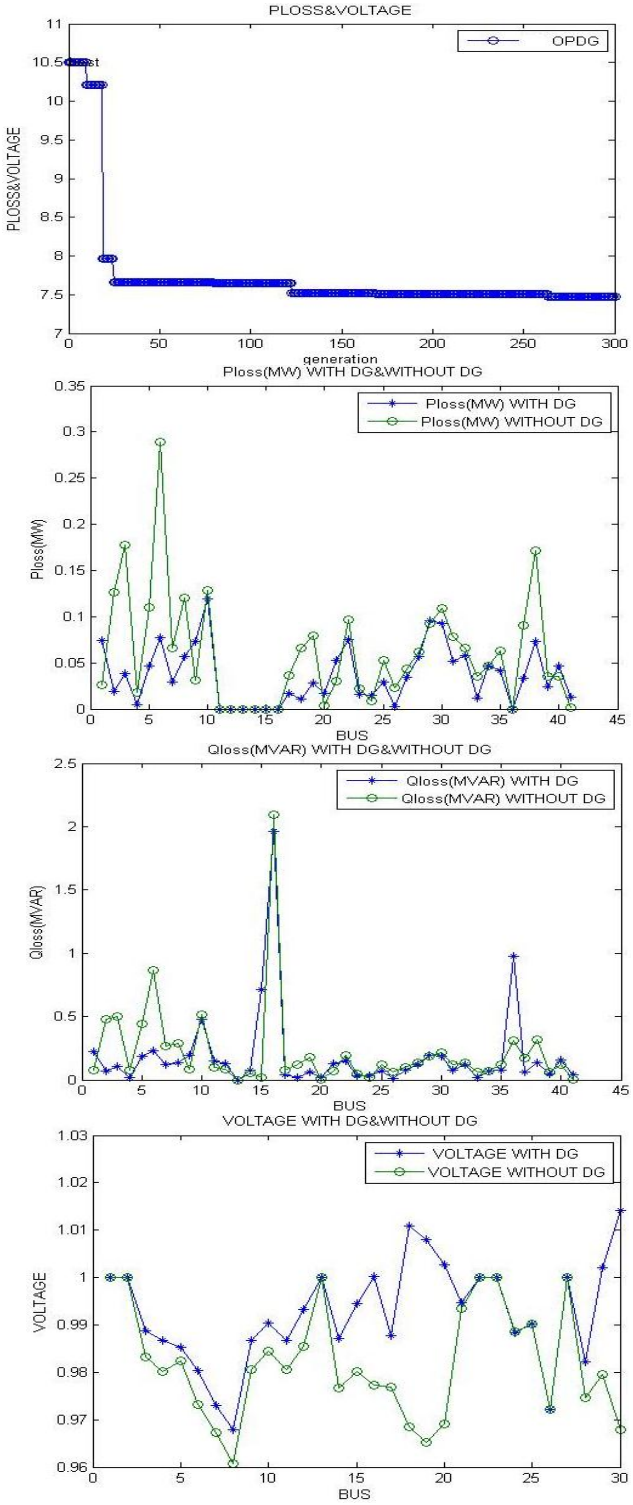

Figure 6. The losses and voltage of active and reactive power in 30-bus system.

	Q(MVAR)					3

VI. CONCLUSIONS

In this paper, we investigated the optimal placement and capacitor sizing DG power problem by employing an evolutionary algorithm based on Imperialist Competitive Algorithm. The DG optimization problem was considered and formulated as single-objective optimization problem with competing objectives of power loss and voltage profile improvement. The concept of Pareto dominance was employed to provide the selection mechanism between different objectives. The proposed algorithm applied to two standard IEEE systems to show advantages of proposed algorithm in DG problem, 34-bus IEEE test system and 57-bus IEEE test system. The numerical results demonstrate that the proposed method has better ability in finding optimal answers and possibility of particle placed in local zone. Moreover, the proposed strategy has simple structure, easy to implement and tune and therefore it is recommended to generate good quality and reliable electric energy in the restructured power systems.

His areas of interest in research are Application of Artificial Intelligence to Power System and Control Design, Load and Price Forecasting, Distribution Generation, Restructuring in Power Systems, Congestion Management, Optimization.

A Cache Management System for a Distributed Deductive Database

Larry Williams[1], Martin Maskarinec[1], and Kathleen Neumann[1]
[1] School of Computer Sciences, Western Illinois University, Macomb, IL

Abstract - *This paper will illustrate what a cache management system for a deductive database will do when a query is executed, or sent through the presented calculation plan. It will also illustrate what the Cache Management System should do when the cache is full. Once the query goes through the calculation plan, it then passes the results to the Cache Management System. The Cache Management System will then decide if the query should be cached or not. The Cache Management System will also have to decide what should be removed from the cache if the cache is full. This paper will also illustrate the how to calculate the recalculation cost.*

Keywords: Intelligent Database, Deductive Database, Cache Algorithms

1. Introduction

According to Ullman, et. al [1]., a deductive database is a conventional database containing facts, a knowledge base containing rules, and an inference engine which allows the derivation of information implied by facts and rules. The knowledge base is expressed in a subset of first-order logic.

The results sets for a deductive database can be extremely expensive. This is because each node may need to get information from many levels to produce its result. Thus, a system is needed to cache the results rather than recalculating them each time.

Conventional caching algorithms as mentioned in [2] do not have to take into consideration the dependency cost if the system removes that result from the cache. For this reason a deductive database system cannot use this conventional method of caching the results. The conventional rules do not apply especially when the system removes items from the cache. This paper will describe how to check the cache to see if the results exist. If the results exist, the system will return them. If not, the system will execute the query on the stored relations and decide if the system should cache the results or not. If the system needs to cache the results and the cache is full, the system will also need to decide which of the results should stay in the cache and which should be removed. In a conventional cache management system, the system does not have to consider the cost to recreate that result or the recalculation cost for the result. The recalculation cost is the cost that is incurred when a result is removed. The system should remove results with a low recalculation cost. This paper will discuss what to do when the results that are set to be removed from the cache have a high recalculation cost. In this case, the system will remove results from the cache that are less time intensive to recreate.

2. Execution Cycle

When the system runs a query it follows the Execution Cycle that is illustrated in Figure 1. The Execution Cycle starts by checking if it is the first query executed. If so it caches the whole result including the nodes on the bottom of the tree. If it is not the first time running a query the system sends a probe query to check the cache keys to see if it is cached. If it is, the system increments the hit counter for that node, and stores the date and time that the node was last hit. The system then increments the hit counter for the cache. Next, the results of the query are returned.

If the node is not cached, ghost data of the cache miss is stored. The ghost data is the cache key, the date and time of the last miss, and a counter that is incremented every time it is missed. The cache miss counter is also incremented at this time. Next, the system checks the node to make sure it is not a leaf node. If it is a leaf node, the system calculates the value and returns the results. If the node is not a leaf node then the system checks if the result of the node can be recalculated. If the system cannot calculate the result, it traverses the tree to the next node and goes through this process again.

3. Traversing a Predicate Graph

The order that the system uses to traverse the predicate graph is a Depth First Search. Figure 2 presents an example of a predicate graph. The order of traversal for the predicate graph shown in Figure 2, assuming there are no results cached, is: a1,b1,p1,c1,d1,d2,c2,d3,d4,p2,c3,d5,d6, c4,d7,d8,l1,m1,n1,o1,o2,u2,o3,o4,m2,n3,o5,o6,n4,o7,o8. If the node can be calculated, the system performs the calculation, and returns the results. After the system returns the results, the Cache Management System determines whether they should be cached. If the system cannot calculate the node directly, it must traverse the tree to nodes that are either cached or are leaf nodes. A result cannot be

calculated for a node until it has all the results for all the children of that node.

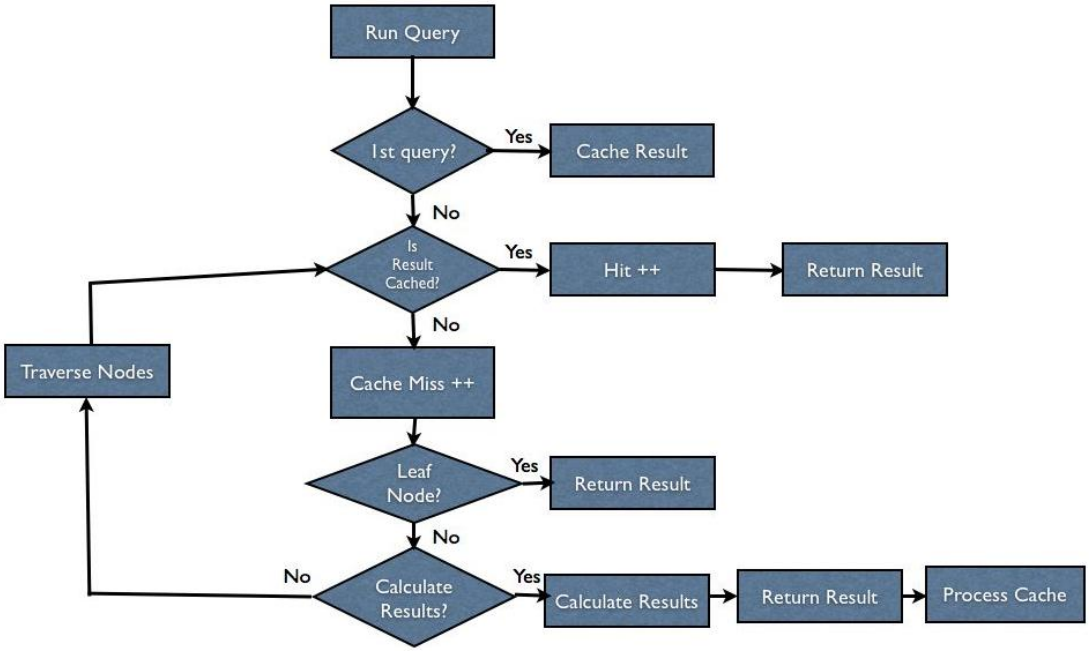

Figure 1. The Calculation Cycle

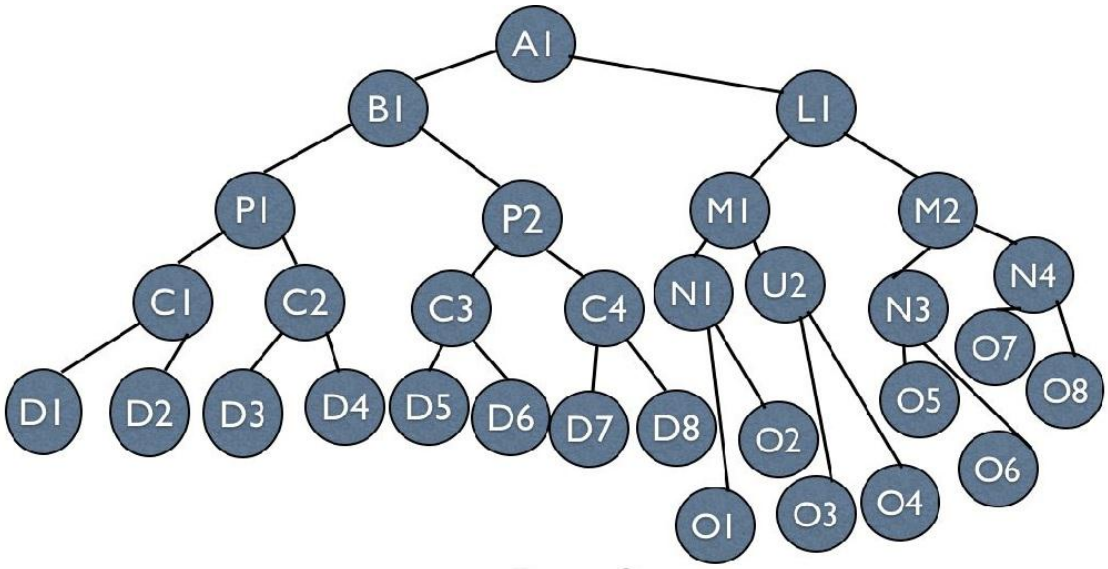

Figure 2. A Sample Predicate Graph

4. The Cache Management System

When the system is initiated, the block size and size of the cache are determined. The number of blocks available in the cache is calculated by dividing the available space by the block size. This is the total number of cache blocks that can be assigned to all cached nodes.

Figure 3 shows the Cache Management System (CMS) process. The results from the Execution Cycle are sent to the CMS. The truth table in Figure 4 illustrates the CMS in Figure 3. If the results fit in the cache then the CMS stores the results there. If they do not fit, the system checks to see if the results' miss count reaches the cache miss threshold. If it does then the CMS makes room for the results. If the initial miss threshold is not reached, a more relaxed threshold is used. If this relaxed threshold is not met, then the result is not cached. If the relaxed threshold is met, the new result must have a high cost to recalculate in order to be cached. If the cost is low, the result is not cached.

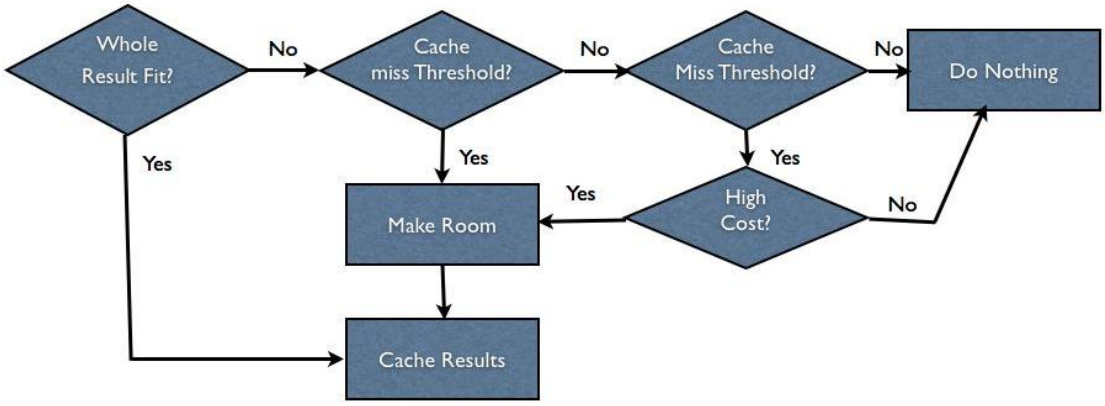

Figure 3. The Cache Management System Flow Chart

Can Whole Result Set Fit?	Is Cache Miss Thres-hold Reached ?	Is Relaxed Cache Miss Thres-hold Reached ?	Is the Re-calculation Cost High?	Action to Take
No	Yes	X	X	**Make Room**
No	No	No	X	**Do Nothing**
No	No	Yes	No	**Do Nothing**
No	No	Yes	Yes	**Make Room**
Yes	X	X	X	**Cache Results**

Figure 4. The Cache Management System Truth Table

In the next sections, the methodologies for calculating the needed data will be discussed.

5. Miss Percentages

As is seen in Figure 1, the hit and miss counts for all nodes are maintained during the Execution Cycle. The Miss Percentage of any node i is:

$$\text{Miss Percentage}_i = \#\text{misses}_i / (\#\text{misses}_i + \#\text{hits}_i)$$

6. Making Room

If the CMS decides a result set needs to be cached, but there are not enough available blocks in the cache, some existing elements must be removed from the cache. This is done by determining a normalized "recalculation cost" for all nodes in the cache. The nodes of lowest recalculation cost are removed until enough blocks are freed up to accommodate the new result set.

7. Recalculation Cost

The recalculation cost is based on normalizing the cost of calculation (discussed in the next section), the number of parents of the node (or the "node dependency"), and the miss percentage. The calculation cost is normalized to a number between 1 and 50. The node dependency and the miss percentage are normalized to a number between 1 and 5.

The recalculation cost uses these normalized values to produce a number on the same scale for all nodes. The actual formulae used are:

Norm Cost = 1 + (Cost - 1)* (50 - 1) / (max_cost - 1)

Norm Parent = 1 + (Parent Count - 1)*(5-1) / (max_parent -1)

Norm Miss = 1 + (Miss Count -1)*(5-1) / (max_node_miss -1)

Recalculation cost = (Norm Parent + Norm Miss) * Norm Cost;

The miss count is maintained in the execution cycle and the parent count is easily determined by examining the predicate graph. The next section describes how the cost of a node is calculated.

8. Cost Calculation for a Node

The cost of calculating a node is based on one of three possibilities: 1) the node is cached, 2) the node is a leaf node, or 3) the node is neither a leaf node nor cached. If the node is cached, it may be retrieved from the cache at minimal cost (we assign zero to this cost). If it is not cached, but is a leaf node, then the cost is simply the cost of retrieving the data. If it is not a leaf node, then all children of this node must be found and their costs added to the total cost (note that this may require many levels of recursive calls). The algorithm used to make this calculation is:

```
Cost_Calaculation(Input Node)
{
  if Input Node is Cached
        return 0;
  if Input Node is a leaf Node
        return b_InputNode ;
  in all other cases:
        Total Cost = Cost_Calculation(Child[0]);
        PreviousResult = Child[0];
        for(cnt =1; cnt< Child Count; cnt++)
        {
           nodeCost = Cost_Calculation(Child[cnt]);
           joinCost = b_PreviousResult + b_PreviousResult *b_Child[cnt];
           PreviousResult = PreviousResult joined to
                        Child[cnt];
           Total Cost = Total Cost + nodeCost + joinCost;
        }
  Return Total Cost;
}
```

9. Future Work

A simulation of the cache management system is currently in development and will be used to fine-tune the miss and recalculation cost thresholds. This will then be fully integrated into a deductive database management system.

10. Conclusion

A cache management system has been proposed to allow a deductive database to manage the cache of the result sets of its nodes as efficiently as possible. A heuristic has been proposed to determine when a result set should be cached, and, if room is not available, how to determine what should be removed in order to make room for this result set.

Abstract— *The main challenge with particle filtering is particle degeneracy and the accurate estimation cannot be achieved generally because of serious impoverishment problem, although resampling operation could solve degeneracy to a certain extent. In this paper, we propose an improved particle filtering approach based on biogeography-based optimization (BBO) algorithm, called BBO-PF, for state estimation of nonlinear and non-Gaussian dynamic system. The novel BBO-PF significantly reduces the degeneracy. The experimental results obtained by applying the BBO-PF to estimate the trajectory of unmanned ground vehicle validate the performance of our approach.*

Keywords: Unmanned ground vehicle; Particle filtering; Particle impoverishment; Biogeography-based optimization.

1. Introduction

The location of unmanned ground vehicle (UGV) determined according to various types of measurements is critical to UGV navigation. In fact, a variety of location algorithms have considerable difference in accuracy, robustness, and computational efficiency. Particle filtering, which is a method based on random samplings, has advantage of being applied to nonlinear and non-Gaussian dynamic systems. But there exist particle degeneracy and difficulty of selecting proposal distribution. To solve particle impoverishment problem, researchers have presented a lot of algorithms such as unscented Kalman particle filter (UKPF)[1] and Gaussian mixture sum particle filter (GMSPF)[2]. Many improved algorithms based on intelligent optimizations are also proposed to solve sample impoverishment problem, including particle swarm optimization-based particle filter (PSO-PF)[3], annealing particle filter (APF)[4], genetic particle filter (GPF)[5], evolutionary particle filter (EPF)[5], and so on. They are used to tackle the difficulty of selecting proposal distribution. Additionally, there are other hybrid algorithms such as MCMC particle filter, kernel smoothing particle filter, rejection particle filter.[6]. In this paper, we propose an improved particle filtering approach based on biogeography-based optimization (BBO) algorithm, called BBO-PF, for state estimation of nonlinear and non-Gaussian dynamic system. Based on the concept of resampling, particles with high weights have move probability to be propagated, and in the BBO-PF, some particles will join in the refining process after calculating the weight of particles, which means that those particles will move to the region with high weights. This process can be regarded as migration to the habitat with high suitability of BBO algorithm. Although the BBO operation increases the computing complexity of algorithm, the optimized weights may make the proposal distribution more closed to the poster distribution and overcome the degeneracy of particles. The proposed BBO-PF algorithm is compared to other several filtering algorithms. The experimental results show that the BBO-PF has better performance due to their lower means and variances.

2. Problem Description

The state and measurement models of the UGV location are built in this section. Our intelligent vehicle platform THIV-I developed by Tsinghua University, the location of various sensors is shown in Fig.1. The position system consists of many on-board sensors, including four ABS speed sensors and steering angle sensors, global position system (GPS), inertia measurement unit (IMU), and environment perception sensor such as lidar and camera, which provide the data of landmark. The information of speed and steering angle can obtained through the CAN bus of the vehicle itself. Meanwhile, the encoders on the rear transmission shafts can be used to obtain the accurate travelled distance during a sample period. The GPS/IMU integrated navigation system working on RTK differential mode provides accurate position reference for performance comparison of different algorithms.

2.1 System model

In this paper, the origin of the vehicle body coordinate frame locates at the center of the rear axle, i.e., the installation position of the IMU, whose position is $P_k\,(x_k, y_k)$ at the time of t_k, and the heading angle is ϕ_k. In 2D environment, the UGV's pose can be expressed by the state vector $\chi_k = (x_k, y_k, \phi_k)$. The position relation of UGV is shown in Fig. 2. In this figure, H represents a half of distance between two rear wheels, while L indicates the distance between a front axle and a rear axle of UGV.

Fig. 1: Intelligent vehicle of Tsinghua University.

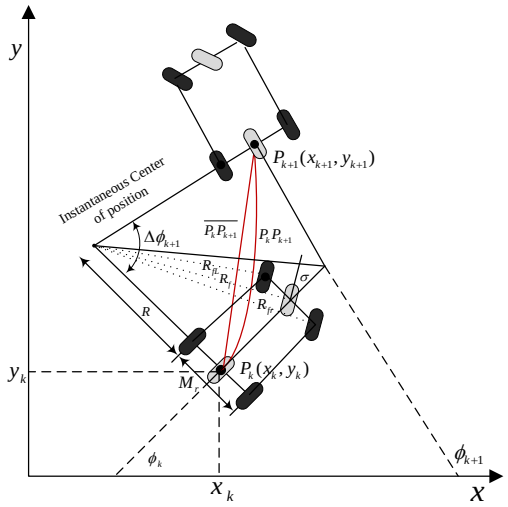

Fig. 2: Schematic diagram of the vehicle's kinematics parameter model.

$$\frac{\widehat{P_kP_{k+1}}}{\overline{P_kP_{k+1}}} = \frac{(R+M_r/2)\Delta\phi_{k+1}}{2(R+M_r/2)\sin[\Delta\ \phi_{k+1}/2]} = \frac{\Delta\phi_{k+1}/2}{\sin[\Delta\phi_{k+1}/2]} \tag{1}$$

Thus, the linear distance $\overline{P_kP_{k+1}}$ between P_k and P_{k+1} is derived below:

$$\overline{P_kP_{k+1}} = \frac{\sin[\Delta\phi_{k+1}/2]}{\Delta\phi_{k+1}/2}\widehat{P_kP_{k+1}} = \frac{\sin[\Delta\phi_{k+1}/2]}{\Delta\phi_{k+1}/2}\Delta D_{k+1} \tag{2}$$

In this formula, ΔD_{k+1} refers to the travel distance of the back wheel center measured by an encoder.

$$\mathrm{X}(k+1) = \begin{bmatrix} x_k + \overline{P_kP_{k+1}}\cos\left[\phi_{k+1} + \Delta\phi_{k+1}/2\right] \\ y_k + \overline{P_kP_{k+1}}\sin\left[\phi_{k+1} + \Delta\phi_{k+1}/2\right] \\ \phi_k + \Delta\phi_{k+1} \end{bmatrix} + \omega_k \tag{3}$$

where ω_k is system noise.

2.2 Observation model

The system of autonomous vehicle utilizes odometer and the IMU to achieve the estimation of basic position and orientation. In order to overcome the error accumulation caused by the relative positioning system, the system applies the 64-line HDL lidar, which is mounted in the anterior part of middle top of UGV, and the relative position relations with respect to UGV is shown in Fig.3.

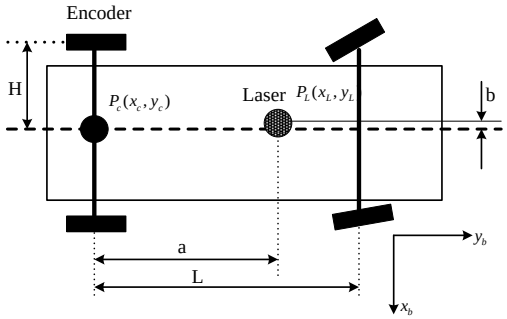

Fig. 3: Installation diagram of UGV sensor.

Then the relationship that the rear axle center transforms to the lidar centre is described by:

$$\begin{aligned} x_L &= x_c + a\cos(\phi) + b\cos(\phi + \pi/2) \\ y_L &= y_c + a\sin(\phi) + b\sin(\phi + \pi/2) \end{aligned} \tag{4}$$

The corresponding measurement equation is given by:

$$z_k = h\left(X, x_k, y_k\right) = \begin{bmatrix} \sqrt{\left(x_k - x_L\right)^2 + \left(y_k - y_L\right)^2} \\ atan\left(\frac{(y_k - y_L)}{(x_k - x_L)}\right) - \phi_L + \pi/2 \end{bmatrix} + \nu_k \tag{5}$$

In this formula, z indicates the measurement vector, i.e., the coordinates of landmark, $\{x_k, y_k\}$ represents the location of landmark identified by the 3D lidar, and ν_k is the measurement noise.

3. BBO-PF state estimation algorithm

3.1 Biogeography-based optimization

According to the island migration model of biogeography, Dan Simon proposed biogeography-based optimization (BBO) in 2008[7]. BBO is an evolutionary algorithm (EA) motivated by the optimality perspective of natural biogeography. Suppose that we have a global optimization problem and a population of candidate solutions, which can be represented by vectors of integers, each integer in the solution vector is considered to be a suitability index variable (SIV). The population consists of $\mathrm{NP} = \mathrm{n}$ solution vectors. Each individual is considered as a habitat with a habitat suitability index (HSI), which is similar to the fitness of EAs, PSO, etc to evaluate individual effectiveness. A good solution means to be an island with a high HSI, and a poor

solution indicates an island with a low HSI. The high HSI solutions tend to share their features with low HSI solutions. The low HSI solutions accept a lot of new features from the high HSI solutions.

Just as species migrate back and forth between islands, BBO operates by sharing information between individuals in a population of candidate solutions. In BBO, each individual has its own immigration rate λ and emigration rate μ. A good solution has higher μ and lower λ. The immigration rate and the emigration rate are functions of the number of species in the habitat. They can be calculated as follows:

$$\mu_{\mathbf{k}} = E\frac{k}{n} \tag{6}$$

$$\lambda_{\mathbf{k}} = I\left(1 - \frac{k}{n}\right) \tag{7}$$

where I denotes the maximum possible immigration rate, E the maximum possible emigration rate, k the number of species of the $k_t h$ individual, and n the maximum number of species[8].

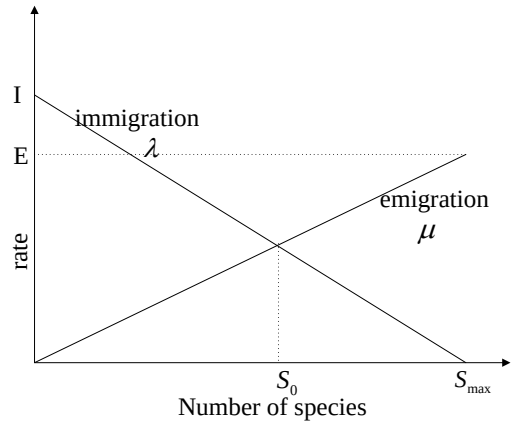

Fig. 4: Linear migration curves for an island.

There are two main operators, the migration and the mutation, in BBO. During migrating, each solution shares the information probabilistically between habitats through the emigration rate λ_i and immigration rate μ_i.

We use the immigration rate to probabilistically decide whether or not to modify each suitability index variable (SIV) in that solution. If a given solution H_i is selected to be modified, then we use the emigration rates of the other solutions to probabilistically migrate a randomly selected SIV to solution H_i. The migration process can be given by[9]:

For mutation, the main idea is deduced from the species count in habitat change drastically for cataclysmic events. A habitat's HSI can, therefore, change suddenly due to apparently random events. This mutation scheme tends to increase diversity among the population. We model this in BBO as SIV mutation, and use species count probabilities to determine mutation rates. Mutation can be described as follows[9]:

```
Select H_i with probability based on λ_i
If H_i is selected
    Select H_j with probability based on μ_i;
    If H_j is selected
        Randomly select an SIV s from H_j
        Replace a random SIV in H_i with s;
    End
End
```

```
For j=1 to length of SIVs
  Select an SIV in H_i with probability based on a priori probability m;
  If H_i is selected
    Replace SIV (H_i) with Randomly generated SIV;
  End
End
```

The BBO algorithm can be described below[9].

```
1) Initialize the BBO parameters, including the maximum species count
   n, the maximum migration rates E and I, and the mutation rate
2) Initialize the random parameter of habitat.
3) For each habitat, HIS is mapped as the number and mobility (λ_k, μ_k)
   of species k.
Calculate and determine whether HIS satisfy the supervision condition.
    If HIS dose not satisfy the supervision condition
     4) Utilize the immigration rate and emigration rate to restore
        the habitat, and then recalculate each HIS.
     5) For each habitat, refresh the probability distribution of species,
        update the species according to mutation operator, and then
        recalculate the fitness.
    End if
6) End the algorithm cycle according to the termination condition.
```

The BBO is also a species optimization algorithm. It is not related to the problems of regeneration and producing next generation, compared to both GA and evolutionary strategy optimization algorithms. There is also a remarkable difference between ACO and BBO. ACO produces a new set of solutions at each of iterations, while BBO maintains the solution set to the next iteration and adjusts the solution space according to the migration probability. BBO has more in common with PSO and DE. Compared to PSO and DE, BBO directly updates by the migration of the solution. Thus, the solutions of BBO algorithm can share properties (suitability index variable, SIVs) with each other. BBO mainly consists of the two processes, including species migration and species variation[6], [7], [8], [9].

3.2 Adaptive particle filtering algorithm based on BBO

The main disadvantage of PF is the so-called particle impoverishment problem, which is the main reason to take

resampling. This problem appears as the likelihood $p\left(y_t|x_t^i\right)$ is very narrow or likelihood lies in the tail of the proposal distribution $q\left(x_t|x_{t-1}^{(n)}, y_{1:t}\right)$. As the observation is more accurate and the prior distribution is much boarder than the likelihood (shown in Fig.5), only a few particles have weights of significant importance, which directly leads to the particle impoverishment problem.

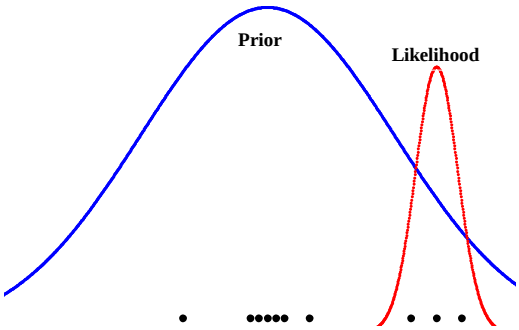

Fig. 5: Prior and Likelihood.

The proposal algorithm, called BBO-PF, incorporate the BBO algorithm into PF to improve the distribution of samples, speed up the convergence of particle sets, and overcome the impoverishment of particle filtering. The purpose is to take samples to move towards regions of the state space where the posterior probability is significant, which is related to the prior probability and likelihood. Thus, a weighted optimization problem arises to balance the contribution of prior probability and likelihood to the posterior probability. The optimization problem can be described as follows:

$$\max_{x \in S} F(x) = \kappa_1 F_1(x) + \kappa_2 F_2(x) \tag{8}$$

where κ_1 and κ_2 are non-negative weight with $\kappa_1 + \kappa_2 = 1$, S is the search space of particle sampling. Thus, the generated samples x_t^i, $i = 1, \cdots, N$, are regarded as the initial SIV in the BBO and moved to maximize the objective function $F(x)$.

Let ω_t and v_t be zero-mean Gaussian white noise with variances Q and R, respectively. Considering that (3) and (5) are nonlinear model with additive noise, the first objective consists of the function maximized at high prior regions as follows:

$$F_1 = e^{-\frac{1}{2}(x_k - \hat{x}_k)Q^{-1}(x_k - \hat{x}_k)^T} \tag{9}$$

The second objective comprises the function maximized at high likelihood regions below:

$$F_2 = e^{-\frac{1}{2}(y_k - \hat{y}_k)Q^{-1}(y_k - \hat{y}_k)^T} \tag{10}$$

Then the objective function of posterior optimization is given by:

$$F(k) = -\frac{1}{2}\kappa_1(x_k - \hat{x}_k)Q^{-1}(x_k - \hat{x}_k)^T - \frac{1}{2}\kappa_2(y_k - \hat{y}_k)Q^{-1}(y_k - \hat{y}_k)^T \tag{11}$$

The BBO-PF algorithm can be summarized below:

1.Initialization the particles $X = \left\{x_0^{(i)}, \omega_0^{(i)}\right\}_{i=1}^N$ from posterior distribution $p(x_0)$ with associated $\omega_0^{(i)} = 1/N$
2.Initialize the BBO parameters, including the maximum species count n, the maximum migration rates E and I, and the mutation rate
3.For time steps $t = 1, 2, \cdots, T$
4.Importance Sampling: for $i = 1, \cdots, N$, draw samples from the importance proposal distribution as follows: $\tilde{x}_t^{(i)} \sim q\left(x_t|x_{t-1}^{(n)}, y_{1:t}\right)$
 1) Consider each particle as a species of universal habitat.
 2) For each habitat, HIS is mapped as the number and mobility (λ_k, μ_k) of species k. Calculate and determine whether HIS can satisfy the supervision condition.
 If HIS dose not satisfy the condition of importance distribution
  3) Utilize the immigration rate and emigration rate to restore the habitat, and then recalculate each HIS.
  4) For each habitat, refresh the probability distribution of species, update the species according to mutation operator, then recalculate the fitness.
  5) Weight update: evaluate the importance weights with (11).
 End if
 6) End the algorithm cycle according to the termination condition.
5. Normalize the importance weights: $\tilde{\omega}_t^{(i)} = \frac{\tilde{\omega}_t^{(i)}}{\sum_{i=1}^N \tilde{\omega}_t^{(i)}}$
6. Output the statics of the particles.
7. Re-sampling: generate N new particles $x_t^{(i)}$ from the set $\left\{\tilde{x}_t^{(i)}\right\}_{i=1}^N$ according to the importance weights $\left\{\tilde{\omega}_t^{(i)}\right\}_{i=1}^N$
Repeat Step 3 to 7.

The BBO moves all particles towards the particles with the best fitness where is the region of having the maximum weight particles. As the best fitness value reaches a certain threshold, the optimal sampling process terminates.

4. Experimental results

To verify the effectiveness and efficiency of the proposed BBO-PF algorithm, this paper carried out experiments on urban road. Ideal two-dimensional environments were chosen as the test sites. In addition, the traffic signs stood on both sides of the road as the landmarks that were detected by the lidar. At first, we measured the accurate position of those landmarks using Span/DGPS integrated navigation system from Novatel. At the same time, the exact location of UGV was recorded during our experiment, i.e., $\chi\left(x_{ref}, y_{ref}, \theta_{ref}\right)$, in order to compare the state estimation results of various algorithms with such an exact location of UGV. The BBO-PF algorithm proposed in this paper was compared to both standard particle filtering (PF) and unscented particle filtering (UPF). The ideal reference trajectory provided by SPAN integrated navigation system and the estimation results are shown in Fig.6. Fig.7 and Fig.8 give

the comparison of eastward and northward errors, respectively. The experimental results indicated that the estimation accuracy of the proposed BBO-PF algorithm was greatly improved, compared to that of PF and UPF algorithms. The statistical distribution of position errors is shown in Fig.9 and Fig.10, respectively.

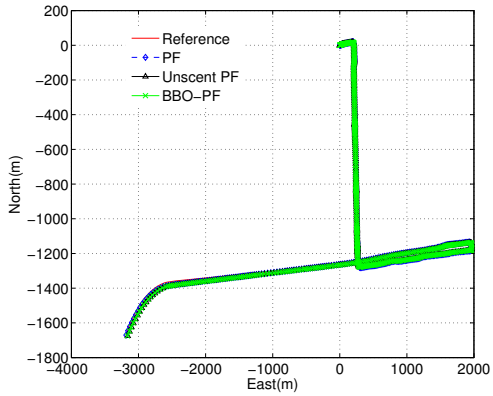

Fig. 6: Comparison of reference trajectory with estimation using PF, UPF, and BBO-PF.

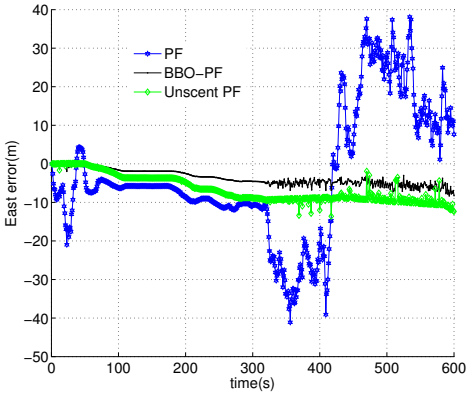

Fig. 7: Eastward deviation comparsion.

5. Conclusions

Particle filtering (PF) is sequential Monte Carlo methods based on the particle representation of probability density. It can be applied to nonlinear/non-Gaussian system and generalizes Kalman filtering. One of the main disadvantages of PF is the particle impoverishment problem, which is caused directly by the resampling process of the algorithm. We propose a BBO optimization algorithm to weight the likelihood and the prior for balancing the contribution of prior and likelihood to the posterior estimation. Our experimental results show that the BBO-PF algorithm can effectively improve the location accuracy of UGVs. In addition, due to

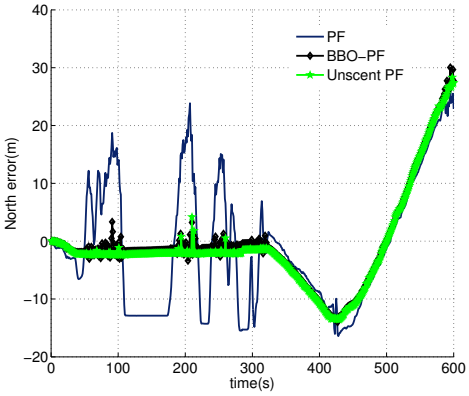

Fig. 8: Northward deviation comparison.

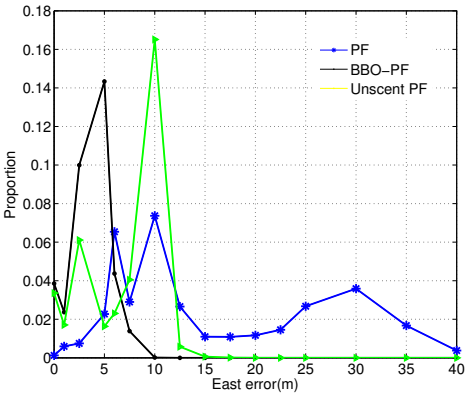

Fig. 9: Distribution of eastward error.

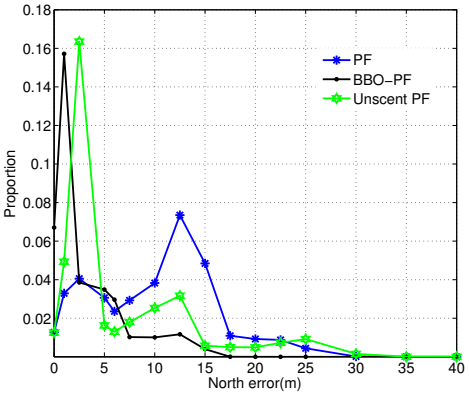

Fig. 10: Distribution of northward error.

the inherent characteristics of BBO algorithm, its efficiency is higher than other intelligent optimization algorithms such as PSO in solving high-dimensional optimization problems, which has provided a guarantee for real-time application of BBO-PF.

Abstract- *Control of power transmission and loss causes complications in the large power systems. Phase Shifter Transformers (PST) according to their capabilities can be appropriate devices for power controlling in the large power transmission systems. Various criteria such as decreasing of loss, saving of generator annual economic cost, improving system static and dynamic behaviors and reducing of congestion have been individually studied in the literature to placement problem of phase shifter transformers (PST). In this paper, loss reduction, voltage profile and congestion improvement indices are assessed and the optimal locations of PST devices evaluated by using Artificial Bee Colony (ABC) algorithm. The effectiveness of the proposed ABC based method is demonstrated on IEEE 30-Bus network through some performance indices in comparison with the genetic algorithm and particle swarm optimization. Results evaluation show that the ABC algorithm has an excellent capability in loss reduction, voltage profile and congestion improvement than the GA and PSO methods.*

Keywords: PST, Allocation, ABC; Power Loss Reduction.

1. Introduction

Nowadays, increment of generation quantity becomes a necessity relating to the ongoing industrials, electrical consumptions growing and consequently the consecutive load increasing. On the other hand, operating of power system must be closed to its nominal capacity considering high development costs of networks and their related devices and environmental concerns. Liberalization of the electricity market and utilities tendency in getting more profits also compel power systems to operate close to theirs rate capacities and sometimes in over load conditions. Moreover, variable distribution of load and generation resources based on their conditions make network operate in heavy congested load conditions in some parts and in light load conditions in others. Accurate evaluating of power transmission and determining its level is investigated in congestion indices concepts. Many various indices already have been represented to quantifying congestion values of transmission lines [1]. Network operation close to its nominal capacity may appear as over load state in some sections and can lead to partial outages. Continuation of this state results in blackout condition possibly. Thus, proper management of network power flow is a main necessity along with holding the operation constraints. Controlling and managing the power flow in network lines can be done by using the various methods and some controlling actions and devices such as Generation Rescheduling (GR), series capacitors, FACTS controlling device and suede-FACTS devices [2-4]. Phase Shifter Transformer (PST) is one of the suede-FACTS devices which can replace the power in related and next lines by changing the transmitting power value that may cause to relieve congestion [5-7]. Phase shifter transformer installation considering its advantages can control the value of line power flows obviously. However, because of investment limitations, the installation and usage of phase shifter transformers only based on their advantages will not be economic.

Proper location and sizing of PST should be noticed and studied because its installation at wrong places and capacities can cause various problems in the operation conditions. In this paper, an Artificial Bee Colony (ABC) algorithm is proposed for finding optimal location of PST aimed at reducing the power loss and

*Corresponding Author (hshayeghi@gmail.com)

improving voltage profile and power congestion. The ABC algorithm is a typical swarm-based approach to optimization, in which the search algorithm is inspired by the intelligent foraging behavior of a honey bee swarm process [12] and has emerged as a useful tool for engineering optimization. It incorporates a flexible and well-balanced mechanism to adapt to the global and local exploration and exploitation abilities within a short computation time. Hence, this method is efficient in handling large and complex search spaces [13].

IEEE 30 Bus network has been used as a test system to demonstrate the effectiveness and robustness of the proposed ABC algorithm and their ability to provide efficient loss reduction and voltage profile improvement. To show the superiority of the proposed approach, the simulations results are compared with the particle swarm optimization and genetic algorithm through some performance indices. The results evaluation shows that the proposed method achieves good robust performance and is superior to the other methods.

2. PST Model [10]

An ideal voltage source with voltage V_s and reactance X_s that is connected in series between nodes i and j is shown in Fig. 1.

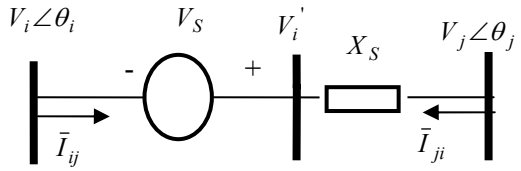

Fig. 1. Series voltage source between buses i and j

V_i is an imaginary voltage source which can be defined as:

$$\overline{V'}_i = \bar{V}_S + \bar{V}_i \quad (1)$$

$$\bar{V}_S = r\,\bar{V}_i\,e^{j\gamma} \quad \text{and} \quad 0 \le r \le 1 \quad (2)$$

Figure 2 shows a phasor diagram that is used to represent the voltage of Fig. 1 with regulating magnitude and angle.

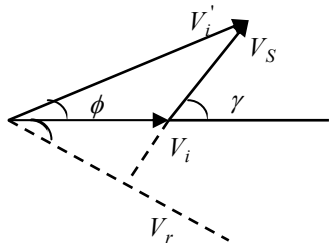

Fig. 2. Voltages phasor diagram of Fig. 1

Figure 3 shows the current source model of PST (the Norton model of voltage source) where, $b_s = \frac{1}{x_s}$ and $I_s = -jb_s\bar{V}_S$.

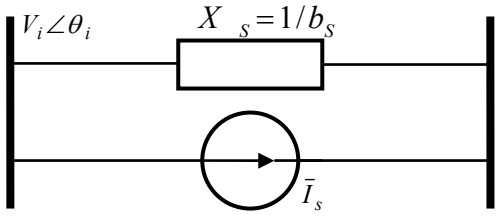

Fig. 3. Norton model of series voltage source

Current source is dependent on the usage of nodes i and j for transmitting power, then $\bar{S}_{is}$ and $\bar{S}_{js}$ are expressed as follows:

$$\bar{S}_{is} = \bar{V}_i(-\bar{I}_S)^* \quad (3)$$

$$\bar{S}_{js} = \bar{V}_j(\bar{I}_S)^* \quad (4)$$

After replacing relations (1) and (2) to (3) and (4) and simplifying, the injected active and reactive powers are calculated using the following equations [10].

$$P_{is} = r\,b_s V_i^2 Sin\,\gamma \quad (5)$$

$$Q_{is} = r\,b_s V_i^2 Cos\,\gamma \quad (6)$$

$$P_{js} = -r\,b_s V_i V_j Sin(\theta_{ji} + \gamma) \quad (7)$$

$$Q_{js} = -r\,b_s V_i V_j Cos(\theta_{ji} + \gamma) \quad (8)$$

The powers injection model of PST has been shown in Fig. 4 as a series voltage resource.

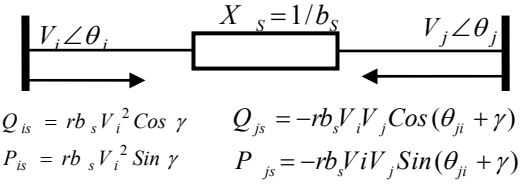

Fig. 4. Injection model of series voltage source

By using Eqs. (5) through (8) and applying a phase shifter transformer, angle γ can be changed and then the value of line power flow will be vary. If a PST is installed between buses i and j, the new admittance matrix formed considering the impedance X_s in the network admittance matrix. The Jacobean matrix is given in Table 1 [10]. Powers injection in PST model can be added to Jacobean matrix elements by a particular sign.

Table 1. Modified Jacobian matrix

$H_{(i,i)} = H^0_{(i,i)} - Q_{si}$ $H_{(i,j)} = H^0_{(i,j)} + Q_{sj}$ $H_{(j,i)} = H^0_{(j,i)} + Q_{si}$ $H_{(j,j)} = H^0_{(j,j)} - Q_{sj}$	$N_{(i,i)} = N^0_{(i,i)} - P_{si}$ $N_{(i,j)} = N^0_{(i,j)} - P_{sj}$ $N_{(j,i)} = N^0_{(j,i)} + P_{si}$ $N_{(j,j)} = N^0_{(j,j)} + P_{sj}$
$J_{(i,i)} = J^0_{(i,i)}$ $J_{(i,j)} = J^0_{(i,j)}$ $J_{(j,i)} = J^0_{(j,i)} - P_{sj}$ $J_{(j,j)} = J^0_{(j,j)} + P_{sj}$	$L_{(i,i)} = L^0_{(i,i)} + 2Q_{si}$ $L_{(i,j)} = L^0_{(i,j)}$ $L_{(j,i)} = L^0_{(j,i)} + 2Q_{sj}$ $L_{(j,j)} = L^0_{(j,j)} + 2Q_{sj}$

3. ABC Algorithm

The ABC algorithm describes the foraging behavior of honey-bees for numerical optimization problems. The algorithm simulates the intelligent foraging behavior of honey bee swarms. It is a very simple, robust and population based stochastic optimization algorithm [11].

The minimal model of forage selection in honey bee swarms intelligence consists of three essential components: food sources, employed foragers and unemployed foragers, and two leading modes of the behavior, recruitment to a nectar source and abandonment of a source, are defined [12]. A food source value depends on many factors, such as its proximity to the nest, richness or concentration of energy and the ease of extracting this energy. The employed foragers are associated with particular food sources, which they are currently exploiting or are ‘‘employed”. They carry with them information about these food sources and share this information with a certain probability. There are two types of unemployed foragers, scouts and onlookers. Scouts search the environment surrounding the nest for new food sources, and onlookers wait in the nest and find a food source through the information shared by employed foragers.

In the ABC algorithm, the colony of artificial bees contains of three groups of bees: employed bees, onlookers and scouts. The food source represents a possible solution of the optimization problem and the nectar amount of a food source corresponds to the quality (fitness) of the associated solution. Every food source has only one employed bee. Thus, the number of employed bees or the onlooker bees is equal to the number of food sources (solutions).

An onlooker bee chooses a food source depending on the probability value associated with that food source, p_i, calculated by the following expression:

$$p_i = \frac{fit_i}{\sum_{n=1}^{SN} fit_n} \tag{9}$$

where fit_i is the fitness value of the solution i evaluated by its employed bee, which is proportional to the nectar amount of the food source in the position i and SN is the number of food sources which is equal to the number of employed bees (BN). In this way, the employed bees exchange their information with the onlookers.

In order to produce a candidate food position from the old one, the ABC uses the following expression:

$$v_{ij} = x_{ij} + \phi_{ij}(x_{ij} - x_{kj}) \tag{10}$$

Where, $k \in \{1,2,...,BN\}$ and $j \in \{1,2,...,D\}$ are randomly chosen indexes. Although k is determined randomly, it has to be different from i. ϕ_{ij} is a random number between [0, 1]. It controls the production of a neighbour food source position around x_{ij} and the modification represents the comparison of the neighbor food positions visually by the bee. Equation (10) shows that as the difference between the parameters of the x_{ij} and x_{kj} decreases, the perturbation on the position x_{ij} decreases, too. Thus, as the search approaches to the optimum solution in the search space, the step length is adaptively reduced.

The food source whose nectar is abandoned by the bees is replaced with a new food source by the scouts. In the ABC algorithm this is simulated by randomly producing a position and replacing it with the abandoned one. If a position cannot be improved further through a predetermined number of cycles called *limit* then that food source is assumed to be abandoned.

After each candidate source position v_{ij} is produced and then evaluated by the artificial bee, its performance is compared with that of x_{ij}. If the new food has equal or better nectar than the old source, it is replaced with the old one in the memory. Otherwise, the old one is retained. In other words, a greedy selection mechanism is employed as the selection operation between the old and the current food sources.

The main steps of the algorithm are given by [13, 14]:

i) Initialize the population of solutions and evaluate them.
ii) Produce new solutions for the employed bees, evaluate them and apply the greedy selection mechanism.
iii) Calculate the probabilities of the current sources with which they are preferred by the onlookers.
iv) Assign onlooker bees to employed bees according to probabilities, produce new solutions and apply the greedy selection mechanism.
v) Stop the exploitation process of the sources abandoned by bees and send the scouts in the search area for discovering new food sources, randomly.
vi) Memorize the best food source found so far.
vii) If the termination condition is not satisfied, go to step 2, otherwise stop the algorithm.

It is clear from the above explanation that there are three control parameters used in the basic ABC: The

number of the food sources which is equal to the number of employed or onlooker bees (*SN*), the value of *limit* and the Maximum Cycle Number (MCN).

4. Problem Formulation

The main goal of this paper is loss reduction, voltage profile and congestion improvements via optimal allocation of PST. Decreasing the amount of loss and boosting the voltage profile are serious issues in new and modern power networks, but the necessity of having an acceptable security margin in network operation is also very important. For obtaining these purposes, utilizing of phase shifter transformers is essentially required. Thus, for balancing lines power flow, it is necessary to assess congestion problem in relevant indices firstly. To investigating the congestion parameter of test system, the PI_l index proposed in reference [15] has been used which is expressed as follows:

$$PI_l = 1 - \frac{1}{N}\sum_{i=1}^{N} \frac{\omega_i}{\sqrt{2\pi}\sigma} e^{\left(\frac{(P_i - \kappa)^2}{2\sigma^2}\right)} \quad (11)$$

Where,

σ: Lines power standard deviation from nominal values

κ: Equals 70 percent of line nominal power (P.U)

ω_i: Weight factor of line *i*

N: Number of lines N

P_i: Power of each line (p.u.)

For calculating PI_l: ω_i and σ is considered 1 and 0.3, respectively.

If all lines are loaded at their nominal value, PI_l index has a low value and if overload condition occurs in networks, PI_l will be have a large value. Thus, optimal location of PST will be evaluated to reduce lines loss and improve congestion and voltage profile indices by ABC algorithm. The objective function used for phase shifter transformers placement is given by:

$$PI = W_1 PI_l + W_2 P_{Loss} + W_3 \frac{1}{m}\sum_{i=1}^{m} |V_i - 1| \quad (12)$$

Where,

m: Total number of buses

V_i: *i*th bus voltage in p.u.

PI_l: Congestion indices in p.u.

P_{loss}: Total value of system losses in p.u

w_1, w_2, w_3: Weight coefficients related to congestion, loss and bus voltage indices, respectively

Minimizing the objective function that is composed of loss, congestion and voltage profile indices will leads to finding PST optimal location. Thus, the allocation problem can be formulated as the following optimization problem, where the constraints are the buses voltage magnitude limits, lines active power transmitting capabilities and generated active and reactive power of generators limitations [12]:

Minimize PI (13)

The proposed approach employs ABC algorithm to solve this optimization problem and search for optimal placement of PST by evaluating the objective cost function as given in Eq. (13) using load flow of power system. The goal is determining the installation place and angle setting of phase shifter transformers. The weight factors w_1, w_2 and w_3 are included in objective function according the importance and effects of P_{loss}, congestion index PI_l and buses voltage magnitudes. It is necessary to mention that in this paper they have set to 20, 1 and 1, respectively.

5. Simulation Results

The proposed method is applied to the electrical network on IEEE 30 bus including six thermal generating units as shown in Fig. 5 to assess the suitability of the algorithm. The system data extracted from [15]. The MARTPOWER-4 toolbox of MATLAB software is used for load flow running.

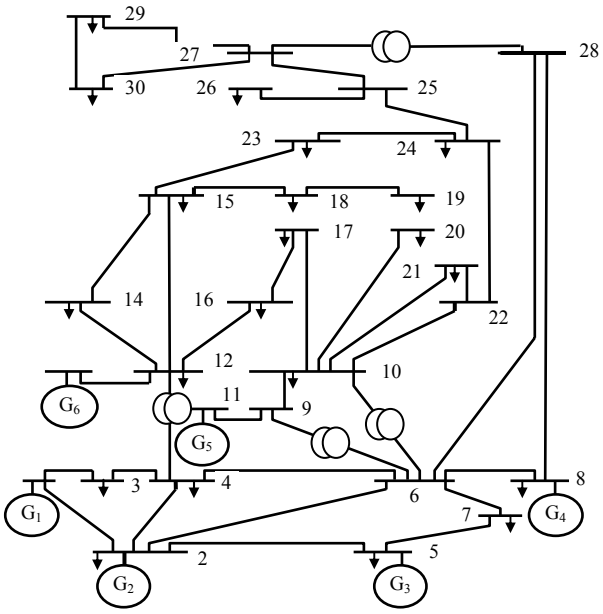

Fig. 5. IEEE 30 bus power system

The goal is determining the installation place and angle setting of phase shifter transformers. The obtained results using ABC is compared with PSO and GA methods in order to illustrate its robust performance and effectiveness for the solution of optimal allocation of PST problem.

Results of the PST placement based on the objective function *PI*, by applying AC power flow using the proposed ABC, PSO and GA algorithms are given in Table 2. Figure 6 shows the minimum fitness functions evaluating process.

Table 2. Optimal PST parameters

Algorithm	Optimized Place of PST	Angle of PST	The best cost Function
GA	11	-9.8787	0.9166
PSO	14	-8.7775	0.9153
ABC	14	-8.7773	0.9153

It can be seen that from Table 1 installing a phase shifter transformer in line 14 between buses 9 and 10 can be reduced loss and improved voltage profile and congestion indices of network clearly than the GA method. Table 3 presents the lines and network loss, PI_l index values before and after installing of PST using three methods. It is evident that the ABC and PSO based solution is identical. Using the GA the reduction at total loss of network is 7.5%, whereas it is 8.5 % using the proposed ABC algorithm.

Table 3. The lines and network loss, PI_l index values before and after installing of PST

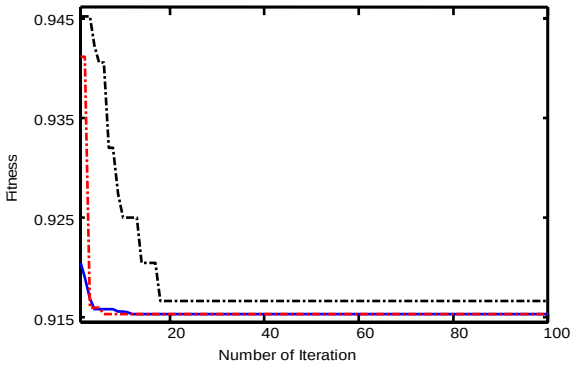

Fig. 6: Fitness convergence, Dotted (GA), Dashed (PSO) and Solid (ABC).

Figure 7 and 8 show the power loss of network lines and PI_l index. It can be seen that the proposed ABC method has good performance and power loss reduction and PI_l index improvement is significantly occurred after PST placement using ABC and PSO techniques. Voltage profile of network before and after PST installation is shown in Fig. 9. Using the proposed ABC algorithm voltage profile is considerably improved. Moreover, it is superior to the GA method.

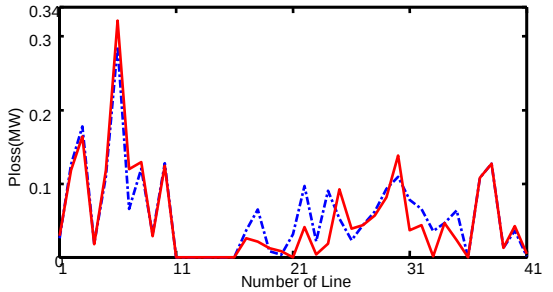

Fig. 7. P_{loss} index before and after PST installation, Dashed (before PST installation), Solid (after PST installation and using ABC)

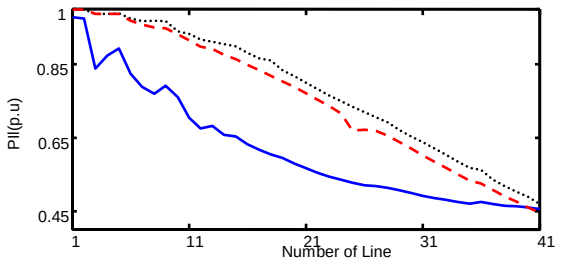

Fig. 8. PI_l congestion index, Dashed (without PST), Dotted (with PST using GA), Solid (with PST using ABC)

6. Conclusions

This paper presents an appropriate method based on ABC algorithm to improve line loss, voltage profile and congestion indices through optimal sitting of a phase shifter transformers. Due to consideration to some practical issues and by defining a new performance index, the optimum allocation of a single PST and its controlling phase angles can be determined. . The proposed ABC algorithm is easy to implement without additional computational complexity. Thereby experiments this algorithm gives quite promising results. The ability to jump out the local optima, the convergence precision and speed are remarkably enhanced and thus the high precision and efficiency are achieved. The performance of the proposed ABC based method is tested on IEEE 30-Bus network and the proper location for installing phase shifter transformers is obtained by minimizing the objective function in short evaluating time. Results evaluation show significant reduction in power loss in addition to voltage profile and congestion improvement than the GA method one.

***Abstract*-The main focus of this research is to develop, implement and test a surveillance system for tracking objects automatically using multiple camera views. A surveillance camera system can be very useful in carrying out tasks like security in public areas, road traffic monitoring. More and more surveillance cameras are being installed and utilized for surveillance task and hence sometimes it becomes difficult to remember their locations and their visible areas. Therefore, with a large number of surveillance cameras, it is not an easy task for people to recognize which camera should be monitored and which region of the camera images should be checked so that all the activities and/or events in a scene can be examined. Also the ability of humans to concentrate on multiple videos simultaneously is limited. A system that could automate this task would be of great use for safety and security for everyday life.**

Keywords- Tracking, multi-perspective video, surveillance, camera handoff.

I. INTRODUCTION

Many cameras are required for covering large field of view. To track the object successfully in multiple camera one needs to establish correspondences among objects captured in multiple cameras. Handshaking can be defined as labeling the object across multiple cameras. This is accomplished by finding the limits of field of view (FOV) of a camera as visible in the other cameras. Using this information, when a person is seen in one camera, we can predict all the other cameras in which this person might be visible. This approach is applicable only when there is a significant overlap in the field of view of the cameras.

In the work of Vera Kettnaker and Ramin Zabih [1], Bayesian probabilistic approach based multi camera surveillance system is developed to predict the appearance of an object in a camera after it exits from another camera. Jehoon Lee, Shawn Lankton, A. [2] gives an approach based on affine transformation. In this approach a simple neural network is trained to predict the parameters of the affine transformation. P H Kelly et al [3] presents an approach for dealing with handoff problem. It proposes the use of calibrated cameras and a 3D model of the environment. The 3D coordinates (voxel) of the object obtained through calibration are used during handoff between cameras to assign label. The 3D coordinates of an object obtained from multiple cameras map [8] to the same point. In Omar Javed et al [4] an approach to handle the handoff [10], [11] problem is presented. This approach does not require the cameras to be calibrated. It uses a model of the relationship between FOV lines of various cameras. The FOV lines bind the FOV of a camera. When an object enters FOV of a new camera it is checked if this person is visible in the FOV of another camera [6]. Here the author presents an improved technique for object tracking. The captured video frames are smoothed by a low pass filter. This method reduces the number of computations and computation time. In addition the noise in the signals is suppressed automatically.

In [5] authors have given techniques for how to detect moving objects from an image sequence, recognize the activity of object and behavior understanding. Background subtraction is a very popular technique for foreground segmentation in a still scene [9], [13].

The technique used is independent component analysis and it is best for indoor surveillance where moving and motionless persons must be reliably detected. In [7] author has cited about how to deal with the changing background. Sometimes it is not possible to take static background and we have to do background modeling so that the background can be adaptive according to the environment. The work [12] presented is based on the GPS system which uses a multi-agent system architecture to track moving objects. In [14] an automatic method for tracking individual across cameras via a surveillance network has been reported. In this work an emerging low computational complexity handoff function that can automatically carry out the camera assignment and handoff task has been depicted.

A. Constrains:

- Cameras are stationary.
- There must be overlapping regions across the cameras.
- The objects should not be very close to each other.

II. METHODOLOGY

IN ORDER TO GET THE MOVING OBJECTS FROM IMAGES, SOME BASIC OPERATIONS ARE REQUIRED SO THAT THE OBJECT CAN BE SEPARATED FROM THE BACKGROUND. THE STEPS USED TO GET FOREGROUND OBJECTS ARE:

A. Background subtraction

Background subtraction method is used for identifying changes in the foreground. By this method we separate the objects from the background. The background subtraction is done by finding the difference between corresponding pixels of two images (taking one of them as background). The image considered as background should not contain any moving objects. Detection of the foreground [13] objects is done by taking the difference between the current frame and an image of the scene's static background.

$$|\text{frame}_i - \text{background}| > \text{Th}$$

Background subtraction method is very sensitive to threshold (Th).

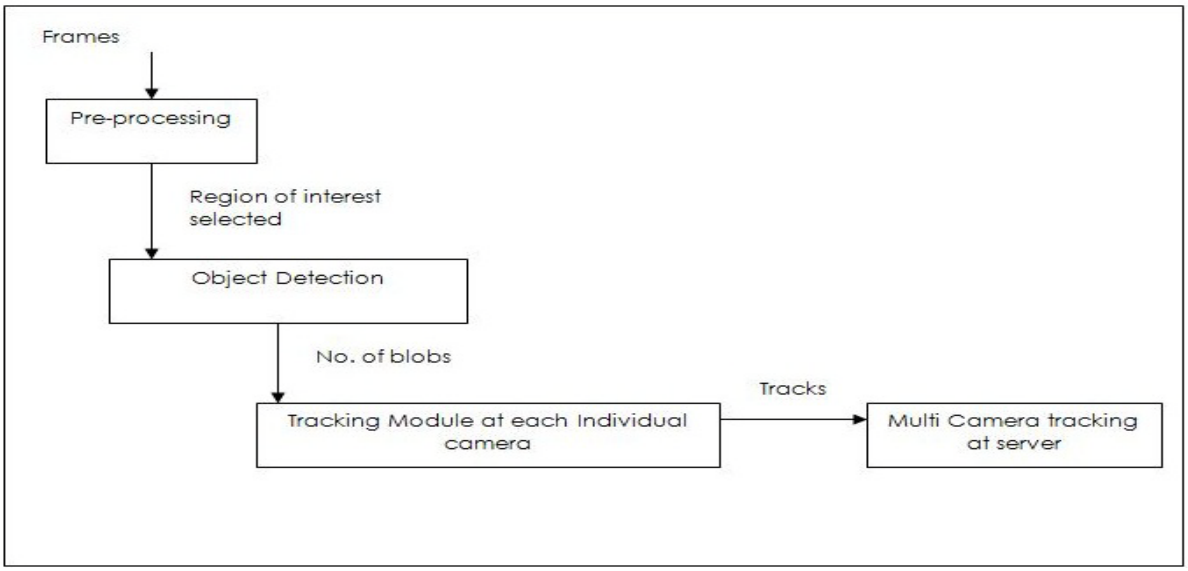

Fig. 1 System Level Diagram

B. Erosion & Dilation

The subtracted image consists of many unwanted tiny objects. To remove these unwanted objects erosion and dilation operations are used. In erosion, the local minimum is computed over an area of a kernel. In dilation, the local maximum is computed over the area of a kernel and the pixels are merged.

$$erode(x,y) = \min_{(x',y') \in kernel} src(x+x',y+y')$$

$$dilate(x,y) = \max_{(x',y') \in kernel} src(x+x',y+y')$$

C. Blob detection

Blob detection creates a box around the detected objects in a region. It takes connected points in an image and draws the box around them. Steps are as following

- Take a 3*3 patch around a point and check if any point in that patch has a label.
- If a point with a label is found, give the same label to the point in center.
- If no point with a label is found, give a new label to the point in center.
- Go to next point and repeat from step 2 until all the points are not labeled.
- Give the same label to the points which are connected (but given different label earlier)
- Draw a rectangular box around all the objects (points with same label).

To draw rectangular box we take two longest diagonal points as (x, y) and (x□, y□). Let length is l and distance is d so

$$d = y' - y$$
$$l = x' - x$$

Then draw a d*l rectangle around the object.

D. Approaches for handshaking-

1) Edge of Field of View Method -I (Perpendicular distance)

For tracking across multiple cameras *edge of field of view* method is used. When a person enters the FOV of a camera, it should be determined, if this person is visible in the FOV of any other camera, and if so, assign the same label to the new view. If the person is not visible in any other camera, then a new label is assigned to this person. Let us suppose a person enters through one of the FOV line, as cameras are stationary we just draw the FOV lines manually and try to find the distance (perpendicular) of all the objects with respect to that FOV line. As we know that the object has just entered through this line so it will be the nearest among all other objects falling in the overlapping region of these cameras with respect to that line. We assign some label to that object. Labels are unique for each object.

Algorithm for handshaking across multiple cameras

```
Repeat for every frame
For every camera C^i
{
    If new object appears in the middle of the frame
    {
        Assign it a new label
    }
    Else If object appears from any side l (FOV line)
    {
        Find s = set of FOV lines of all the cameras (C^j) in which the object is visible
        If s = 0
        {
            Assign current object new label
        }
        Else
        {
            For every camera C^j, j □ s
            {
                For every object k in C^j
                {
                    d(j,k) = D(P_k^j, L_l^ij)
                }
            }
        }
    }
}
```

For any object in C^j who is nearest to particular FOV line, assign the same label as in C^i.

2) Edge of Field of View Method-II (Distance from some point on the EOFOV)

If some objects are at the same distance from the FOV, the situation can be tackled by considering some point on the FOV line. Calculate the distance of all objects from this point and compare with the distances of the objects from the same point in view of the other camera which already contains these objects. Using the additional distance measure, the objects can be labelled accurately.

Another technique for tackling the same situation is to take a point at the foot of the perpendicular of the object of interest and calculate the distance of all the objects from the corresponding point in view of the other camera. The distance will be minimum for the same object in the other camera and same label can be assigned to that particular object.

E. Approaches for Tracking

1) Distance Based Tracking

We first take the centre of the object in the present frame and find the distance of all the objects in the next frame from this point (centre of the object in the present frame). Now assign the label to that object that has minimum distance from that point. Euclidean distance is considered. Suppose an object is at (x_1, y_1) and in the next frame it is at a point (x_2, y_2). The distance between them is:

$$d = \sqrt{(y_2 - y_1)^2 + (x_2 - x_1)^2}$$

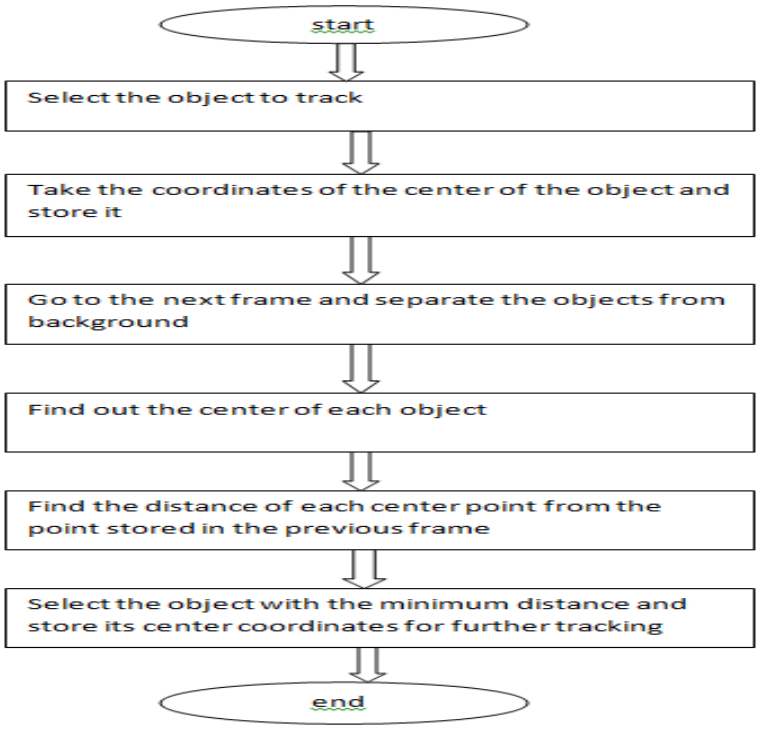

Fig. 2 Block diagram for distance based tracking

2) Direction Based Tracking

In this method we find the blob in the direction of the motion of the object. If the variation in the direction of the blob is within some range; then accept it, otherwise discard it. Suppose an object moves from point (x_1, y_1) to (x_2, y_2), slope is determined by the equation:

$$\theta = \tan^{-1}\left(\frac{y_2 - y_1}{x_2 - x_1}\right)$$

3) Shape Based Tracking

In the shape based tracking for multiple camera based surveillance, an object is selected first. The method for finding the variation between the objects in the current frame and the object in the last frame is as follows:

- Take the minimum and maximum coordinates of the object, say (x_1 ,y_1) and (x_2 ,y_2).
- Find the height and width of the object as:

$$Height(h1) = y_2 - y_1$$
$$Width(w1) = x_2 - x_1$$

- Store these data and find the height (h_2) and width (w_2) of each object in the next frame.
- Find the variation for each object by the following formula:

$$Variation(v) = (h_2 - h_1)^2 + (w_2 - w_1)^2$$

- The object with least variation is tracked object in the current frame.
- Repeat the above steps for the next frames.

III. Results and Discussion

Module wise results are shown below. Firstly, foreground and background separation is demonstrated. However, it is observed that the image obtained after background subtraction is noisy. As we know that noise in the context of image processing is anything which is not useful at particular moment though it may be useful for other context. To remove this noise we used the technique called erosion and dilation. These techniques remove and add the *unwanted and wanted data* from the image. After erosion and dilation we have used technique called blob detection to find particular object. Handshaking is performed after blob detection. In handshaking we try to find the correspondences across the cameras. If an object in one camera is at a particular position, its position in the other camera is determined. Finally in the process of tracking, we use distance based and *shape* based features.

IV. FUTURE WORK

When two objects are closer to each other and cameras are mounted at different heights and angles with respect to ground, 3D co-ordinate mapping combined with direction vectors along the length and width of the object blobs can be used to give correct results. For 3D co-ordinate mapping, height and angle of the mounted cameras are required. Blobs can be used to give the direction vector along the length and width of the object in both the cameras.

In the presence of an obstacle, tracking methods used sometime fails and we need to consider velocity based features of the objects. When single feature is not sufficient for efficient result we need to use combination of both the methods. It fails when two objects are at the same distance from the objects in the previous frame and have the same shape. We need to consider direction features of the objects.

V. CONCLUSION

2D co-ordinate mapping gives correct result when the cameras are mounted at same height and angle with respect to ground. A change in the camera setup would require the calculation of all the parameters again. Color based matching can be used as an additional feature to match the objects in different camera views. It would be inefficient if color or lighting effect changes. Under the conditions when foreground objects can be separated from the background, the results of FOV approach are satisfactory and can be used for handshaking between two cameras. We can use the EOFOV methods for efficient handshaking & it is giving satisfactory results under given constrains.

Mean shift tracking gives correct result for single object. However, it may fail when there are many objects. The method (distance & shape based) used in our approach is giving satisfactory results.

Abstract - *In this paper an analysis of the influence of generation scheduling when a reconfiguration method is applied in order to reduce voltage sag indices in a power system is presented. The description of the reconfiguration method based on a Tabu Search algorithm is presented. The method implemented in Matlab® is applied to analyze several case studies in the IEEE-57 bus test system, and different conditions of generation demand in the electrical network were considered. The obtained results demonstrate the good performance of the proposed methodology*.

Keywords: voltage sags, reconfiguration, voltage sag indices, tabu search.

1 Introduction

Nowadays, voltage sags are one of the principal concerns regarding power quality, because a lot of equipment used by commercial and industrial users is sensitive to this phenomenon of power quality; consequently, industrial processes are more sensitive and companies are less tolerant to these phenomena, since they cause malfunction of their equipment which results in significant economic losses. The most severe voltage sags are usually caused by faults such as short-circuits in the electrical system. However, they may also be caused by overloads and starting of large motors [1].

A voltage sag is a short reduction in RMS voltage at the power frequency with durations from 0.5 cycles to 1 minute. At the present time, there are different methodologies to estimate and analyze voltage sags, such as stochastic methods [2]-[5] and others based on the state estimation concept [6][7]. On the other hand, there are indices that define the quality of voltage variations, for example, the System Average Interruption Duration Index (SAIDI); however, one of the most widely used for assessing the impact of voltage sags is the SARFIX index (System Average RMS Frequency Index) [1][8]. This index indicates the average number of sags and swells during an evaluation period (usually a year) per customer [8].

Furthermore, the scheduling of generators in a power system is constantly changing, and this change represents an important factor in the stochastic prediction of voltage sags [9]. Several studies have analyzed the influence of generation and topology network changes on the voltage sag estimation [9]-[11].

Currently, there are several ways to mitigate the frequency of occurrence of voltage sags. For instance, the installation of mitigation devices can be seen as a possible solution for customers; nevertheless, these devices have a mitigation capability that is limited by the energy storage capacity [12]-[15]. The network reconfiguration constitutes an alternate method to improve the system performance. Over the years, several investigations applying reconfiguration methods have been carried out in order to minimize losses in networks subjected to certain restrictions [16]-[18].

In order to improve power quality aspects, in particular the occurrence of voltage sags, a network reconfiguration is performed in this paper, with the objective of obtaining the configuration that best reduces the frequency of occurrence of voltage sags [19]. Also, the process to achieve an optimal topology that minimizes the voltage sag indices under different conditions of generation demand of the network is carried out by means of an implemented Tabu Search (TS) algorithm. Some case studies in the IEEE-57 test system are presented in order to demonstrate the performance of the proposed method.

2 Formulation of reconfiguration method

The aim of this paper is to obtain the optimal state of switches in a network in order to identify a topology that minimizes voltage sag $SARFI_X$ indices under different conditions of generation demand.

The $SARFI_X$ index represents the average number of specified rms variation measurement events that occurred over the assessment period per customer served; where the

specified disturbances are those whose magnitude is less than *x*, for sags, and greater than *x*, for swells [8]:

$$\text{SARFI}_X = \frac{\sum N_i}{\sum N_T} \quad (1)$$

where x is the rms voltage threshold; N_i is the number of customers experiencing short duration voltage deviations with a magnitude above or below x, for sags and swells respectively; and N_T is the total number of customers served from the section of system to be assessed [8].

The SARFIx index, when is calculated per single monitored point, can also be regarded as the number of disturbances in a given measurement point, over a specified period of time [8]. In this paper, for purposes of comparison between different configurations of the same system, this definition is assumed.

This paper proposes an automatic reconfiguration method of a power system, by applying Tabu Search in order to reduce voltage sags, and taking into account different generation scheduling.

The connection/disconnection state of a transmission line is represented by means of a binary vector whose length is equal to the number of switches available in the system [19]; the number of possible topologies also depends on the number of switches. Thus, the number of possible topologies will be equal to $2^{number\ of\ switches}$, and every possible topology should be evaluated in order to get the best one. However, if the number of switches increases the evaluation number will also increase, making the computational cost prohibitive.

Voltage sags rates can vary depending on the system characteristics, such as the operation conditions in an electrical system which are constantly changing according to energy demand.

Generally, statistical data about the occurrence of voltage sags in an electrical system can be obtained. These values can be considered as typical values for a particular node; another aspect to consider is that in a determinate network there are particular buses in which, due to the contract requirements specifications, there is a maximum number of voltage sags allowed in a period of time [13]. The typical values or the values specified by contract requirements can be considered as reference values of voltage sags for a particular bus. Then, when a voltage sags analysis is carried out in order to obtain voltage sag indices, and it is found that some buses have higher voltage sags rates than the specified reference values, this can be considered as an undesirable system condition that can be solved through a reconfiguration process [19].

Considering a generic electrical system of n buses and l lines, it is assumed that l_{sn} lines have switches that can change their status (open/close). Every configuration, which is obtained by changing the open/close status of the l_{ns} lines, can be described by a Y vector. The Y vector's length is equal to the number of l_{sn} lines. It is important to note that, in this analysis, even lines which regularly contain more than one switch were represented by means of a single switch in order to specify its open/close status.

For instance, taking into account a generic system with n buses and a determinate number of sn switches, a possible configuration for a given voltage threshold t can be,

$$\begin{array}{c} \quad l_1 \quad l_2 \quad l_3 \qquad l_{sn} \\ Y = [\ \ 1 \quad 1 \quad 0 \quad \ldots \quad 1 \quad] \end{array} \quad (2)$$

where l_3 is open, which means that line l_3 is not energized. Therefore, line l_3 does not belong to the new configuration. Then, a voltage sag evaluation by means of the analytical method described in [5] is applied in order to obtain the voltage sag number in the electrical system. When some buses of the system have a voltage sag number higher than the reference value, a reconfiguration process is applied to reduce the voltage sag number in those buses, thus ensuring that all voltage sag values are equal or lower than the reference values. Mathematically this can be written as follows

$$\min\left(f_{est_i} - f_{ref_i}\right) \quad \forall i \quad (3)$$

subject to

$$V_i^{\min} \le V_i \le V_i^{\max}$$

$$P_{Gi}^{\min} \le P_{Gi} \le P_{Gi}^{\max}$$

$$Q_{Gi}^{\min} \le Q_{Gi} \le Q_{Gi}^{\max}$$

where:

$f_{est\,i}$ is the voltage sags number for the i bus
$f_{ref\,i}$ is the voltage sags reference value for the i bus
$V_i^{\min}$ is the minimum voltage at bus i
V_i is the voltage at bus i
$V_i^{\max}$ is the maximum voltage at bus i
$P_{Gi}^{\min}$ is the minimum real generation at generator i
P_{Gi} is the real generation at generator i
$P_{Gi}^{\max}$ is the maximum real generation at generator i
$Q_{Gi}^{\min}$ is the minimum reactive generation at generator i
Q_{Gi} is the reactive generation at generator i
$Q_{Gi}^{\max}$ is the maximum reactive generation at generator i

In this paper, the optimal configuration of a system in order to minimize voltage sags indices is found by solving the optimization problem formulated in (3) by applying TS and taking into account the generators schedule.

3 Implementation of the reconfiguration method by applying Tabu Search

In this work, a basic TS algorithm and the reconfiguration methodology described in section II, implemented in Matlab®, are presented [19]. Fig. 1 shows a flow chart of the implemented method.

This process, which is shown in Fig. 1, is repeated until a convergence criterion is satisfied. In this work, the TS process can stop in two ways: when it reaches the maximum iteration number or when the voltage sag number at each bus is equal or lower than the corresponding reference value.

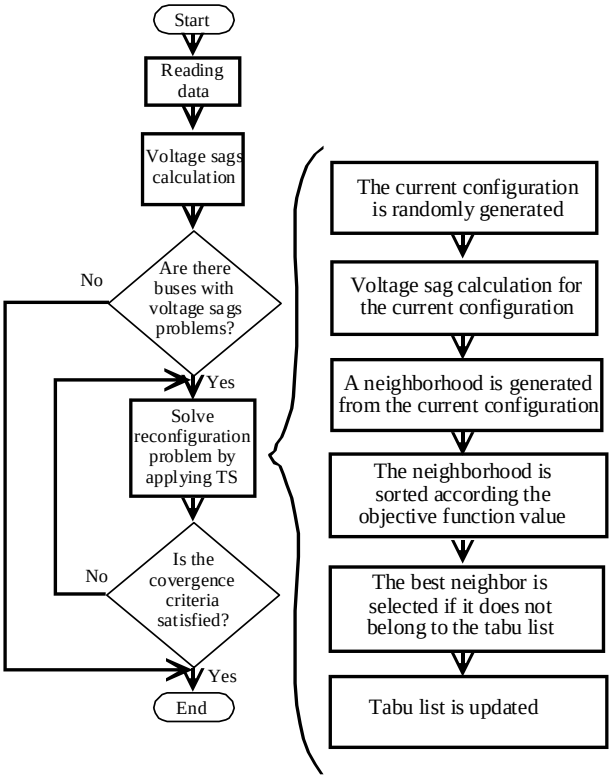

Fig. 1 Flow chart of the reconfiguration process

4 Case studies

The implemented reconfiguration method has been applied to the IEEE 57-bus test system in order to reduce the occurrence frequency of voltage sags when different conditions of energy demand are considered. The cases have been analyzed considering that voltage sags are caused by balanced three-phase faults.

The system consists of 57 buses which are interconnected by means of 63 lines, 15 transformers and 7 generating units [20]. To obtain the reference vector of voltage sags ($SARFI_x$, according to the assumed definition [8]), the method described in [5] was used and the resultant values were randomly fixed for each bus of the system with values close to those obtained by the stochastic method. The vector shown in Table I is taken as a reference vector (column 2), and it was obtained considering a voltage threshold of 0.8 p. u. ($SARFI_{80}$).

4.1 Analysis of influence of generation schedule

The analysis of the influence of generation schedule on the reconfiguration of the IEEE-57 bus test system was carried out by using the implemented method based on a TS algorithm for the following case studies assuming a fault rate of 1 faults/year for all system lines:

Case A1. Base case. Generators data provided in [20] are considered.

Case A2. 20% generation increase, achieved by increasing generation at all generation buses.

Case A3. 20% generation reduction, achieved by decreasing generation at all generation buses.

Table I shows that, in Case A1, the system has a total of 31 buses (approximately 54% of the buses) which have values of voltage sags/year (that is, $SARFI_{80}$ index) above the reference values (the shaded ones). Table I also shows that the total of voltage sags in the electrical network is 2606.44 per year, before the reconfiguration process (actual values). When the system has been reconfigured, all buses have values under the reference ones; therefore, the total of voltage sags is decreased by almost 18 %.

Table II shows that, in Case A1, the solution process requires six neighborhoods to find the solution, that is, six iterations of TS are required in order to accomplish that all 31 buses with values of voltage sags higher than their corresponding reference values reach values of voltage sags lower than the reference ones.

In Case A2, when a reduction of generation of 20% is considered, the total of buses that have values above the reference ones is less than in Case A1. In Case A2 only 15 buses have values greater than the reference.

In Case A3, when an increase of generation of 20% is considered, the total of buses (with values above the

reference) increases to 44, a significant difference when compared with Case A1.

TABLE II. NUMBER OF REQUIRED NEIGHBORHOODS TO ACHIEVE THE SOLUTION FOR CASE STUDIES

Case	Required Neighborhoods
A1	6
A2	3
A3	7

Once reconfiguration is carried out, all buses have values under the reference. Table III shows the switches status for the optimal reconfiguration after the optimization process, for cases A1 to A3. It can be observed that case A1 requires 6 lines open, while cases A2 and A3 require 4 and 10 lines open, respectively.

The results for Cases A1 to A3 can be observed graphically in Fig. 2 to Fig. 4. It can be observed that in all case studies the implemented methodology ensures that all buses have $SARFI_{80}$ values below the values specified by the reference. For instance, in Case A2, when a reduction of generation is considered, just 15 buses have values above the reference; once the reconfiguration process is made, all buses have values of voltage sags below the reference ones (Fig. 3). Case A2, after reconfiguration process, has a total of voltage sags/year of 2044.3 per year. In Case A3, 44 buses have values greater (black solid line in Fig. 4) than the reference values (gray solid line in Fig. 4); after the reconfiguration process is carried out, all buses have values lower than the reference values, giving a total of voltage sags of about 1965 per year.

4.2 Analysis of influence of generation schedule assuming fault rate variations

Usually, fault rates in the electrical system are obtained from statistical data for a determinate period of time, typically a year. However, fault rates have variations throughout the year, which can be estimated for seasonal or monthly periods [9]. In these cases, the variation of fault rates when the generation schedule changes is analyzed. The following case studies are presented:

Case B1. 20% generation reduction, achieved by decreasing generation at all generation buses, and a decrease of 10% in the fault rate (λ=0.9 faults/year).

Case B2. 20% generation increase, achieved by increasing generation at all generation buses, and an increase of 10% in the fault rate (λ=1.1 faults /year).

Cases B1 and B2 are similar to cases A2 and A3; the difference is the consideration of variations of fault rates: in case B1 a 10% fault rate decrease is considered, and in case B2 a 10% fault rate increase is considered. Before reconfiguration process, in Case B1, the system has a total of 13 buses that have values of voltage sags/year above the reference, as can be seen in Fig. 5. In Case B2, the most critical, the system has a total of 48 buses that have values of voltage sags/year above the reference (see Fig. 6).

From Fig. 5 and Fig. 6, it can be observed that after applying the process to reconfigure the system, all nodes have appropriate values, that is, voltage sag values below reference values.

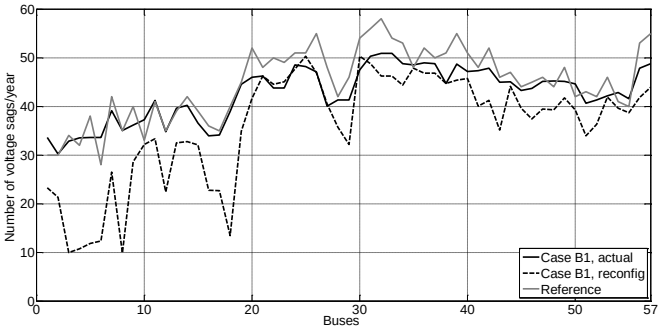

Fig. 5 Voltage sags/year for Case B1 considering a voltage threshold of 0.8 p.u.

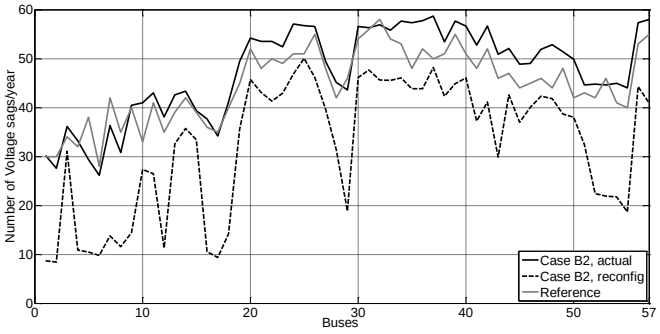

Fig. 6 Voltage sags/year for Case B2 considering a voltage threshold of 0.8 p.u.

5 Conclusions

In this paper the influence of generation scheduling on reconfiguration of power systems to minimize voltage sag indices has been analyzed. A methodology based on a Tabu Search technique has been implemented to find the optimal configuration of the power system to reduce the voltage sags number at system buses. In order to demonstrate the performance, the methodology has been applied to the IEEE-57 bus test system, taking into account that voltage sags are caused by three-phase faults.

In general, the results obtained by using this methodology show that generation demand has a meaningful impact on the expected number of voltage sags at system buses: to lower generation levels correspond higher number of sags. Consequently, when the reconfiguration process is applied in order to decrease voltage sags indexes in a power system, the schedule of generation demand is an aspect that must be considered to obtain results as close as possible to the actual conditions of the electrical network.

Exploring Multiple Features for POS Guessing of Chinese Unknown Words with Maximum Entropy Models

Qi Wang, Yu He, and Guohong Fu
School of Computer Science and Technology, Heilongjiang University, Harbin 150080, China

Abstract - *A key requirement for high-performing part-of-speech (POS) tagging systems is capable of predicting with accuracy the POS categories of unknown words in open-ended text. However, the topic of unknown word guessing has not been much explored for Chinese so far. This is because Chinese plain text contains very little explicit clues for unknown word guessing. In this paper, we attempt to explore morphological features for POS prediction of Chinese unknown words. To this end, we first take morphemes as the basic units in Chinese word formation, and then decompose each unknown word in Chinese sentences into a sequence of morphemes associated with their morphological position patterns. Finally, we incorporate different word-internal morphological clues with contextual information under the framework of maximum entropy modeling. Experimental results show that our method performs better in unknown word guessing than most of the best systems for POS tagging closed tracks at the fourth ACL-SIGHAN bakeoff, demonstrating that morphological features are of great value to POS guessing of Chinese unknown words.*

Keywords: Part-of-speech tagging, Chinese unknown word guessing, morphological features, maximum entropy models

1 Introduction

Part-of-speech (POS) tagging is a process of labeling each word in a sentence with a proper tag indicating its POS category. As a fundamental natural language analysis task, POS tagging play a key role in many natural language processing applications, including machine translation, information extraction and text mining.

POS disambiguation of known words (viz. in-vocabulary words) and POS guessing of unknown words (also referred to as out-of-vocabulary words) are two key issues in Chinese POS tagging. On the one hand, many Chinese words have multiple possible POS categories. POS disambiguation is thus aiming at finding proper POS categories for such ambiguous words according to their context. On the other hand, real text in Chinese may contain a number of words that are unknown to POS tagging systems because they do not occur in the training corpora or the system dictionaries. Therefore, a key requirement for high-performing POS tagging systems is capable of predicting with accuracy the POS categories for such unknown words or out-of-vocabulary (OOV) words in open-ended texts.

Despite significant progress in POS tagging over the past years, POS guessing of unknown words is still a great challenge for Chinese. As shown in [1], the best POS tagging closed tract accuracy at the 2007 ACL-SIGHAN Bakeoff is about 93.89%, 96.29%, 95.57%, 96.79% and 97.38% for in-vocabulary words over the five corpora (viz CityU, CKIP, CTB, PKU and NCC), while the counterpart figures for unknown words are only 47.33%, 58.75%, 75.22%, 60.36% and 60.59%, respectively. This is because in comparison with some other western languages like the English language, Chinese has several specialties with respect to POS tagging. Firstly, Chinese has weak morphology in that plain Chinese texts contain very little explicit morphological clues such as inflexion and capitalization in English that are of great value to correct POS disambiguation of ambiguous known words and POS prediction of unknown words. A Chinese word can function as different POS categories without any changes in its word form. Secondly, the Chinese language seems to allow very free word formation. In theory, any combination of Chinese characters could be a potential Chinese word. Free word formation inevitably introduces a great number of unknown words and ambiguities to Chinese POS tagging. Take the five POS tagging corpora used for the fourth ACL-SIGHAN Bakeoff as an example [1], 33.3-53.5% of words in the training corpora have multiple POS tags, while 5.2%-9.2% of words in the test datasets are unseen in the training corpora.

Furthermore, Chinese has a vague definition of words**.** Although a number of criteria have been proposed for word definition in Chinese linguistic literature from different perspectives, including orthographic, lexical, morphological, and phonological criteria [2], there is not a commonly acceptable and practically applicable definition for Chinese words. The vague definition of Chinese words raises another question: What kind of linguistic unit is most suitable for POS guessing of Chinese unknown words [3]. The notion of character-based tagging takes characters as the basic units in word formation [4]. Unknown word guessing based on characters is simple and efficient because it does not require any additional preprocessing. Within such a character-based

framework, however, it is not convenient to make use of word-level contextual information for POS disambiguation. To avoid this problem, Fu and Luke (2006) [5] suggest using lexicon or in-vocabulary (IV) words as the basic component tokens for word formation. Obviously, lexicon word based approach is capable of capturing both word-level contextual information and word-internal features for POS tagging, it requires a larger training corpus to achieve a reliable estimation for language models. Furthermore, most existing dictionaries for Chinese are not compiled in strict compliance with a consistent definition of words. While both true words and morphologically derived words are included in a dictionary, it becomes very difficult, or even infeasible, to explore prominent and reliable features for unknown word resolution. To address these problems, a more resent study by Fu et al. (2008) [6] chooses morphemes as the basic components of Chinese words. They have showed that compared with the character- or word-based approaches, the morpheme-based method provides a more straightforward and effective way of capturing both morphological and contextual features for Chinese word segmentation.

In fact, Chinese contains many implicit morphological cues for unknown word guessing, while common sense seems to indicate its weak morphology [2][6]. For example, some suffixes like 性 *xing4* '-ity' and 主义 *zhu3-yi4* '-ism' are indicators of nouns while some other suffixes such as 化 hua4 '-ize' are indicators of verbs. In this light, this paper attempts to explore such word-internal morphological features for POS prediction of Chinese unknown words. To this end, we first take morphemes as the basic units in Chinese word formation, and then decompose each unknown word in a given Chinese sentence into a sequence of morphemes associated with their morphological position patterns. Finally, we incorporate different word-internal morphological features with word-external contextual information under the framework of maximum entropy models (MEMs). To evaluate our approach, we have also conducted several experiments on the fourth ACL-SIGHAN Bakeoff data. The experimental results show that the proposed method performs better in unknown word guessing than most of the best systems for the ACL-SIGHAN Bakeoff POS tagging closed tracks, demonstrating that word-internal morphological features are of great value to Chinese unknown word guessing.

The rest of this paper is organized as follows: Following a brief review of the related work on POS tagging in Section 2, Section 3 describes in detail the morpheme-based MEMs for Chinese unknown word guessing. Section 4 reports our experimental results over different datasets for the fourth ACL-SIGHAN Bakeoff, with a discussion of the effects of different features on Chinese unknown word guessing. Finally, section 5 concludes our work and discusses some possible directions for future research.

2 Related work

As a fundamental task in natural language processing (NLP), POS tagging has drawn much attention within the NLP community, and a great progress has made over the past decades. Current POS tagging focuses on machine learning approaches, including hidden Markov models (HMMs) [7], lexicalized HMMs [5], transformation-based error-driven learning [8], maximum entropy models (MEMs) [9], contextual random fields (CRFs) [10], and support vector machines (SVMs) [11].

Recent research on POS tagging attempts to resolve the problems of unknown word guessing by exploring more potential features. Ratnaparkhi (1996) [9] explored multiple orthographical features such as suffixes, prefixes, capital first letters and hyphens, and incorporated them with local contextual information using MEMs. To predict the POS categories of Chinese unknown words, Lu (2008) [12] developed a set of morphological rules that encode knowledge about the relationship between the POS categories of unknown words and those of their component morphemes, and further integrated such morphological knowledge into trigram models. In addition, Qiu et al. (2008) [13] combined internal component information with local contextual information for Chinese unknown word guessing under the framework of CRFs. In addition to local information, Nakagawa and Matsumoto (2006) [14] also exploited global information to unknown word guessing. More recently, Umansky-Pesin et al. (2010) [15] presented a web-based technique for POS guessing of unknown words. They attempted to acquire knowledge for unknown words from web in order to achieve domain-adaptive POS tagging.

Motivated by the morpheme-based lexical chunking method for Chinese word segmentation [6], the present study is aiming at exploiting word-internal morphological clues to Chinese unknown word guessing. To this end, we take morpheme as the basic components of unknown words, and further employ the extended IOB chunk tags to represent the position of morphemes within words. Such morphological position pattern tags are thus combined with local context information for POS prediction of Chinese unknown words under the framework of MEMs.

3 Approach

Given an input sequence of words, our approach for POS tagging consists of three main parts: First, a word decomposition module is employed to decompose unknown words within the input sentence into a sequence of morphemes. To explore word-internal morphological clues for POS guessing, the extended BIO tagset is then used to represent the position patterns of morphemes within words. Finally, MEMs are used to incorporate word-internal morphological features with local contextual information for POS tagging. The following subsections will detail the proposed approach.

3.1 Chinese morphemes

Packard (2000) [2] has proposed two criteria for Chinese morpheme classification: whether a morpheme is free or bound and whether a morpheme is function (grammatical) or content (lexical). Morpheme classification based on the second criterion requires more lexical and grammatical knowledge about morphemes. However, such knowledge base is still not available for Chinese so far. Thus, we have to rest on the first criterion in practice. In particular, in the present study we consider two major types of morphemes, namely free morphemes and bound morphemes (viz. affixes). A free morpheme can stand by itself as a word (viz. a basic word), whereas an affix can show up if and only if being attached to other morphemes to form a word. In terms of their positions within words, Chinese affixes can be further subdivided into three groups: prefixes (e.g. 非 *fei1* 'non-', 伪 *wei3* 'pseudo'), infixes (e.g. 分之 *fei1-zhi1* 'an infix used in fractions') and suffixes (e.g. 性 *xing4* '-ity', 主义 *zhu3-yi4* '-ism').

To explore word-internal clues for POS guessing of Chinese unknown words, we employ the extended IOB tagset [6] to represent the position patterns of Chinese morphemes in word formation. Table 1 presents the detailed definition of the extended IOB tags and the correspondence between IOB tags and morpheme types.

Table 1. The extended IOB tagset for the representation of component morphemes within Chinese words

Tag	Definition	Corresponding morpheme types
O	A morpheme as a word by itself	Free morphemes
I	A morpheme inside a word	Free morphemes and infixes
B	A word-initial morpheme	Free morphemes and prefixes
E	A word-final morpheme	Free morphemes and suffixes

3.2 Word decomposition

Word decomposition is the process of decomposing a word to a sequence of morphemes associated with their IOB tags defined in Table 1. Here we employ the forward maximum matching (FMM) word segmentation technique [16] to perform this task. While FMM has the advantage of simplicity and efficiency in word decomposition, it does not work well for some words such as 非常规 *fei1-chang2-gui1* 'unconventionality' and 不安全感 *bu4-an1-quan2-gan3* 'insecurity' that involve multiple possible way of decomposition. To resolve such ambiguity, we use a set of case-based rules to correct error word decomposition yielded by FMM. a case rule for correction have the following form: *Error FMM-decomposition → correct decomposition*.

Table 2 presents some typical rules for correcting errors in FMM-based word decomposition. These rules can be extracted form the training data using the semi-automatic strategy proposed by Wang et al. (2000) and Fu et al. (2008) [6].

Table 2. Some typical case-based rules for correcting FMM-based word decomposition

Unknown words	Rules for correcting FMM word decomposition	
	Error FMM-decomposition	Correct decomposition
不安全感 'sense of insecurity'	不安 全 感	→ 不 安全 感
不平衡性 'inbalance'	不平 衡 性	→ 不 平衡 性
古人类学 'paleoanthropology'	古人 类 学	→ 古 人类 学
总装备部 'General Armament Department'	总装 备 部	→ 总 装备 部
被服务者 'service object'	被服 务 者	→ 被 服务 者

3.3 Maximum entropy models for POS tagging

Let $W = w_1 w_2 \cdots w_n$ be an input sequence of words, and $T = t_1 t_2 \cdots t_n$ be a potential sequence of POS tags corresponding to W. From a statistical point of view, the task of POS tagging is to find the most likely sequence of POS tags $\hat{T}$ that maximizes the conditional probability $P(T|W)$ of the POS tag sequence given the word sequence over all of its possible POS tag sequences {T}. MEMs decompose the conditional probability $P(T|W)$ of a POS sequence into a product of conditional probabilities $P(t_i \mid h_i)$, namely

$$\begin{aligned} \hat{T} &= \arg\max_T P(t_1 t_2 \cdots t_n \mid w_1 w_2 \cdots w_n) \\ &\approx \arg\max_T \prod_{i=1}^{n} P(t_i \mid h_i) \end{aligned} \quad (1)$$

Where $t_i (1 \le i \le n)$ is a candidate POS tag of the word w_i, and h_i is the history or context of word w_i. The

parameters $P(t_i \mid h_i)$ can be estimated from the training data with Equation (2).

$$\begin{cases} P(t \mid h) = \frac{1}{Z(h)} \exp(\sum_{j=1}^{K} \lambda_j f_j(t,h)) \\ Z(h) = \sum_{t} \exp(\sum_{j=1}^{K} \lambda_j f_j(t,h)) \end{cases} \quad (2)$$

Where *Z(h)* is a normalization term, and f_j is the j^{th} binary feature function for the current word w, associated with a weight λ_j. Its value is 1 if the feature condition is satisfied by the tag-history pair and 0 otherwise.

3.4 Features

Feature selection plays a critical role in maximum entropy modeling. In the present study, we consider two main groups of features for Chinese POS tagging, namely contextual features around words and word-formation features within words. In particular, we intend to examine the effects of word-internal features on POS guessing of Chinese unknown words, and thus focus feature selection on exploring word-internal clues for POS prediction. As such, we utilize a set of relatively simple contextual features for POS disambiguation, and define a variety of word-internal mono- or multiple-morpheme features for unknown word guessing.

Table 3 presents the feature templates for Chinese POS tagging. Where w_i denotes the current word, w_{i-1} denotes the preceding word, w_{i+1} denotes the following word; p_i, p_{i-1} and p_{i+1} denote their respective POS tags. m_{iB} m_{iI} and m_{iE} stand for the prefix, infix and suffix of the current word, respectively.

Table 3. The feature templates for Chinese POS tagging

Feature types	Feature template
Word external features	$w_i p_{i-1} p_{i+1}$ = XYZ & p_i
Word-internal mono-morpheme features (atomic features)	m_{iB} = X & p_i
	m_{iI} = X & p_i
	m_{iE} = X & p_i
Word-internal multiple morpheme features	$m_{iB}m_{iI}$ = XY & p_i
	$m_{iI}m_{iE}$ = XY & p_i
	$m_{iB}m_{iE}$ = XY & p_i
	$m_{iB}m_{iI}$ m_{iE} = XYZ & p_i

4 Experiments

To evaluate our approach, we have conducted several experiments on three data sets for the closed tracks of POS tagging at the fourth ACL-SIGHAN bakeoff [1]. This section reports the related experimental results.

4.1 Experimental setup

The POS tagging task at the fourth ACL-SIGHAN bakeoff consists of five closed tracks. Here we use three of them, namely CTB, NCC and PKU as the experimental data. In particular, we train our system only using the three training data sets for the ACL-SIGHAN bakeoff and evaluate it using the relevant counterparts for test, respectively. In addition, we have also extracted three morpheme dictionaries for word decomposition automatically from the training corpora using the method presented by (Fu et al., 2008) [6]. Table 4 presents the basic statistics of the experimental corpora and the extracted morpheme lexica.

Table 4. Statistics of the experimental corpora and the extracted morpheme lexica

		CTB	NCC	PKU
Training data set	Token	642246	535023	1116754
	Word type	42123	45108	55178
Test data set	Token	59955	102344	156407
	Word type	9797	17493	17643
	OOV	3794	5392	9295
	OOV rate	0.0633	0.0527	0.0594
Number of morphemes from training set		26330	28432	30085

Furthermore, four measures are employed in ACL-SIGHAN bakeoffs to score POS tagging performance, namely the overall accuracy (denoted by A_{Total}) and the recalls with respect to in-vocabulary words (denoted by R_{IV}), OOV words (denoted by R_{OOV}) and multi-POS words (denoted by R_{MT}). In view of the fact that our current study is concentrated on unknown word guessing, we only use the former three metrics in our evaluation. The detailed definitions of these metrics can be seen in [1].

4.2 Experimental results

4.2.1 Effects of different features on POS tagging

Our first experiment intends to examine the effects of different features, particularly word-internal morphological features on POS guessing of Chinese unknown words. In this experiment, we first use the system only using word-external

features as the baseline. In the hereafter runs, we introduce different word-internal morphological clues (viz. different mono-, bi- or tri-morpheme cues within words) into MEMs, and evaluate the yielded outputs of each run over the above three test sets. The experimental results are summarized in Tables 5-8, respectively.

Table 5. POS tagging results for the baseline only using word-external features

Test set	R_{OOV}	R_{IV}	A_{Total}
CTB	0.4090	0.9304	0.9021
NCC	0.3238	0.9632	0.9241
PKU	0.3107	0.9493	0.9107

Table 6. POS tagging results for all runs combining word-external information and word-internal mono-morpheme features

Test set	Feature template	R_{OOV}	R_{IV}	A_{Total}
CTB	$w_ip_{i-1}p_{i+1}m_{iB} = XYZA \ \& \ p_i$	0.6555	0.9319	0.9169
	$w_ip_{i-1}p_{i+1}m_{iI} = XYZA \ \& \ p_i$	0.5363	0.9306	0.9092
	$w_ip_{i-1}p_{i+1}m_{iE} = XYZA \ \& \ p_i$	0.6214	0.9319	0.9151
NCC	$w_ip_{i-1}p_{i+1}m_{iB} = XYZA \ \& \ p_i$	0.5428	0.9631	0.9374
	$w_ip_{i-1}p_{i+1}m_{iI} = XYZA \ \& \ p_i$	0.4014	0.9631	0.9288
	$w_ip_{i-1}p_{i+1}m_{iE} = XYZA \ \& \ p_i$	0.5434	0.9632	0.9375
PKU	$w_ip_{i-1}p_{i+1}m_{iB} = XYZA \ \& \ p_i$	0.5507	0.9554	0.9401
	$w_ip_{i-1}p_{i+1}m_{iI} = XYZA \ \& \ p_i$	0.4904	0.9554	0.9379
	$w_ip_{i-1}p_{i+1}m_{iE} = XYZA \ \& \ p_i$	0.6106	0.9555	0.9425

Table 7. POS tagging combining word-external information and word-internal bi-morpheme features

Test set	Feature template	R_{OOV}	R_{IV}	A_{Total}
CTB	$w_ip_{i-1}p_{i+1}m_{iB}m_{iI}=XYZAB \ \& \ p_i$	0.6813	0.9312	0.9176
	$w_ip_{i-1}p_{i+1}m_{iI}m_{iE}=XYZAB \ \& \ p_i$	0.6583	0.9316	0.9167
	$w_ip_{i-1}p_{i+1}m_{iB}m_{iE}=XYZAB \ \& \ p_i$	0.7188	0.9317	0.9201
NCC	$w_ip_{i-1}p_{i+1}m_{iB}m_{iI}=XYZAB \ \& \ p_i$	0.5547	0.9625	0.9376
	$w_ip_{i-1}p_{i+1}m_{iI}m_{iE} =XYZAB \ \& \ p_i$	0.5854	0.9625	0.9394
	$w_ip_{i-1}p_{i+1}m_{iB}m_{iE}=XYZAB \ \& \ p_i$	0.6441	0.9627	0.9432
PKU	$w_ip_{i-1}p_{i+1}m_{iB}m_{iI}= XYZAB \ \& \ p_i$	0.5760	0.9551	0.9408
	$w_ip_{i-1}p_{i+1}m_{iI}m_{iE}= XYZAB \ \& \ p_i$	0.6213	0.9556	0.9430
	$w_ip_{i-1}p_{i+1}m_{iB}m_{iE}= XYZAB \ \& \ p_i$	0.6377	0.9553	0.9433

Table 8. POS tagging results for all runs combining word-external information and word-internal triple-morpheme features

Test set	Feature template	R_{OOV}	R_{IV}	A_{Total}
CTB	$w_ip_{i-1}p_{i+1}m_{iB}m_{iI}m_{iE}$ $= XYZABC \ \& \ p_i$	0.7326	0.9317	0.9200
NCC	$w_ip_{i-1}p_{i+1}m_{iB}m_{iI}m_{iE}$ $= XYZABC \ \& \ p_i$	0.6470	0.9620	0.9428
PKU	$w_ip_{i-1}p_{i+1}m_{iB}m_{iI}m_{iE}$ $= XYZABC \ \& \ p_i$	0.6500	0.9551	0.9436

These results reveal that the morphological features within words are of great value to POS prediction of Chinese unknown words. Take the runs over the CTB data set as an example, the POS tagging accuracy for unknown words is 40.09% for the baseline that only uses contextual features for POS tagging. This figure increases to 68.13% or 62.14% while introducing prefix or suffix cues, and reach the highest value of 73.26% while combining all the three word-internal morphological position patterns with contextual information. Furthermore, as potential cues, prefix and suffix patterns prove to be more informative for Chinese unknown word guessing in comparison with infix patterns.

4.2.2 Comparison

To asses the effectiveness of our approach, we also compare our system with the best systems for the POS tagging closed tracks at the ACL-SIGHAN bakeoff. Note that in this experiment we incorporate the triple word-internal morphological patterns with contextual features. The results are given in Table 9.

Table 9 Comparison of our system with the best systems in the closed track of POS tagging at the 4th ACL-SIGHAN bakeoff

Test set	Our system			The best performance at ACL-SIGHAN bakeoff		
	R_{OOV}	R_{IV}	A_{Total}	R_{OOV}	R_{IV}	A_{Total}
CTB	0.7326	0.9317	0.9200	0.7522	0.9557	0.9428
NCC	0.6470	0.9620	0.9428	0.5998	0.9738	0.9541
PKU	0.6500	0.9551	0.9436	0.5818	0.9694	0.9450

From Table 9, we can see that compared with the relevant best system at the 2007 ACL-SIGHAN bakeoff, our method performs better in unknown word guessing than on NCC and PKU data sets, but slightly worse on the CTB corpus. However, the POS tagging performance is not satisfactory for in-vocabulary words. The reason may be that in the present study we focus our current study on explore word-internal morphological clues for Chinese unknown word guessing, and use a set of relatively simple contexture

features (viz. bi-tags), resulting in a limited capacity of in-vocabulary POS disambiguation.

5 Conclusions

In this paper, we have attempted to explore word-internal morphological clues within Chinese words, and incorporate them with word-external contextual features for POS guessing of Chinese words. We evaluated our method using some data sets for POS tagging closed tracks at the fourth ACL-SIGHAN bakeoff. The experimental results show that word-internal morphological information plays a key role in correct prediction of POS categories for Chinese unknown words.

While our system has achieved promising performance, there is still much space for improvement. Due to the lack of deep morphological knowledge for Chinese, in the present study we only took into account surface morphological clues for Chinese unknown word guessing, namely the position patterns of morphemes in word formation. In future work we intend to explore systematically deep morphological knowledge, including the POS categories of morphemes and morpho-syntactic rules for POS prediction of various unknown words in real Chinese texts. In addition, in the present study we only used contextual POS features, resulting in limited capacity in POS disambiguation. So we are also planning to enhance the overall POS tagging accuracy of our system by incorporating more complicated contextual features such as contextual lexical information with word-internal morphological features.

Abstract - *This work examines recent publications in forecasting in various fields, these include: wind power forecasting; electricity load forecasting; crude oil price forecasting; gold price forecasting energy price forecasting etc. In this review, categorization of the processes involve in forecasting are divided into four major steps namely: input features selection; data pre-processing; forecast model development and performance evaluation. The various methods involve are discussed in order to provide the overall view about possible options for development of forecasting system. It is intended that the classification of the steps into small categories with definitions of terms and discussion of evolving techniques will provide guidance for future forecasting sytem designers.*

Keywords: Forecasting; Prediction; Feature selection; Modeling; Performance evaluation

1 Introduction

This paper gives a brief overview of forecasting techniques published in the last ten years. An attempt has been made in categorizing relevant published work into series of steps needed for understanding forecasting techniques.

Forecasting involve predicting future behavior or value of certain phenomena. Forecasting has been applied in various fields such as wind power [1,2] ; electricity load consumption [1] ; energy price forecast in power systems [1,2,3] ; gold price forecasting[4] ; price spike prediction [5] ; financial sequence prediction [6] ; fatigue life prediction [7] ; car fuel consumption forecasting [8] and so on.

Generally, forecasting activity can be divided into three relevant classes, namely short term, medium term and long term forecasting. Short term forecast activity concentrates on predicting unknown values of price for a short period of time. These periods include few minutes, hours, or days. Monthly forecast activity falls into medium term while long term forecast activity may cover period of one to few years. Short term forecast is informative for profit maximization [1, 2] while medium term price forecast is useful for negotiations of bilateral contract between suppliers and consumers. Long term forecast is a valuable tool for assets expansion [1].

The first difficulty associated with forecasting activity is the linearity of data. Forecast activity becomes easier when dealing with linear historical data [3]. Linear data normally undergo linear changes such as linearly increasing or linearly decreasing over certain period of time. On the other hand, forecasting activity become very challenging issues when dealing with non-linear data [9]. External influence has been identified as one of the reasons responsible for non-linearity nature of data. Electricity power system, load and demand system, crude oil and gold price prediction are some of the sectors known for having non-linear data.

Lots of forecasting models and techniques have been proposed in literature with each achieving various degree of success. Among the reported methods are Moving Average (MA), Linear Prediction (LPC), Auto-Regressive Moving Average (ARMA) and the Box-Jenkins approach based on Auto-Regressive Integrated Moving Average (ARIMA). These methods are preferred by some researchers when dealing with linear data [5,10].

The remaining part of this paper is organized as follows: Section II describes the common methodology used for forecasting while the last section provides a list of commonly used performance metrics.

2 Review of forecasting techniques

Extensive study of various forecasting techniques have shown four major steps; namely, input features selection, data pre-processing, Modelling cum data training and performances evaluation. Modelling and data training have been the major areas of focus in the literature. Model represent the forecast system since it is to receive input data, analyse it and produce output called predicted value. Most forecasting models are based on assumption of relationship between inputs (historical time series data) and outputs (future values). A typical forecasting block diagram is shown in Fig. 1.

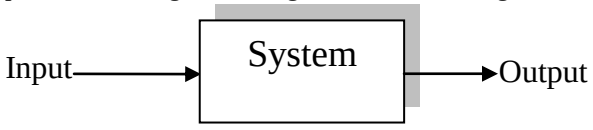

Figure 1: Block diagram of system

The overall review done in this paper based on the forecasting steps consist of (i) Input features selection (ii) Data Preprocessing step (iii) Forecasting models development step and (iv) Performance evaluation step and their

components in each step are shown in Fig. 2. The details of each components are subsequently discussed.

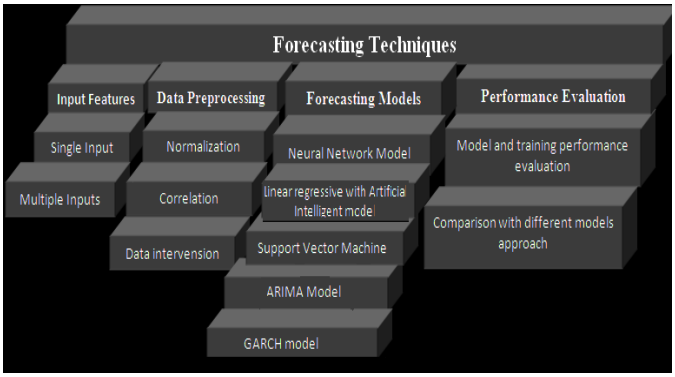

Figure 2: Major steps for forecasting

2.1 Input features selection

Input data in forecasting consist of collection of historical information that used to forecast the future values. Input data are fed into forecasting model for analysis in order to determine future output value. Input data can be developed through collection of various information that influence the data. Therefore, proper selection of input data is of utmost importance. Adequate input may give enough information to forecasting model to analyze the future trend of data accurately, whereas insufficient features in the input data may lead to serious error in forecast. Time series historical data is mainly used in forecasting system. However, in some forecasting field, time series data alone is inadequate to accurately forecast the future trends of data. Therefore, utilization of historical information base on other features may be used to enhance the forecast output. The utilization of both types of data is discussed as follows.

2.1.1 Time series historical data

Information from historical time series data is very useful for forecasting models to learn the trend of future data. Generally, time series data can be obtained from historical documents. The trend of a time series historical data is normally assumed to shows certain repetitive pattern. List of the time series data were used in lituretures such as Market Clearing Price (MCP) for forecasting electricity demand[14, 15], and previous time electricity price and load price data to forecast a day ahead electricity price [16]. In addition, utilization of previous three months data in forecasting monthly price was reported in [17] and previous hours data were used to forecast next hour data in [18].

2.1.2 Combination of time series with other features data

Multiple features input utilization have been reported in [19, 20, 25]. Seasonal factors and weather conditions were included as additional as input besides time series data for electricity demand forecasting model [19]. Ignoring the external factors may lead to inadequate training to the forecasting model which may lead to forecast error. For example, daily whether information is unignorable in electricity forcasting field since people will definitely use more electricity during hot days as compare to cold weather[19]. Other factors such as added value and number of customer were also incorporated as input features in [20], while total number of weeks, yearly number of weeks, world events impact factor and global demand were used as input features in [9,51]. Similarly, market clearing price (MCP) and other influence factors such as previous competitive load, competitive generating capacity, system running style, previous market have also been considered in forecasting electricity price [22].

2.2 Data pre-processing

The second stage in forecasting is data pre-processing stage. The objective of data pre-processing step is to remove abnormalities in the data such as noise. Besides that, data pre-processing technique is used to regulate the input and output range of data. Through this step, original historical data will be altered in order to produce new set of input data. Some of the known data pre-processing techniques are (i) Normalization, (ii) Correlation and (iii) Data intervention. Each of the preprocessing techniques is discussed as follows.

2.2.1 Normalization

Normalization is the most popular data preprocessing technique reported in literature as part of forecasting technique [9, 19, 24, 25, and 34]. Data normalization reduces data range into smaller scale such as in the range from 0 to 1. In other word, normalization process helps to rescale the huge number of data to lie between the scaling ranges.

2.2.2 Correlation

The purpose of correlation is to detect non randomness in time series data [26]. Informally, correlation technique is used to find the similarity between different observations in a given time series data. Furthermore, correlation is used for features selection from large size of data. Autocorrelation analysishas been used for feature selection process by removing irrelevant and redundant features and selecting a small set of informative features that are necessary and sufficient for good forecasting [27,28].

2.2.3 Data intervention technique

Data intervention technique function is to improve forecasting result. This technique removes intervention effects such as changes of whether condition or political instability that may produce spike to time series data. In [29], sudden high peak in the data is removed from input data since it is considered as intervention effect [29].

2.3 Forecast Model Development

The third stage in forecasting is the development of the forecast model. This is the art of the whole process and lots of efforts are usually expended in the development of such a model. Some of the reported forecast models include:

i. Artificial Intelligence model.
ii. Linear regressive with Artificial Intelligence mathematical model.
ii. Support Vector Machine (SVM) approach.
iv. Autoregressive Integrated Moving Average (ARIMA) model.
v. Generalized Autoregressive Conditional Heteroskedastic (GARCH) model.

2.3.1 Artificial Intelligence model

Artificial intelligence (AI) model in forecasting field has received favourable success in the last few years. Among the AI techniques reported in literature are fuzzy inference[11], fuzzy-neural models[12] and Artificial Neural Network (ANN) [13]. The application of ANN approach for nonlinear data, such as load forecasting in power system has received much attention in recent years, since ANN has the ability to learn complex and nonlinear relationships [5].

Modeling using Artificial Neural Network (ANN) plays the important role in forecasting field because of its capability to learn both linear and nonlinear relationship from a given input data during training process. Different types of learning algorithms for training this model has been proposed in literature. A list of studies have used Gradient Descent learning rule with momentum [19,30,31], Levenberg-Marquardt (LM) algorithm [15][18], conjugate gradient (SCG) algorithm [15] and multi ELM training algorithm [16]. Levenberg-Marquardt (LM) algorithm and scaled conjugate gradient (SCG) algorithm are proposed to overcome slow convergence of BP algorithm. Genetic Algorithm has been used as an alternative training rules to BP algorithm in order to overcome local minima problem associated with BP algorithm[14]. Combination of Levenberg-Marquardt back-propagation algorithm(LM-BP) and evolutional algorithm approach to train their MLN model was proposed in [18]. Similarly, LM-BP and Particle Swarm Optimization is reported in [18].

Radial Basis Network(FBN) is another type of feed forward network used as an alternative to Multi Layer Network in forecasting model [25]. RBN use Euclidean distance as activation function for hidden layer instead of linear activation function that used in Multi Layer Network (MLN). Elman neural network forecasting model with BP learning algorithm was reported in [17]. Elman neural network or Elman regression neural network (ERN) has an additional of one layer compared to MLN, which is the context layer. In other words, ERN developed with 4 layers; namely, input layer, hidden layer, context layer and output layer. The outputs data from hidden layer are stored in the context layer (also called accepter layer) before sending it to output layer. Therefore, ERN offers the system the capability to adapt the time variability by its dynamic character mapping function supported via internal status memory [17]. Artificial Neural Networks- Quantitative (ANN-Q) Model has been introduced in [23]. Hybrid of ANN and Adaptive Neuro-Fuzzy Inference System (ANFIS) has also been proposed to accomplish the forecast purpose in [31]. These two model are combined (in series) in such a way that one of forecasted data will be fed into ANFIS network.

2.3.2 Linear regressive with artificial intelligent mathematical model

The objective of regression analysis is to develop mathematical model that can forecast the values of dependent variables (e.g. *y* plane in the data graph) by using independent variables (e.g. *x* plane in the data graph) as input. In the case of daily gold price forecasting, the price of the gold will be dependent variables, while the date of that price occur will be independent variables. The general form of linear regressive model is :

$$y = mx + c \quad (1)$$

Where *y* is the forecast value, *m* is the slope of 'best fit' line, *x* is prediction date and *c* is intercept point of best fit line to *y* axis. In the classical method, the 'best fit' line is considered as linear line that follows the trend of data as illustrated in the Fig. 3.

Figure 3: 'Best fit line' across historical data of gold price data

The best fit line is drawn in the way that it not bias to any points. However, in case of nonlinear relationship between input and output, straight linear line unable to follow the trend of graph closely. Consequently, classical linear regressive model is not suitable for forecasting non linear data because it has tendency to produce high error in forecast value. Therefore, Artificial Intelligent technique is used to find the *m* variable, to be substitute in the linear regressive model for forecasting non-linear data. For example, in [32], Genetic Algorithm is used to find five 'best fit' coefficients for four independent variables. Similarly, Particle Swarm Optimization (PSO) algorithm has been used for tuning linear algorithm coefficients from electricity consumption data for electric consumption forecasting model of the following year [20].

2.3.3 Support Vector Machine approach (SVM)

SVM's is a supervised learner that used to analyse and recognize the patterns of data. SVM is used to constructs set of hyperplanes (gap between different classes) in a high or infinite- dimensional space in order to classify data. SVM has the advantage of reducing the problem of over-fitting or local minima because its learning algorithm is based on the structural risk minimization principle compared to ANN, which use learning algorithm based on the empirical risk minimization principle. The four basic kernel types in SVM include Linear Kernel, Polynomial Kernel, Radial, Basis Function Kernel (RBF) and Sigmoid Kernel. Kernel is used to compute dot product in terms of the variables in the original space. SVM with RBF kernel function has also been developed for forecast purpose in [9].

2.3.4 Autoregressive Integrated Moving Average (ARIMA) model

ARIMA model can be used to get better understanding of time series data and forecast the future points. ARIMA model consist of three parts : namely, an autoregressive part of order *p*, moving average part of order *q* and the first derivative of the time series of order *d*, known as the integrated part. Thus, the model is generally referred to as an ARIMA(*p*,*d*,*q*). ARIMA model can be called an Autoregressive model (AR(*p*)) whenever the order *d* and *q* becomes zero (e.g *ARIMA(1,0,0))*. Similarly, the model may be regarded as ARMA model when only the *d* term is set to zero. SARIMA model is developed with addition of seasonal component to this model. In [28], two ARIMA models was proposed to forecast hourly prices in the electricity markets. Furthermore, a model called seasonal autoregressive integrated moving Average (SARIMA) was developed to forecast electricity price [29].

2.3.5 Generalized Autoregressive Conditional Heteroskedastic (GARCH) model

The GARCH time series model was introduced in [29]. It overcomes the ARIMA and linear regression models that have limitation to deal with non linear data. This model determine the explicit relationship of the nonlinear data series. In order to get acceptable accuracy, the formulation of non linear model is developed to capture the entire important features in the historical data.

2.4 Performance evaluation

Performance evaluation is the crucial part to test the performance of the newly developed model. Normally, the performance of forecasting model is evaluated by using standard performance evaluation formula. Once the performance of the model is satisfied, the scope of evaluation is expanded to compare this newly developed model with other existing models. In the following subsections, both methods of evaluating the results obtained from the model are discussed herewith.

2.4.1 Modeling and training performance evaluation

In order to evaluate the forecast results, the facts or empirical results are normally presented. In forecast issue, standard performance evaluation metrics include mean square error (FMSE)[24], RMS error[16], [23], [33], mean absolute percentage error (MAPE) [15], [18], [30], [31], Relative absolute error (RAE) [27] and correctly forecasted percentage error[9],[16]. MAPE evaluation metric are among of the frequently used performance metric. MAPE was used as the fitness function for measuring the evolutionary algorithm optimization in [15], [18], [30], [31]. Percentage error and RMS error are used to compare performance between two or more forecast models. These metrics are calculated using (2)-(5) :

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(actual - forecast)^2} \quad (2)$$

$$FMSE = \frac{1}{N}\sum_{i=1}^{N}(actual - forecast)^2 \quad (3)$$

$$MAE = \frac{1}{N}(\sum_{i=1}^{N}[\left|\frac{actual - forecast}{actual}\right|] \quad (4)$$

$$MAPE = \frac{1}{N}(\sum_{i=1}^{N}[\left|\frac{actual - forecast}{actual}\right| \times 100\%] \quad (5)$$

where *N* is the data length.

Combination of more than one performance metrics have been used in some literature. Combination of MAE, RAE and MAPE was proposed in [27] while the combination of RMSE and NMSE was used in [23]. *Dstat* is used to evaluate the forecasted price movement.

2.4.2 Performance comparison of different methodology

The main objective of forecast research nowadays is to develop the best and reliable forecast model that will give minimal error between the forecasted value and actual value. Methodology comparison in term of performance metrics is a mean for evaluating any new model performance in order to compare the result among existing models. For example, RBF performance was compared with autoregressive forecasting model in [25]. Similarly, ARIMA and linear regression technique performance was compared in [32]. In [10], it was shown that ANN method leads to better prediction than time series ARIMA method, while GA performance is better than linear regression technique model. The performance of SVM and BPNN is compared in [9]. In another study, ANN performance was compared with similar day (SD) forecast approach[19].

3 Conclusion

This paper contains review of some of the forecasting techniques that have been published in the last ten years. The steps associated with forecasting are categorized into four primary steps: namely, of input features selection (step one) ; data preprocessing (step two); forecast model development (step three) and performance evaluation (step four). The various methodology proposed in each step are highlighted and discussed.

Abstract

Collaborative filtering (CF) systems have been proven to be very effective for personalized and accurate recommendations. These systems are based on the recommendations of previous ratings by various users for various products. Since the very beginning of the research on Collaborative Filtering, different systems have been developed for different domains and application areas. Besides some general features, which are expected to be present in any system, Collaborative Filtering Algorithms have their own extra features that make them different from other systems. Through a careful study of a large number of Collaborative Filtering Algorithms, hierarchies of primary features based on which one can evaluate different Collaborative Filtering Algorithms are proposed. The methodology is applied to evaluate Mean Absolute Error (MAE) with real data. An evaluation scheme is also derived based on the prediction quality for the given features. The results are evaluated through experimental tests and results were tabulated to see the effect of different parameters on the performance of the algorithm. A comparative analysis has been evaluated with various collaborative filtering techniques and found that hybrid collaborative algorithm approach is performs better than other collaborative filtering algorithms.

Key words
Prediction, Collaborative Filtering, Mean Absolute Error

1. Introduction

The explosive growth and availability of data on the World Wide Web (www) has caused information overload. Searching for a query is not easy in the sources of information available for the interest of an individual user. Recommender system form a specific type of information filtering technique that attempts to present information items that are likely of interest to the user. A recommender system compares the user's profile to some reference characteristics, and seeks to predict the 'rating' that a user would give to an item that they had not yet considered. These characteristics may be from the information items or user's social environment Recommender systems are designed to help a user to survive with this situation by selecting a small number of options to present the user. Recommender systems helps to users to overcome information overload by providing personalized suggestions based on a history of a user's likes and dislikes. On-line web portals like Amazon.com [6]; eBay.com [7]; Netflix.com [8] etc. are providing these recommending services to know about the personalized interests.

Collaborative filtering recommender systems [1] recommend items by identifying other users with similar taste and use their opinions for recommendation; whereas content-based recommender systems recommend items based on the content information of the items. These systems suffer from scalability, data sparsity, over specialization, and cold-start problems resulting in poor quality recommendations and reduced coverage. Recommender System is to generate significant recommendations to a collection of users for items or products that might interest them. Content-based filtering and collaborative filtering (CF) are two technologies used in recommender systems. Content-based filtering systems analyze the contents of a set of items together with the ratings provided by individual users to conclude which non-rated items might be of interest for a specific user.

2. Collaborative filtering (CF)

CF is one of the most frequently used technique in personalized recommendation systems which is also making predictions about the interests of a user based on previous preferences by all users based on the idea that users who liked similar things in the past will tend to favor similar items. CF is the process of filtering for information or patterns using techniques involving collaboration among multiple agents, viewpoints, data sources, etc. They are mainly classified into three categories: namely, memory- based collaborative filtering, model- based collaborative filtering and hybrid collaborative filtering techniques [1].

2.1 Memory-based Collaborative Filtering

Memory-based algorithms utilize the entire user-item database to generate a prediction. These systems employ statistical techniques to find a set of users, known *as* neighbors. Once a neighborhood of users is formed, these systems use different algorithms to combine the preferences of neighbors to produce a prediction or *top*-N recommendation for the active user. The techniques, also known as *nearest-neighbor* or user-based collaborative filtering [1] are more popular and widely used in practice.

2.2 Model-based collaborative filtering

Model-based collaborative filtering algorithms provide item recommendation by developing a model of user ratings initially. Algorithms in this category take a probabilistic approach and envision the collaborative filtering process as computing the expected value of a user prediction, given user ratings on other items. The model building process is performed by different machine learning algorithms such as Bayesian network, clustering, Singular Value Decomposition (SVD) [1] and rule-based approaches.

2.3 Hybrid Collaborative Filtering (HCF)

HCF [1] systems combine CF with other commendation techniques to make predictions or recommendations. Hoping to avoid limitations of either recommender system and improve recommendation performance, HCF recommenders are combined by adding content-based characteristics to CF models, adding CF characteristics to content-based models, combining CF with content-based or other systems, or combining different CF algorithms.

3. The Characteristics and their Rationale

Usually, a recommender system providing fast and accurate recommendations will attract the interest of customers and bring benefits to business. For CF systems, producing high-quality predictions or recommendations depends on how well they address the challenges, which are characteristics of CF tasks as well are described.

3.1 Data Sparsity

The data sparsity challenge appears in several situations in collaborative filtering, specifically, the cold start problem [1] occurs when a new user or item has just entered the

system; it is difficult to find similar ones because there is not enough. New items cannot be recommended until some users' rate it, and new users are unlikely given good recommendations because of the lack of their rating or purchase history. This could reduce the effectiveness of a recommendation system and therefore generating predictions.

Hybrid CF algorithms [1], such as the content-boosted CF algorithm, are found helpful to address the sparsity problem, in which external content information can be used to produce predictions for new users or new items. In Ziegler et al., a hybrid collaborative filtering approach was proposed to utilize bulk information designed for exact product classification to address the data sparsity problem of CF recommendations, based on the generation of profiles.

3.2 Scalability

When numbers of existing users and items grow tremendously, traditional CF algorithms will suffer serious scalability problems, with computational resources going beyond practical or acceptable levels. As well, many systems need to react immediately to online requirements and make recommendations for all users regardless of their purchases and ratings history, which demands a high scalability of a CF system [6].

3.3 Synonymy

It refers to the tendency of a number of the same or very similar items to have different names or entries. Most recommender systems are unable to discover this latent association and thus treat these products differently. For example, the seemingly different items "children movie" and "children film" are actual the same item, but memory-based CF systems would find no match between them to compute similarity. The frequency of synonyms decreases the recommendation performance of CF systems. The drawback for fully automatic methods is that some added terms may have different meanings from intended, thus leading to rapid degradation of recommendation performance.

3.4 Gray Sheep

Gray sheep refers to the users whose opinions do not consistently agree or disagree with any group of people and thus do not benefit from collaborative filtering. Black sheep are the opposite group whose individual tastes makes recommendations nearly impossible. Although this is a failure of the recommender system, non-electronic recommenders also have great problems in these cases, so black sheep is an acceptable failure. Claypool et al. provided a hybrid approach combining content-based and CF recommendations by basing a prediction on a weighted average of the content-based prediction and the CF prediction.

3.5 Shilling Attacks

In cases where anyone can provide recommendations, people may give tons of positive recommendations for their own materials and negative recommendations for their competitors. It is desirable for CF systems to introduce precautions that discourage this kind of phenomenon [2]. Item-based CF algorithm was much less affected by the attacks than the user-based CF algorithm, and they suggest that new ways must be used to evaluate and detect shilling attacks on recommender systems. The item-based CF systems have been examined by Mobasher et al., and alternative CF systems such as hybrid CF systems and model-based CF systems were believed to have the ability to provide partial solutions to the problem.

4. Description of Algorithms Evaluated

It is proposed to choose the following algorithms to evaluate which are frequently mentioned in the literature and works on explicit ratings data. Further, the algorithms are proposed for modification by introducing new approach. In some cases, the proposal made for minor modifications to existing algorithms in order to improve performance. All the tested algorithms with basic information are described.

Classification	Name of the Algorithm	Advantages	Disadvantages
Memory-based CF	User-based Collaborative Filtering(UBCF) K- Nearest Neighbor(K-NN)	1.easy implementation 2. need not consider the content of the items being recommended 3.scale well with co-rated items	1.dependent on human ratings 2. cannot recommend for new users and items 3. have limited scalability for large datasets
Model-based CF	Apriori algorithm Singular Value Decomposition (SVD)	1.better address the sparsity, scalability and other problems 2. improve prediction performance	1. expensive model-building 2. lose useful information for dimensionality reduction techniques 3. have trade-off between prediction performance and scalability
Hybrid CF	Content-boosted Collaborative Filtering(CBCF)	1. improve prediction performance 2. overcome CF problems such as sparsity and gray sheep 3. overcome limitations of CF and content-based or other recommenders	1. need external information that usually not available 2. have increased complexity and expense for implementation

Table 1: Summary of the proposed algorithms for evaluation

5. Methodology

In this work (i) user-based collaborative filtering, (ii) k-NN algorithm, (iii) item-based collaborative filtering (iv) Apriori algorithm, (v) singular value decomposition (SVD) (iv) Simple Bayesian CF Algorithm and (iiv) content-boosted algorithm are implemented and are further examined for several combinations of suitability for making an effective combination to form a hybrid collaborative filtering algorithm by reducing the quality of predictions. Based on the performance, user-based collaborative filtering, singular value decomposition (SVD) and content-boosted algorithm are modified for further reducing the quality of prediction.

The experimental methodology used for computing the different prediction algorithms namely CF predictor, Content-based algorithm and CBCF are presented and evaluated. Then prediction times and the quality of their predictions are measured for each evaluated algorithm. All the experiments were performed on an Intel Pentium-IV Processor, 2 GB RAM system and implemented in Java and executed. The dataset is stored in database MySQL in the same computer.

6. Dataset

To carry out the research and analysis for content boosted collaborative filtering system, the GroupLens Research Project agency at the University of Minnesota developed Internet Movie Database which contains the user-movie ratings and the movie details, called the **Movie Lens dataset** [5]. This dataset may be used to derive the results. The data set consists of 100,000 ratings (1-5) from 943 users on 1682 movies. Each user has rated at least 20 movies. It provides demographic data such as age, gender, and the zip code supplied by each person. The content of the information of every movie is considered as a set of slots. Each slot is represented by number of words. Further, the data has been segregated and discarded for having less than 20 ratings or in complete demographic information. Now the dataset provides the actual rating data provided by each user for various movies and used in the implementation process to generate prediction values for various algorithm systems.

7. Experimental Evaluation

A subset of the ratings data from the MovieLens data set is used for the purposes of comparison. 20% of the users were randomly selected to be the test users. In the each movie data downloaded from grouplens website [9], it mentioned that the data sets u1.base and u1.test through u5.base and u5.test are 80%/20% splits of the u data into training and test data. Each of u1, u2, u3, u4, and u5 has disjointed test sets for cross validation. These data sets can be generated from u.data by mku.sh. Source file u.data contained the u dataset by 943 users with 100000 ratings on 1682 items. Each user has rating at least 20 movies. This is a tab separated list of user id, item id, rating and timestamp.

MAE calculates the irrelevance between the recommendation value predicted by the system and the actual evaluation value rated by the user. The measurement method of evaluating the recommendation quality of recommendation system mainly includes statistical precision measurement method it includes to measure the recommendation quality [6]. The generated prediction values are stored in an arraylist as mentioned above and tabulated.

8. Performance Evaluation and Comparative Analysis

The influence of various nearest neighbors set on predictive validity is tested by gradually increasing the number of neighbors. The dataset predicts item rating of the users are evaluated as per the opinions of the users chosen ratings. The results are shown in graphical representing MAE values Vs respective their neighbor set sizes. MAE values are computed using different test data sets and tabulated in table 2. The Comparative analysis of these computed values are presented.

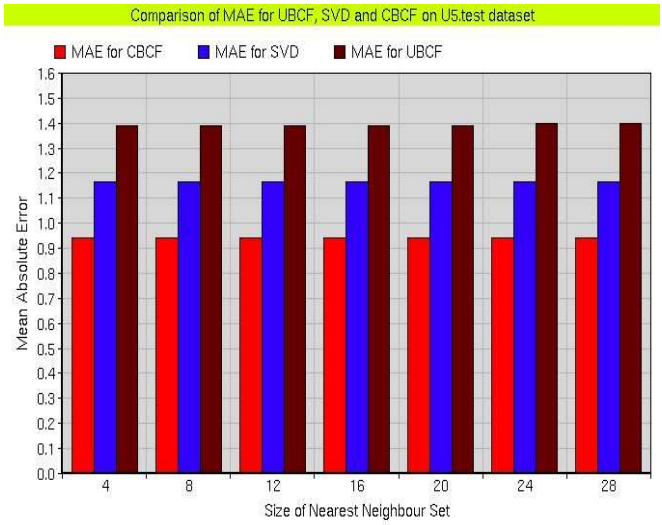

Fig.1. Comparing the performance of three modified collaborative filtering algorithms i.e., UBCF, SVD and CBCF.

The results presented in table 2 shows the MAEs for the different NNSs evaluation users using test dataset is 32.3% and 19.5%. In most of the cases, it is observed modified algorithms are performed well and showed increase in the quality perdition performance. One thing that it is important to notice is the differences between the overall performances of the modified UBCF, SVD and CBCF. CBCF performs better than the other compared algorithms.

10. CONCLUSION

In this paper, a sequence of collaborative filtering algorithms that are known for their efficiency, relevant collaborative filtering algorithms found in the literature are only presented and evaluated. The conclusions that presented are based on the results produced by the experiments conducted with the different algorithms and performance evaluation during the development of work.

As observed from the results obtained in the experiment, among all the modified collaborative filtering methods, the performance of content-boosted collaborative filtering algorithm could be proven better, which one is

related with traditional collaborative filtering algorithms.

Recursive Tensor Factorization for Multi-Linear Regression

A. Eliseyev[1] **and T. Aksenova**[1]
[1]CEA, LETI, CLINATEC, MINATEC Campus, 17 rue des Martyrs, 38054 Grenoble, France

Abstract - *In the present article a Recursive Multi-Way Partial Least Square Regression (RNPLS) algorithm for recursive tensor factorization and multi-linear regression is considered and tested in the model experiments. The method combines the Multi-Way Partial Least Square (NPLS) tensors decomposition with a scheme of recursive calculation. This recursive algorithm allows treating data arrays of huge dimension. In addition, it provides a fast adjustment of the regression to changes of the analyzed data. The recursive algorithm demonstrates fast and robust convergence in a set of experiments with artificial data in comparison with generic approach. The algorithm can be applied to solve a wide range of problems.*

Keywords: partial least square regression, recursive estimation, multi-way analysis, tensor factorization.

1 Introduction

In the variety of tasks several domains must be analyzed simultaneously to obtain the proper results (e.g., time-series analysis, chromatography, neuronal activity processing, etc.). Several multi-model data processing approaches were proposed, for instance, Parallel Factor Analysis [1], Multi-Way Partial Least Square [2], Iterative Multi-Way Partial Least Square [3]. Unlike the vector oriented algorithms that can be applied to the multi-way (tensor) data after unfolding, the multi-way modeling preserves the structure of the data, improves robustness of the results as well as allows identifying relative impact of each dimension. The specificity of the multi-way data is their huge size, which leads to high time- and resources consumption of the modeling procedure. In addition, in numerous applications, the analyzed signals vary significantly in time. Recursive calculations provide a fast adjustment of the model to changes of the signals. Recently, the Recursive Multi-Way Partial Least Square Regression algorithm, uniting the scheme of recursive calculation with multimodal data representation, was proposed by Eliseyev et al., [4]. This work is devoted to study of convergence of the RNPLS approach.

2 Method

The Recursive NPLS method is derived from the NPLS and Recursive PLS [5] approaches, thus it unites both the multi-way data representation of the first one, and the recursive calculation scheme of the second one. In the recursive method, the information used for decomposition of the tensors of observation of independent variables $\underline{\mathbf{X}}$ and dependent variables $\underline{\mathbf{Y}}$ is captured by their loading tensors, as well as by the coefficient matrix. They are iteratively updated according to the new data and are used instead of current tensors of observation. The size of the loading tensors and the matrix of coefficients are defined by the dimensionality of the observed variables and do not depend on the number of observations. As a result, the algorithm always keeps the size of the processing data.

3 Computational experiments

3.1 Data description

To test the convergence of the RNPLS algorithm, a set of computational experiments were carried out with artificial data. The tests were performed for matrix input and binary output variables. It leads to the observation tensor of the 3rd order. The artificial dataset $\left\{\mathbf{x}_k \in \mathbb{R}^{100\times 200}, y_k \in \{0,1\}\right\}_{k=1}^{1600}$ was created in the following way. Binary y_k were randomly generated with equal probabilities. Matrices $\mathbf{x}_k$ were calculated according to $\mathbf{x}_k = \mathbf{c}(y_k) + \lambda \boldsymbol{\varepsilon}_k$, where $\mathbf{c}(y_k) \in \mathbb{R}^{100\times 200}$ is set as $c_{ij} = \cos(2.5\pi(i-0.4j)+2)$ if $y_k = 0$, and $c_{ij} = \sin(2.5\pi(i+0.4j)+1)$ if $y_k = 1$ (Fig. 1). The random noise $\boldsymbol{\varepsilon}_k \in \mathbb{R}^{100\times 200}$ was drawn from a multivariate normal distribution $\mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma})$. It was added to the templates with parameter λ introducing signal-to-noise ratio: $\lambda = \{0.5; 1; 5; 10\}$. The noise has the same amplitude as the signal $\mathbf{c}(y_k)$ in the case of $\lambda = 1$. The entire data set was split into training and test data sets of equal size.

3.2 Results

Results of the calibration process of the RNPLS algorithm can be represented as the linear regression: $\hat{y} = \sum_{i,j} x_{i,j} c_{i,j}$, where $\mathbf{C} = \left\{c_{i,j}\right\}_{i,j} \in \mathbb{R}^{100\times 200}$ is a matrix of the regression coefficients. To analyze the convergence of the set of matrixes $\{\mathbf{C}_i\}$ we calculate the distance between two matrices $\mathbf{C}_i$ and $\mathbf{C}_j$ as: $\rho(\mathbf{C}_i, \mathbf{C}_j) = \left\|\mathbf{C}_i - \mathbf{C}_j\right\|_F$, where $\|\cdot\|_F$

is the Frobenius norm. The estimations found by the NPLS and the RNPLS approaches are compared with theoretical coefficients of regression. Behavior of the mean values and the standard deviations of $\rho(\mathbf{C}_{theor}, \mathbf{C}_{RNPLS})$ for the different noise levels λ over the algorithms iterations are shown in Fig. 2 (the statistics calculated for 10 data realizations). In parallel, the means and the standard deviations of $\rho(\mathbf{C}_{theor}, \mathbf{C}_{NPLS})$ computed for the data generated by the NPLS algorithm is represented for every level of noise. As it could be seen, the mean value of the distances between the RNPLS and theoretical regression coefficients already after 1-2 iterations (20-40 points) are significantly less than the ones between the NPLS and theoretical coefficients computed for the whole training sets (800 points). In addition, the standard deviations of the RNPLS results are less than those obtained by NPLS. Thus, the RNPLS approach demonstrates fast convergence and is considerably noise-steady. For all tested levels of noise the disturbance in the RNPLS solution was appreciably less relatively to NPLS one.

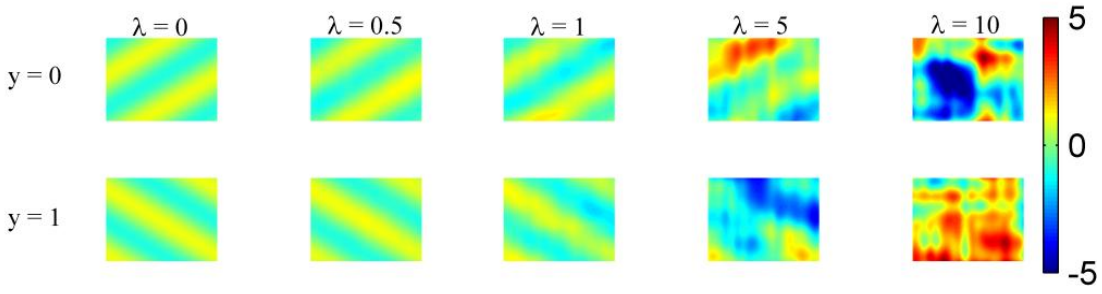

Figure 1. Examples of points from the artificial dataset, with different levels of noise.

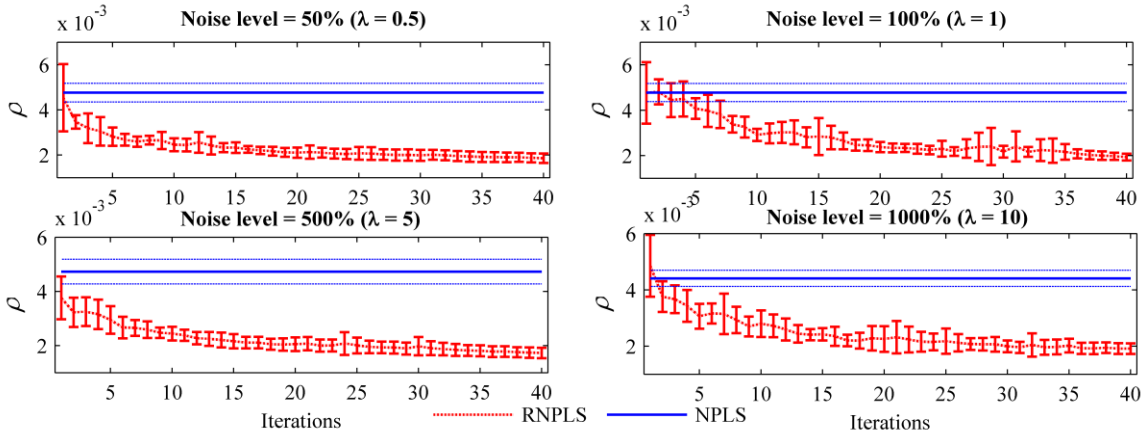

Figure 2. Comparison of RNPLS and NPLS in terms of approximation of the theoretical regression coefficients.

Applet Java Applied Fault Interpretation in Power Apparatus using Dissolved Gas Analysis

Mrs.Indra Getzy David[a] and Dr.M.Rajaram[b]

[a]getzy_wilson@yahoo.co.in ,[b]rajaramgct@rediffmail.com

Abstract: **To adapt the changing environments and uses and to implement refinements and improvements in the art of programming java is chosen for implementing a simple algorithm in protecting a Power Apparatus (PA), in which the limiting of damage becomes a by-product of the Protection System Function. To interpret the type of fault by analysing the dissolved gases which have evolved from the Insulation Media of the Apparatus and dissolved in the oil, a simple algorithm is developed and implemented in Java. To interpret the faults occurring in Power Apparatus like Power Transformers (PT), Load Tap Changers (LTC) and Bushings from the Dissolved Gas Analysis (DGA) data, the Algorithm Hexagon is developed that interprets the faults when the DGA data is imported and a visual presentation is reported. This window based Hexagon of applet java developed in java version jdk 1.6.0 may be useful for data sets pertaining to DGA of mineral or non mineral oil in PT, LTC or Bushings and to a Control and Protection Engineer in the Electricity Transmission and Distribution side .**

Keywords*: Applet Java, Hexagon, Dissolved Gas Analysis, Power Apparatus, Power Transformers.*

1. Introduction

For the interpretation of the type of fault by analysing the dissolved gases which have evolved from the Insulation Media of the Apparatus and dissolved in the oil, a simple algorithm is developed and implemented in Java. An application is a program that runs on computer under operating system of the computer. That is an application created by Java is more or less like one created using C or C++. An applet is a window based tiny java program. As such its architecture is different from the so called normal, console based programs. Applets which are event driven resemble a set of interrupt service routines. In applet the user interacts as events to which the applet waits until an event occurs and responds. The important difference is

that an applet is an intelligent program, not just an animation or media file. An applet is a program that can react to user input and dynamically change. The applet begins with import statements. Applet interacts with the user through the abstract windowing toolkit (AWT), not through the console based I/O classes. The AWT contains support for a window based, graphical interface. Every applet that is created must be a subclass of Applet. The class in the Applet must be declared as public, because it will be accessed by code that is outside the program. Once an applet has been compiled, it is included in an HTML file using the APPLET tag. The applet will be executed by a Java enabled web browser when it encounters the APPLET tag within the HTML file. The AWT notifies the applet about an event by calling an event handler that has been provided by the applet. Once this happens, the applet must take appropriate action and then return and then quickly return control to the AWT.

The window based Hexagon of applet java developed in java version jdk 1.6.0 may be useful for data sets pertaining to DGA of mineral or non mineral oil in PT, LTC or Bushings and to a Control and Protection Engineer in the Electricity Transmission and Distribution side where the Gas Chromatography help the electrical power engineer to device techniques for the identification of fault gases dissolved in transformer insulating oil from the early nineteen sixties [1]. An IEEE standard (C57.104-1991) [2] introduced the DGA as one of the most accepted methods for detecting incipient fault conditions in PTs. The correlation between the DGA and the corresponding fault conditions in the transformers has been well established and formulated and for the routine monitoring of in-service transformers it is used over the past five decades [3]. IEC Standard 60599 and IEEE Standard C 57 provide guidance for the interpretation of DGA results in service [4].

In addition to mineral oil non mineral oils like Midel, Silicone, FR3, and BioTemp are increasingly used as insulating liquids in electrical equipments because they are less flammable and more environmentally friendly. The non mineral oils have high percentage of biodegradability and are more hygroscopic in nature. Due to their high percentage of biogradability and more hygroscopic than mineral oils non mineral oils are slowly introduced into applications like PA insulation and cooling purposes in order to replace the mineral oils as the non mineral oil also has the same DGA fingerprints as mineral oil [5].

Due to its speciality of arc-quenching ability, non mineral liquids evolve gas only by one-fourth of the gas that would have been produced by the regular transformer oil [6]. In this work a simple algorithm is developed in Java platform to interpret faults

- in Equipments like LTC filled with mineral oil
- in Equipments filled with non mineral oils
- in Equipments for low temperature faults where stray gassing of oils [7]may interfere with diagnostics and
- in PT immersed in Mineral oil

The number of characteristic faults due to thermal stress and electrical stress are classified as seven by Duval by using the relative percentages of three gases namely Methane (CH_4), Ethylene (C_2H_6) and Acetylene (C_2H_2). These three gases correspond to the increasing levels of energy necessary to generate gases in transformers in service [8].The gas ratios as well as the relative proportions of gases and the rules from case studies are used for fault diagnosis from DGA data of mineral oil [9]. A combination of neural network and fuzzy system for enhancing the performance of the diagnostic system has been presented to identify only five types of faults [10].Faults have been analysed and compared with the conventional methods but none of the non mineral liquids have been considered [11]. Evolving wavelet network methodology have been proposed to monitor the condition of only PT immersed in mineral oil [12]. Data from [13-16] and the DGA data samples collected from various substations of South India are used to test this algorithm for fault interpretation. Hexagon is a single algorithm into which the data of fault gases from various PA evolved from mineral as well as non mineral cooling and insulating media is given as input and the type of fault interpreted by the algorithm is obtained as output. All the cases of Equipments and Insulating media can be tested using this single Algorithm Hexagon.

Visually presented information can be accessed by human perception in a most natural way. Complex structures and relation can be perceived in less time in greater number and with fewer errors than in any other way. Models of the real world or Models of abstract concepts are hardly dealt with by humans without taking resort to visual representations. This is the reason why the prediction of faults by visual presentation has been proposed.

2. Interpretation of Fault Gases

In the DGA method oil samples are taken from the transformer at various locations. Then, chromatographic analysis will be carried out on the oil sample to measure the concentration of the dissolved gases. The extracted gases are then separated, identified and quantitatively determined such that the DGA method can then be applied in order to obtain reliable diagnosis [17]. The extracted gases meant for analysis purpose are Hydrogen (H_2), Methane (CH_4), Ethane (C_2H_6), Ethylene (C_2H_4), Acetylene (C_2H_2), Carbon

Monoxide (CO), Carbon Dioxide (CO_2), Nitrogen (N_2) and Oxygen (O_2). C_2H_2 and C_2H_4 are used in all interpretation methods to represent high energy faults such as arcing and high temperature faults. H_2 is preferred in several of these methods to represent very low energy faults such as PDs, where it is produced in large quantities. CH_4, however, is also representative of such faults and always formed in addition to H_2 in these faults. CH_4 has been chosen rather than H_2 because it not only allows identifying these faults, but provides better overall diagnosis results for all the other types of faults than when using H_2. For the interpretation of faults The Duval Triangle was developed by Michel Duval in 1974 using three of these hydro carbon gases in relative proportions of percentage. Michel Duval proposed regions to represent seven types of faults [8]. The fault zone boundaries proposed by Michel Duval slightly differ when the insulation media differs with different sets of fault gases. The electronic version of the Duval Triangle has to be changed every time when the type of Power Apparatus or the type of insulation media changes [18].

To save time and memory a single algorithm is implemented incorporating all the different zone areas for fault interpretation regardless of whether it is a mineral oil or nonmineral oil or any type of PA. The Interpretation of Faults in the proposed Algorithm Hexagon is listed in Table1. When the data pertains to P3, the algorithm checks for four cases of non mineral liquids, viz. Silicone, FR3, Bio Temp and Midel. These polygons uses the same types of fault gases but their zone boundaries slightly differ. So they are designated as P3S, P3F, P3B and P3M representing Polygon3 for Silicone, Polygon 3 for FR3, Polygon3 for Bio Temp and Polygon3 for Midel respectively. For interpretation of faults in both mineral oil and FR3(Nonmineral oil P6) at low temperatures(P4),the fault gases of importance are H_2, CH_4 and C_2H_6.As the Polygon4 and Polygon6 differ in their inner zone boundaries alone, they are represented by the same polygon with difference in zone boundaries.

TABLE 1. Interpretation of faults in the proposed Hexagon

Location of Point inside the Polygon (Gas Type)/Zone			Interpretation of Type of Fault
Polygon		Zone	
P1 (CH_4,C_2H_4,C_2H_2)		PD	Partial Discharge
		D1	Discharges of low energy
		D2	Discharges of high energy
		T1	Thermal faults of temperature $< 300^0$C
		T2	Thermal faults of temperature 300^0C$< T < 700^0$C
		T3	Thermal faults of temperature $>700^0$C.
		DT	Combination of Thermal and Electrical Fault.
P2 (CH_4,C_2H_4,C_2H_2)		N	Normal
		T3	Thermal faults of temperature $>700^0$C.
		X3	Fault T3 or T2 in progress, or severe arcing D2
		T2	Thermal faults of temperature 300^0C$< T < 700^0$C
		D1	Abnormal Arcing D1
		X1	Thermal fault in progress
P3	P3S (CH_4,C_2H_4,C_2H_2)	PD	Partial Discharge
	P3F (CH_4,C_2H_4,C_2H_2)	D1	Discharges of low energy
	P3B (CH_4,C_2H_4,C_2H_2)	D2	Discharges of high energy

3. Proposed Hexagon in Java Platform

For speedy and easy interpretation of faults in any type of PA , a window based Hexagon is developed in Java, version jdk 1.6.0 to determine visually whether a fault evolves from a relatively harmless thermal fault into a potentially more severe electrical one or not. The Hexagon consists of number of polygons as shown in Fig.1 with respect to that listed in Table .1. The result of implementation of generating the electronic form of hexagon in java platform with the fault coordinates M, N, H, I, J, K obtained inside the different fault zones on implementation of the algorithm is presented in Fig.2. The user friendly phase to import DGA data in Java applet is presented in Fig.3; the user can select the option of his choice by clicking the buttons.

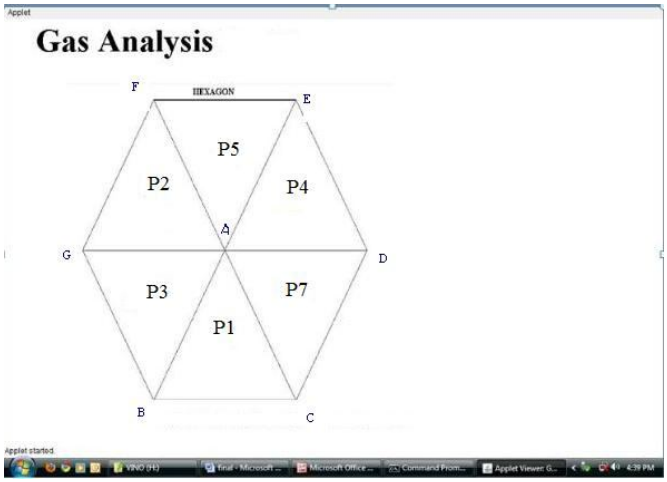

FIG. 1 HEXAGON DIVIDED INTO SIX POLYGONS P1, P2, P3, P4, P5, P7 WITH EACH SIDE OF EACH POLYGON REPRESENTING A GAS VALUE IN %

.

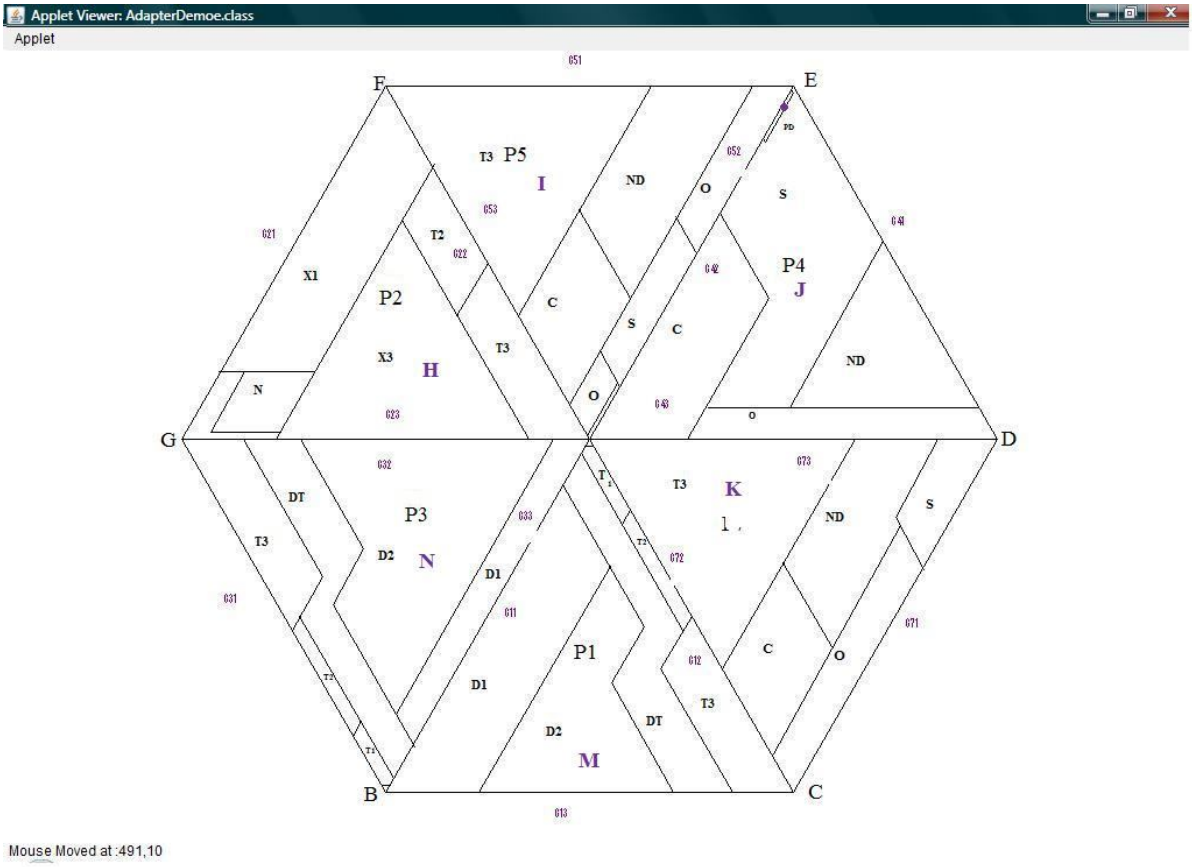

FIG.2.FAULT CO-ORDINATES M, N, H, I, J, K

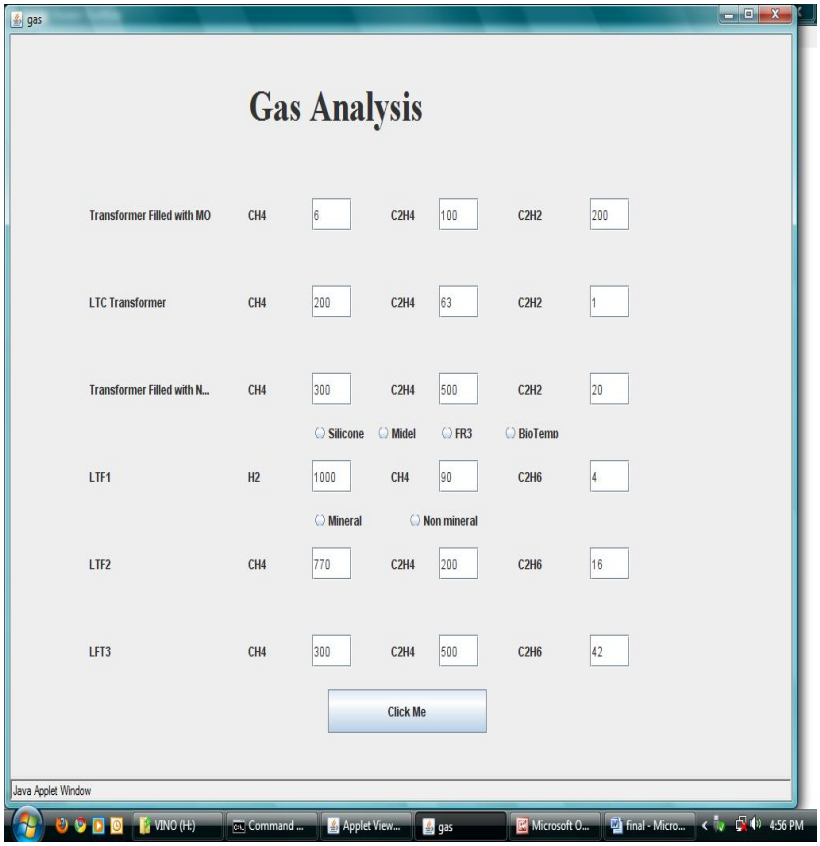

FIG.3. SAMPLE WINDOW OF PHASE II FUNCTION OF THE SOFTWARE WHICH IS USER FRIENDLY

The algorithm is implemented making use of the Cartesian Co-ordinate system. The standard co-ordinate system used on the computer systems differ from that of Cartesian co-ordinate system. The abscissa values of rectangular co-ordinate systems remains the same for the Processor Co-ordinate System, but the Ordinate values are changed by subtracting from the maximum value of the screen resolution. The algorithm developed in this work adopts modular fashion minimizing the number of "goto" statements. The notations used in this algorithm are standard notations as per Jean-Paul Tremblay and Paul G. Sorenson [19].

3.1 Algorithm *Hexagon* This algorithm when implemented in window based Java first draws the Hexagon with polygons and zones inside and then checks the presence of O_2 and N_2 from the n number of DGA data imported to it. If $O_2 / N_2 < 0.3$, then the algorithm tests the Total Combustible Gases (TCG) value and proceeds for further calculation of co-ordinate values corresponding to gas values in percentages

of parts per million (ppm) and interpretation of fault. The DGA data imported are integer values and the relative proportions of the gas values are real values.

With respect to coordinates of B (BX and BY), all the coordinates are computed by letting the length of each side of the Hexagon as L. The fault coordinates are calculated taking relative proportions of gas values G11, G12 etc in percentage. For the points that lie on the boundary lines, the probability of the type of fault is predicted by computing a small circular area around that point and evaluating the maximum number of predicted types inside the circle. The fault on the boundary then will be included to the type of fault which resulted as maximum cases of prediction. For example in Polygon 5 in Fig.1 (b), if the point lies on the zone boundary between C [Hot spot with carbonization of paper ($T>300^0C$)] and T3 [Thermal faults of very high temperatures ($T > 700^0C$)], the maximum number of predicted fault around that point if computed belong to T3, then the fault point under prediction is included into the maximum predicted case of fault i.e. T3.

case P5 : (Z46 thru Z50)

g.drawString ("low temperature fault in Power Transformer immersed in Mineral Oil with different sets of Gases")

case P6 : (Z51 thru Z54)

g.drawString (" low temperature faults in FR3 Oil")

case P7 : (Z55 thru Z58)

g.drawString ("low temperature faults in FR3 oil with different sets of Gases")

Default: Read (r ,fault1,fault2)

If (M,N,H,I,J,K) on (Z1-Z58) boundary lines, g.drawCircle(c,r) (*C is M,N,H,J,K*)

Compute max(fault1,fault2)

7.[Finished]

Exit.

4. RESULTS AND DISCUSSION

Java provides facilities to the programmer to define a set of objects and a set of operations (methods) to operate on that objects. All types of data are declared as per standard syntax of java. On compilation of the Algorithm Hexagon shown in Section 3.1, the results are visually presented.

The software for interpreting the faults in transformers is designed in java platform by developing a Hexagon where all the faults are interpreted. This algorithm provides more flexibility

in diagnosing the faults occurring in PT, LTC and PA immersed in mineral and non mineral liquids. This software is designed in such a way that data obtained from DGA for various PA which differ in insulation media employed in them can be used for importing input at an instant of time. The results obtained for few sets of data samples listed in Table 2 are presented in Fig.4.The dots display the interpretation of the faults inside the respective zones.

5. CONCLUSION

This being a software implementation gives a visual picture of the indication of type of fault and user friendly modules and warns the Control Engineer to be caucious to protect the environment before failure takes place by analyzing the severety behind the shifting of the fault from less severe thermal into more severe electrical one.The effectiveness of the Hexagon Program is verified by DGA data collected from Oil Testing Centres in South India and the non mineral liquid data [13-16]. The probability of failure of a transformer due to fault in service can be determined by the studies made on the actual fault data reports obtained from the Electricity Boards Oil testing Centres in addition to this Interpretation. The Future work is to employ clustering algorithms for grouping the data sets.

Model free adaptive control with pseudo partial derivative based on fuzzy rule emulated network.

Chidentree Treesatayapun[1]
[1]Department of Robotic and Advanced Manufactory, CINVESTAV-Saltillo, Ramos Arizpe, 25900, Mexico

Abstract— *In this article, a model free adaptive control with the estimated pseudo partial derivative (PPD) is introduced by multi-input fuzzy rules emulated network (MiFREN) for a class of discrete-time systems. The resetting mechanism can be relaxed in this adaptation scheme. Human knowledge about the controlled plant is rearranged to define the IF-THEN rules directly. Those fixed parameters are designed according to guarantee the convergence related on the controller performance. All adjustable parameters inside MiFREN are tuned by the proposed on-line learning algorithm. The design example and simulation results demonstrate the performance of the proposed controller under the nominal system and system with disturbances.*

Keywords: Fuzzy logic; Model-free adaptive controller; Pseudo-partial derivative; Discrete-time

1. Introduction

Model free adaptive control (MFAC) has been continuously developed for several systems with unknown or ill-defined model especially for a class of discrete-time domain [1], [2]. With out any mathematic model of the plant, a linearization concept based on pseudo-partial derivative (PPD) is composed as the equivalent system. Due to the comparison with other adaptive controllers, only real time measured data of the controlled plant is necessary to establish MFAC. Unlike model reference adaptive control based on neural networks, the off-line tuning phase can be excluded because the time-varying PPD can be tuned by real time measurement data only [3].

In general, The control law has been determined by PPD under some necessary constrains and the resetting technique. It's clear that the control system performance depends on the accuracy of PPD estimation. The compensation system based on an artificial neural network has been discussed in [4] by the additional of another control effort. By using the on-off controller [5], the system dynamic can be considered as the unknown system when the switching sequence can be adapted by a feedback controller.

According to the controlled plant, in practice, PPD seems like the system sensitivity which can be understood by human knowledge related on input-output behavior. In this work, this knowledge can be reformulated into IF-THEN rules for an adaptive network called multi-input fuzzy rule emulated network(MiFREN) [6]. The on-line adaptation is developed to tune all adjustable parameters inside MiFREN. Thus, the time variation of PPD can be directly estimated by MiFREN according to our proposed cost function. Moreover, the resetting algorithm, which is needed for tuning PPD [7], can be relaxed in this work because of MiFREN's property [8] which is directly related on the change of input respectively to the plant's output. All fixed parameters are designed to guarantee the convergence which can affect the performance of controller.

This paper is organized as the follows. Section 2 introduces the problem formulation and some details about the dynamic linearization equivalent model. The control law is proposed with the estimated PPD based on MiFREN in section 3. Section 4 presents the MiFREN configuration together with the parameters adaptation. The design example and simulation results are demonstrated in section 5 including the consideration of disturbance effect. Section 6 represents our conclusions.

2. Problem Formulation

In this work, the nonlinear system for a class of discrete-time domain can be described by

$$y(k+1) = f(y(k), \cdots, y(k-n_y), u(k), \cdots, u(k-n_u)), \tag{1}$$

where $y(k) \in \mathbb{R}$ and $u(k) \in \mathbb{R}$ denote as the time index k system output and input, respectively with the unknown orders n_y and n_u. The nonlinear function $f(\cdot)$ is definitely unknown. According to the conventional MFAC algorithms, those following assumptions are stated.

Assumption 1: The partial derivatives of $f(\cdot)$ are continuous with respect to the control effort $u(k)$.

Assumption 2: The nonlinear system described in (1) is generalized Lipschitz. That means the positive constant l must be defined when $|\Delta y(k+1)| \leq l|\Delta u(k)|$, when $\Delta y(k+1) = y(k+1) - y(k)$ and $\Delta u(k) = u(k) - u(k-1)$.

According to those upper assumptions, the following lemma can be obtained.

Lemma 1: The nonlinear system (1) satisfied assumption 1 and 2 with $|\Delta u(k)| \neq 0$ for time index k, can be transformed into the equivalent compact form dynamic linearization (CFDL) as

$$\Delta y(k+1) = \Phi(k)\Delta u(k), \tag{2}$$

when $\Phi(k)$ denotes the pseudo partial derivative (PPD).
Proof: The proof is omitted here. Reader can refer to [3] for more details and complete proof.

□

The parameter PPD can be estimated by several learning algorithm such as the modified projection. On the other hand, in this work, PPD is determined by the adaptation network MiFREN which can be operated under the human knowledge according to the controlled plant.

3. Control law

In this section, the control effort $u(k)$ will be formulated. Let define the cost function as

$$J(u(k)) = [r(k+1)-y(k+1)]^2+\lambda[u(k)-u(k-1)]^2, \quad (3)$$

when λ is a designed weighting constant. By using (2), the cost function can be rewritten as

$$J(u(k)) = [r(k+1) - y(k) - \Phi(k)\Delta u(k)]^2 + \lambda[\Delta u(k)]^2. \quad (4)$$

Differentiating (4) with respect to $u(k)$, we have

$$\begin{aligned}\frac{\mathrm{d}J(u(k))}{\mathrm{d}u(k)} &= -2[r(k+1) - y(k)]\Phi(k) + 2\Phi^2(k)\Delta u(k) \\ &\quad +2\lambda\Delta u(k). \quad (5)\end{aligned}$$

Let $\frac{\mathrm{d}J(u(k))}{\mathrm{d}u(k)} = 0$, thus

$$\Delta u(k) = \frac{\Phi(k)[r(k+1) - y(k)]}{\lambda + \Phi^2(k)}. \quad (6)$$

The idea control law can be obtained as

$$u(k) = u(k-1) + \frac{\Phi(k)[r(k+1) - y(k)]}{\lambda + \Phi^2(k)}. \quad (7)$$

In practice, the output $y(k)$ can be measured but $\Phi(k)$ cannot be directly determined because of the unknown nonlinear system $f(\cdot)$. To realize this control law, $\Phi(k)$ will be estimated by MiFREN as $\hat{\Phi}(k)$, thus, the control effort can be generated by

$$u(k) = u(k-1) + \rho\frac{\hat{\Phi}(k)[r(k+1) - y(k)]}{\lambda + \hat{\Phi}^2(k)}, \quad (8)$$

when ρ is a step-size constant. Both ρ and λ are designed parameters which can be given by the following lemma to guarantee the convergence of $u(k)$. Before the proof of control effort boundary, the follow assumption is necessary.
Assumption 3: The direction of $\hat{\Phi}(k)$ or sign$\left\{\hat{\Phi}(k)\right\}$ is unknown but it doesn't change such as sign$\left\{\hat{\Phi}(k)\right\}$ = sign$\left\{\hat{\Phi}(k-1)\right\}$.
Remark: This assumption can be existed in several practical systems such as the chemical process, robotic system and so on. Moreover, this assumption will be proved again by the experimental results next.

Lemma 2: According to assumption 2 and the MiFREN's property, the maximum of $\hat{\Phi}(k)$ must be existed as $\hat{\Phi}_M, \forall k \in \mathrm{N}$ and both parameters ρ and λ are designed by following this relation

$$0 < \rho < \frac{2\lambda}{\hat{\Phi}_M}, \quad (9)$$

thus, the control effort from (8) is bounded.
Proof: Substitute $y(k) = \hat{\Phi}(k-1)[u(k-1) - u(k-2)] - y(k-1)$ into (8), we have

$$\begin{aligned}u(k) &= u(k-1) - \frac{\rho\hat{\Phi}(k)\hat{\Phi}(k-1)}{\lambda + \hat{\Phi}^2(k)}u(k-1) \\ &\quad +\frac{\rho\hat{\Phi}(k)}{\lambda + \hat{\Phi}^2(k)}\Big[r(k+1) + \hat{\Phi}(k-1)u(k-2) \\ &\quad +y(k-1)\Big], \\ &= A_u(k)u(k-1) + \xi_u(k), \quad (10)\end{aligned}$$

where

$$A_u(k) = 1 - \frac{\rho\hat{\Phi}(k)\hat{\Phi}(k-1)}{\lambda + \hat{\Phi}^2(k)}, \quad (11)$$

and

$$\xi_u(k) = \frac{\rho\hat{\Phi}(k)}{\lambda + \hat{\Phi}^2(k)}\Big[r(k+1)+\hat{\Phi}(k-1)u(k-2)+y(k-1)\Big]. \quad (12)$$

Substitute (9) into (13) and use assumption 3, it is clear that

$$A_u(k) < 1. \quad (13)$$

□

4. MiFREN for pseudo partial derivative

4.1 PPD based on MiFREN

MiFREN is an adaptive network which can be operated by human knowledge in the format of IF-THEN rules. The design of IF-THEN rules is also a key of the performance. The knowledge based on the controlled plant is roughly necessary. Due to (2), we can rearrange the relation of $\hat{\Phi}(k)$ as

$$\hat{\Phi}(k) \doteq \frac{\Delta y(k)}{\Delta u(k-1)}, \quad (14)$$

when $\Delta u(k) \neq 0$.

According to the upper relation, we can define some example IF-THEN rules as the followings:

- IF $\Delta y(k)$ is Positive Large and $\Delta u(k-1)$ is Positive Large THEN $\hat{\Phi}(k)$ should be Positive small,
- IF $\Delta y(k)$ is Positive Large and $\Delta u(k-1)$ is Positive small THEN $\hat{\Phi}(k)$ should be Positive Large,
- ...,
- IF $\Delta y(k)$ is Negative Large and $\Delta u(k-1)$ is Positive Large THEN $\hat{\Phi}(k)$ should be Negative small,
- ...,

- IF $\Delta y(k)$ is Negative Large and $\Delta u(k-1)$ is Negative small THEN $\hat{\Phi}(k)$ should be Positive Large,
- IF $\Delta y(k)$ is Negative Large and $\Delta u(k-1)$ is Negative Large THEN $\hat{\Phi}(k)$ should be Positive small.

With this implementation, unlike the conventional algorithms to determine $\hat{\Phi}(k)$, the sign of $\hat{\Phi}(k)$ is directly determined by those IF-THEN rules. To simplify, those IF-THEN rules can be defined by Table 1.

$\Delta y(k)$					$\Delta u(k-1)$
PL	PS	AZ	NS	NL	
P_1	P_6	C_{11}	N_{16}	N_{21}	PL
P_2	P_7	C_{12}	N_{17}	N_{22}	PS
ε_3	ε_8	ε_{13}	ε_{18}	ε_{23}	AZ
N_4	N_9	C_{14}	P_{19}	P_{24}	NS
N_5	N_{10}	C_{15}	P_{20}	P_{25}	NL

Table 1: IF-THEN rules

The linguistic variables PL, PS, AZ, NS and NL denote as Positive Large, Positive Small, Almost Zero, Negative Small and Negative Large, respectively. In this case, the number of IF-THEN rules is 25 and the relation the THEN-part can be given by other linguistic variable as $\square_i$ for $i = 1, 2, \cdots, 25$. The variables P, C and N stand for Positive, Close to zero and Negative, respectively. Unlike the conventional technique, when Δu nearly reaches to zero or stays in the range to AZ-membership function, the designed parameter ε is defined as a small positive constant and $\varepsilon_3 = \varepsilon_8 = \varepsilon_{13} = \varepsilon_{14} = \varepsilon_{23} = \varepsilon$. Moreover, the parameters ε_i can be given by difference values with the on-line learning algorithm which will be discussed next.

According to those IF-THEN rule, the network architecture of MiFREN can be constructed in Fig.1. The estimated

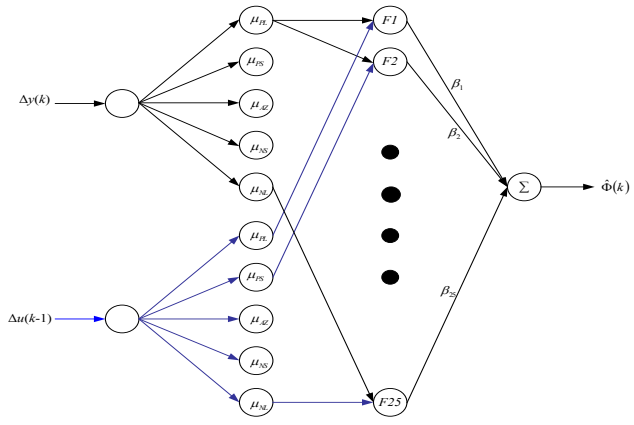

Figure 1: MiFREN networking structure.

PPD or $\hat{\Phi}(k)$ can be obtained by

$$\hat{\Phi}(k) = \sum_{i=1}^{25} F_i(\Delta y(k), \Delta u(k-1))\beta_i, \tag{15}$$

when β_i is a Linear Consequence (LC) parameter for THEN-part linguistic variable $\square_i$. The function $F_i(\cdot)$ is the i^{th} rule relation determined by membership functions related on the i^{th} rule. For example, according to Table 1, we have $F_1(k) = \mu_{PL}(\Delta y(k))\mu_{PL}(\Delta u(k-1))$ at rule # 1, $F_{16}(k) = \mu_{NS}(\Delta y(k))\mu_{PL}(\Delta u(k-1))$ at rule # 16 and $F_{25}(k) = \mu_{NL}(\Delta y(k))\mu_{NL}(\Delta u(k-1))$ at rule # 25. In this work, we can set those membership functions and LC parameters or β_i by the human knowledge based on the controlled plant. More explanations with example will be discussed in the next section.

4.2 Parameters adaptation

The on-line learning algorithm will be applied in this work for LC parameters. Thus, the estimated PPD in (15) can be rewritten by

$$\hat{\Phi}(k) = \sum_{i=1}^{25} F_i(k)\beta_i(k), \tag{16}$$

when $\beta_i(k)$ denotes the LC parameter for the i^{th} rule at time index k. To tune this parameter, the cost function $J(\hat{\Phi}(k))$ can be given as the following:

$$\begin{aligned} J(\hat{\Phi}(k)) &= \frac{1}{2}[\Delta y(k) - \hat{\Phi}(k)\Delta u(k-1)]^2 \\ &\quad + \frac{\gamma}{2}[\hat{\Phi}(k) - \hat{\Phi}(k-1)]^2, \end{aligned} \tag{17}$$

when γ is a positive defined constant. Determine the derivative with respect to $\beta_i(k)$, thus, we obtain

$$\begin{aligned} \frac{\partial J(\hat{\Phi}(k))}{\partial \beta_i(k)} &= \frac{\partial J(\hat{\Phi}(k))}{\partial \hat{\Phi}(k)} \frac{\partial \hat{\Phi}(k)}{\partial \beta_i(k)} \\ &= \Big[[\gamma + \Delta u^2(k-1)]\hat{\Phi}(k) - \gamma\hat{\Phi}(k-1) \\ &\quad - \Delta y(k)\Delta u(k-1)\Big] F_i(k). \end{aligned} \tag{18}$$

According to gradient search, the tuning law can be defined by

$$\beta_i(k+1) = \beta_i(k) - \eta_\beta \frac{\partial J(\hat{\Phi}(k))}{\partial \beta_i(k)}, \tag{19}$$

where η_β is the learning rate which can be designed as a small positive constant. By using (19) and (18), the tuning law can be formulated as

$$\begin{aligned} \beta_i(k+1) &= \beta_i(k) - \eta_\beta \Big[[\gamma + \Delta u^2(k-1)]\hat{\Phi}(k) \\ &\quad - \gamma\hat{\Phi}(k-1) - \Delta y(k)\Delta u(k-1)\Big] F_i(k). \end{aligned} \tag{20}$$

The designed parameters γ and η_β can effect to the convergence of β. The following lemma introduces the relation which guarantees the convergence of tuned parameters β_i.

Lemma 3: The LC parameters β_i for $i = 1, 2, \cdots, N_F$, when N_F denotes the number of IF-THEN rules, are

bounded with the tuning law given by (20) when the learning rate and γ are all satisfied this following requirement

$$0 < \eta_\beta < \frac{2}{\gamma + \Delta u^2(k-1)}. \quad (21)$$

Proof: Rearrange (20) in vector format, we obtain

$$\beta(k+1) = \big[1-\eta_\beta[\gamma+\Delta u^2(k-1)]||F(k)||^2(k)\big]\beta(k)+\xi(k), \quad (22)$$

when $\xi(k)$ stands for the remain terms which are not related on $\beta(k)$. Let $A = 1 - \eta_\beta[\gamma + \Delta u^2(k-1)]||F(k)||^2(k)$, we have

$$\beta(k+1) = A\beta(k) + \xi(k). \quad (23)$$

$||F(k)||^2(k)$ is the multiplication of two membership grades, thus $0 < ||F(k)||^2(k) \leq 1$ and substitute with (21) it can be obtained

$$A < 1. \quad (24)$$

□

The relation of the learning rate η_{beta} and γ obtained by this lemma can be used to support the design of both parameters which will be demonstrated in the next section. Furthermore, this result can be valid even $\Delta u(k-1) = 0$ or the previous control effort is constant.

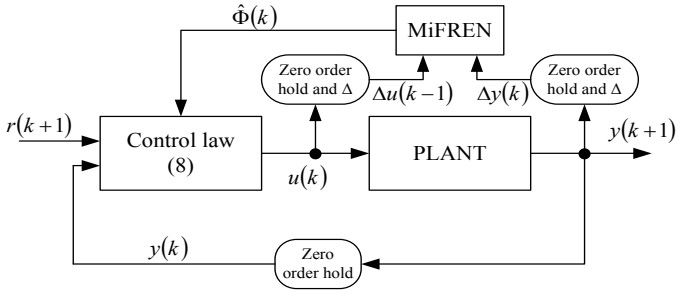

Figure 2: Control system configuration.

Furthermore, the block diagram illustrated in Fig. 2 represents the design concept and signal flow.

5. Design example and simulation results

The nonlinear discrete-time system which is selected to demonstrate the performance is described as

$$y(k+1) = \sin(y(k)) + u(k)[5 + \cos(y(k)u(k))], \quad (25)$$

when $y(k)$ denotes the output and $u(k)$ stands for the control effort. The desired trajectory $r(k)$ is given by this following:

$$r(k) = 2\sin(\frac{2\pi k}{100}). \quad (26)$$

To design the controller which is suitable for the system described in (25), in this case, we have the range of Δy and Δu in ± 2, thus the membership functions can be defined by Fig. 3 and 4 for Δy and Δu, respectively.

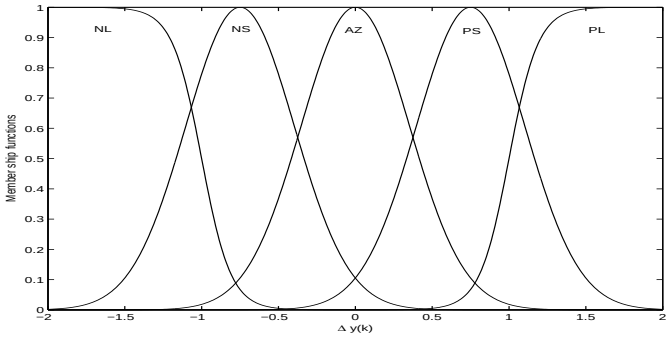

Figure 3: Membership function of $\Delta y(k)$.

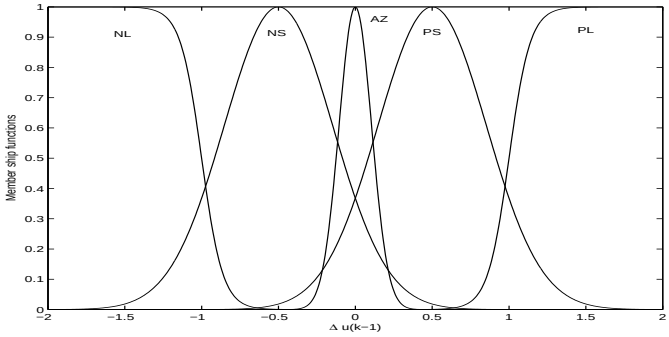

Figure 4: Membership function of $\Delta u(k-1)$.

According to (9) and (21), those designed parameters can be given as $\rho = 0.35$, $\lambda = 0.75$, $\eta_\beta = 1.5$ and $\gamma = 0.1$.

The adjustable parameters β_i can be defined by Table 2 regarding to the IF-THEN rules.

The tracking performance can be demonstrated in Fig. 5 as plots of the desired trajectory $r(k)$ and the system output $y(k)$. Finally, in Fig.6, the control effort is shown.

The demonstration of robustness is introduced next. In this setup, the time varying disturbance $d_1(k)$ is added in the original system (25) as

$$y(k+1) = \sin(y(k)) + u(k)[5 + d_1(k) + \cos(y(k)u(k))]. \quad (27)$$

such as constant parameters and $\beta_i(1)$ are same as the previous test. Fig. 7 represents the tracking performance and time varying $d_1(k)$. The control effort $u(k)$ is illustrated in Fig. 8.

For more complicity, another disturbance $d_2(k)$ is also included from the nominal system (25) as

$$\begin{aligned} y(k+1) \quad = \quad & \sin(y(k) + d_2(k)) \\ & + u(k)[5 + d_1(k) + \cos(y(k)u(k))]. \end{aligned} \quad (28)$$

With all same initial settings, the tracking performance and disturbances can be shown in Fig. 9 according the control effort displayed in Fig. 10.

$\Delta y(k)$					Δu
PL	PS	AZ	NS	NL	$(k-1)$
$\beta_1(1)$ $= 3$	$\beta_6(1)$ $= 1.5$	$\beta_{11}(1)$ $= 0.2$	$\beta_{16}(1)$ $= 0$	$\beta_{21}(1)$ $= 0$	PL
$\beta_2(1)$ $= 4$	$\beta_7(1)$ $= 2.5$	$\beta_{12}(1)$ $= 0.5$	$\beta_{17}(1)$ $= 0$	$\beta_{22}(1)$ $= 0$	PS
$\beta_3(1)$ $= 0.1$	$\beta_8(1)$ $= 0.1$	$\beta_{13}(1)$ $= 0.1$	$\beta_{18}(1)$ $= 0.1$	$\beta_{23}(1)$ $= 0.1$	AZ
$\beta_4(1)$ $= 0$	$\beta_9(1)$ $= 0$	$\beta_{14}(1)$ $= 0.5$	$\beta_{19}(1)$ $= 2.5$	$\beta_{24}(1)$ $= 4$	NS
$\beta_5(1)$ $= 0$	$\beta_{10}(1)$ $= 0$	$\beta_{15}(1)$ $= 0.2$	$\beta_{20}(1)$ $= 1.5$	$\beta_{25}(1)$ $= 3$	NL

Table 2: IF-THEN rules with initial parameters $\beta_i(1)$

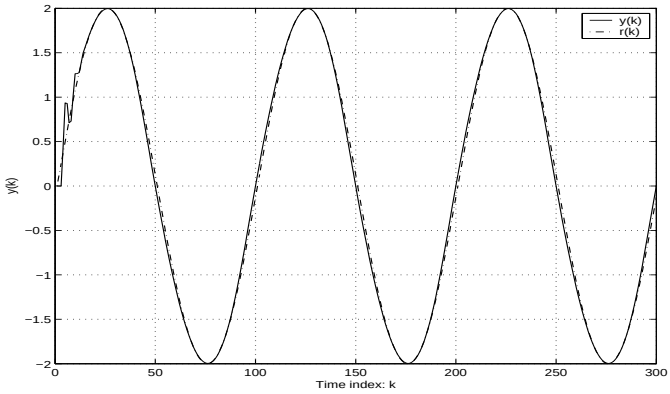

Figure 5: Tracking performance $y(k)$ and $r(k)$.

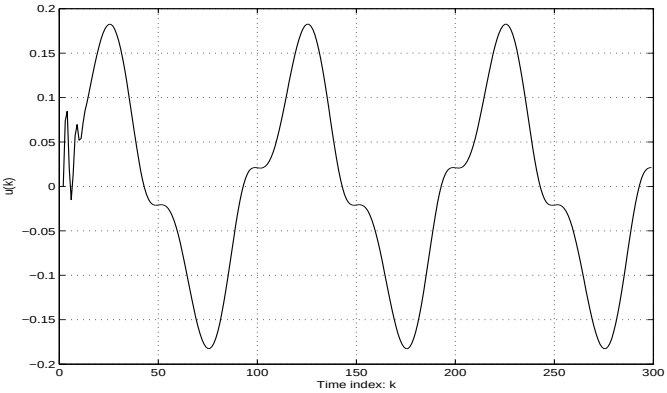

Figure 6: Control effort $u(k)$.

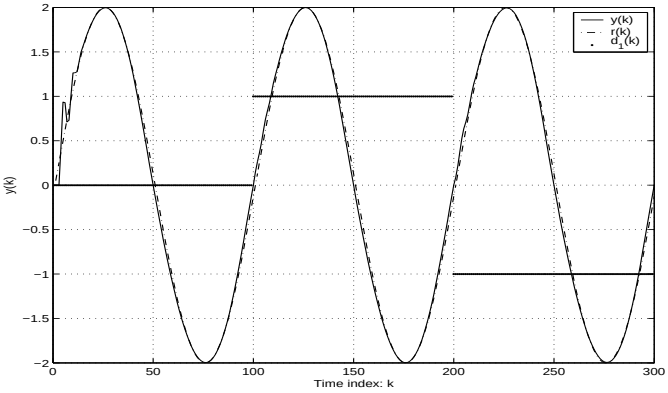

Figure 7: Tracking performance $y(k)$ and $r(k)$ with disturbance $d_1(k)$.

Remark: Any information related on those disturbances is not necessary to incorporate to the controller. That means the original controller designed based on the knowledge about the nominal plant is enough to handle those disturbance.

6. Conclusion

The model-free adaptive controller with the estimation of pseudo-partial derivation is proposed in this article. The estimation of PPD is implemented by a self-adjustable network called MiFREN. The initial setting of MiFREN's structure can be given by the human knowledge according to the controlled plant and the relation of plant's input-output within IF-THEN rules format. Moreover, all adjustable parameters inside MiFREN are begun by the knowledge of the plant directly. That can improve the system performance at the beginning. Other fixed parameters are designed by proved lemmas to guarantee the convergence. The simulation system demonstrates the design example and the effectiveness of the proposed algorithm. Both nominal system and disturbed plant have been considered to validate the controller performance and robustness.

Application of Genetic Algorithms in Shape Optimization for Aerodynamic Bodies

V. Nejati[1]
[1]Mechanical Engineering Department, Islamic Azad University – Mashhad Branch, Mashhad, Khorasan Razavi, Iran

Abstract - *The objective of this study is to minimize the drag coefficient of aerodynamics bodies for a specified design Reynolds number regime. With the aerodynamics model the gradient of the objective function (drag coefficient) cannot be determined analytically. Furthermore, it is expected that the objective function is multi-modal, i.e. it shows more than one minimum. Therefore, the optimization algorithm must be efficiently applicable to such multi-dimensional, multi-modal and nonlinear objective functions. A powerful optimization procedure called Genetic Algorithms (GA) has been combined with the aerodynamics calculation to find the optimal shape with minimum drag coefficient. The aerodynamics calculation of flow field around the body of revolution is determined to get accurate drag coefficient. An effective numerical calculation called the Finite Volume Method is considered. For the laminar to turbulent transition locations, the linear stability analysis is applied to predict the natural transition location. The results were compared with those obtained from integral method and also experimental results and indicate a good agreement. It is concluded that for the purpose of the shape optimization of streamline bodies, the Genetic Algorithms and the Finite Volume Method with natural transition criterion is an essential approaches to indicate the optimal shape for various ranges of Reynolds number.*

Keywords: Drag Reduction; GA; FVM; Natural Transition

1 Introduction

Recently there has been a growing interest in problem solving system based on principles of evolution and heredity: such systems maintain a population of potential solutions, and they have some selection process based on fitness of individuals and some recombination operators. One type of such system is a class of Evolution Strategies which imitate the principles of natural evolution for parameter optimization problems (Rechenberg, Schwefel). Fogel's Evolutionary Programming is a technique for searching through a space of small finite state machines. Glover's Scatter Search technique maintains a population of reference points and generates offspring by weighting linear combinations. Another type of evolution based systems are Holland's Genetic Algorithms (GAs). For the large spaces, special artificial intelligence techniques must be employed. Genetic algorithms are a class of general search methods, which strike a remarkable balance between exploration and exploitation of the search space.

Drag reduction is important in considering the aerodynamic aircraft design. There have been many suggestions for reducing the skin friction drag on bodies of revolution, including extension of laminar flow regions and relaminarization of turbulent flow. For the aerodynamic design of three-dimensional fuselages with low skin friction drag, laminar bodies of revolution are often used as a design basis.

Laminar flow on a two-dimensional or an axisymmetric body can be achieved by designing the geometry so that there is an extensive region of favorable pressure gradient. This technique is frequently referred to as natural laminar flow control and may be implemented on a body of revolution by changing the location of the maximum body thickness as far aft as possible. A favorable pressure gradient and laminar flow may be maintained over a large percentage of body length, but this causes the flow separation at the remaining part of the body, with consequent increase in pressure drag.

The objective of our study is to find the optimal body shape with the minimum drag coefficient for specified Reynolds number regimes. For this purpose, an optimization process must be employed and linked to the aerodynamics calculation program. The combined computational program must be able to search through several body shapes and to choose those shapes with long laminar flow without separation. We also prove that the laminar and turbulent boundary layer calculations and the determination of the transition location must be extremely accurate for getting acceptable optimal body shape.

The aerodynamics calculation of streamline bodies is usually started from potential flow around the body to find inviscid velocity distribution. A numerical calculation called Finite Volume Method (FVM) is employed for both laminar and turbulent boundary layer calculation and those body shapes which show separation in the boundary layer domain must be rejected. Laminar to turbulent transition location is determined by using natural transition criterion based on linear stability theory. The total drag coefficient can be calculated directly.

Numerical shape optimizations were performed first by Parsons et al. [1]. In Pinebrook's study [2], the body geometry is not optimized in a direct method. Instead, a source and sink singularity distribution on the axis is used to model the body contour and to calculate the corresponding inviscid flow field. A statistical technique derived from Rechenberg's evolution strategy was also applied. In the shape optimizations presented by Lutz–Wagner [3], a semi-empirical e^n criterion based on the linear stability theory was applied to determine the natural transition location. Nejati and Matsuuchi [4] improved the Pinebrook's work by employing a powerful optimization procedure called Genetic Algorithms to find optimal shape with the global minimum drag coefficient.

2 Boundary layer flow

For the purpose of numerical shape optimization, high computational efficiency is required, and a numerical procedure, FVM, which is consistent to the geometry and physics of the problem, is applied for solving laminar and turbulent boundary layer equations for airship bodies. The coordinate system (x, y) is curvilinear, where x is parallel to the body surface and y is normal to it. This is illustrated in Fig. 1.

By assumption that flow is steady incompressible and axisymmetric, the governing equations for turbulent boundary layer are given as

$$\frac{\partial}{\partial x} ru + \frac{\partial}{\partial y} rv = 0 \qquad (1)$$

$$\rho u \frac{\partial u}{\partial x} + \rho v \frac{\partial u}{\partial y} = -\frac{dp_0}{dx} + \frac{1}{r}\frac{\partial}{\partial y} r\left\{ \mu \frac{\partial u}{\partial y} - \rho \overline{u'v'} \right\} \qquad (2)$$

where μ is viscosity, $r(x, y) = r_0(X) + y.\cos\alpha(X)$ and $r_0(X)$ is the body radius. It is worth to note that both longitudinal and transverse curvatures effects are considered in the formulation. The transverse curvature effects of solution domain become quite important when the radius of the body is small compared with the boundary layer thickness.

In order to model the Reynolds stress term $-\rho\overline{u'v'}$, one of the most frequently used two equation models $k-\varepsilon$ is employed. According to Launder and Spalding [5], at high Reynolds numbers, the final form of the transport equations for the turbulence kinetic energy k and its dissipation rate ε can be derived and by using Mangler transformation thetransport equations adequate for steady and axisymmetricturbulent boundary layer flow can be written as

$$\rho u \frac{\partial k}{\partial x} + \rho v \frac{\partial k}{\partial y} = \frac{1}{r}\frac{\partial}{\partial y} r\left\{ \left(\mu + \frac{\mu_t}{\sigma_k} \right) \frac{\partial k}{\partial y} \right\} + \mu_t \left(\frac{\partial u}{\partial y} \right)^2 - \rho\varepsilon \qquad (3)$$

$$\rho u \frac{\partial \varepsilon}{\partial x} + \rho v \frac{\partial \varepsilon}{\partial y} = \frac{1}{r}\frac{\partial}{\partial y} r\left\{ \left(\mu + \frac{\mu_t}{\sigma_\varepsilon} \right) \frac{\partial \varepsilon}{\partial y} \right\} + \mu_t C_{\varepsilon 1} \frac{\varepsilon}{k} \left(\frac{\partial u}{\partial y} \right)^2 - \rho C_{\varepsilon 2} \frac{\varepsilon^2}{k} \qquad (4)$$

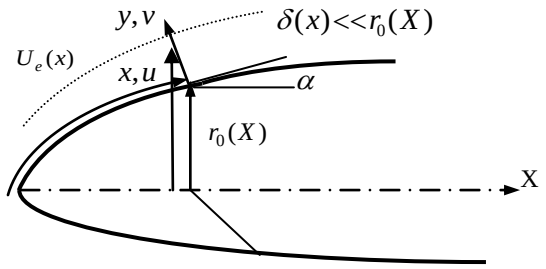

Figure 1. Curvilinear coordinate system for boundary layer on a body surface

where μ_t is turbulence viscosity given as

$$\mu_t = C_\mu \rho \frac{k^2}{\varepsilon}$$

In above equations C_μ, $C_{\varepsilon 1}$, $C_{\varepsilon 2}$, σ_k and σ_ε are modelconstants.

Since the boundary layer width is not uniform, the curvilinear (x, y) system is replaced by the mildly non-orthogonal (ξ, η) system. The lateral extent of the mesh is boundary layer thickness $\delta(x)$, which must be computed as a part of the solution procedure.

3 Transition predication

The reliable and consistent transition prediction is of essential importance for a successful shape optimization of laminar bodies. For this purpose a natural transition prediction such as linear stability theory should be employed. However transition prediction based on a complete analysis of stability theory requires too much computational effort and laborious calculations for the purpose of numerical shape optimization. An alternative is offered in the form of a database method.

The influence of the pressure gradient can be expressed by the use of a shape factor of the velocity profile and if this tedious calculation is carried out once for any shape factor, then a useful database reference can be generated. In this study, the exact velocity profile for axisymmetric body shape is calculated with the FVM and the dimensionless shape factor introduced by K. Pohlhausen can be calculated directly. For the determination of the instability point the method proposed by Schlichting and Ulrich (see Schlichting [6]) is used, and the transition point is determined based on the diagram found by Granville [7].

4 Genetic Algorithms

There are several optimization processes such as Rechenberg's Evolution Strategy (RES) and Genetic Algorithms (GA). GA can reach minimum objective function faster through a better path compared to the other optimization procedures such as RES. Since GA represents a special artificial intelligence technique for large spaces, it's one of the best optimization methods for such multi-dimensional, multi-model and nonlinear objective functions [8].

Genetic algorithms use a vocabulary borrowed from natural genetics. We would talk about *individuals* (or *genotypes*, *structures*) in a population; quite often these individuals are called also *strings* or *chromosomes.* This might be a little bit misleading: each cell of every organism of a given species carries a certain number of chromosomes (man, for example, has 46 of them); however, here we talk about one-chromosome individuals only. Chromosomes are made of units *genes* (also *features*, *characters*, or *decoders*) arranged in linear succession; every gene controls the inheritance of one or several characters. Genes of certain characters are located at certain places of the chromosome, which are called *loci* (string positions). Any character of individuals (such as hair color) can manifest itself differently.

Each genotype (here a single chromosome) would represent a potential solution to a problem; an evolution process run on a population of chromosomes corresponds to a search through a space of potential solutions. Such a search requires balancing two (apparently conflicting) objectives: exploiting the best solutions and exploring the search space. Hillclimbing is an example of a strategy, which exploits the best solution for possible improvement; on the other hand, it neglects exploration of the search space. Random search is a typical example of a strategy, which explores the search space ignoring the exploitations of the promising regions of the space. Genetic algorithms are a class of general-purpose (domain independent) search methods, which strike a remarkable balance between exploration and exploitation of the search space.

For the study we have selected two genetic algorithm implementations differing only by representation and applicable genetic operators, and equivalent otherwise: The binary implementation and floating-point implementation. Such an approach gave us a better basis for a more direct comparison. Both implementations used the same selective mechanism: stochastic universal sampling.

In particular, for parameter optimization problems with variables over continuous domains, we may experiment with real coded genes together with special genetic operators developed for them. The main objective behind such implementations is (in line with the principle of evolution programming) to move the genetic algorithm closer to the problem space. Such a move forces, but also allows, the operators to be more problems specific by utilizing some specific characteristics of real space.

In floating point representation each chromosome vector is coded as a vector of floating point numbers of the same length as the solution vector. Each element is initially selected as to be within the desired domain, and the operators are carefully designed to preserve this constraint (there is no such problem in the binary representation, but the design of the operators is rather simple; we do not see that as a disadvantage; on the other hand, it provides for other advantages mentioned below). The precision of such an approach depends on the underlying machine, but is generally much better than that of the binary representing. Of course, we can always extend the precision of the binary representation by introducing more bits, but this considerably slows down the algorithm.

The operators we use are quite different from the classical ones, as they work in a different space (real valued).

However, because of intuitive similarities, we will divide them into the standard classes, mutation and crossover. In addition, some operators are non-uniform, i.e., their action depends on the age of the population.

4.1 Crossover group

4.1.1 Simple crossover

Simple crossover**,** defined in the usual way, but with the only permissible split points between v's, for a given chromosome x.

4.1.2 Arithmetical crossover

Arithmetical crossover is defined as a linear combination of two vector: if s_v^t and s_w^t are to be crossed, the resulting offspring are $s_v^{t+1} = a.s_w^t + (1-a).s_v^t$ & $s_w^{t+1} = a.s_v^t + (1-a).s_w^t$. This operator can use a parameter a, which is either a constant (uniform arithmetical crossover), or a variable whose value depends on the age of population (non-uniform arithmetical crossover).

Here we have some new mechanisms to apply these operators; e.g., the arithmetical crossover may be applied either to selected elements of two vectors or to the whole vectors.

4.2 Mutation group

4.2.1 Uniform mutation

Uniform mutation**,** defined similarly to that of the classical version: if $x_i^t = (v_1,...,v_n)$ is a chromosome, then each element v_k has exactly equal chance of undergoing the mutative process. The result of a single application of this operator is a vector $(v_1,...,v_k^{'},...,v_n)$, with $1 \le k \le n$, and $v_k^{'}$ a random value for the domain of the corresponding parameter *domain.*

4.2.2 Non uniform mutation

Non uniform mutation is one of the operators responsible for the fine tuning capabilities of the system. It is defined as follows: the non uniform mutation operator was defined as follows: if $s_v^t = (v_1,...,v_m)$ is a chromosome and the element v_k was selected for this mutation (domain of v_k is $[l_k, u_k]$), the result is a vector $s_v^{t+1} = (v_1,...,v_k^{'},...,v_m)$, with $k \in \{1,...,n\}$, and

$$v_k^{'} = \begin{cases} v_k + \Delta(t, u_k - v_k) & if \quad random \quad digit \quad is \quad 0, \\ v_k - \Delta(t, v_k - l_k) & if \quad random \quad digit \quad is \quad 1, \end{cases}$$

where the function $\Delta(t, y)$ returns a value in the range $[0, y]$ such that the probability of $\Delta(t, y)$ being close to 0 increases as t increase. This property causes this operator to search the space uniformly initially (when t is small), and very locally at later stages. We have used the following function:

$$\Delta(t, y) = y.\left(1 - r^{(1-\frac{t}{T})^b}\right),$$

where r is a random number from [0,1], T is the maximal generation number, and b is a system parameter determining the degree of non uniformity.

Moreover, in addition to the standard way of applying mutation we have some new mechanisms: e.g., non uniform mutation is also applied to a whole solution vector rather than a single element of it, causing the whole vector to be slightly slipped in the space.

5 Results and Discussion

Pinebrook [2] applied Rechenberg's Evolution Strategy for the optimization of the airship bodies. For one example with a certain initial set of singularity elements, the minimum drag after 9600 generations was reported as 0.0273. We also carried out this example by employing the available computational program, but it could run only up to 400 generations. The minimum drag was compared with our result obtained from genetic algorithms for the same number of generations (also with the same initial parameters and Reynolds number). Fig. 2 shows that the best drag coefficient for evolution strategy is 0.0283 whereas the minimum drag in genetic algorithms is 0.0234, which is better, even than the reported result. This is because Rechenberg's evolution strategy is a type of random search, which explores the search space ignoring the exploitation. To show that GA has a remarkable balance between exploration and exploitation a 3-dimensional demonstration of reduction of drag coefficient for an example is plotted in Fig. 2 and it indicates clearly how GA exploits the best solution.

In the aerodynamics model presented by Nejati–Matsuuchi [4], the integral method and empirical relations are used to calculate the laminar and turbulent boundary layers. For simplicity, we call this model IM-FT, which is abbreviation of Integral Method and Forced Transition criterion. In this

study a new model is proposed. To improve the boundary layer calculation, IM together with the empirical relations is substituted with a powerful numerical method FVM. Furthermore the transition prediction is also modified and the natural transition criterion is added to aerodynamics calculations to get better estimation of the transition location. This model is abbreviated as FVM-NT which is referred to Finite Volume Method and Natural Transition.

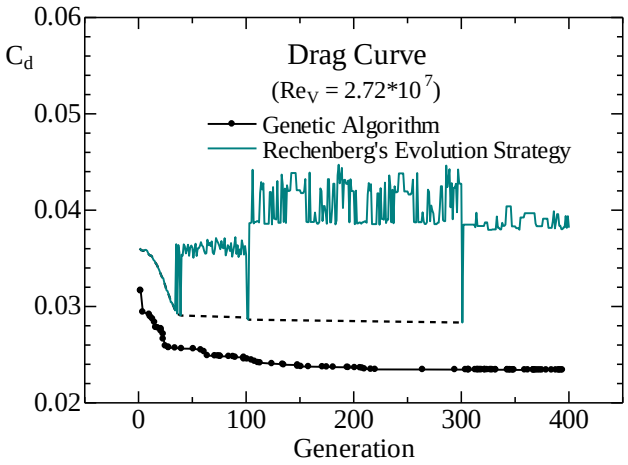

Fig. 2 Comparison of drag curves

The aerodynamics calculation is performed for a specified body shape with a volumetric Reynolds number $\mathrm{Re}_v = 9.39 \times 10^5$. The boundary layer calculations using FVM are carried out for this typical body shape. The natural transition point in this calculation is found to occur at 45% of the body length. The free-stream velocity distribution and the mean velocity profiles for some stages on the body surface are plotted in Fig. 3. The velocity profiles indicate laminar form up to 45% of the body length and exactly before the transition point *E*, flow approaches the laminar separation but transition occurs and flow becomes turbulent. It can be seen that around 50% of the body length, in point *F*, the flow becomes laminar one which means relaminarization. Downstream of this point, flow stays turbulent and near the end of the body at point *I* flow is ready to separate, but flow separation is avoided.

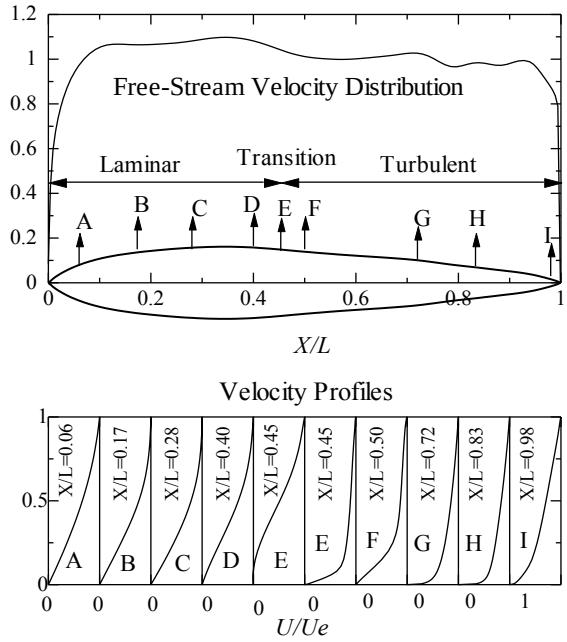

Figure 3. Free-stream velocity distribution and mean velocity profiles for specified body shape

To show the natural transition location effects on the drag coefficient in the various ranges of the Reynolds number another example is consideredfor a specified body shape used by previous investigators. For this example the airship body R101 (see Lutz–Wagner [3]) shown in Fig. 4 is taken into account, and present FVM-NT model is used to determine the drag coefficient. By increasing the free-stream velocity the Reynolds number is increased. As a validation aspect, the drag curve calculated by other investigators for this airship body is also given in Fig. 4. The experimental investigations for this shape were conducted independently by Jones and Schirmer. Schirmer performed his measurements in the wind tunnel of the former Zeppelin Company. To find the drag coefficient for this example, Lutz and Wagner used the integral method with semi-empirical e^n method. The calculated drag coefficient in this study shows satisfactory agreement with the experimental results, but in higher Reynolds number there occurs a turbulent separation almost near the end of the body and induce higher drag coefficient.

The shape optimization program is coupled with two different aerodynamics models, IM-FT and FVM-NT, in order to show the importance of aerodynamics calculation for achieving the optimal body shape. Lutz–Wagner [3] suggested five design regimes for the Reynolds number as shown in table 1. In the present research, we also carried out the optimization process for these five design regimes

to compare our results with those obtained by Lutz–Wagner.

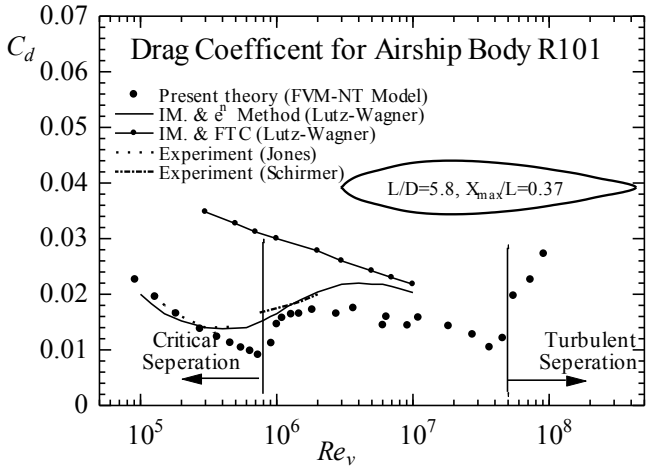

Figure. 4 Drag coefficient for airship body R101

Table 1 Design regimes

Regime	Re (min)	Re (max)
I	1.00E+06	3.16E+06
II	3.16E+06	1.00E+07
III	1.00E+07	3.16E+07
IV	3.16E+07	1.00E+08
V	1.00E+08	3.16E+08

Several optimization processes with IM-FT and FVM-NT models are carried out to find the optimal body shape with the minimum drag coefficient in each design regime. The minimum drag coefficient curves related to these two models are depicted in Fig. 5 and the results of Lutz–Wagner using the integral method with the semi-empirical e^n method are also drawn for comparison. Using FTC at 3% of the body length in IM-FT model gives bigger drag coefficient and has different drag curve.

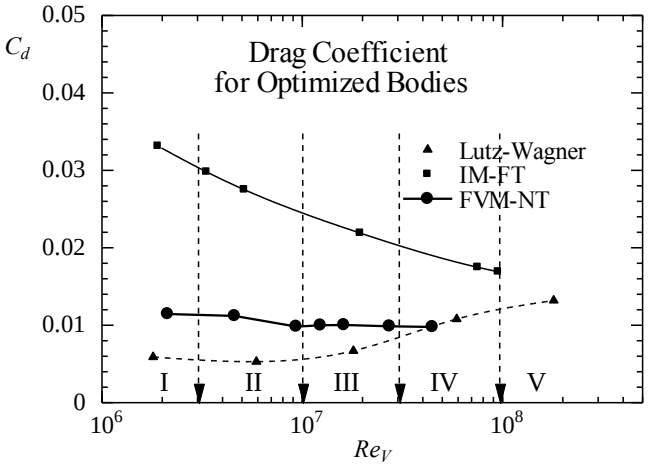

Fig. 5 Drag curve for range of Re_V

The drag coefficient obtained by FVM-NT model has a curve much similar to that obtained by Lutz–Wagner. However in low Reynolds number we get bigger drag coefficient because the transition in the optimal body shapes occurs earlier. In Lutz–Wagner results for low Reynolds numbers, the maximum radius position is located very far from the body nose. This means the existence of long favorite pressure gradient and long laminar flow on the body surface. As a result, much lower drag coefficient can be achieved.

6 Conclusions

The Finite Volume Method for boundary layer calculation is employed in order to improve the drag reduction process and to obtain the reliable optimal body shapes. We summarize our study as follows:

1) Since the Integral Method gives no velocity profile in the boundary layer domain, the drag coefficient cannot be found directly and is calculated with somewhat poor accuracy. On the other hand, in the Finite Volume Method the drag coefficient is obtained directly from the boundary layer solution. In the Integral Method the separation of the turbulent flow is judged according to the value of the shape factor and therefore the results showing no separation may be unreliable. In contrary to the Integral Method, the Finite Volume Method can estimate the separation correctly because it evaluates the velocity profiles. Furthermore the transverse curvature effects are neglected in the Integral Method. The Finite Volume Method can take these effects into account completely.

2) The laminarization plays an important role in the shape optimization. It is concluded that the natural transition criterion should be used to estimate correctly the region of

natural laminar flow. As a result, the body geometry changes as the location of the maximum body thickness moves as far aft as possible.

3) Since Genetic Algorithms strike a remarkable balance between exploration and exploitation of search space, it can reach to minimum objective function faster through a better path, whereas Rechenberg's evolution strategy is a random search type method ignoring the exploitation. Comparing the two methods, it is concluded that for large spaces, with multi-dimensional, multi-modal and nonlinear objective functions, GA is more accurate.

7 Acknowlegement

I would like to appreciate Professor Kazou Matsuuchi from University of Tsukuba, Japan. He was my supervisor in PHD program and conducted me to improve my computational calculations.

***Abstract*—The understanding of several phenomena requires unbounded data collections, called data streams. These phenomena often present unstable behavior and are studied by means of unsupervised induction processes based on data clustering. Currently, clustering processes have shown serious limitations in their applications to data streams due to the demands imposed by behavioral changes and unlimited data collection. However, despite the key distinctions in between traditional data sets, which are finite and unordered, and data streams, which are essentially infinite sequences, studies have overlooked the dynamic and transient nature of streams, limiting the appropriate understanding of phenomena. The lack of a theoretical analysis for the problem of data streams clustering led us to propose, in this paper, a formalization based on Set Theory. This formalization made it possible to identify and propose basic properties for the design and comparison of data stream clustering algorithms. It is expected to be a starting point to understand the foundations of unsupervised induction based on clustering and, mainly, the modeling of phenomena.**

I. Introduction

The literature from several research fields has described two main types of phenomena that produce endless sequences of data also referred to as data streams [11], [12]. The first type is characterized by the need for data storage space and fast computation. In this situation, data is stored in secondary memory, which presents low transfer rates, and usually accessed in a contiguous manner. The second type is even more computationally demanding: data is collected at high rates and shortly afterwards is disposed. In this type, clustering models must be continuously obtained throughout the endless data-gathering process, whose dynamical properties, i.e., behavior, are expected to evolve over time [7], [12]. Data streams are frequently found in computationally intensive environments, such as climate and weather analysis [2], text mining [10], [9], genomic analysis, and advanced scientific experiments [18], [19].

The typical clustering process has been designed to approach finite and unordered data sets and, consequently, does not meet data streams requirements [20]. There exist great distinctions between clustering requirements for data sets and data streams. Firstly, a data stream must be accessed and processed sequentially as it cannot be completely stored in memory. Secondly, the open-endedness nature of data streams demands continuous and automatic analysis. Thirdly, while stable phenomena can be accurately represented by bounded data sets and are suitable to traditional data clustering, data streams, on the other hand, usually represent unstable phenomena [7], whose characteristics tend to change over the collection. This tendency indicates the transient nature of data streams and demands a continuous re-evaluation of clustering models. Finally, the role of domain experts when clustering data streams is different from clustering data sets. In the latter, specialists are often required to empirically extract, select and analyze data features in order to define the clustering algorithm and the validation criterion. Conversely, in data streams, the fast and continuous production of large amounts of data restricts human intervention, due to the limited capability of specialists to make well-founded decisions under such constraints.

In order to better understand data set clustering, Kleinberg [8] formalized three properties, which allow the analysis of algorithm capabilities independently of the target application. The formalization of the data-set clustering problem is an important step towards its deep understanding. Recently, several studies concerning the usage and proposition of properties to related problems have been developed [5], [4], [22]. These studies have broadened the possibilities to analyze clustering algorithms, although very few of them have been conducted in the context of data streams.

The lack of formal studies on the problem motived our formalization of data stream clustering as an extension of Kleinberg's approach to data sets [8]. In

such a definition, data stream clustering is described in terms of an infinite sequence of partitions, which are modified along time. The endless and changing nature of data streams requires properties different than those proposed by Kleinberg for finite and unordered data sets. Data streams, as infinite and ordered sequences, need clustering properties representative of the time evolution and behavior changing.

We have extended Kleinberg's properties to represent clustering partitions evolving according to the data stream behavior. In addition, we introduce the **Coherence** property, which states that partitions must continously evolve over time in order to preserve the meaning of the clustering process. However, we observed that this property is incompatible with the Kleinberg's Richness, which states that a data-set clustering function must be capable of generating any partition. This conflict indicates that trade-off analyses are needed in order to demand properties from algorithms. Additionally, we noticed that it is difficult to find an algorithm to comply with Richness in a data stream context.

The remainder of this paper is organized as follows: Section II introduces studies on data set clustering; Section III describes our formalization approach to data streams; Section IV draws conclusions and present ideas for future work; and, finally, references are listed.

II. Related Work

Kleinberg [8] considered concepts of Set Theory [14] to describe clustering algorithms in general terms, i.e., without relying on a specific algorithm, objective function for optimization, or statistical model. This analysis is important to understand the functioning of algorithms beforehand, i.e., without the need for experimental trials, and also to provide design guidelines for new approaches.

The concepts involved in Kleinberg's formalization are illustrated in Figure 1. This formalization assumes data elements are organized in set E, whose measurements of dissimilarity in between elements are provided in a square matrix. This matrix, d, is described in the form of a function $d : E \times E \rightarrow \mathbb{R}^+$, and is applied to two elements $\{i, j\} \in E$ to obtain a dissimilarity value $d(i, j)$ in $[0, \infty)$. The construction of d determines the possibility of a clustering algorithm to organize the elements in E. A cluster is essentially an organization of elements of E into subsets, so that each element is contained in one, and only one, subset. This structure is known as the **partition** of a set. Partitions are denoted by uppercase Greek letters, such as Γ (Gamma) and Υ (Upsilon). A clustering algorithm is, therefore, a function $f(d)$, which considers a distance matrix d for mapping elements in E into a partition belonging to the universe of partitions U.

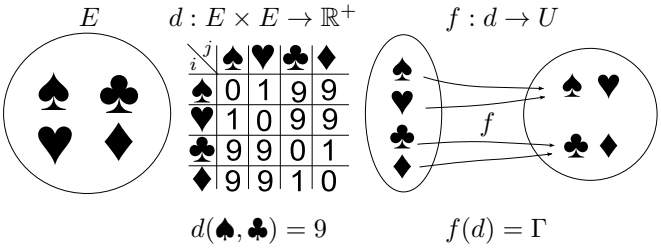

Figure 1. Illustration of concepts of data set clustering

By using this formalization, Kleinberg proposed properties to data set clustering introduced in the form of statements of principles or self-evident conditions to a well-succeeded clustering algorithm. The author initially proposed three properties: Scale-Invariance, Richness and Consistency.

Scale-Invariance refers to the ability of algorithms to abstract the measurement scale of elements, i.e., for any distance function d and constant $\alpha > 0$, we have $f(d) = f(\alpha \cdot d)$. This property reflects the expectation that the magnitude of the scale of elements should not change the partition; for example, adapting elements from centimeters to inches should not modify the partitions obtained.

Richness refers to the ability of an algorithm to induce all possible partitions for a set of elements. When Richness holds, for any partition Γ of E, there exists a distance matrix d for which $f(d)$ results in Γ. It applies the concept of surjection of Set Theory [14], which defines the image of the surjective function as being equal to its counter-domain. This property assumes it is possible to arrange elements by modifying their relative distances in order to obtain all partitions. A clustering algorithm complies with **Richness** if and only if it permits obtaining all partitions for the elements in E, otherwise some partitions are impossible to be found.

Ensuring the possibility of finding all partitions for a data set, as required by Richness, appears, at first, desirable for an algorithm whose data nature is unknown. However, this property may be difficult to comply with [8].

Consistency refers to the ability algorithms have to maintain the same partition when distances among elements within the same group are reduced while distances among elements of different groups are increased. For example, consider a partition Γ generated by a clustering function f, according to a distance function defined by d. Also consider changing d into d' in a way that it increases the distances among elements of distinct subsets of Γ and reduces the distances among elements of the same subset. A consistent clustering function $f(d')$ always generates a partition Γ' equivalent to Γ, in the sense

that $f(d') = f(d)$.

The previously described Kleinberg's properties have proven too demanding for a clustering function to comply with, resulting in the incompatibility among them. Kleinberg [8] proved, in an impossibility theorem, that only two out of these three properties could be satisfied by any algorithm. Although the practical consequences of the impossibility theorem are limited, mainly because small adaptations to the properties avoid the impossibility, Kleinberg's approach has motived several studies to further understand data clustering [5], [4], [22]. Among those studies, very few are relevant to data streams. To the best of our knowledge, the only exception is the paper by Ryabko [15]. It deals with the problem of clustering stationary stochastic processes, in which the author claims that two elements must be associated with the same cluster if and only if they are generated by the same probability distribution. Nonetheless, the usefulness of this result is limited in the context of data streams, in which the behavior of sequences changes over time.

III. Clustering data streams

Data streams differ from other types of data traditionally considered in Machine Learning. They are infinite sequences with unknown and unstable behavior [6]. These characteristics contrast with traditional data sets, which are finite, have no particular order, and are characterized by a stable behavior. These distinctions have motivated the adaptation of Kleinberg's data set properties to data streams.

In this context, a data stream is defined as an infinite and ordered set of elements, that is, a sequence $S = (s_{t_{-\infty}}, \ldots, s_{t_{-k}}, \ldots, s_{t_0})$, in which elements are indexed by $t \in \mathbb{R}$. The data collection is performed at time instants t whose order is given by integers $k \in (0, \infty)$.

The complete sequence is represented by S, while a sub-sequence of data collected up to a time instant t is S_t. Every element s_t in this sequence consists of a vector of values v, i.e., the data features obtained. The elements in S_t are comparable by a dissimilarity function $d : S \times S \to \mathbb{R}^+$.

The main goal of a data-stream clustering algorithm $f(d, S)$ is to generate a sequence of partitions $\bar{\Gamma}_{t_0} = \{\Gamma_{t_{-\infty}}, \ldots, \Gamma_{t_0}\}$ for elements in S_{t_0}, in which $\Gamma_{t_0} = f(d, S_{t_0})$. The sequence of partitions is created from the first data-stream element $S_{t_{-\infty}}$ until the most recent element S_{t_0}. Although S is infinite, partitions in $\bar{\Gamma}$ have a finite number of non-intersecting subsets. As a result of practical requirements of the data streams analysis, although S is infinite, every partition in $\bar{\Gamma}$ may use only a finite subset of S. Therefore, the design of f can consider the option of removing a convenient subset of elements R if they are represented by other elements or even expired.

In summary, the main difference of the problem of data stream clustering, when compared to data set clustering, originates from the infinite and ordered nature of such scenarios, which demands a sequence of partitions over time, instead of a single one.

A. Data-stream clustering properties

The differences between the data-set clustering problem and the data stream one motivated the adaptation of Kleinberg's properties. We observed these properties do not assure that clustering partitions *smoothly* evolve according to the data stream behavior. Therefore, we introduce the property of **Coherence**, which states that a coherent algorithm for data-stream clustering creates partition sequences in which elements do not drastically change from one cluster to another. This property ensures that clustering algorithms maintain continuity in between consecutive partitions.

Firstly, the Time-space Scale Invariance property, equivalent to Kleinberg's property of Scale Invariance, suggests that algorithms should produce the same partition if the measurement scale of space or times is transformed by a multiplicative constant.

Property 1: Time-space Scale Invariance – Consider the multiplication of distances d by a positive constant α, $\alpha \cdot d$, and the time indexes of each element $s_t \in S$ by another positive constant β, $s_{\beta \cdot t}$. The sequence of partitions $f(d, s_t)$ is equal to $f(\alpha \cdot d, s_{\beta \cdot t})$.

Similarly, the properties of Richness in Data Streams and Time-space Consistency are adaptations of Richness and Consistency for data sets. Both properties consider a notion of temporal proximity, and, therefore, differ from properties to data set clustering in terms of a reference point in time to conduct comparisons among partitions.

Property 2: Richness in Data Streams – Consider a reference point in time t_0, a sequence $S_{t_0} = (s_{-\infty}, \ldots, s_{t_0})$ observed until t_0, and a matrix of dissimilarity d among elements in S_t. The clustering function f complies with Richness in Data Streams at instant t_0 through an arbitrary transformation of d and in the order of elements in S_t if it is capable of obtaining all possible partitions for $(s_{-\infty}, \ldots, s_{t_0})$.

The Time-space Consistency property extends Consistency by including the notion of temporal proximity. It states that if elements in the same cluster are temporal and spatially closer to each other and, at the same time, elements of different clusters are farther, then the partition sequence is maintained.

Property 3: Time-space Consistency – Consider d' and S'_t are transformations of matrix dissimilarity d and observation sequence S_t such that the intervals of the occurrence of elements within a cluster become shorter and those of different clusters become longer.

A clustering function f complies with space-temporal consistency if and only if $f(d, S_t) = f(d', S'_t)$.

The proposed properties are directly related to those defined for data-set clustering. Nonetheless, the data stream properties based on Kleinberg's study do not oblige a clustering algorithm to obtain a logical sequence of partitions for data streams. For practical purposes, the guarantee that an algorithm will not randomly assign samples to distinct clusters in consecutive partitions is desirable. For example, in the context of concept drift [13], the evaluation of clusters over time is required. However, if consecutive partitions do not share a sense of continuity, the evaluation becomes meaningless.

The continuity of partitions (Definition 2) is formalized by a relation named **reach**, represented by $\triangleright$, according to Definition 1. It is inspired in the concept of **refinement** by Kleinberg [8], which states that a partition Γ is a refinement of Υ if and only if each subset in Γ either belongs to Υ or is contained in one of its subsets.

Definition 1: A partition Γ **reaches** another partition Υ if, for every subset $A \in \Gamma$, there is another subset $B \in \Upsilon$, such as $(A \setminus R^{\Gamma}) \subseteq (B \setminus R^{\Upsilon})$ or $(B \setminus R^{\Upsilon}) \subseteq (A \setminus R^{\Gamma})$, given that operation $\setminus$ is defined by $B \setminus A = \{s \in B | s \notin A\}$ and R^{Γ} is the subset of elements in Γ that do not belong to Υ, and R^{Υ} is the subset of elements in Υ that are not in Γ. The relation **reach** is denoted by $\Gamma \triangleright \Upsilon$.

Continuity (see Definition 2) is relevant to the analysis of capability of clustering algorithms to capture the behavior evolution of data streams.

Definition 2: A partition sequence $\bar{\Gamma}_t$ is **continuous** if and only if for all consecutive partitions, i.e., Γ_{t-i-1} and Γ_{t-i}, in which $i \geq 0$, the relation $\Gamma_{t-1} \triangleright \Gamma_t$ is true.

The guarantee of generating continuous partitions is stated by the Coherence property. The Coherence of a clustering algorithm allows, for example, employing measurements to evaluate partition sequences and support the exploratory analysis of phenomena.

Property 4: Coherence – For any d, S_t, and $\Gamma_t = f(d, S_t)$, the partition sequence $\bar{\Gamma}_t$ is always continuous.

The time dimension is included in the first three properties proposed to formalize the data stream clustering. However, these properties do not approach the generation of an infinite sequence of partitions, which contrasts with the data set clustering defined only by one partition. In this sense, the coherence of data-stream clustering algorithms is probably the most important property. The main relevance of the Coherence property relies on the fact it provides a parallel between clustering continuity and function continuity, allowing to evaluate differences in clustering models over time. By measuring such differences, it is possible to better the understand phenomena represented by data streams. However, as shown in the next subsections, Coeherence can be incompatible with other properties, and, sometimes, is not respected by some current important algorithms. For example, the usage of the k-means algorithm for clustering data streams, whose data are pre-organized in the form of micro-clusters, as performed by BIRCH [23] and CLUSTREAM [1] will not guarantee the continuity of partitions and, eventually, may not represent phenomena behavior.

B. Analysis of clustering algorithm properties

The formalization we have proposed is aimed at evaluating and supporting the design of data-stream clustering algorithms. In a similar approach, Kleinberg [8] considered the three previously mentioned data-set clustering properties to prove no algorithm respects them simultaneously.

Based on Kleinberg's study, we have observed a similar impossibility theorem to obtain a data-stream clustering algorithm for the first three properties proposed. Furthermore, we have also observed that Properties 2, Richness in data streams, and 4, Coherence, are mutually exclusive, because the latter limits the possibilities to produce partitions. In order to prove it, we show that if a data-stream clustering function f complies with Richness, then it necessarily generates sequences of partitions $\bar{\Gamma}$ in which at least a pair of consecutive partitions does not respect the relation **reach**; and, also, if f generates only continuous sequences of partitions, then it does not complies with Richness. Theorem 1 shows the impossibility of designing a data-stream clustering algorithm with the properties of **Coherence** and **Richness** in data streams.

Theorem 1: There is no data-stream clustering function f that complies with Properties 2 and 4.

Proof:

First part: suppose f complies with Richness in data streams, then f generates a partition sequence $\bar{\Gamma}_t$ containing consecutive partitions that do not **reach** each other.

We will show that there is a sequence $\bar{\Gamma}_t$ with partitions that do not **reach** each other, regardless of changes in both distances d and the sequence of elements S_t. A partition Γ_t is unreachable when there is no partition Γ_{t-1} preceding it, so that the relation $\Gamma_{t-1} \triangleright \Gamma_t$ is not respected, that is, the set of all possible partitions at instant $t-1$ is empty.

It suffices to provide an example in order to prove that there is an unreachable Γ_t. Take a partition at time instant t, $\Gamma_t = \{\{a_1, b_2\}, \{a_2, b_1\}\}$, where elements a_i, $\forall i$ and b_j, $\forall j$ in $\Gamma_{t-1} = \{\{a_1, a_2\}, \{b_1, b_2\}\}$ are in different clusters.

It is known that $\{\{a_1, a_2\}, \{b_1, b_2\}\} \triangleright \{\{a_1, b_2\}, \{a_2, b_1\}\}$ is not valid, because, according to the definition of the relation **reach**, no subset of the

first partition is contained in a subset of the second one, and reciprocally. It is also known that, by definition, any f that complies with Richness in data streams is supposed to generate such a sequence of partitions.

Second part: if f generates only continuous partition sequences, then f does not comply with Richness in data streams. Consider the following partition $\Gamma_{t-1} = \{\{a_1, a_2\}, \{b_1, b_2\}\}$, then f cannot generate $\Gamma_t = \{\{a_1, b_2\}, \{b_1, a_2\}\}$ in the next time instant t, and, similarly, if we take $\Gamma_{t-1} = \{\{a_1, b_2\}, \{b_1, a_2\}\}$, then f will not generate $\Gamma_t = \{\{a_1, a_2\}, \{b_1, b_2\}\}$.

Therefore, no f that generates continuous partition sequences may comply with Property 2. □

C. Analysis of data stream clustering algorithms

The use of properties for the analysis of clustering algorithms is incipient. However, such properties allow the understanding of theoretical principles for the design and selection of algorithms, taking into account utility and economic factors inherent to the application domain [3].

The properties we have introduced are the first to represent the inherent characteristics of data streams. In summary, these properties are Time-space Scale Invariance, Richness in Data Streams, Time-space Consistency and Coherence. We present a comparison among the most relevant data stream clustering algorithms, which is summarized in[1] Table I based on the properties proposed. Among the algorithms are Birch [23], WaveCluster [16], CluStream [1], Olindda [17] and *Starvation* Wta [21]. Observe that none of the algorithms complies with the property of Richness.

Table I
Evaluation of properties for data stream clustering algorithms

Algorithm	T-S Scale Invariance	T-S Consistency	Coherence
Birch	N	N	N
WaveCluster	N	—	N
CluStream	N	N	N
Olindda	Y	N	N
Wta	Y	Y	Y

(1) T-S means Time-space.

(2) Value 'Y' means yes and 'N' means no.

Usually, to verify that algorithms comply with such properties, one can prove a theorem or present a counterexample. However, in some cases none of the two options is possible. On the other hand, there are other options to check whether an algorithm respects a given property. For example, when an algorithm limits the number of groups, it does not comply with the property of Richness. An algorithm does not comply with Property 1, i.e., Time-space Invariance, if it considers any threshold for accepting elements in clusters as there is always a scalar constant that, multiplied by the distances among elements, will modify the partition produced. Still, an algorithm does not comply with Property 1 and Property 4 if it does not consider the order of data during clustering.

Another analytic option considers the evidence previously established for algorithms used to cluster traditional data sets, such as k-means and hierarchical algorithms (e.g., Single-linkage) [1], [23]. For example, algorithms that use k-means in the clustering process do not comply with Property 4 because k-means does not guarantee the continuity in sequences of partitions. Among such algorithms, Birch and CluStream are some of the most commonly considered data stream clustering algorithms.

[1]The symbol '—' represents that it was not possible to achieve an evaluation. We omit further details on verifying algorithm properties due to lack of space.

IV. Conclusions and Future Work

Despite the fundamental differences between data set and data stream clustering, many studies have overlooked the infinite, dynamic and transient nature of the latter. In this paper, we formally tackled the problem of data-stream clustering as an infinite sequence of partitions. This approach is an extension of Kleinberg's properties. Besides adapting Kleinberg's properties to data streams, we also proposed a new property referred to as **Coherence**, which deals with the infinite and sequential properties of data streams. This new property was proven to be incompatible with **Richness**, evidencing the trade-off in between both properties when designing data-stream clustering algorithms. The existence of few related studies in this theoretical branch indicates that this is a seminal study and also that there are plenty of possibilities towards developing a clustering theory.

Abstract— **The network lifetime is one of the important factors in wireless sensor networks and is dependent on the network energy. Energy source in the network is very limited. In order to increase the network lifetime, energy saving should be considered. Clustering method is the one of the ways to consume energy efficiently that causes uniform load distribution and balanced energy consumption. In this essay, a new method for optimal selecting cluster head and clustering is presented using fuzzy logic. In the proposed method, a radius can be assigned for sensor with the help of fuzzy rules and fuzzy variables, energy and distance. Then cluster head sensors are elected with the help of fuzzy rules and energy and number of neighboring sensors as two fuzzy variables. Thus, the best sensors are selected as a Cluster head. Furthermore, with the help of obtained radius, cluster size is controlled with regard to distance from the base station. It means that clusters close to the base station are larger than far clusters. Therefore, in the proposed protocol the network energy consumption, which is uniformly distributed in the network, is reduced. MATLAB simulation results indicate that the proposed protocol managed to increase network lifetime more than LEACH and EECS protocols.**

Keywords- Cluster head, clustering, fuzzy logic, wireless sensor networks, network lifetime, sensor (node)

I. INTRODUCTION (HEADING 1)

Wireless sensor networks consist of many small, inexpensive sensors. Sensors are capable of processing, energy and have a limited memory. In wireless sensor networks, they collect data related to the environment events and send them to the base station [1]. Nowadays, wireless sensor networks have many usages in human life. Among these applications, monitoring the environment of humans and animals life, fire detection, flood, medical applications and military issues can be mentioned [2].

One of the most important factors in designing wireless sensor networks is energy. It is not possible to recharge or replace the sensors energy sources since the energy source in sensors is limited (because of the numerous number of sensors) and lack of access to them in different geographic environments in the network, [3] [4].

Therefore, energy is very important in saving wireless sensor networks and many researches have been presented on the field of optimizing energy consumption and increasing network lifetime. Among the protocols presented, hierarchical protocols based on clustering are efficient in energy consumption.
In these protocols, the network is divided into parts called clusters. In each cluster, a sensor is selected as a cluster head. Other cluster sensors collect data from the environment and send them to cluster head. After data collection, cluster head aggregates them in order to delete repetitive data and eventually sends them to the base station. In these protocols, only cluster heads communicate with the base station and other sensors are connected to cluster heads.

Therefore, in these protocols, selecting a sensor as cluster head and aggregating data will significantly result in saving energy. Reducing energy consumption can increase the network lifetime because of direct connection in wireless sensor networks between reducing energy consumption and increasing the lifetime of the network. In this essay, a new efficient protocol in energy consumption is presented with the help of fuzzy logic and considering distance and energy as two variables to determine the sensors radial range and considering energy and number of the neighboring sensors as two variables in cluster head selecting process.

As we follow, in section 2 past works are discussed, in section 3 the proposed protocol is presented and in section 4 simulation is performed.

II. REVIEWING PAST WORKS

There have been many researches to optimize energy consumption in wireless sensor networks and a lot of clustering algorithms have been discussed. LEACH algorithm [1] [7] is one of the first cluster routing methods presented for sensor networks .In LEACH protocol, time is divided into the parts called the round and each round is divided into two phases. The first phase is called set-up phase in which clusters are formed and the second phase, which is related to normal network function, is called the steady-state phase .In the first phase, using a probability function, head clusters are selected. Each sensor selects a random number between zero and one. If this number is smaller than a specified threshold (T), the sensor is

selected as the cluster head during the round. This probability function is designed so that each sensor is selected as cluster head only once within a certain number of rounds, and thus energy consumption is spread over the entire network. After cluster heads were selected in the set-up phase, each cluster head announces the selecting news to the other sensors and other sensors select the nearest cluster head as their cluster head, then they inform the related cluster head. In the second phase, each sensor sends data to its cluster head and cluster head combines the received data and sends it to the base station.

LEACH protocol also has disadvantages. For example, the cluster head may be placed close to each other. In addition, remaining energy of the sensor for selecting cluster head is not considered; therefore, a sensor containing very little energy may also be selected as cluster head. Similarly, cluster head may be placed in one low-density position or be placed on the edge of the network.

LEACH-C algorithm [1], is the way in which the cluster heads are selected based on sensors position data and the amount of remaining energy. In the set-up phase, each sensor sends information about its status and remaining energy to the base station. Then the base station chooses the cluster heads based on this information. One of the advantages of this method is that by placing the head clusters in the center of cluster, the energy consumption will evenly be distributed between the sensors.

In algorithm [8], a cluster head selecting method is presented using fuzzy logic. In this protocol, cluster heads are selected with the help of two variables, energy and local distance, within a constant radius. Local distance is the total of the distances of neighboring sensors within the radius.

In [9], a fuzzy algorithm for selection of cluster heads has been suggested. In this algorithm, cluster heads are elected by the base station. It means at first the sensors send data to the base station in the network and the base station selects cluster head with the help of three fuzzy variables: energy, concentration and centrality.

In EECS-M algorithm [10], a clustering method based on energy level is presented. In this algorithm for each level of networks energy, a competitive radius is taken. Sensors at every level within their radius compete to be Cluster Head. Sensors within their radius are selected as cluster head based on remaining energy. In this protocol, clusters size are different from each other in terms of area in which the sensors are placed. It means that clusters close to the base station are larger than far clusters.

In EECS algorithm [11], the author considers a constant radius for all sensors. In addition, he/she uses a competitive algorithm for the phase in which cluster heads are selected. The candidate sensors in the constant competitive radius examine that if there is a sensor with more energy, they exit the competition and broadcast the exit message. A sensor, which has maximum energy in this radius, elects itself as a cluster head and broadcast the advertisement message. In this protocol, Cluster heads are uniformly distributed in the Network. Therefore, the size of the clusters is constant due to the constant competitive radius.

III. THE PROPOSED ALGORITHM

The proposed algorithm is among those clustering algorithm. In this protocol, it has been attempted to reduce energy consumption and increase network lifetime using fuzzy rules .Cluster head energy consumption is different with regard to the distance from the base station. Cluster heads, which are close to the base station, consume the less energy for sending aggregated data than cluster heads far from the base station. For this reason, the far cluster heads lose their energy faster in the protocols that elect cluster heads without regard to the remaining energy and distance. In addition, the size of the clusters is effective in the cluster heads energy consumption. It means that cluster heads will consume more energy in the large clusters. Therefore, in this paper, using fuzzy rules for sensors, based on the amount of remaining energy and the sensor distance from the base station, a radius is considered. Then for selecting cluster heads for sensors, a chance is obtained in terms of fuzzy rules and based on remaining energy of the sensor and the number of neighbors within the related radius. Then the sensor, which has a maximum chance within its radius, is selected as cluster head and broadcasts the advertisement message to the network. Thus, the proposed protocol with selecting high-energy sensors as cluster head and limiting the size of clusters with regard to the distance from the base station cause energy consumption to reduce and ultimately lead to increasing network lifetime.

A. Network Model

Network is intended with the following specifications:

- Sensors are homogeneous and are distributed uniformly in the square area.
- Base station and sensors are fixed (static and unchanging).
- The base station is located outside square area.
- All sensors have the same initial energy.
- Sensors are aware of their position.

B. radio model

Radio model is discussed in [12] and used as the connecting model among the sensors. Equation (1) shows the amount of energy to transfer an L-bit packet to the distance d. E_{elec}, shows the amount of consumption energy of the transmitter and receiver circuits. $\boldsymbol{\varepsilon_{fs}}$ and $\boldsymbol{\varepsilon_{mp}}$, shows the amount of waste energy to boost the RF at a distance d_0 which is obtained by using equation (2):

$$E_{TX} = \begin{cases} L \times E_{elec} + L \times \varepsilon_{fs} \times d^2 & d \langle d_0 \\ L \times E_{elec} + L \times \varepsilon_{mp} \times d^4 & d \geq d_0 \end{cases} \quad (1)$$

$$d_0 = \sqrt{\frac{\varepsilon_{fs}}{\varepsilon_{mp}}} \quad (2)$$

Consumed energy to receive an L-bit packet is also calculated by using equation (3):

$$E_{RX} = L \times E_{elec} \quad (3)$$

Consumed energy in cluster heads is also calculated during a round by using equation (4):

$$E_{CH} = (\frac{n}{k} - 1) L \cdot E_{elec} + \frac{n}{k} L \cdot E_{DA} + L \cdot E_{elec} + L \cdot \varepsilon_{fs} \cdot d^4_{to-BS} \quad (4)$$

K shows the number of clusters and E_{DA} determines data combination cost. $d^4_{to\text{-}bs}$ is the average distance between cluster head and the base station. The consumed energy in conventional sensors is also calculated by using equation (5):

$$E_{CM} = L \cdot E_{elec} + L \cdot \varepsilon_{fs} \cdot d^2_{to-CH} \quad (5)$$

$d^2_{\textbf{to-bs}}$ is the average distance between the cluster member sensors and cluster head.

C. *The working process of the proposed algorithm*

This essay assumes that the sensors calculate their distance from the base station by receiving the message from the base station. Each sensor is aware of its position and its remaining energy. In the proposed protocol like LEACH protocol, time is divided into parts that are called the round. In each round, there are both set-up phase and steady-state phase. In set-up phase, radius and a chance are calculated for the sensors. Then cluster heads are selected and clustering is performed. In stable phase, data is collected, aggregated and sent to the base station by cluster heads.

1) Determining the radius for sensors with the help of fuzzy function

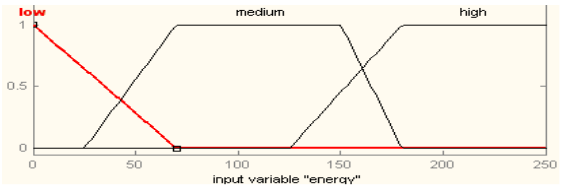
As previously discussed, each sensor is aware of its remaining energy and distance from the base station. In this protocol, for reducing energy consumption a radius is considered for each sensor in terms of the remaining energy and distance from the base station. In the case of electing as a cluster head, this radius makes sensor have a clustering limited to its radius in order to prevent rapid energy discharge; because cluster heads, which are far from the base station, have more energy consumption. For determining the radius in fuzzy function, fuzzy rules use two fuzzy variables, which are defined as follows:

- Energy: The amount of remaining energy of sensor.
- Distance: the distance of a sensor from the base station.

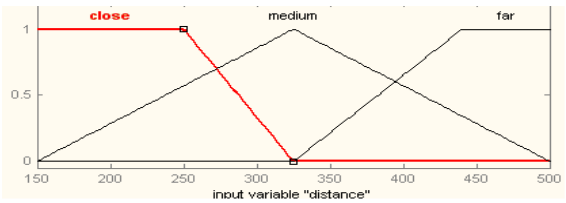
Fuzzy function acquires the radius in terms of these two variables with the help of fuzzy rules. Thus, if energy is high and distance is close, radius will be become larger. Energy consumption for data transmission to the base station is low in those sensors, so large radius is considered in order to have a bigger cluster. On the other hand, if energy is low and the distance is far, radius is considered too small. The used fuzzy rules to calculate the radius are shown in table 1 and fuzzy sets are shown in figure 1.

TABLE I. FUZZY IF-THEN RULES FOR RADIUS

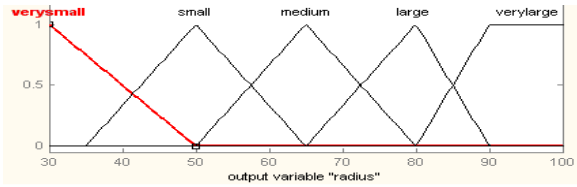
Energy	Distance	Radius
1-low	Far	Very small
2-low	Medium	Very small
3-low	Close	Small
4-medium	Far	Small
5-medium	Medium	Medium
6-medium	Close	Large
7-high	Far	Medium
8-high	Medium	Large
9-high	Close	Very large



1-a) energy



1-b) distance



1-c) radius

Figure 1. fuzzy sets for radius

2) Calculating the chance for sensors with the help of fuzzy rules

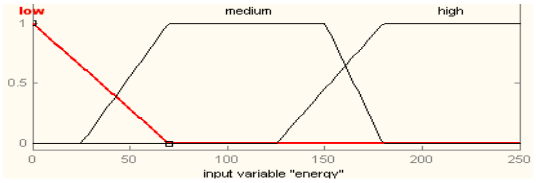
After determining the radius for the sensors, the amount of chance to be cluster heads is calculated. To calculate the chance in terms of fuzzy rules, the following two variables are used:

- Energy: the remaining energy of the sensor.
- Neighbor: the number of neighbors in the sensor radius.

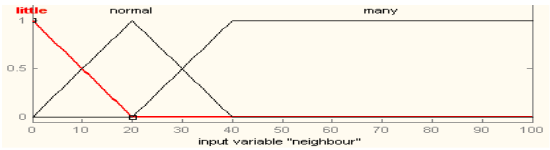
In this protocol, sensors, which contain high-energy and a great number of neighbors, have more chance to become cluster head, because these sensors are able to manage large clusters. Considering the number of neighbors will result in minimizing the number of cluster heads. Energy consumption is more in cluster heads; therefore, it reduces energy consumption in the network. The used fuzzy rules for chance calculating are shown in Table 2 and fuzzy sets in Figure 2.

TABLE II. FUZZY IF-THEN RULES FOR CHANCE

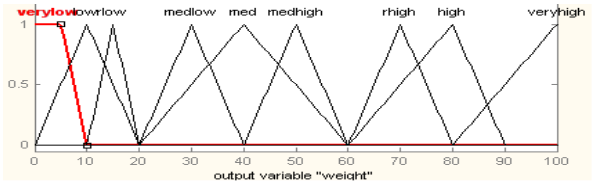
Energy	Neighbor	Chance
1-low 2-low 3-low 4-medium 5-medium 6-medium 7-high 8-high 9-high	Little Normal Many Little Normal Many Little Normal Many	Very low Low Rather low Med low Med Med high Rather high High Very high



2-a) energy



2-b) Neighboring sensors



2-c) chance

Figure 2. Fuzzy sets for the chance

3) *Eelecting cluster head and clustering*

After determining the radius and calculating the chance using fuzzy rules, cluster heads should be elected. A sensor with maximum chance is elected as a cluster head. Each sensor searches the area within its radius for maximum chance. If there is no sensor with more chance, the sensor elects itself as the cluster head and broadcasts the advertisement message to the network. Other sensors, after receiving the message, inspect that if they place within several cluster heads limits, they choose the nearest cluster head as their cluster head and send the Join message to it.

IV. SIMULATION

In this paper, the provided protocol and LEACH and EECS protocols have been simulated using MATLAB. For this purpose, a 300m × 300m network is considered. Sensors are uniformly distributed in the network. The position of the base station is in the 150m × 450m in the network. Initial energy is 0.5 J for each sensor. The test values for Eelec, ε fs, ε mp and E DA is respectively considered 50 nJ/bit, 10 pJ/bit/m2, 0.0013 pJ/bit/m4 and 5 nJ / bit / signal. In Figure 3, the average of live sensors (node) in the network is shown with scenarios (different cases), 100,200,300,400, and 500 sensors. As we can see, the average of live sensors in proposed algorithm is more than the LEACH and EECS algorithms because in the proposed algorithm, cluster heads and the size of clusters are selected in terms of fuzzy rules; as a result, load is optimally distributed.

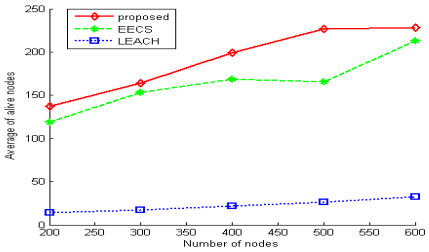


Figure 3. the average of live sensors in the network with scenarios, 100,200,300,400 and 500 sensors

In Figure 4, the average energy of total network is shown with scenarios, 100,200,300,400 and 500 sensors. As we can see, the average of the network energy in the proposed algorithm is more than LEACH and EECS algorithms because in the proposed algorithm the sensors radius is determined in terms of fuzzy rules; therefore, the far cluster heads lose their energy slower. In addition, the best sensors are selected as cluster head.

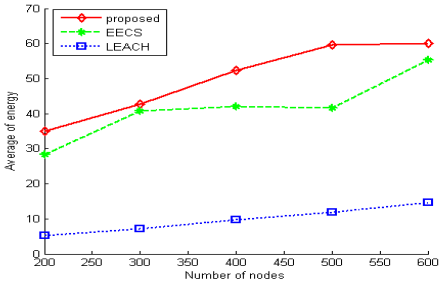

Figure 4. Average energy network with scenarios, 100,200,300,400 and 500 sensors

In figure 5, the average number of sent packets to the base station in network is shown respectively in the proposed algorithm and EECS and LEACH algorithms.

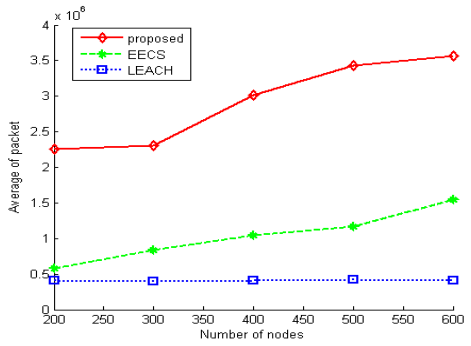

Figure 5. Average number of sent packets to BS with scenarios, 100,200,300,400 and 500 sensors

In figure 6, number of cluster heads in the network with 100,200,300,400 and 500 sensors is shown respectively in the proposed algorithm and EECS and LEACH algorithms. As we can see, the number of the cluster heads is higher than the proposed algorithm.

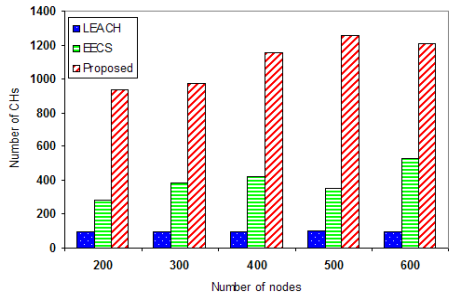

Figure 6. number of cluster heads of in the network with scenarios, 100,200,300,400 and 500 sensors

In figure 5, the first dead sensor based on number of round in the network with 100,200,300,400 and 500 sensors is shown respectively in the proposed algorithm and EECS and LEACH algorithms. As we can see, in the proposed algorithm, the network loses its first sensor slower than the EECS and LEACH algorithms.

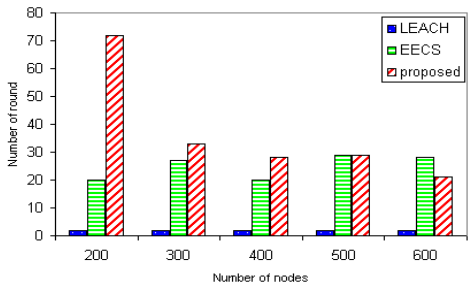

Figure 7. The first dead sensor based on number of round

V. CONCLUSION

In this paper, a protocol has been presented for the selection of cluster head using fuzzy logic. In this protocol, using fuzzy logic, a radius is considered for each sensor. Then with the help of fuzzy rules, Cluster Heads are chosen based on the variables such as remaining energy and the number of neighboring sensors within the related radius. Since energy consumption is high in cluster heads, selecting them based on energy will result in having enough energy to perform and avoiding rapid discharge energy.

Determining the radius in terms of fuzzy rules for the sensors also helps to obtain the number of neighbors within the radius. In addition, the size of the clustering is limited to the radius. Therefore, large clusters can be formed nearer than the small clusters to the base station. Thus, the proposed protocol reduces the energy consumption and increases the network lifetime. Simulation results confirm that the proposed protocol performs better than the LEACH and EECS protocols in terms of energy consumption and lifetime.

Abstract - *The article presents a method for obtaining the contour of an object in real time from not binarized images and for objects that can be assembled on line in automated manufacturing processes. The contour information is integrated into a descriptive vector called [BOFnew], which is used by a neural network model of the type FuzzyARTMAP to test the feasibility of the method using the generated contour to learn of the object and then recognize it later To this end, it requires a fast and robust method to acquire process and communicate to a robot the information about positioning and orientation of an object for assembly purposes. The used algorithm and its simulation was developed in MatLab 7.0.*
Having this method for object recognition manufacturing tasks improves this methodology and allows the implementation of these algorithms in FPGA´s, which gives in manufacturing cell a real possibility performance demanded by industrial environments.

Keywords: robot, vision, manufacture, FPGA

1 Introduction

The process of locating and recognizing an object to perform fixtureless robotic assembly tasks in line and in an intelligent manufacturing cell, is an open research goal, since they are obvious advantages with using robots in assembly lines, and the automation of industrial processes (DeSouza 2002). In order to perform autonomous assembly operations in manufacturing processes, requiring high levels of accuracy, robustness and speed of operation, this vision machines are very useful to the be used as a sensory robot capability because they make it possible to close the mesh of control for the calculation of the POSE of the end effector of a robot (Hutchinson, 1996), the importance of the issue is demonstrated in the application performed by Bone and Capson (2003) for the assembly of components online in the automotive industry.

Recognition, tracking in real time and the estimation of the POSE of an industrial object using methods based on geometric characteristic is shown by Yoon and DeSouza (2003), in these applications, the speed and accuracy are primordial factors of the order of milliseconds (commercial video box) with errors of an estimation of millimeters in the operation; as a successful alternative methods based on the use of primitive characteristics based on silhouettes allow to satisfy these requirements (Miller et. to the.)(2003); There are numerous approaches in the area of image processing to recognize and locate objects, like using descriptors of chain codes (Bribiesca, 1999), use of invariant features of silhouettes (format watery et.al., 2002), artificial intelligence techniques as neural network to implement systems for the classification of patterns invariant to scaling, translation, and rotation (Andüceer and Oflazer, 1993) and intelligent manufacturing systems guided by vision (Langley)(, et.al., 2003). On the other hand, much effort has been focused on the development of effector right-handers mounted on the end terminals of robots manipulators (Bicchi and Kumar, 2001).

The article, presents an algorithm which allows to obtain the POSE of an object in an assembly line based on extracted information of an acquired image in real time, the centroid calculation is performed, which in our method is basic information for the recognition of the object and its orientation obtaining critical points within an image to represent the border/contour points border and the centroid of the object; a set of numerical sorted pairs, is generated by the algorithm, and form the basis for the formation of an object descriptive vector (Current Frame Descriptor). Descriptor vector is presented to a neural network of the type Fuzzy ARTMAP (Carpenter, 1991); This integrated process concludes a process of learning online; new vectors calculated with new images, refine the learned information thereby obtained a process of incremental learning thanks to the strength and rapidity of the neural network model used; in order to make more robust in terms of lighting and speed, the method performs an analysis of the 1D histogram to calculate threshold levels of gray scale for optimal segmentation of the image with different conditions of illumination, 2D histogram might be used to obtain the region of interest (ROI) and make the process of descriptive vector generation of the object with a lower

resolution and therefore faster, the integration of the algorithm with neural network, makes the method substantially a robust process with characteristics of invariance for its real application environments in manufacturing processes.

2 Methodology

The process begins with the acquisition of the image in gray levels of the object, then the distribution frequency of grey levels within the image (histogram 1D, Figure 3), to establish the levels of comparison, an "Operator Threshold" is used for image segmentation, then a binary image process is carried out within a certain dynamic range for lighting to obtain a silhouette of the object. In order to reduce processing time, the algorithm that generates the descriptive vector (CFD), applies only on the region of interest (ROI), which can be obtained on the basis of the 2D histogram. In this way, with the 1D histogram analysis are obtained the criteria of segmentation to generate the binary image and with the 2D histogram for spatial distribution of gray levels information in order to reduce the resolution of the image.

Once you have an image of the ROI, the method proceed to obtain a primitive binary image (PbinIm), which serves as a basis for the necessary information for calculating the POSE; applying the algorithm, we obtain a set of ordered pairs of critical points in the image used to generate information of the object containing the properties of invariance for rotation, translation and scaling as well as the centroid of the upper surface and orientation with reference to the NN point (North).

This information represents a model as a vector CFD vector with the information needed to extract properties that allow to recognize the object.

2.1 1D and 2D histogram

The 1D histogram shown in Figure 1, allows to know the frequency distribution of grey levels of an image (probability density function).

A model of an image is:

$$\mathrm{Im} = f(x, y) \tag{1}$$

for a range of grey levels:

$$0 \le Gl \le L - 1 \tag{2}$$

where Gl is the gray level of each point in the image as:

$$\exists Gl(i, j) \in \mathrm{Im}(xi, yj)$$

where

$$Gl(i, j) = 0, L - 1, \forall i, j = 1, N \tag{3}$$

1D Histogram methods, provide a selection of peaks or valleys using a Bayesian estimation of the probability density function of grey levels in the image or with a numerical analysis of the histogram for image segmentation (Sahoo et al., 1988); in our case, segmenting the image means separating the elements of interest for the computation of parametric or not/parametric properties, by providing us with the separation of desirable segments in the image for the subject and background, and a further segmentation separates the parts to acquire orientation information. On the other hand, traditionally optimization continued to obtain comparison thresholds are based on criteria attached to the variance and the entropy of the distribution of colors in the image, but they provide greater computational consumption in processes (Pun, 1981).

Having a grayscale levels image F(x,y) with MxN pixels, where lower numeric values represent the most dark colors and higher values the clearest colors, a function called "1D Thresholding Function" can be obtained as follows:

$$F_T(x, y) = \begin{cases} bo \text{ if } f(x, y) \le T \\ b1 \text{ if } f(x, y) > T \end{cases} \tag{4}$$

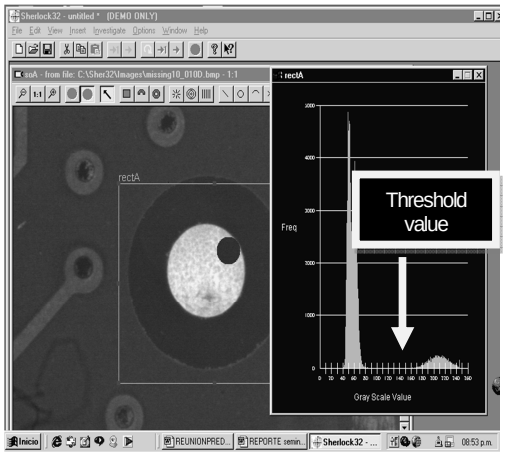

Figure 1 - 1D Histogram

The 2D histogram is used to represent the probability of the co-occurrence of two values of gray levels when their corresponding pixels are separate at a specific distance. It can be defined as a matrix H_{2d} containing information of the grey level of each pixel and the level of grey average in the vicinity of a pixel within the scale used, i.e.:

$$H_{2d} = \begin{cases} r_{i,j} / r_{i,j} = number\ of\ bin(i,j), \\ 0 \le r_{i,j} \le MN, \\ i, j = 0,1,2,...,L-1 \end{cases} \quad (5)$$

where MN is the size of the image, and where the local averages values represent the spatial information, without having a representation of the precise point of information that reflects every pixel, but if it allows to get an idea of the spatial distribution of the pixels associated with certain regions in the image base for the criterion of the definition of the ROI (Ahuja et al., 1978). The value of the local average in a window of small dimensions (2w + 1)2 centered in a pixel (x, and), is defined as:

$$g(x,y) = 1/(2w+1)^2 \sum_{k=-w}^{w} \sum_{l=-w}^{w} f(x+k, y+l) \quad (6)$$

where

$$\begin{Bmatrix} x = 1,2,...., M \\ y = 1,2,..., N \end{Bmatrix}$$

and thus gets a 2D Thresholding Function f(T,S_) defined as:

$$f(T,S)_{(x,y)} = \begin{Bmatrix} bo, \text{if } f(x,y) \le T \vee g(x,y) \le S \\ b1, \text{if } f(x,y) > T \wedge g(x,y) > S \end{Bmatrix} \quad (7)$$

where

$$0 \le bo, T, b1 \le L-1$$

and (T,S) is a 2D comparison vector.

2.2 Algorithm [CFD & POSE]

The algorithm for the descriptive vector generation, called [CFD & POSE] is shown below and is illustrated by an example of a 32 x 32 image resolution rectangle showed in Figure 2.

Of the original image, a data structure is obtained, and using the above explained process, to determine of comparison thresholds to binary operation and the ROI (Figure 3), [CFD & POSE] algorithm is applied that uses a transformation we call *Weight Matrix Transformations* as follows:

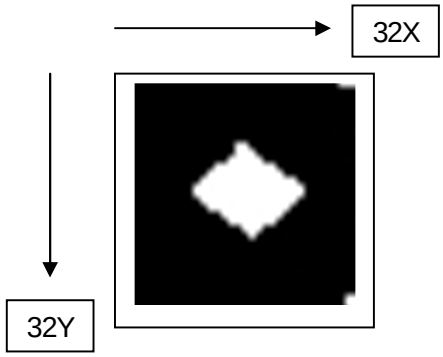

Figure 2 - 32 x 32 resolution original square image to generate a descriptive vector.

Apply the Weights Transformation Matrix of (HWf), calculation of numerical ordered pairs and generation of vector Vx (m) and Vy (m), this process allows boundary points and centroid information generation very fast.

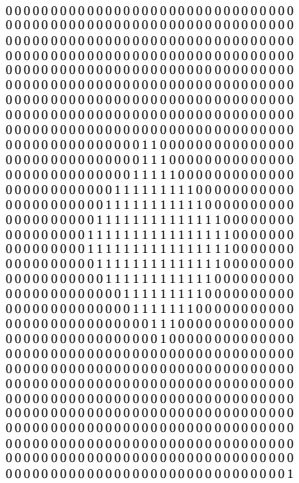

Figure 3 - Binary image

2.3 Weight Factor Matrix Transformation

This transformation get an array with numerical values in the image according to its weight and on the basis of a binary image, each numerical value is related to a couple of coordinates to establish its location, the weight number is defined as:

$$number\ \ NWf \rightarrow \left[numericalp\ aircooordi\ nates \right]$$

Where

$$NWf\min \le \sum(1's)\ en\ (\text{kxk})\ Kernel \le NWf\max \quad (8)$$

where k = 3 and numbers are obtained between:

$$0 \le NWf \le 9 \quad (9)$$

the image shown in Figure 4 is obtained, which is the transformation of the binary image to an image with the representative of the centroid and contour weights; from collection of numbers, we find the Median of Nwfmax provides the centroid of the object and the NWf min the extreme points of the outline of the object.

Numerical ordered pairs and vector Vx (m) and Vy (m) calculation

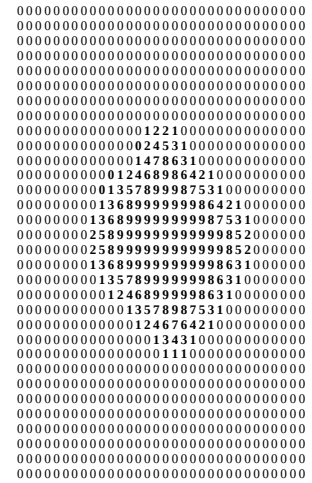

Figure 4 - Image with representative weights for centroid and border points.

Following the algorithm for calculating the numerical pairs of coordinates and vectors Vx (m) and Vy (m) is showed, image scanning is left-right and top-down directions.

- Find a different number of zero and save it as a minimum.
- Stores X and Y coordinates in vectors Vx (m) and Vy (m).
- Progresses, if new number greater than the previous save it as a maximum, and retains the minimum.
- Progresses, if new maximum number greater than the largest stored, save it as bigger and if less than the smaller stored, save it as a minor.
- Store the minimum of minimum and maximum of maximum as well as the possible number of them.

Application of the transformation of matrix of weights (HWf) proceeds as follows:

- Calculation of numerical ordered pairs and obtain vector Vx (m) who (m)
- Border points extraction and centroid.
- Among the number of maximum´s, get the coordinates of the median of the related coordinates.
- Border points and centroid extraction.

Applying the algorithm, the vectors containing the coordinates of X and Y, and the contour points are accumulated in vectors that we call:

$$vectorX\ (m) = \{x0, x1, x2, ... xn\}_{NWf\ \min}$$

and :

$$vectorY\ (m) = \{y0, y1, y2, ... yn\}_{NWf\ \min} \quad (10)$$

For the showed rectangle image ROI of 32 x 32, the boundary points for the X´s and Y´s are:

Array

(Xm)={15,18,14,19,13,20,12,21,11,22,9,23,24,9,24,10,24,11,23,12, 22,13,21,20,14,19,15,18}
Array
(Ym)={9,9,10,10,11,11,12,13,14,14,15,16,17,18,18,19,19,20,20,22 ,22,23,23,24,25,25,26,26 }

the calculation of centroid grouping all the maximum points for X-Y´s as follows:

$$Xc = {}^{1}\!/_{No}\,.NWf_{\max - X}\left[\sum NWf_{\max - X}\right]$$
$$Yc = {}^{1}\!/_{No}\,.NWf_{\max - Y}\left[\sum NWf_{\max - Y}\right] \quad (11)$$

and for the case example, the centroid is at: C = (Xc, Yc)xy(16,17) (13)

outline coordinates in the example are: Contour = {(15.9), (18.9),..., (18,26)}, then having the coordinates of the border points and the centroid, border distances are calculated, in an order defined in a clock wise direction (CW), and we can get a border points function that we call *Boundary Object Function* (BOF) with:

$$Dn = \sqrt{(X2 - X1)^2 + (Y2 - Y1)^2}$$

$$\forall \quad 0 \le n \le \text{tamaño(angular grid)} \quad (12)$$

The process is illustrated in Figure 5, on the basis of the original rectangle image until a BOF table. Is generated.

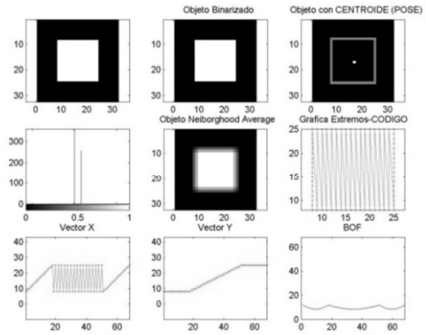

Figure 5 - Process for obtaining of the Boundary Object Function for the rectangle.

The descriptive vector is then formed with the previously calculated distances that are normalized to have independence of scaling, which defines a grid/angle for the border function points BOF, with normalizes n points, and where each of these points in the angular grid represents the degrees which form the angular increase for each standard step. Angular position of the object of 180º rotation represents a move of 90 steps on angular grid in the direction CW.

2.4 A new method using an angular scanning of the objects obtained from not binarized images

The descriptor is a vector of values that represent certain characteristics of an object as the nth distance that exists between the centroid and a border point of the object. In such a way that no matter the position, scale and rotation of an object, its descriptive vector is always the same. Calculate the BOF of an object, is part of a method by (Peña and Lopez 2006) for the recognition of objects on line for assembly of parts with robotic arms.

To calculate the BOF with the new method we have the following considerations:

- image processing is a simulation of an object.
- set image size is 100 x 100 pixels
- is a solid and filtered image with values in each pixel of 255 for white and 0 for black.
- The region of interest (ROI) has been established to focus on the object in the image.

Procedure to calculate the BOF with this method:

I. Calculate the centroid of the image

II. From the centroid define a straight line trajectory

$$y = \tan(\varphi n)x + b_0 \qquad (13)$$

where φn is an angle that varies from 0 to π, and b_0 is the ordered to the source that is based on the angle φn, and x are the matrix index of the image and represent the position of a pixel (figure 6).

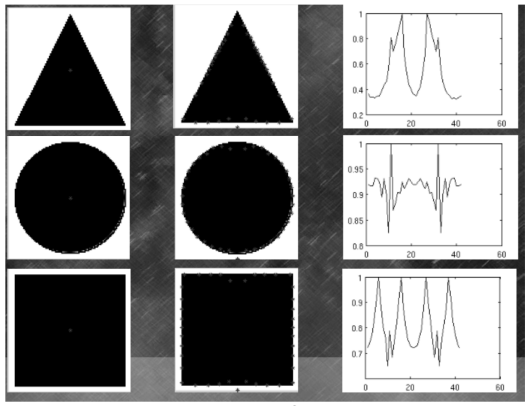

Figure 6 - A generated BOF for a square object with different grid resolution

A tentative resolution, *pre*, was defined as 0.1; it means 22 points. Which give a very low resolution that could confuse the ANN. Remember, in time computers topic, more points imply more resolution therefore more spent computer calculation time. Then variable pre was set in 0.01 with 202 points (figure 7).

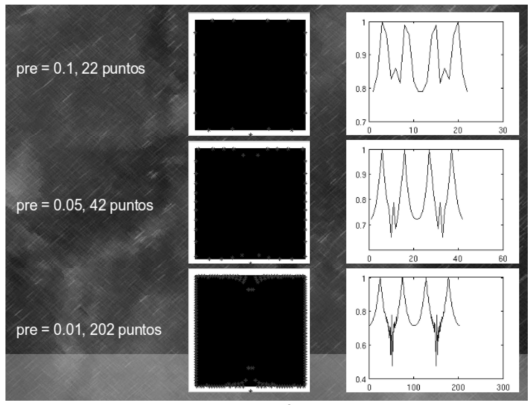

Figure 7 A generated BOF for a square object with different grid resolution

III. According to the trajectory, each pixel is evaluated and if its value is 255 returns to position x - 1 back to calculate the coordinate which will be the border pixel.

IV. The distance of that point border to the centroid is calculated with the equation:

$$Dn = \sqrt{(X2 - X1)^2 + (Y2 - Y1)^2} \qquad (14)$$

$$\forall \quad 0 \leq n \leq \text{size(angular grid)}$$

V. The distance Dn is storing in the BOF [n] vector

VI. Φn with precision p increases.

VII. Repeat steps 2 to 7 until φn reaches the value of π. To determine the best accuracy, for our purposes we change the variable *pre's* as shown in Figure 6.

2.5 FPGA implementation. First approximation process

Since there are some works around ANN implemented on FPGA (Liu, 2005) it is important to standardize and format the inputs and outputs. Thus, the late described method represents an effortless way to calculate BOF in logic design level.

A 2D image is a integer matrix with index i and j and supposing that the centroid is well known, the implementation of equation (13) in VHDL (VHSIC hardware description language) is simple.

3 Conclusions

The algorithm presented to calculate the BOF is an original idea that seeks to make a proof of concept and an assistant to train and qualify RNA for assembly object recognition purposes. To tracking pixel to pixel is not necessary a binarization process for the image. We realize the method is efficient, but might be improved in some aspects like due to the possibility that in the border point tracing procedure might catch more than one pixel. Arriving the 90 and 270 degrees, the slope of the line is so great that the advance from pixel to pixel exceeds the 4/1 ratio in x, which causes that border point found can be far away of the border. This was corrected improving the algorithm to the limits to 90 and 270 degrees an improved figures are shown in figure 8. At the same time, the error committed with pixel tracking, specifically on the slopes close to 90 and 270 degrees can be minimized increasing the resolution of the image. It is also possible to modify the algorithm of the BOF following an upward and downward trajectory for 90 and 270 degrees respectively. As for the RNA stands that largely reaches to recognize images that occur when train you with three basic figures. Even though it modifies the image resolution to recognize, succeeds in a 66.6% the only failing is the circle. However it worthwhile to perform the experiment again with other figures to dispose of the problem of the non-recognition is due to intrinsic characteristics of a circle as for example their distances to the centroid are constant, but the BoF presented here shows some noise Figure 8.

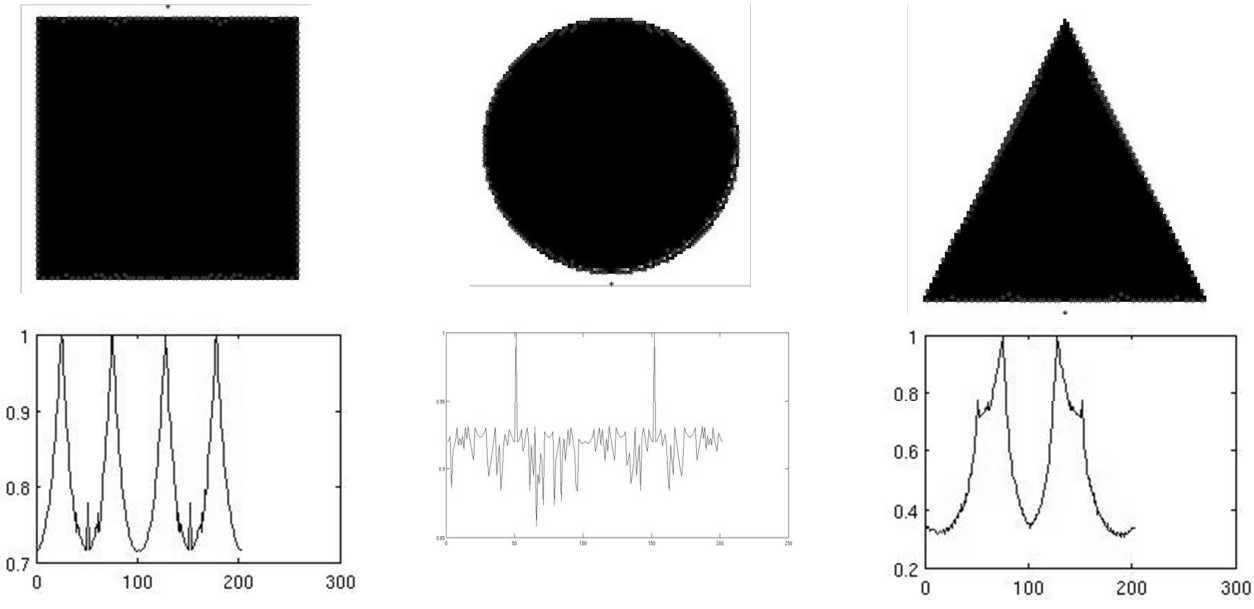

Figure 8 generated BOF for a triangle, circle and square objects and improved process

A sEMG-SKELETAL MUSCLE FORCE DATA FUSION BASED ON MINIMUM DESCRIPTION LENGTH CRITERION

Madhavi Anugolu, Chandrasekhar Potluri, Steve Chiu, Alex Urfer, Jim Creelman and Marco P. Schoen

Abstract–*This paper provides a method of fusing the sEMG/skeletal muscle force sensor array data using a Minimum Description Length (MDL) data fusion algorithm. The sEMG data and the corresponding skeletal muscle force data are acquired from a test subject. A nonlinear Bayesian Half-Gaussian filter is utilized to filter sEMG data and the skeletal muscle force signal is filtered by using a Chebyshev Type-II filter. A System Identification Technique is employed to derive the mathematical relationship between the sEMG (input) and the skeletal muscle force (output) data. We implemented linear and nonlinear parametric- Auto-Regressive with eXogenous input (ARX), Auto-Regressive Moving Average with eXogenous input (ARMAX), Output Error (OE) and Weiner Hammerstein modeling. The estimated model output from the three sensors are combined by using a probabilistic based Minimum Description Length (MDL) fusion algorithm. The results are thought provoking and the overall fused output has better correlation with the actual force when compared with the individual sensor estimated force.*

Keywords: *sEMG, hand prostheses, data fusion, system identification, minimum description length criterion*

I. INTRODUCTION

In the United States, there are more that 2 million amputees and according to the statistics provided by the National Limb Loss information Center, this number will reach 3.6 million by 2050 [1].

Marco P. Schoen is with the Department of Mechanical Engineering, MCERC, Idaho State University, Pocatello, Idaho 83209, USA (email: schomarc@isu.edu).

The etiologies of hand amputations include cardiovascular disease, congential deformities, nerve injuries, tumors, and trauma [2]. Over the past few decades, numerous research and clinical studies have concentrated on the field of prosthetics. Even today, however, most individuals with upper extremity and hand amputations have difficulty acquiring an affordable prosthesis which allows for good functional hand motion. [3] Due to recent advances in technology, a great interest has emerged in the design of a better hand prosthesis controlled by integrated Electromyographic (EMG) signaling. In general, the EMG signal is a composition of action potentials produced by the electrical activity of the muscle groups. This signal depends on the flow of ions such as sodium (Na+), calcium (Ca++), and potassium (K+). These signals can be measured either by inserting the needle electrodes into the muscle tissues or by affixing the surface electrodes to the skin.

In this work, we used surface Electromyographic (sEMG) data since it does not require any surgical monitoring. The sEMG signals can be used in various engineering and clinical applications [4, 5]. One must be careful in analyzing sEMG signal [6]. Especially in engineering application, sEMG can be used to control the position and force of the prosthetic hand [7]. The sEMG signal amplitude varies from person to person and it depends on the applied force. Some other factors like cross-talk from different muscle groups, and biochemical reactions in the muscle fibers influence the sEMG/skeletal muscle force relationship. Therefore, these factors contribute to randomness and complexity of the sEMG signal.

From our particular perspective, it is desirable to combine the data from the array of sensors. So, in this work, we implemented a Minimum Description Length (MDL) criterion to fuse the sEMG/skeletal muscle force data from the three sensors. After collecting the data, the sEMG signals are filtered using a Genetic Algorithm (GA) based nonlinear Bayesian Half-Gaussian filter. The skeletal muscle force data is filtered by using a Chebyshev Type-II filter. Considering the sEMG as input and skeletal muscle force as output, System Identification (SI) technique is utilized to extract the dynamic relationship between the sEMG data and its corresponding skeletal muscle force data. The estimated output models are fused with a probabilistic based Minimum Description Length (MDL) criterion.

II EXPERIMENTAL DESIGN

For this work, the experiments were conducted on a healthy male subject to acquire the sEMG and its corresponding skeletal muscle force signal. Prior skin preparation was done by following the ISEK standards [8]. A muscle point stimulator manufactured by Richmar Corporation™ was used to identify the muscle motor point. For this particular experiment, the ring finger motor location on the flexor muscle was chosen. Fig. 1 illustrates the experimental design. Three sensors were placed on the skin surface, one on the ring finger flexor digitorium superficials muscle motor point and the other two adjacent to it. A Delsys Banglo-16, was used to capture the sEMG signal and the Force Sensitive Resistor (FSR) was used to acquire the corresponding skeletal muscle force signals. Both the signals were acquired through LABVIEW at a sampling rate of 2000 sample/sec.

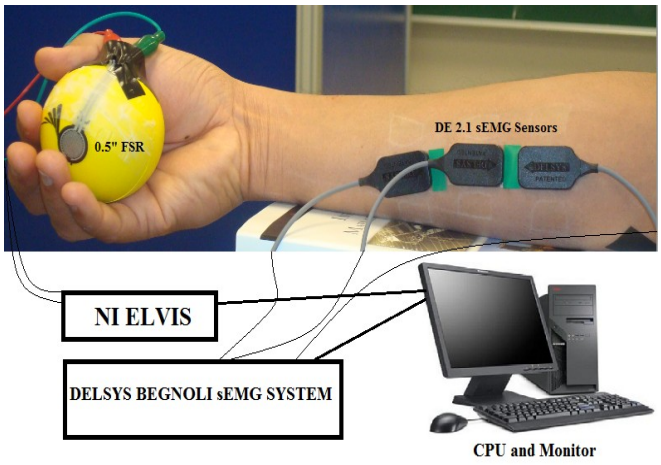

Fig. 1: Experimental Set-up

III. THEORITICAL BACKGROUND

The sEMG data acquired from the surface of the skin is rectified and filtered using a GA based nonlinear Bayesian Half-Gaussian filter. In our previous work [9] we explored different filters for sEMG filtration. We concluded that the Bayesian Half-Gaussian filter works better when compared to other filters like Butterworth, Chebyshev, Bayesian Poisson. As mentioned earlier, sEMG depends on various factors. The relationship between the actual force and the resulting sEMG after filtration can be given by the conditional probability density function $(EMG|x)$. Under the assumption that the conditional probability of the rectified EMG signal is a filtered random process at a random rate the Half-Gaussian filter is given by:

$$p(EMG|x) = 2\frac{exp\left\{\frac{-EMG^{\,2}}{2x^2}\right\}}{\sqrt{2\pi x^2}}\,, \qquad (1)$$

where $p(EMG|x)$ is the conditional probability, x is the latent driving signal, and EMG is the acquired data. According to Fokker-Planck partial differential equation, the likelihood function for the rate evolves in time [10]. The discrete time Fokker–Planck equation is given by (2)

$$p(x,t-) \approx \alpha p(x-\varepsilon,t-1)+(1-2\alpha)p(x,t-1)+ \alpha p(x+\varepsilon,t-1)+\beta+(1-\beta)p(x,t-1) \qquad (2)$$

Here, α and β are two free parameters, where α is the expected rate of gradual drift in the signal, and β is the expected rate of sudden shifts in the signal. The unknown driving signal x is discretized into bins of width ε. These two free parameters (α, β) of the non-linear Half-Gaussian filter model are optimized for the acquired EMG data using an elitism based GA. A Chebyshev Type-II filter with 550 Hz cutoff frequency is used to filter to skeletal muscle force signal.

Linear and nonlinear System Identification Models:

System Identification uses statistical methods to implement the dynamic relationship between the measured input/output data. This is done by altering the parameters within a given model until its output tracks the measured input, [11]. System identification is an alternative to the physical based modeling [11]. In this work, linear parametric models- Auto-Regressive with eXogenous input (ARX), Auto-Regressive Moving Average with eXogenous input (ARMAX), Output Error (OE) and nonlinear models- Wiener Hammerstein are implemented

The output error model structure is

$$y(t) = \frac{B(q)}{F(q)}u(t-n_k) + e(t) \qquad (3)$$

The ARX model is a random process. It predicts the output based on the previous output. Its mathematical notation is given by equation (4)

$$A(q)y(t) = B(q)u(t-n_k) + e(t) \qquad (4)$$

Based on the given data, the ARMAX model predicts the future values in a series. The mathematical notation is given by Equation (5). It consists of two parts, the autoregressive part and the moving average part.

$$A(q)y(t) = B(q)u(t-n_k) + C(t)e(t) \qquad (5)$$

In Equations (3), (4) and (5), y is output, t is time, $B(q)$, $F(q)$, $A(q)$, $C(q)$, $D(q)$, are polynomials, q is a backward shift operator, u is input, nk is delay and e is error

Nonlinear Wiener Hammerstein

A model with a fixed nonlinearity at the input is called a Hammerstein model. When the nonlinearity is at the output is called a Wiener model. The combination of these both is the Wiener-Hammerstein model, [11]. The structural representation of the Weiner- Hammerstein model is given in Fig. 2, [12]. It consists of two nonlinear blocks with a linear block in series.

Fig. 2: Weiner-Hammerstein model structural representation

The mathematical depiction of the modeling is given by,

$$w(t) = f(u(t)) \quad , \tag{6}$$

$$x(t) = \frac{B_{j,i}(q)}{F_{j,i}(q)} w(t-nk) + e(t) \quad , \tag{7}$$

$$y(t) = h(x(t)) \quad , \tag{8}$$

where $u(t)$ is the sEMG signal and $y(t)$ is the skeletal muscle force signal. f and h are nonlinear functions, $w(t)$ and $x(t)$ are internal variables, $B_{j,i}(q)$ and $F_{j,i}(q)$ are polynomials, q is the back shift operator, and $e(t)$ is the output error.

Minimum Description Length (MDL) Criterion

In 1978, the Minimum Description Length (MDL) concept was introduced by Jorma Rissanen [13]. The fundamental idea behind the MDL principle is based on the algorithmic complexity of Solomonoff, Kolmogorov and Chaitin [14]. In this work, we are inspired by [15] and used the Minimum Description Length criterion to fuse the estimated models. It is given by

$$MDL(p_i) = \frac{n}{2}\log(\hat{\sigma}_i^2) + \frac{p_i+1}{2}\log F_i + L_i \quad , \tag{9}$$

where $F_i = (Y^T Y - R_i)/(p_i \hat{\sigma}_i^2)$,

$$L_i = \frac{1}{2}\log(\frac{n-p_i}{p_i^3}) \quad ,$$

$$\hat{\sigma}_i^2 = {R_i}/{(n-p_i)} \quad .$$

Based on [9 and 15], the following fusion algorithm is implemented for sEMG-skeletal muscle models.

1. Identify the models $M_1, M_2 \ldots M_k$ using sEMG data (u) as input and fingertip force data (y) as output, for k number of sEMG sensors.
2. Calculate the residual square norm

$$R_i = \left\|y - \Phi_i \hat{\theta}_i\right\|^2 = \left\|y - \hat{y}\right\|_2 \text{ where } \hat{\theta}_i = \left\{\Phi_i^T \Phi_i\right\}^{-1} \Phi_i^T y \quad ,$$

and $\vec{\Phi} = \begin{bmatrix} y_p^T & u_p^T & y_{p-1}^T & \cdots & \\ & u_{p+1}^T & y_p^T & \cdots & \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ y_{n-1}^T & u_{n-1}^T & y_{n-2}^T & \cdots & \end{bmatrix}$

3. Model criteria coefficient is calculated using Equation (9).
4. Compute the model probability as given by

$$p(M_i \mid Z) = \frac{e^{-l_i}}{\sum_{j=1}^{k} e^{-l_j}} \quad , \text{ where } l \text{ is the model selection criteria coefficient, i.e.}$$

5. Compute the fused model output $\hat{y}_f = \sum_{i=1}^{k} p(M_i \mid Z)\hat{y}_i$

RESULTS AND DISCUSSION

Fig 3. shows the raw sEMG data acquired from the surface of the skin Vs the sEMG filtered data by using Bayesian Half-gaussian filter.

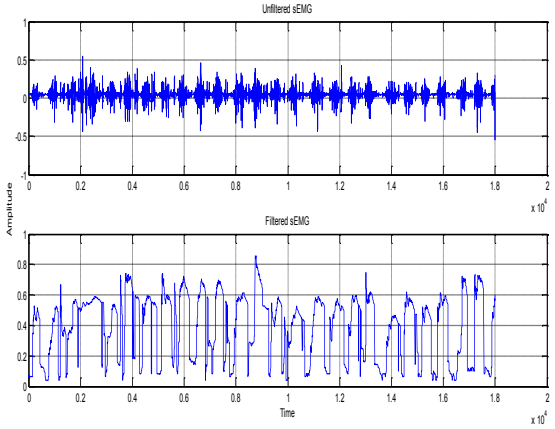

Fig.3: Raw sEMG data Vs filtered Data

Fig. 4 depicts the actual skeletal muscle force data Vs the filtered force data using Chebyshev type-II filter.

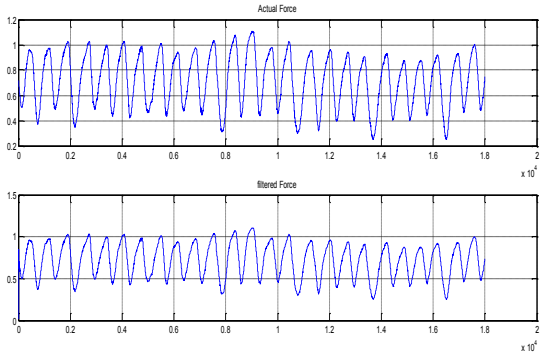

Fig. 4: Actual force and filtered force using Chebyshev Type-II filter

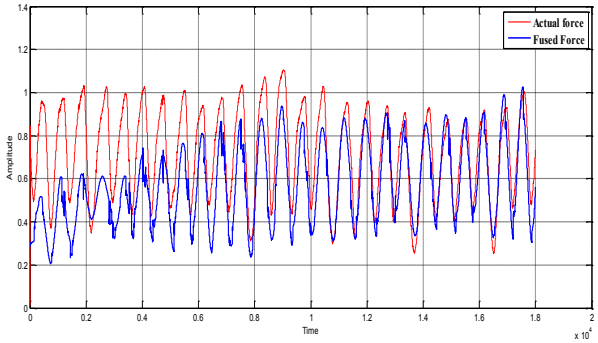

Fig. 5. Actual force and the overall estimated force for the Output Error (OE) Models

TABLE I: INVIDUAL ESTIMATED LINEAR PARAMETRIC MODELS AND THE OVERALL FUSED OUTPUT

SI Models	M_1	M_2	M_3	$\hat{Y}_f$
ARX	12.77	17.57	33.5	43.2
ARMAX	11.6	14.6	35	46.1
OE	54.42	60.39	64.96	75.6

Table I gives the individual estimated model correlation values (M_1, M_2, M_3) of the three sensors. $\hat{Y}_f$ gives the overall fused force correlation values for the linear parametric models. The individual models are computed by using the SI technique - ARX, ARMAX, OE. In all the cases, the values are high for M_3 which is the estimated model output for the sensor placed on the motor unit. All the three models are fused by using the above proposed Minimum Description Length based fusion algorithm. Even thought, the fusion algorithm shows improvement in the overall correlation value, the proposed fusion algorithm worked best for the linear Output Error (OE) models.

TABLE II: INVIDUAL ESTIMATED NONLINEAR MODELS AND THE OVERALL FUSED OUTPUT

SI Models	M_1	M_2	M_3	$\hat{Y}_f$
WH	52.37	56.8	60.35	70.32

Table II gives the individual estimated nonlinear Wiener Hammerstein models and the overall fused output using a MDL criterion based fusion algorithm. Fig 5 gives the plots of the actual skeletal muscle force and the overall fused output from the MDL fusion algorithm for OE models.

IV CONCLUSION AND FUTURE WORK

In this paper, we addressed a methodology to fuse the sEMG/skeletal muscle force data using a Minimum Description Length (MDL) criterion based fusion algorithm. Compared to the individual estimated models, the fusion-based output is showing improvement in correlation with the actual force.

In the future, we are planning to implement the same criteria for the spectral models [17] and to work on larger data sets and apply this proposed fusion algorithm to them for generalization.

Distributed Graph-Partitioning based Coalition Formation for Collaborative Multi-Agent Systems

Some Lessons Learned and Challenges Ahead

Predrag T. Tošić
Department of Engineering Technology and Department of Computer Science,
University of Houston, Houston, Texas, USA
pedja.tosic@gmail.com

Abstract - *We study algorithms for distributed collaborative multi-agent coalition formation. The focus of our recent and ongoing research has been on coalition formation via scalable distributed graph partitioning of the underlying agents' communication network topology. In that endeavor, we have been analyzing, simulating and optimizing our original graph partitioning algorithm called* Maximal Clique based Distributed Coalition Formation (MCDCF). *MCDCF is a fully distributed graph partitioning algorithm that was designed in a topology-independent manner, the only requirement being that the underlying graph be relatively sparse, which is a realistic assumption in most applications of our interest. In the present paper, we summarize our recent experimental findings on the performance of our algorithm on specific types of graph and draw some general lessons from those results. In particular, we focus on comparison and contrast between the MCDCF behavior on* small-world networks *and on* Erdös-Renyi random graphs. *We draw several insights from the considerable differences in MCDCF performance on these two types of underlying graphs (even when the underlying average densities or even node degree distributions are the same), identify key areas for further improvement, and outline some challenges ahead.*

Keywords: distributed algorithms, distributed AI, multi-agent systems, coalition formation, graph partitioning

1 Introduction and Motivation

We study, devise and analyze scalable distributed algorithms for challenging and important coordination problems in *Distributed Artificial Intelligence* (DAI), specifically, for medium- to large-scale collaborative multi-agent systems (MAS). We are interested in ensembles of artificial agents such as softbots, robots, unmanned vehicles or smart sensors that are autonomous, capable of sensing the environment, acting to affect changes in that environment, and also communicating and coordinating with each other. The communication and coordination capabilities enable such agents to self-organize in order to accomplish complex resource-demanding tasks that in general may exceed the computational, sensing and/or acting capabilities of the individual agents.

We have been particularly interested in mechanisms and protocols that enable large ensembles of such autonomous agents to coordinate with each other in a *fully decentralized* manner. The kinds of agents we have in mind are commonly referred to as *distributed problem solvers* in Distributed AI literature (e.g., [2, 21, 28]).

Among various interesting problems in distributed coordination and control of such agent ensembles, we have been extensively studying genuinely autonomous, fully distributed, dynamic multi-agent *coalition formation* [15-18]. We have designed a fully distributed, scalable and robust coalition formation graph algorithm named *Maximal Clique based Distributed Coalition Formation* (MCDCF) [15].

In the present paper, we build on the top of our earlier work on MCDCF [15-22], summarize and interpret our recent simulation results on the small-world and the random graph underlying network topologies, discuss possible reasons behind considerable differences in performance of our algorithm on these two types of topologies, identify some areas for further improvement, and outline future research directions. The rest of this paper is organized as follows. In Section 2, we motivate the problem of multi-agent coalition formation, briefly review the most relevant prior art, and describe our specific problem setting. In Section 3, we briefly describe how the MCDCF algorithm works. In Section 4, we summarize and discuss our simulation results when MCDCF is run on three sub-classes of small-world graphs. Section 5 summarizes and discusses our simulation results on Erdös-Renyi random graphs. In Section 6, we provide a brief comprehensive performance comparison-and-contrast on these two types of graphs. Section 7 summarizes the paper and outlines some challenges ahead.

2 Distributed Coalition Formation

Distributed coalition formation in multi-agent domains is an important coordination and collaboration problem that has been extensively studied by the MAS research community [1,

2, 8, 10-12, 15-20]. There are many collaborative MAS applications where autonomous agents need to form temporary groups or coalitions. Reasons behind multi-agent coalition formation may vary. In the context of *Distributed Problem Solving* (DPS) collaborative agents, possible motivations include resource sharing, dividing-and-conquering tasks that exceed the abilities of individual agents, and/or to improving some system-wide performance metric such as the speed of joint task completion [7, 12, 17].

In most research on multi-agent coordination and coalition formation, limitations on local computational and communication resources, as well as on each agent's local knowledge of the world around it, have been explicitly incorporated into the models and algorithms in order to make the proposed approaches realistic and relevant to the real-world distributed coordination problems; see, e.g., [8, 9]. The common formal framework for studying coalition formation is that of distributed constraint satisfaction or optimization (DCS or DCO, resp.). For a general overview of these important techniques, see e.g. [27, 28]; for a recent DCO-based work on coalition formation, see e.g. [23]. We remark that our distributed graph partitioning approach can be readily phrased in DCS/DCO terms, as well, as discussed in [16, 17]. For brevity and simplicity of notation, in this paper (as well as the two papers that are the immediate predecessors to the present work, [21, 22]), we avoid DCO formalisms and stick to graph-theoretic terminology and notation.

One well-studied general coalition formation domain is a collaborative multi-agent environment populated with a variety of distinct, mutually independent tasks, where each task requires a tuple of resources on the agents' part in order for the agents to be able to complete that task [10 - 12, 17-18]. In this *distributed task allocation* context, agents need to form coalitions such that each coalition has sufficient cumulative resources or capabilities across the coalition members in order to be able to complete the assigned task(s).

We study the problem of distributed coalition formation in the following scenario. We assume a collaborative multi-agent, multi-task dynamic and partially observable environment. The tasks are atomic (that is, a task has either been completed or it has not; we don't consider partial task completion) and *mutually independent* of each other. In general, different tasks may have different values or utilities associated with them. Moreover, the utility of a particular task may be differently perceived by different agents. This problem setting is particularly appropriate for many MAS applications involving *team robotics* and *autonomous unmanned vehicles* [5, 17, 18]. In particular, our agents are distributed problem solvers: they are assumed to be *strictly collaborative*. The agents have certain capabilities that may enable them to service various tasks. The tasks have certain resource or capability requirements, so that no agent or coalition of agents whose joint capabilities do not meet a particular task's resource requirements can serve that task [10, 17]. Each task is of a certain value to an agent. Agents are assumed capable of communicating, negotiating and making agreements with each other [2, 8, 10, 27]. Communication is accomplished via exchanging messages. This communication is not free: an agent has to spend time and effort in order to send and receive messages [17].

An important difference between our problem setting and that found in [10] is that we assume that neither *an agent's resources nor a task's utility are transferable to other agents* [15, 17]. In particular, the only way for an agent A_i to use the internal resources of agent A_j for the purpose of servicing some task is that A_i and A_j join the same coalition, and then jointly complete that task.

Our *distributed maximal clique-based coalition formation* algorithm is based on the idea that, in a *peer-to-peer* MAS, an agent would prefer to form a coalition with those agents that it can communicate with directly, and, moreover, where every member of such potential coalition can communicate with any other member *directly*. That is, the preferable coalitions are (maximal) cliques. However, finding a maximal clique in an arbitrary graph is **NP**-hard in the centralized setting [3, 4]. This implies the computational hardness that, in general, each agent faces when trying to determine the maximal clique(s) it belongs to. However, if the degree of a node is, that is, if the number of 1-hop neighbors that an agent can directly communicate with, is sufficiently small, then finding some or even all maximal cliques that this node belongs to might be computationally feasible. If one cannot guarantee that all the nodes in a given underlying interconnection topology are of small degrees, then the system designer may want to impose additional constraints, in order to ensure that coalition formation according to the MCDCF protocol is computationally feasible [15, 17]. Alternatively, the system designer may want to consider modifying the objective function, so that the candidate coalitions an agent would consider forming need not necessarily be *maximal cliques* that this agent belongs to. The most appropriate design choice clearly depends on the application at hand, the nature of agents' tasks, and the agents' communication and computational resources. For a more detailed discussion, we refer the reader to our prior work [15 - 21].

3 Outline of the MCDCF Algorithm

The MCDCF coalition formation protocol [15, 17, 18] is a *distributed graph algorithm*. The underlying undirected graph captures the communication network topology among the agents. Each agent is a node in the graph. The necessary requirement for an edge between two nodes to exist is that the two nodes be able to directly communicate with one another. Communication takes place by local or group broadcasts. The group broadcast nature of the assumed communication model is primarily inspired by the applications that drove the original MCDCF design, namely team robotics, autonomous unmanned aerial and underwater vehicles -- in particular, *micro-UAVs* [18, 19] -- as well as smart sensor networks.

The basic idea behind MCDCF is to *partition* the communication topology graph into (preferably, maximal) *cliques* of mutually connected nodes. These maximal cliques would in practice usually also need to satisfy some additional criteria in order to form coalitions of desired quality. The resulting coalitions are then maintained until they are no longer preferred by the agents involved in them.

To ensure overall scalability and computational feasibility of the protocol, the candidate coalitions in MCDCF are required to be cliques of uniformly bounded sizes. This requirement, in practice, means one of the two possibilities. One possibility is that it is *a priori* known that the underlying MAS network topology is such that it can be guaranteed that there are no cliques that are prohibitively large. Otherwise, the system designer, based on the application at hand and the available system resources, a priori chooses a threshold $K = K(n)$, where n is the total number of nodes, such that only the coalitions of sizes up to K are considered.

Agents form coalitions in a fully distributed manner as follows. Each agent (i) first learns of who are its neighbors, then (ii) determines the appropriate candidate coalitions, that the agent hopes are cliques that it belongs to, then (iii) evaluates the utility value of each such candidate coalition, measured in terms of the joint resources of all the potential coalition members and how valuable are the tasks that such a coalition can complete, then (iv) chooses the most desirable candidate coalition, and, finally, (v) sends this choice to all its neighbors. An agent also receives similar coalition proposals from some subset of its one-hop neighbors. The agent compares its current coalition proposal against those received from the neighbors. If there is an agreement among all agents in the current proposal of our agent, let's call it A_i, then this condition is recognized and a new coalition is formed. Once this happens, A_i's other neighbors, namely, those not in the newly formed coalition (if there are any such neighbors left), are notified of the formation of the new coalition. If there is no agreement, meaning, if at least one agent in the current proposal of A_i does not agree with that proposal, then the process continues and the protocol moves to the next round.

The basic procedure outlined above is repeated, together with all agents updating their knowledge of (a) what are the preferred coalitions of their neighbors, and (b) what coalitions have already been formed – until eventually every agent has joined some coalition. Note that, when an agent has no available coalition partners left, the agent is basically forced to form the trivial, "singleton coalition" (with itself as the only member). Hence, it is guaranteed that each agent will join some coalition eventually, i.e., after finitely many rounds.

Detailed description, communication and computation complexity analysis, and pseudo-code for the MCDCF algorithm can be found in [16, 17]. Considerable algorithmic and software optimizations and improvements are summarized in [20]. Among the main goals of our recent experimental investigations [21, 22] was to determine, just how effective these optimizations are when MCDCF is applied to (i) small-world-like underlying topologies and (ii) random (Erdös-Renyi) graphs.

4 Running MCDCF on Small-World Graphs

We have conducted extensive experiments to investigate how well MCDCF performs on small-world graphs [21], and also to verify theoretical predictions related to scalability [16, 17]. The two key parameters for the MCDF algorithm are the number of nodes n and the average node degree *avg_deg*. In this section, we briefly summarize the main findings of that study. We considered three subclasses of small-world graphs. The first subclass were the regular k-rings, with no random edges; strictly speaking, k-rings aren't "small-world" networks but were used as the starting point from which genuine small-world topologies were obtained, as well as the "yardstick" for MCDCF performance on highly structured graphs. We recall that MCDCF design was topology- and structure-oblivious, the only requirement being that the topology has to be relatively sparse [15-18].

The second and third subclasses were genuine small-world networks, with different probabilities of some of the local edges of a k-ring being replaced by random (hence, in general, non-local) edges. In the second subclass, 10% of the total number of edges were random edges, implying that up to 10% of all edges in the graph were non-local (but the exact fraction of non-local edges would of course vary from one randomly generated graph with p = 0.10 of a regular ring edge being replaced by a random edge to another). In the third subclass, with p = 0.20 a ring edge would get replaced by a random edge, meaning, up to 20% of all edges were non-local.

In summary, the regular k-rings, which are not truly small world networks, were used as the "yardstick" to see how would the MCDCF performance get affected with an increase in non-local network connections. We were also interested in quantifying the speed of convergence of MCDCF as the probability of random, non-local edges increases.

We considered two basic scenarios. In the first scenario, we maintained the number of nodes as a constant and varied the average node degree. In the second scenario, the average node degree was held constant and we varied the total number of nodes.

Scenario 1:

The varying parameter in this scenario was the average node degree, whereas the number of nodes remained fixed (n = 200). We have incremented the average node degree in multiples of 2, from *avg_deg* = 4 up to *avg_deg* = 20. We briefly summarize the main lessons learned from the simulation results for this scenario and their statistical analysis. Details can be found in our WorldComp ICAI-2011 paper [21].

Insofar as the rates of convergence are concerned, the increase in graph density only mildly affected the speed of convergence on the regular k-rings. However, genuine small-world networks (with non-zero probabilities of random edges) were considerably affected: the average number of rounds until convergence, in general, showed *exponential increase* with the increase in average node degree for both subclasses 2 and 3. Not surprisingly, subclass, which has a higher percentage of non-local edges, was affected more drastically, that is, the increase in the average number of rounds until convergence was steeper than for the subclass 2. For details, we refer the reader to Fig. 1 in [21] and related discussion.

The number of formed coalitions showed a gentle increase with the increase in the total graph density. Interestingly, the maximum size of coalitions that MCDCF was able to find did not show any clear trend. In particular, the fact that higher density implied expected larger maximum coalition sizes did not imply that our protocol would be able to effectively find

those larger cliques. Therefore, the optimizations discussed in detail in [20], while considerably improving the quality of found coalitions (as well as the convergence times) for certain types of underlying networks, did not result in desirable improvements for the genuine small-world networks.

Scenario 2:

In this scenario we varied the number of nodes and the average node degree remained constant: *avg_node* = 10 throughout. We incremented the number of nodes each time by 20, starting from n = 40 up to n = 200 nodes. As in Scenario 1, for each pair of values (n, *avg_deg*), we ran MCDCF on ten different, randomly generated graphs. We summarize the most important observations and lessons learned from this scenario below.

When the graph density is held constant, the number of rounds to reach convergence increases approximately *linearly* with the total number of nodes; see Figure 4 and related discussion in [21]. According to theoretical predictions [15-17], how long it takes for MCDCF to converge on an arbitrary graph primarily depends on the neighborhood sizes, not the total number of nodes in the graph.

Insofar as how many coalitions get formed and what their average and maximal sizes tend to be (as a function of the total number of nodes), it turned out that the number of coalitions was a monotonically increasing function of n as well as of the probability of random rewiring. This was in accordance with our expectations. In particular, the fixed average node degree implies that we should not expect more larger-sized coalitions as n increases; rather, we tend to get more coalitions of roughly the same average sizes as for smaller n. We also note that, for rewiring probabilities of 0.1 and 0.2, due to random nature of our test graphs, most nodes ended up in singleton and doubleton coalitions basically irrespectively of n and *avg_deg* (see Figures 3 and 5 in [21]). In particular, as the number of nodes and the probability of random rewiring increase, the total number of formed coalitions also tends to increase – but not the coalition sizes.

5 Running MCDCF on Random Graphs

In the context of Erdös-Renyi (E-R) random graphs, we essentially performed the same sets of experiments as with the small-world graphs. In particular, we considered two scenarios. In the first scenario, we maintained the number of nodes as a constant and varied the average node degree. In the second scenario, the average node degree was held constant and we varied the total number of nodes. The results for the two scenarios are summarized in this section. For much more details on MCDCF performance on random graphs, we refer the reader to [22].

We remark that we are well aware that Erdös-Renyi graphs, while often considered "the default" type of random graphs, are not a kind of network topologies frequently encountered in practice in general, or in any of the collaborative MAS applications of our interest, in particular. There are two main reasons why we have been studying MCDCF performance on these random graphs. One, E-R random graphs are a good choice of the baseline topology structure on which to test our algorithm to establish the "ground truth" on how scalable and efficient MCDCF really is in practice, as opposed to theory [15-17]. Various aspects of performance (such as the speed of convergence and the average sizes / quality of the resulting coalitions) on these random graphs therefore serve as a benchmark to better understand and appropriately calibrate the MCDCF performance on more realistic types of underlying topologies of the same or comparable sizes and/or densities. Two, the design of MCDCF was utterly oblivious with respect to the underlying graph structure: when originally designing and prototyping this algorithm [15, 16], we only cared that the node degrees be appropriately bounded – but no aspect of the original protocol, or the subsequent modifications and optimizations of it [20], made any attempt to take advantage of any local or global structural property of the underlying topology. Hence, we felt it was appropriate to first test such a structure-oblivious algorithm on a kind of underlying graphs that are, arguably, as structure-free as communication network topologies can be [22].

While our experimental results on Erdös-Renyi graphs in [22] are admittedly based on a fairly small statistical sample, we have tried to identify some general trends and properties of the MCDCF performance that, based on our experience with graph algorithms in general and MCDCF in particular, we would expect not be too significantly affected even had we performed thousands (instead of only dozens) of runs for each set of parameter values. We acknowledge that, in the future work, it is recommendable to include confidence intervals or another measure of statistical significance. We summarize the main findings below, and refer the reader to [22] for the performance plots and detailed analyses and discussion.

Scenario 1:

The varying parameter in this scenario is the average node degree, while the number of nodes remains constant (n = 100). We have incremented the average node degree in multiples of two, from avg_deg = 2 up to avg_deg = 20.

The speed of convergence shows the same general trend as in the case of small-world networks. In particular, the number of rounds required in order for all agents to join coalition clearly grows *exponentially* with the average node degree, in accordance with theoretical expectations [15-17]. We recall that, as the average node degree increases, so does the average size of a node's neighborhood list, and hence the number of candidate coalitions to consider. Moreover, the number of candidate coalitions grows exponentially with the number of neighbors. This general behavior, based on theoretical analysis [15-17], has been observed experimentally on all types of graphs that we have experimented with to date, including the small-world graphs and the Erdös-Renyi graphs.

However, unlike with the small-world networks, in case of the random graphs the total number of coalitions formed stayed roughly the same. However, the average size of coalition showed a clear trend of growth with the increase in average graph density. In particular, MCDCF is capable of finding increasingly larger maximal cliques on presumably structure-less Erdös-Renyi random graphs as the graph density (and therefore, the expected max. coalition size that a typical

node belongs to) increase; see Figure 2 in [22]. In contrast, MCDCF showed unsatisfactory performance in finding relatively large cliques in non-trivial small-world graphs as those graphs' densities grew. We were initially surprised with these findings, as MCDCF was not designed or optimized for any particular underlying structure or type of network topology. We suggest some possible explanations in the next section.

Scenario 2:

In this scenario, we varied the number of nodes *n* while the average node degree re-mains constant: *avg_node = 10* throughout. We incremented *n* each time by 10, starting from n = 10 up to n = 100 nodes. The purpose of this second set of experiments was to validate our prior theoretical predictions that MCDCF's performance, in general, should be affected very mildly by increase in the overall graph size, as long as the average neighborhood sizes are held fixed. Some general observations and the main lessons learned from this scenario fare summarized below; more details can be found in [22].

We observed a very modest increase in the number of rounds until convergence as a function of the total number of nodes (see Figure 4 in [22]. Namely, how long it takes for a node to agree with some subset of its neighbors on which coalition to form is primarily controlled by the neighborhood size and hence the size of both the initial candidate coalition and the total number of candidate coalitions that may be considered during the protocol's execution. However, the overall number of rounds can be generally expected to relatively slowly increase with *n*, since the total number of rounds is determined by the "slowest negotiators" among the agents. Hence, with an increase of the number of nodes, and given the random nature of underlying graphs, the variability in convergence speeds of different nodes can be expected to gently increase, thereby resulting in an average increase in the total number of rounds until every node in the graph joins a coalition.

Insofar as the relationship between the number of nodes and the total number of coalitions formed, it turned out that the number of coalitions is a monotonically increasing function of *n*, as expected. Moreover, this dependence turned out to be approximately linear (see Figure 6 in [22]). We think that the reason behind this is that, due to random nature of our graphs, most nodes end up in singleton and doubleton coalitions basically almost irrespectively of *n* and *avg_deg*. Therefore, as the number of nodes increases, the total number of formed coalitions increases – while the average coalition size remains roughly the same (around or below two).

6 MCDCF on Small-World vs. Erdös-Renyi Random Graphs: Comparison-and-Contrast

We summarize the key findings and insights from the comparative analysis of MCDCF performance on the two types of network topologies studied in [21, 22] and discussed in the previous two sections of the present paper. We focus on those aspects where the MCDCF behavior has turned out to be considerably different depending on whether the underlying graph was of the small-world variety or of the random (in the Erdös-Renyi sense) variety.

Insofar as the scenario where the total number of nodes *n* was held fixed but the number of edges, and hence overall connectivity and density, were gradually increased, the convergence times showed an exponential increase with the average node degree for both network topologies. That much was in accordance with theoretical predictions and our expectations. The difference is that, whereas MCDCF was fairly successful in finding cliques of relatively larger sizes in the random E-R graphs (whenever such larger cliques existed), our algorithm was not very successful in identifying such cliques in genuine small-world networks. (By "genuine" we mean, those that aren't mere regular k-rings.) This is at least in part due to the tie-breaking mechanisms in MCDCF, in situations where an agent needs to pick one among two or more "equally preferable" candidate coalitions. While MCDCF design is indeed topology-blind, the tie-breaking mechanisms are heavily based on the lexicographic ordering (that is, indexing) of different nodes. Even with the optimizations (and, in particular, some randomizations, to escape the curse of lex-based indexing) introduced in [20], the small-world graphs obtained from regular k-rings still have a considerable correlation between the probability of two nodes being adjacent (that is, connected by an edge) on one hand, and having indices close to each other (that is, small $|i - j|$), on the other. In contrast, by their very definition, the Erdös-Renyi random graphs (to within the quality of the underlying pseudo-random random generator) have no correlation between indices of the nodes and the likelihood of node pairs being connected by an edge.

While some randomization introduced in the process of selecting which candidate coalitions of a size one less than the most recent proposal (that has not been accepted by peers) an agent would consider in the future rounds has diminished the correlation between $|i - j|$ and probability of A_i and A_j being adjacent, that correlation still exists. Moreover, some of the optimizations in the traversal of the lattice of candidate coalitions of a given node [20], while making this traversal in general faster than in the original, unoptimized MCDCF [15-17], may also have undesirable side-effects on the ability of MCDCF to find relatively large cliques when index proximity and likelihood of being connected are positively correlated yet, due to introduced randomness, it isn't the case (informally speaking) that "my neighbor is also likely my neighbor's neighbor". These observations also provide a hint why MCDCF converges very fast on regular k-rings even as the graph density is increased, whereas the rates of convergence drop very significantly once random edges are introduced.

When it comes to the second scenario, where the average node degree is held fixed but the total number of nodes is varied, we see less dramatic difference between the performances on the two types of topologies. However, the speed of convergence is still more affected in the small-world than the E-R random graphs. Interestingly, while among small-world-like graphs the convergence on regular k-rings is the fastest (which is to be expected), this difference is not very pronounced – quite unlike the drastic difference between the

regular rings and the genuine small-world topologies when it comes to the speed of convergence as a function of average node degree (that is, graph density). In particular, the increase in graph size appears to slow down coalition formation convergence more on highly structured k-rings than it does on structure-free E-R random graphs for the same total sizes and densities. This is another indication that the tie-breaking mechanisms and the selection of candidate coalition(s) strictly smaller than the current choice, with their dependencies on node labels (that is, indexing), have a considerable impact on the overall effectiveness of MCDCF – even after the considerable optimizations and even some randomization have been introduced into those processes (see [20] for details on those optimizations).

When it comes to the limited ability of MCDCF to form relatively large coalitions (which, in our context, means triples or larger) on regular k-rings and small-world graphs derived from k-rings, one needs to distinguish between the protocol failures to identify larger coalitions that actually are present in the graph, and the lack of existence of such coalitions due to randomization in edge "re-wiring". We recall from [21] however that k-rings are deterministic and, for relatively high k, contain multiple what we consider to be sizable cliques. That MCDCF in general fails to find those cliques effectively is perhaps the single most important indication that, in spite of all our efforts as discussed in [20], our protocol needs to be considerably further fine-tuned and optimized.

7 Conclusions and The Road Ahead

We have applied our distributed coalition formation algorithm to small-world and random graphs. In particular, we studied our MCDCF algorithm's performance on the network topologies that, to various extents, exhibit small-world structure. We have tested our algorithm on random small-world graphs with up to 200 nodes. Our simulations have produced several generally expected results, which partly validate the claim that our approach to distributed coalition formation is applicable to a broad variety of underlying topologies. However, we have also obtained some rather unexpected and, in some instances, disappointing results. One lesson learned is that the optimizations of MCDCF reported in [20], while very helpful when the algorithm is run on random graphs [22], appear inadequate when MCDCF is run on small-world graphs [21]. Therefore, one immediate objective of our ongoing research is to improve inter-agent coalition negotiation as well as individual agent's candidate coalition search mechanisms, in order to ensure faster convergence, as well as better resulting coalition structures, when our algorithm is run on small-world-like underlying networks. We also need to investigate in more depth what properties of small-world graphs cause subpar performance of MCDCF with respect to some of the metrics discussed in this paper and its predecessor [21].

We have generally found that, most of the time, MCDCF successfully identifies larger cliques when those are indeed present in the underlying random graph. We acknowledge that further experimental validation is needed – especially on graphs that (a) exhibit some type of structure and (b) are important from an application standpoint (i.e., are more likely to arise in practice than the Erdös-Renyi graphs). Examples of such graphs include scale-free graphs, power-law graphs, and social network graphs with the assortativity property. For instance, we would expect MCDCF to be able to efficiently find relatively sizable cliques / coalitions in social network graphs with node degrees and total number of nodes comparable to the graphs in our experiments to date, yet with the property that above-average connected nodes tend to be predominantly connected to each other.

Moving forward, we will explore MCDCF performance on small-world networks when the node indices are scrambled in order to eliminate the correlation between proximity and being connected by an edge. Furthermore, from the lessons learned in the context of small-world networks, we will also study MCDCF performance on other types of interesting topologies (power-law graphs, social networks, etc.) both with and without pre-processing step that scrambles the node indices. That way, we will be able to quantify to what extent the tie-breaking mechanisms, as discussed in [15-18, 20], that are in part based on index ordering, have an impact on our algorithm's overall speed of convergence and effectiveness in finding non-trivial cliques.

Acknowledgments

The author would like to thank his former graduate student at University of Houston, Naveen K.R. Ginne, as well as his own former PhD advisor, professor Gul Agha, and members of Dr Agha's Open Systems Laboratory at University of Illinois at Urbana-Champaign, for several years of fruitful collaboration on multi-agent distributed coalition formation. The author would also like to thank Dr Yuriy Fofanov, Dr Carlos Ordonez, Dr Ioannis Kakadiaris, Dr Nikolaos Tsekos and Dr Ricardo Vilalta (all at University of Houston) for their support during 2011-2012.

Abstract— *Autonomous Underwater Vehicles (AUVs) have gained importance over the years as specialized tools for performing various underwater missions in military and civilian operations. This study presents the on-line system identification of AUV dynamics to obtain the coupled nonlinear dynamic model of AUV. This proposed model has an input-output relationship based upon neural fuzzy network (NFN) model technique to overcome the uncertain external disturbance and the difficulties of modelling the hydrodynamic forces of the AUVs instead of using the mathematical model with hydrodynamic parameters estimation. Initially the models' parameters are generated randomly and tuned by Differential Evolution algorithm (DE) with a set of real input-output data. Secondly, the back propagation algorithm based upon the error between the identified model and the actual outputs of the plant are used to adopt the model's parameters. The proposed NFN model adopts a functional link neural network (FLNN) as the consequent part of the fuzzy rules. Thus, the consequent part of the NFN model is a nonlinear combination of input variables. Simulation results show the superiority of the proposed adaptive neural fuzzy network (ANFN) model in tracking of the behavior of the AUV .*

Keywords: AUV dynamic model, fuzzy modeling, adaptive fuzzy system, system identification, neural fuzzy model, FLNN.

1 Introduction

Autonomous Underwater Vehicles (AUVs) have gained importance over the years as specialized tools for performing various underwater missions in military and civilian operations. The autonomous control of underwater vehicles poses serious challenges due to the AUVs' dynamics. AUVs dynamics are highly nonlinear and time varying and the hydrodynamic coefficients of vehicles are difficult to estimate accurately because of the variations of these coefficients with different navigation conditions and external disturbances.

According to [1] the two most significant technological challenges in AUV's design are power and autonomy. Power sources limit the mission time of the vehicle and autonomy limits the degree to which an AUV can be left unattended by human operators.

Reference [2] presented a simple model identification method for UUV and applied this method to the underwater robot GARBI. The system identification was aimed at decoupling the different degrees of freedom in low speed vehicles. Least Square techniques were used to estimate the UUV dynamics. Experiments in lab and real underwater environments were carried out. A neural fuzzy system based on modified differential evolution for nonlinear system control is discussed in [3]. The proposed controller adopts a nonlinear combination of input variables to the consequent part of fuzzy rules and uses a differential evolution to optimize the system parameters. This controller is applied to the planetary-train-type inverted pendulum system and the magnetic levitation system in the VisSim solving nonlinear control problems.

The FLNN is a single-layer neural structure capable of forming arbitrarily complex decision regions by generating nonlinear decision boundaries with nonlinear functional expansion. The FLNN [4] was conveniently used for function approximation and pattern classification with faster convergence rate and less computational loading than a multilayer neural network. Recently, genetic fuzzy systems [5,6] have received increasing attention mainly because they combine the approximate reasoning method of fuzzy systems with the learning capabilities of evolutionary algorithms. However, the search is extremely time-consuming, which is one of the basic disadvantages of all genetic algorithms (GAs). Similar to GAs, differential evolution (DE) has emerged as a robust numerical optimization algorithm and has been successfully applied to solve various difficult optimization problems [7, 8]. Basically, DE is fast, easy to use, and not only astonishingly simple, but also performs extremely well in a wide variety of test problems. The basic strategy employs the difference of two randomly selected individuals as the source of random variations for a third individual. However, DE usually explores too many search points before locating the global optimum. In addition,

although DE is particularly simple to work with, having only a few control parameters, the choice of these parameters is often critical for the performance of DE [8, 9]

This study proposes an online system identification of AUV dynamics as a black box which has an input-output relationship instead of using the mathematical model with hydrodynamic parameters to obtain an accurate dynamic model to overcome the uncertaininaty, nonlinearity and the difficulties of modelling the AUVs. The only information required for generating and tuning the neural fuzzy systems is the input -output data without any prior knowledge of the physical relationship inside the system and it offers a 'black box' modelling tool. ADFA AUV has been developed and built in UNSW@ADFA. The hydrodynamic coefficients of this AUV are calculated under certain conditions using CFD method to derive the exact mathematical model. Simulation program is built up to simulate the dynamic behaviour of the AUV based upon the calculated mathematical model of the AUV.

The general dynamic equation describing the mathematical model of the ADFA AUV is provided in Section 2. The design details of identification of AUV using adaptive neural fuzzy network (ANFN) techniques are presented in section 3. The optimization and tuning techniques for the system identification are provided in section 4. Moreover, Numerical simulation results are presented in section 5. Finally, the paper is concluded in Section 7.

2 AUV's mathematical model

Fig. 1 shows a typical UNSW@ADFA AUV during one of the experiments. One electrical thruster powers the vehicle for forward motion. Two electrical pumps are used for maneuvering in the horizontal plane. In addition, two electrical pumps help the AUV to navigate in the vertical plane. The middle box is used for carrying the sensors, battery and the electronic accessories.

The hydrodynamic forces per unit mass acting on each axis will be denoted by the uppercase letters X, Y and Z. *u*, *v* and *w* represent the forward, lateral and vertical velocities along x, y and z axes respectively. Similarly, the hydrodynamic moments on AUV will be denoted by L, M and N acting around x, y and z axis respectively. The angular rates will be denoted by *p*, *q* and *r* along x, y and z axes respectively.

Dynamics of AUVs, including hydrodynamic parameters uncertainties, are highly nonlinear, coupled and time varying. According to [10], the six degrees-of-freedom nonlinear equations of motion of the vehicle are defined with respect to two coordinate systems as shown in Fig. 2. The dynamic models of thrusters and pumps have been included in the present study. The AUV model is simulated by a mathematical model based on physical laws and design data of the ADFA AUV.

3 NFN System Identification of AUV

The NFN uses a nonlinear combination of input variables (FLNN) [11] with the fuzzy system. Each fuzzy rule corresponding to the `FLNN comprises a functional expansion of input variables. The FLNN, initially proposed by [4], is a single-layer ANN structure capable of forming complex decision regions by generating nonlinear decision boundaries. In a FLNN, the need of hidden layer is removed.

Figure 1. Australian Defence Force Academy AUV.

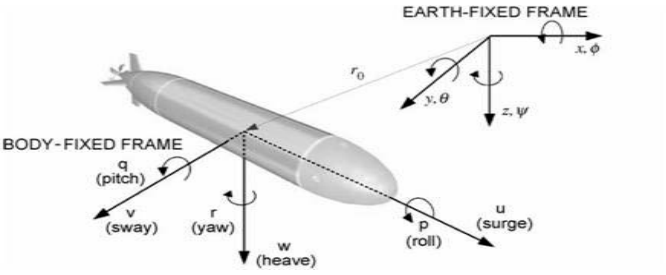

Figure 2. Six degrees of freedom of an AUV.

In this study, the functional expansion block comprises of a subset of orthogonal polynomials bases function. The FLNN has been inserted to the consequent part of the fuzzy rules. The local properties of the consequent part in the NFN model enable a nonlinear combination of input variables to be approximated more effectively.

3.1 Functional link neural network structure (FLNN)

The FLNN is a single-layer network while the input variables generated by the linear links of neural networks are linearly weighted, the functional link acts on an element of input variables by generating a set of linearly independent functions, orthogonal polynomials for a functional expansion, and then evaluating these functions with the variables as the arguments. Therefore, the FLNN structure considers trigonometric functions. In the FLNN structure as shown in Fig. 3, a set of basis functions Φ and a fixed number of

weight parameters W represent $f_{W(k)}$. The theory behind the FLNN for multidimensional function approximation has been discussed in [12]. Consider a set of basis functions $B = \{\varphi_k \in \Phi(A)\}_{k\in K}$, K = {1, 2, . . .}. Let $B = \{\varphi\}_{k=1}^{M}$ be a set of basis functions. The FLNN comprises M basis functions$\{\varphi_1, \varphi_2, \dots\dots\dots, \varphi_M\} \in B_M$. The linear sum of the j[th] node is given by

$$\hat{y}_j = \sum_{k=1}^{M} w_{kj}\varphi_k(X) \qquad (2)$$

where $X \in A \subset \Re^N, X = [x_1, \dots\dots, x_N]^T$ is the input vector and $W_j = [w_{j1}, \dots\dots, w_{jM}]^T$ is the weight vector associated with the j^{th} output of the FLNN. $\hat{y}_j$ denotes the local output of the FLNN structure and the consequent part of the j^{th}fuzzy rule in the NFN model. The m-dimensional linear output may be given by $\hat{y} = W\Phi$, where $\hat{y} = [\hat{y}_1, \hat{y}_2, \dots\dots, \hat{y}_m]^T$, m denotes the number of functional link bases, which equals the number of fuzzy rules in the NFN model, and W is an (m×M)-dimensional weight matrix of the FLNN given by $W = [w_1, w_2, \dots\dots, w_M]^T$.

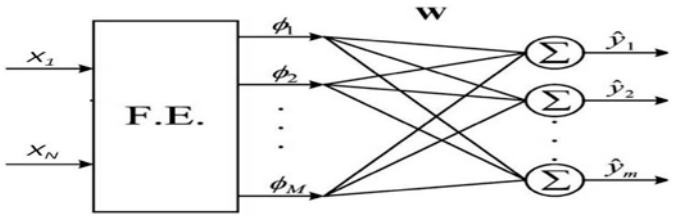

Figure 3. FLNN structure.

3.2 NFN model structure

The NFN model uses a nonlinear combination of input variables (FLNN). The structure of the NFN model is presented in Fig. 4. The ANFN model changes a fuzzy IF–THEN rule in the following form.

$$R^{(l)}: \text{IF } \left(x_1 \text{ is } F_1^l \text{ and } \dots\dots\dots \text{ and } x_N \text{ is } F_N^l\right) \text{ THEN}$$

$$\hat{y}_j = \sum_{i=1}^{M} w_{ij}\varphi_k(X) \qquad (3)$$

$$= w_{1j}\varphi_1 + w_{2j}\varphi_2 + \cdots + w_{jM}\varphi_M$$

where x_i and $\hat{y}_j$ are the input and local output variables, respectively; F_N^l is the linguistic term of the precondition part with Gaussian membership function, N is the number of input variables, w_{ij} is the link weight of the local output, φ_M is the basis trigonometric function of input variables, M is the number of basis function, and rule j is the j^{th} fuzzy rule.

In this study, each degree of freedom of underwater vehicle dynamics is represented by one NFN model. Therefore, there are six SISO NFN models to represent six degrees of freedom of AUV. In the precondition part, the input is represented by five Gaussian membership functions (mean five means and variance). In the consequent part, the output is generated by FLNN. The function expansion in FLNN uses trigonometric functions, given by $[1, \hat{x}_1, \sin(\pi\hat{x}_1), \cos(\pi\hat{x}_1)]$ for one input variable.

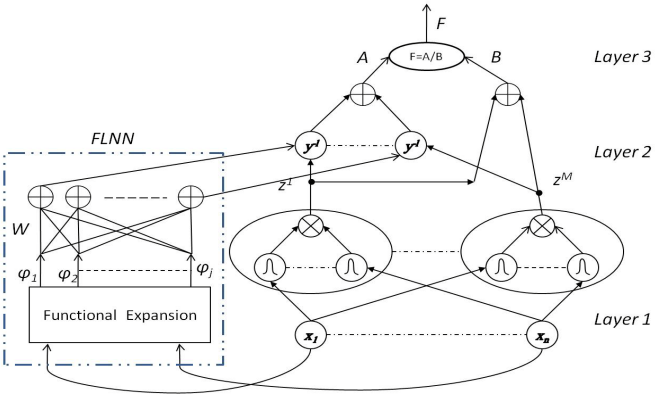

Figure 4. NFN structure

4 Tuning the NFN model

Sets of real input-output data with different operation conditions and disturbance are the only the information required for tuning the model.

The proposed technique consists of two phases. The first phase is the off-line procedure and the second one is the on-line procedure. The target of the off-line phase is to tune and optimize the model's parameters using an optimization technique according to a set of real input-output data. The on-line procedure aims to identify the model of the process online by using the input-output measurements from the mathematical model, set of real input-output data or a real system.

4.1 OFF-LINE procedure

This section presents the off-line stage as a first step in optimizing and tuning the model.

4.1.1 Parameter optimization phase

After the NFN structure has been established, the model enters the parameter-optimization phase based on Differential Evolution (DE) to adjust the parameters of the network optimally based on a different input-output training data set.

DE is known as a powerful algorithm for real parameter optimization. In DE, an initial population is generated and, for

each parent vector from the current population (target vector), a mutant vector (donor vector) is obtained. Finally, an offspring is formed by combining the donor with the target vector. A tournament is then held between each parent and its offspring with the better being copied to the next generation [13, 14]. The DE learning algorithm consists of four major steps— the initialization step, the evaluation step, the reproduction step, and the mutation step.

A. Initialization step: The first step in DE is the coding of the neural fuzzy network model parameters into an individual. Equation (4) shows the way of the individual coding of NFN parameters, where i and j represent the i^{th} input variable and the j^{th} rule, respectively. In this study, a Gaussian membership function is used with variables that represent the mean and variance of the membership function. m_{ij} *and* σ_{ij} are the mean and variance of a Gaussian membership function, respectively, and w_{Mj} represents the corresponding link weight of the consequent part that is connected to the j^{th} rule node.

$$\text{Individual} = \mathrm{m_{1j}, m_{2j}, \ldots\ldots m_{ij}, w_{1j}, \ldots. w_{Mj}} \qquad (4)$$

B. Evaluation step: The objective function is used to provide a measure of how individuals have performed in the problem domain. In the minimization problem, the fit individuals will have the lowest numerical value of the associated problem objective function. This raw measure of fitness is usually only used as an intermediate stage in determining the relative performance of individuals in a DE. Another function, the fitness function, is normally used to transform the objective function value into a measure of relative fitness.

$$F(x) = g(f(x)) \qquad (5)$$

where $f(x)$ is the objective function, g transforms the value of the objective function to a non-negative number and F is the resulting relative fitness. The cost function that attempts to optimize the whole NFN model parameters keeping the interaction between the different degree of freedom is ITSE (Integral Time of Square Error) over the total simulation time.

$$ITAE = \int_{t_1}^{t_2} e^2\, dt \qquad (6)$$

$$J_{E1} = Max(ITAE) \qquad (7)$$

$$F_{E1} = 1/J_{E1} \qquad (8)$$

where J_{E1} is the objective function of each degree of freedom separately for all population. F_{E1} is the overall fitness function of that degree of freedom. The objective function using fitness produces distribution in the range (0, 1).

C. Mutation and crossover step: This operation enables DE to explore the search space and maintain diversity. The simplest form of this operation is that a mutant vector is generated by multiplying an amplification factor, F, by the difference between two random vectors and the result is added to a third random vector (DE/rand/1) [9] as:

$$\vec{\mathrm{V}}_{\mathrm{z,t}} = \vec{\mathrm{x}}_{\mathrm{r_1,t}} + \mathrm{F} \times \left(\vec{\mathrm{x}}_{\mathrm{r_2,t}} - \vec{\mathrm{x}}_{\mathrm{r_3,t}}\right) \qquad (9)$$

where r_1, r_2, r_3 are random numbers (1,2, ..., PS), $r_1 \neq r_2 \neq r_3 \neq z$, x is a decision vector, PS is the population size, F is a positive control parameter for scaling the DE and t the current generation. For more details, readers are referred to [8].

D. Reproduction and selection step: To keep the population size constant over subsequent generations, the next step of the algorithm calls for selection to determine whether the target or the trial vector survives to the next generation, i.e., at G = G + 1. The selection operation is described as

$$\begin{aligned} \vec{\mathrm{X}}_{\mathrm{i,G+1}} &= \vec{\mathrm{U}}_{\mathrm{i,G}} \ \text{ if } \mathrm{f}\left(\vec{\mathrm{U}}_{\mathrm{i,G}}\right) \leq \mathrm{f}\left(\vec{\mathrm{X}}_{\mathrm{i,G}}\right) \\ &= \vec{\mathrm{X}}_{\mathrm{i,G}} \ \text{ if } \mathrm{f}\left(\vec{\mathrm{U}}_{\mathrm{i,G}}\right) > \mathrm{f}\left(\vec{\mathrm{X}}_{\mathrm{i,G}}\right) \end{aligned} \qquad (11)$$

where $f(x)$ is the objective function to be minimized.

4.2 ON-LINE procedure

The learning algorithm is using the back propagation technique. The back-propagation algorithm minimizes a given cost function, Eq (13), by adjusting the parameter of the membership in the antecedent part of the NFN system as mentioned in Eq (15, 16) and the link weight parameters of the FLNN in the consequent part of the NFN system as mentioned in Eq (18, 19).

4.2.1 Parameter learning phase

After the NFN parameters have been tuned in the optimization phase according to a certain input-output training data set, the network enters the parameter-learning phase to adjust the parameters of the network based on a different real input-output data, mathematical model simulation or real system. The final output of the NFN model is given by equation (12) with c_i^j and σ_i^j representing the centre and width of Gaussian memberships for input variable x_i for the rule i, j and n being the number of rules of fuzzy model and number of inputs respectively.

$$\mathrm{y_m(k+1)} = \frac{\sum_{\mathrm{j=1}}^{\mathrm{R}} \hat{\mathrm{y}}_{\mathrm{j}} \left[\prod_{\mathrm{i=1}}^{\mathrm{n}} \exp\left(-0.5\left(\frac{\mathrm{x_i - c_i^j}}{\sigma_{\mathrm{i}}^{\mathrm{j}}}\right)^2\right)\right]}{\sum_{\mathrm{j=1}}^{\mathrm{R}} \left[\prod_{\mathrm{i=1}}^{\mathrm{n}} \exp\left(-0.5\left(\frac{\mathrm{x_i - c_i^j}}{\sigma_{\mathrm{i}}^{\mathrm{j}}}\right)^2\right)\right]} \qquad (12)$$

The adaptive neural fuzzy network model is a neural fuzzy network model with a training algorithm where the model is synthesized from a bundle of fuzzy If-Then rules. As

shown in Figure 5, the fuzzy model is placed in parallel with the process to be identified. This process could be a real system, set of input-output data or mathematical model. It aims to identify the model of the process online by using the input-output measurements of the process based on a training algorithm. The learning process involves determining the minimum of a given cost function (13). The gradient method is used to adapt the model parameters based on the following objective function

$$E(k) = \frac{1}{2}\left(y_m(k+1) - y_f(k+1)\right)^2 \quad (13)$$

where E(k) is error between the NFN model and the actual plant outputs. If Z(k) represents the parameter to be adapted at iteration k in the NFN model, the back propagation algorithm seeks to minimize the value of the objective function by [15].

$$z(k+1) = z(k) - \alpha\frac{\partial E}{\partial Z} \quad (14)$$

To train c_i^j;

$$c_i^j(k+1) = c_i^j(k) - \alpha\frac{y_m - y_f}{b}(\hat{y}^j - y_m)z^l\frac{2(x_i - x^j(k))^2}{\sigma_i^{j2}(k)} \quad (15)$$

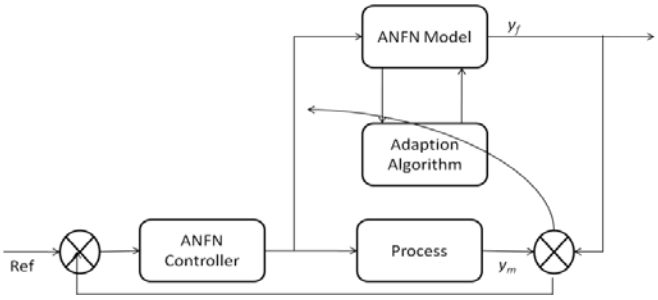

Figure 5. Figure 5. Tracking of error function between the process and ANFN model.

To train σ_i^j;

$$\sigma_i^j(k+1) = \sigma^j(k) - \alpha\frac{y_m - y_f}{b}(\hat{y}^j - y_m)z^l\frac{2(x_i - x^j(k))^2}{\sigma_i^{j3}(k)} \quad (16)$$

where

$$b = \sum_{i=1}^{M} Z^l; \qquad Z^l = \prod_{i=1}^{n}\exp\left(-0.5\left(\frac{x_i - c_i^l}{\sigma_i^l}\right)^2\right) \quad (17)$$

By following the same sequence, the equation for adapting parameter w is derived as shown in the following equations.

$$w_{ij}(k+1) = w_{ij} - \alpha_w\frac{\partial E}{\partial w_{ij}} \quad (18)$$

$$\frac{\partial E}{\partial w_{ij}} = e\left(\frac{b\,\varphi_j}{z^j}\right) \quad (19)$$

where α_w is the learning rate parameter of the FLNN weight. The learning rate α in equation (15, 16 and 18) [10] has a significant effect on the stability and convergence of the system. A higher learning rate may enhance the convergence rate but can reduce the stability of the system. A smaller value of the learning rate guarantees the stability of the system but slows the convergence. The proper choice of the learning rate is therefore very important.

In this technique, the fuzzy network is adapted through two ways. The back propagation algorithm is applied to tune the membership function parameters in antecedent part. The consequent part of the fuzzy rules is adapted through the FLNN. In addition, the back propagation algorithm is used for tuning the parameters of FLNN as well.

4.3 Convergence analysis of ANFN system

Each learning rate parameter of the weight, the mean, and the variance, α, has a significant effect on the convergence. To ensure a quick and stable convergence of fuzzy controller parameters a convergence analysis of the learning rate α will be considered according to the following theorem.

Theorem [16]: Let α be the learning rate for the parameters of fuzzy controller and g_{max}be defined as $g_{max} := \max_k\|g(k)\|$ where $g(k) = \delta y(k)/\delta z(k)$ and $\|.\|$ is the usual Euclidean norm in $\Re^n$ and let $S = \delta y_m/\delta u$. Then the convergence is guaranteed if α is chosen as

$$0 < \sigma < \frac{2}{S^2 g_{max}^2} \quad (20)$$

5 Simulation Results

This study demonstrated the performance of the NFN model for nonlinear system modeling. This section simulates the AUV system behavior and compares the performance of the NFN model with the mathematical model of the AUV.

Fig. 6 shows the motion of the AUV in square trajectory in XY plane, which means the yaw angle control. It is obviously seen that DE has a good job to tune the model's parameter from initial values and get them close enough to the original behavior of the vehicle and it makes the job easier for the online tuning to get the model track successfully the behavior of the vehicle. The motion of the AUV with NFN model with online tuning algorithm does a better job

compared to the performance of the same model without adaptive algorithm in terms of accuracy as well as the speed.

Fig. 7, Fig. 8 and Fig. 9 provide an example of the performance of NFN model and its tracking capability of the mathematical model. These figures show the angular velocity in pitch motion, q, the error between the mathematical and NFN model in pitch motion, q, and the error between the mathematical and NFN model in yaw motion, r, respectively. It is clearly seen that the behavior of the NFN model has same as the mathematical model. The NFN system identification has the capability to track the plant successfully whatever the change in the operation condition.

The learning rates, for all models were initially set to 1 to train the model parameters. Then the convergence conditions were verified at every sampling time. In the present work, the learning rate belongs to the range [0.009, 0.236] was always within the limit of convergence for parameters in NFN model.

5.1 Open loop accuracy evaluation of AUV model

The most widely used method for measuring performance and the accuracy indicators of the system is the root mean square error (RMSE). Table 1 shows the RMSE values of the modeling error in velocity in each degree of freedom. Those errors are the error between the actual velocities generated from the mathematical model and velocities generated from NFN model with and without online adaptive.

TABLE I. THE RMSE VALUES FOR AUV ANFN MODEL AND FUZZY MODEL IN EACH VELOCITY COMPONENT.

Velocity Error	NFN Model without online adaptive	NFN Model with online adaptive
u	0. 0539	3.4493e-004
v	0. 1072	0.0048
w	0.0214	1.5662e-006
q	0. 0361	4.3173e-006
r	0. 1288	9.8547e-007

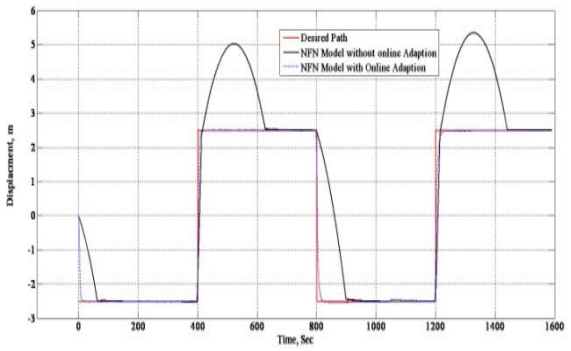

Figure 6. AUV square motion in XY plane with NFN model with and without online Adaptive.

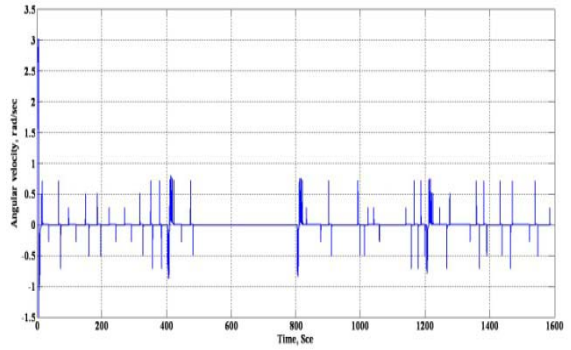

Figure 7. The angular velocity of the mathmatical model in pitch mption, *q*.

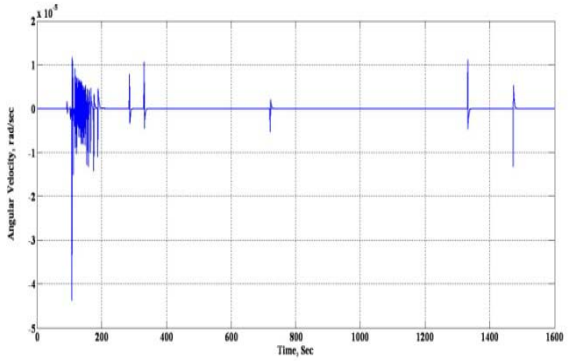

Figure 8. The error between mathematical model and adaptive NFN model in *q*.

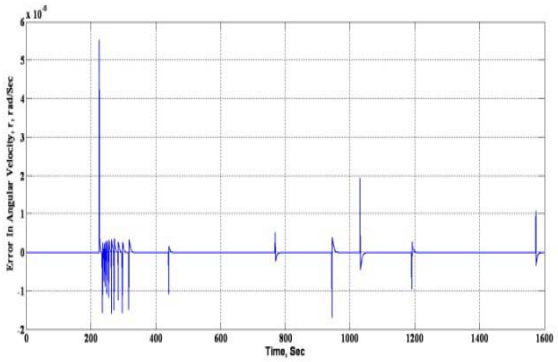

Figure 9. The error between mathematical model and ANFN model in *r*.

6 Concluding Remarks

The paper presents the numerical simulation results of the online adaptive NFN modeling with and without online adaptive as system identification of the mathematical modeling of the AUV. System identification with the NFN with FLNN structure is found to be quite effective for the coupled nonlinear, six degree of freedom dynamic model. It is shown that the overall performance of a suitably chosen NFN structure is superior to an adaptive fuzzy structure for identification of nonlinear dynamic systems.

NFN modeling is used to identify the model of the AUV using input-output data. The back propagation as a training algorithm for the system proves the fast convergence of the NFN model identifier successfully achieved a similar performance of the process.

***Abstract*-- In recent years image classification has emerged as the most significant area of research in the field of remote sensing. Image classification helps us to acquire the geo-spatial information from the satellite data which can be useful to industries like defence, intelligence, natural resources etc. There exist various techniques like Biogeography Based Optimization (BBO), Ant Colony Optimization (ACO) etc for image classification. Here, we are applying a metaheuristic approach called Cuckoo Search in the area of image classification. The main advantage of this algorithm over other metaheuristic approach is that its search space is extensive in nature. The proposed methodology is applied to the Alwar region of Rajasthan. The image used is a 7 band image of 472 X 546 dimensions from Indian Remote Sensing Satellite Resiurcesat. This algorithm has captured almost all the terrain features and showed high degree of efficiency for almost all the regions (water, vegetation, urban, rocky, and barren) with a Kappa coefficient of 0.9465.**

Keywords-- ***Cuckoo Search, image classification, artificial intelligence, natural computation, Multi spectral dataset.***

I. INTRODUCTION

Remote sensing [3] is the acquisition of information about an object or phenomenon, without making physical contact with the object. Now a day's sensor technology is also being used to detect and classify the objects by the means of signals propagated by satellites. Image classification plays an important role in the area of remote sensing. The intent of the classification process is to categorize all the pixels of a Multi spectral image into one of the several land cover classes; the resultant data can then be used to create thematic maps which are used for digital image analysis. At present there exist several traditional classifiers such as Minimum Distance Classifier (MDC), Maximum Likelihood Classifier (MLC) and natural computation techniques (or nature inspired algorithms) such as BBO [1], ACO [2], Particle Swarm Optimization and Artificial Neural Networks which are being applied in the field of image classification. Thus, the decision about the classifier to be used for a particular task is to be taken by the analyst. Though various Natural Computation techniques have already been introduced as a classifier, Cuckoo Search which also comes under Natural Computation was very recently introduced in this category.

Cuckoo Search (CS) [4] is a new nature inspired metaheuristic algorithm which hardly has any footprint in any of the application. And it is different from other existing metaheuristic algorithms (such as PSO, GA) in the following ways [5]:

- CS is a population based algorithm as similar to GA and PSO but the selection mechanism is different and it is more similar to harmony search.
- The randomization is more efficient as the step length is heavy tailed and thus any large step is possible.
- Number of parameters in CS is less than GA and PSO and thus it is more general and it can be adapted to wider class of optimization problems. CS can even be extended to meta-population algorithm.

CS satisfies two crucial characteristics of modern metaheuristic algorithm: intensification and diversification [6]. Intensification refers to the fact that the problem initially searches for current best solution and then finally for global solution while diversification means the algorithm explores the search space efficiently.
We have worked on Alwar region of Rajasthan, India. The aim of this paper is to capture the natural terrain features like water, vegetation,

urban, rocky, and barren from the satellite image using Cuckoo Search. The image of Alwar region is shown in figure 1.

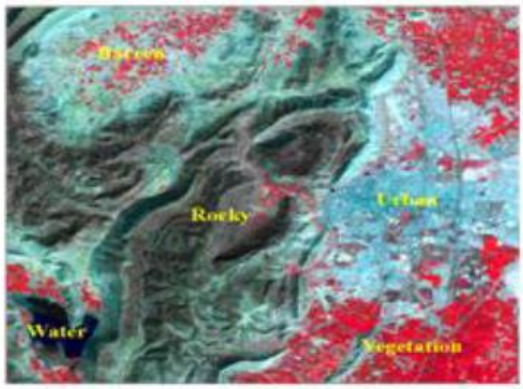

Figure 1: Alwar Region image

The organization of this paper is as follows: - Section II represents the basic concepts of Cuckoo search. Section III represents the proposed methodology. The sub-sections are organized as- problem definition, flowchart, algorithm, dataset. Section IV represents experiment and results. Section V represents conclusion of our proposed work.

II. UNDERLYING TECHNOLOGY

A. Cuckoo Search (CS)

Cuckoo Search proposed by Yang and Deb [4] is a nature inspired algorithm that is based on their aggressive reproduction strategy i.e. some species of cuckoo lay eggs in other bird's nest in a parasitic manner. There are three basic types of brood parasitism [7]:

- Intraspecific brood parasitism.
- Cooperative breeding
- Nest takeover.

Some species such as Ani and Guira cuckoos lay their eggs in the communal nests, though they may remove others' eggs to improve the hatching probability of their own eggs [8].
In cuckoo search three idealized rules [4] are formalized as follows:

- Each cuckoo lays one egg at a time, and dumps its egg in randomly chosen nest.
- The best nest with high quality of eggs will carry over the next generation.
- The number of available hosts is fixed and the egg laid by the cuckoo is discovered by the host nest with a probability $p_a \in [0, 1]$. In this case, the host bird can either throw the egg away or abandon the nest so as to build a completely new nest in a new location.

The fraction p_a of n nests is being replaced by new nests. For a maximization problem, the quality or fitness of a solution can simply be proportional to the objective function. Based on the above three rules an algorithm of cuckoo search is given by Yang and Deb [4]. This algorithm is shown in the form of flowchart in figure 2.

B. .Algorithm

Main steps involved in the process of Cuckoo search are given below:

- Compare the cuckoo's egg with the set of available hosts.
- Randomness is added to it by using Levy flight to choose host nests.
- The above steps produce a set of quality solutions and a set of discarded solutions.
- Based on the Ranking function best solution is obtained from the set of quality solutions while discarding the worst nests.

When a new solutions is generated $x^{(t+1)}$ for, say, a cuckoo i, a Levy flight is performed [4] as :

$$\mathbf{x}_i^{(t+1)} = \mathbf{x}_i^{(t)} + \alpha \oplus \text{Lévy}(\lambda),$$

Where $\alpha > 0$, it is the step size which should be related to the scales of the problem taken under consideration. In most cases, we use $\alpha = 1$. The Levy flight essentially provides a random walk while the random step length is drawn using Levy distribution given by the equation given below [4]:

$$\text{Lévy} \sim u = t^{-\lambda}, \qquad (1 < \lambda \leq 3),$$

It has an infinite variance with an infinite mean. The steps form a random walk process with a power-law step-length distribution with a heavy tail. Some of the new solutions are being generated by Levy walk nearby the best solution obtained so far, this helps to speed up the local search. However, some fraction of the new solutions is generated by taking into consideration the randomization concept. But, whose locations should conceptually be far enough from the current best solution, this

ensures that the system does not get trapped in a local optimum.

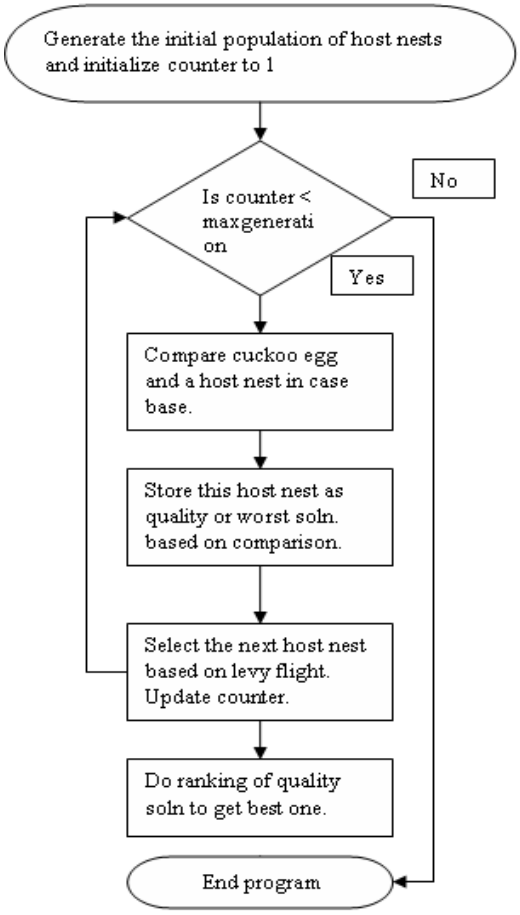

Figure 2: Cuckoo Search algorithm

III. PROPOSED METHODOLOGY

A. Problem Definition

The main aim of this section is to describe our problem domain along with the algorithm proposed to obtain a solution. Experts have provided us with the database of cases. Each of the case is a tuple of the form C={R, G, NIR, MIR, RD1, RD2, DEM} where C represents the case, R represents the value of the pixel for Red band, G represents the value the pixel for Green band, NIR represents value of the pixel for Near Infra-Red band, MIR represents the value of the pixel for Middle Infra-Red band, RD1 represents the value of the pixel for Rdarsat-1, RD2 represents value of the pixel for Radarsat-2, DEM represents the value of the pixel for Digital Elevation Model band (i.e. each of the pixel contains 7 band information obtained from the multi-spectral image of Alwar region of Rajasthan). Analyzing this case base we have to obtain the class to which the query pixel will belong using the 7 band values of the query pixel. The output classes (to which the pixel will belong) can be one of the following: water, vegetation, urban, rocky, and barren.

B. Dataset Used

We have taken a multi-spectral, multi resolution and multi-sensor image of size 472 X 546 pixels of Alwar area in Rajasthan, India. The satellite image is taken for 7 different bands. These bands are Red, Green, Near Infra-Red (NIR), Middle Infra-Red (MIR), Radarsat-1 (RD1), Radarsat-2 (RD2), and Digital Elevation Model (DEM). The ground resolution of these images is 23.5m and is taken from LISS-III sensor. The 7-band satellite image of Alwar area in Rajasthan is given in figure 3.

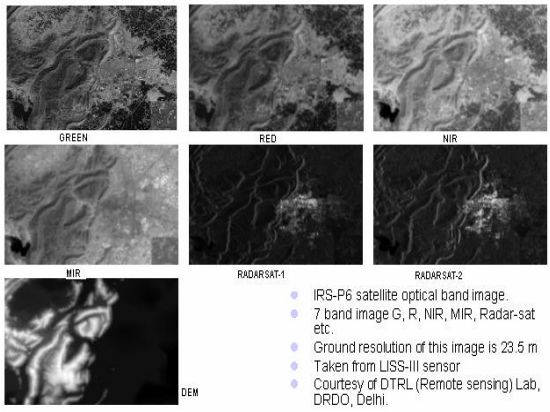

Figure 3: Band satellite image of Alwar region in Rajasthan, India

C. Algorithm

Input: Training set that consists of pixels (host nests) of different classes and other input is the image to be classified.
Output: classified image

1- Initialization
a. Generate initial population. Calculate the objective function value for all these host nests using the 7 band values.

b. Read the image to be classified. Each of the pixels of this image is to be classified.

2-Find Best Solutions

Begin Outer Loop repeat until all the pixels of the image are being classified

a. Find quality solutions

Begin Inner Loop to take into consideration all the host nests in the training set. Point the counter to the first host nest in the case base.

- Find similarity b/w host nest & cuckoo egg (pixel).(for this calculate distance between two pixels)
- Store similarity value in a database.
- Increment counter.

End Inner Loop

b. Sort the above evaluated database to find the top quality solutions.

c. The top k (taken as the square root of number of pixels in the training set) solutions are stored in a database and the worst nests are discarded.

d. Loop for the above obtained quality solution

Do the ranking of the quality solutions by calculating Pearson correlation b/w cuckoo egg & a quality solution. (Value of the coefficient varies between -1 to +1. If the value is positive it means both the quantities are positively correlated. If it's negative then the quantities are negatively correlated. But if the value is between -0.09 to +0.09 that means there is no relation between them)

End this Loop

e. Sort the quality solutions on the basis of correlation value. The one with the highest correlation value is the best solution or the required solution. The best solution is the one that matches our cuckoo egg to great extend.

f. Find the class to which best solution belongs based on the expert data. The query pixel will also belong to the same class to which the best solution belongs. Hence the query pixel is classified.

End Outer Loop

D. Flowchart

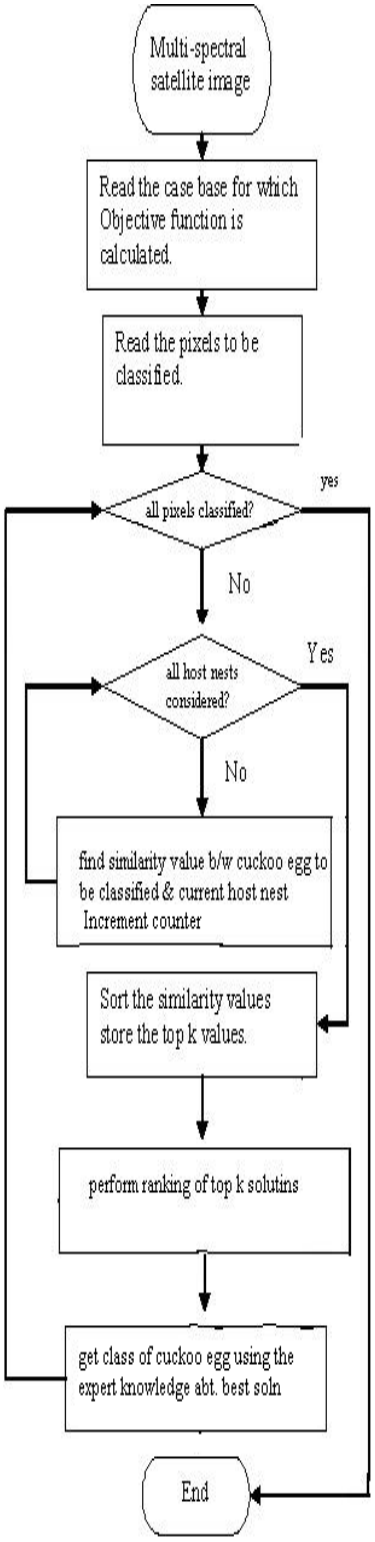

Figure 4: Flowchart of the proposed algorithm

IV. EXPERIMENT & RESULTS

To determine the efficiency of our algorithm we need to find the error matrix. Error matrix [3] compares, on category-by-category basis, the relationship between known reference data and the results obtained from an automated classification [9]. For the validation process we have taken into consideration following number of pixels:

- 68 water pixels.
- 109 vegetation pixels.
- 139 urban pixels.
- 96 rocky pixels.
- 63 barren pixels.

Using the training set the classification is performed and based on the result error matrix is calculated which is shown in table 1. The diagonal elements are representing number of properly classified pixels while non-diagonal elements are representing number of wrongly classified pixels.

Table1. Error Matrix when Cuckoo Search is applied

	Water	Vegetation	Urban	Rocky	Barren	Total
Water	68	0	0	0	0	68
Vegetation	0	109	1	0	0	110
Urban	0	0	122	0	3	125
Rocky	0	0	0	96	0	96
Barren	0	0	16	0	60	76
Total	68	109	139	96	63	475

The above table shows that with water, vegetation and rocky pixels 100% efficiency, in case of urban pixels almost 88% efficiency and with barren pixels almost 95% efficiency is obtained.

The Kappa coefficient (K) also [3] is usually considered for evaluating and analyzing the accuracy of the proposed approach in remote sensing domain. The Kappa coefficient of the Alwar image when Cuckoo search was applied is 0.9465. Comparing this value with the Kappa coefficient of MDC, MLC, BBO [9] and Membrane Computing (MC) [10], we deduced that Cuckoo search has shown best results for image classification since it has obtained the highest Kappa coefficient. The comparison is shown in figure5.

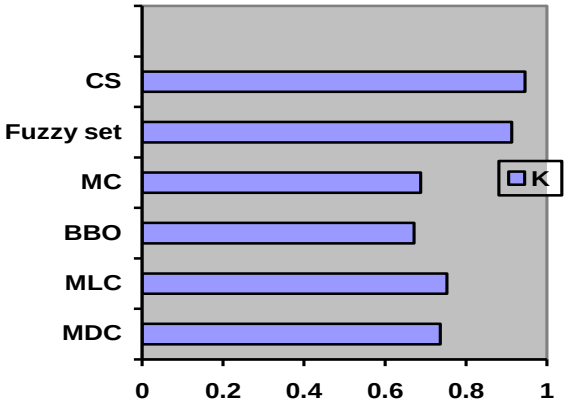

Figure 5: Classification comparison

The image showing the 257,712 classified pixels of Alwar image using Cuckoo Search is shown in figure6. The blue colour represents water region, green colour represents vegetation region, red colour represents urban region, yellow colour represents rocky region and black colour represents barren region. The output can be compared with the original image of Alwar (given by experts) shown in figure1. We analyzed that Cuckoo search has almost perfectly classified all the 5 land cover features of Alwar region.

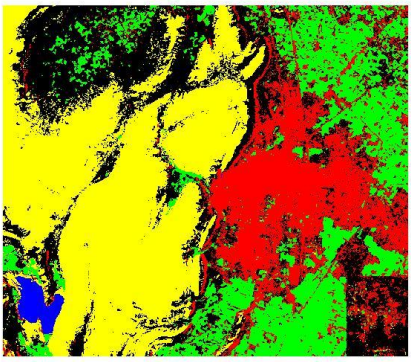

Figure 6: Classified Alwar image

V. CONCLUSION

A large numbers of soft computing techniques have been used for the classification of multi-spectral satellite image. All these techniques classified the terrain features but suffered from some uncertainties. In this paper we have presented a Cuckoo Search based search algorithm for efficiently classifying the remote sensing image. Our proposed implementation is pixel by pixel and hence overcomes the

disadvantages of the previous techniques like BBO, ACO which were implemented as cluster based approaches [1, 9]. From figure 5 we can see the higher performance for Cuckoo based search. The Kappa coefficient obtained is 0.9465 which is considered to be highly accurate as compared the Kappa coefficient of MDC, MLC, BBO, Fuzzy set and Membrane Computing which were 0.7364, 0.7525, 0.6715, 0.913 and 0.68812 [9, 10] respectively. The result of the experiment shows that the water, vegetation and rocky regions are classified with 100% efficiency while urban region with almost 88% and barren region with 95% of efficiency. Thus our proposed method for the classification of pixels was successfully able to extract the land cover features from the given dataset and also maintained high levels of classification accuracy.

Abstract - *Studies have shown that computations of visual kinematics relations are highly complicated and do require a considerable amount of time. This is due to dependent on Jacobians and massive inter-related relations. This hinders even complicated visual servo algorithm for real-time applications. In this respect, the proposed methodology is based on approximating the highly nonlinear relations and epipolar geometry relating changes of object visual features to changes in joint space of a robotics arm system, which are usually expressed in terms of kinematics relations, in addition to time-dependent Jacobian matrix. Artificial Neural system have been proposed for that purpose. A supervised learning artificial neutral network have been employed for learning the visual nonlinear kinematics relations. For validation, the concept have been applied to the well known Rives visual servo algorithm [1], with Two Scenes Epipolar Geometry. Results have shown that, highly accurate visual serving was achieved, while considerable amount of time has been reduced with the proposed methodology*

1 Introduction

Visual servoing aims to control a robotics system through artificial vision in a way as to manipulate an environment, comparable to humans actions. Intelligence-based visual control (e.g. neural or fuzzy systems) has also been introduced by research community as a way to supply robotics system even with more cognitive capabilities, [2]. There have been few number of research on the field of intelligent visual robotics arm control. For instant, an Image Based Visual Servoing using Takagi-Sugeno fuzzy neural network controller has been proposed by Miao et. al. [3]. In this paper, a Takagi-Sugeno Fuzzy Neural Network Controller (TSFNNC) based Image Based Visual Servoing (IBVS) method is proposed. Firstly, the eigenspace based image compression method is explored, which is chosen as the global feature transformation method. After that, the inner structure, performance and training method of T-S neural network controller are discussed respectively. Besides, the whole architecture of the TS-FNNC is investigated. Panwar and Sukavanam in [4] have introduced Neural Network Based Controller for Visual Servoing of Robotic Hand Eye System. In [5], Gilles et. al. have proposed neural networks organizations to learn complex robotic functions. The study considers a general problem of function estimation with a modular approach of neural computing. In [6] an approximate for exploring motion control for eye-in-hand visual servoing was presented by Mariko and Masaaki. Their study proposes a visual servo control method for exploring motion of eye-in-hand robot to recognize a three-dimensional object. In [7] an adaptive visual servo regulation control for camera-in-hand configuration with a fixed camera extension was presented by Chen, et. al. In this paper, image-based regulation control of a robot manipulator with an uncalibrated vision system is discussed. To compensate for the unknown camera calibration parameters, a novel prediction error formulation is presented. To achieve the control objectives, a Lyapunov-based adaptive control strategy is employed.

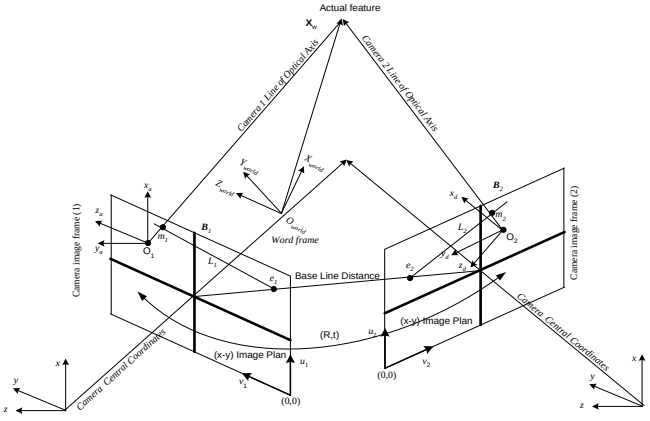

Fig. (1) : Camera image frame and Epipolar Geometry for the PowerBot AGV.

The control development for the camera-in-hand problem is presented in detail and a fixed-camera problem is included as an extension. The EGT (Epipolar Geometry Toolbox) [8], was also created to grant MATLAB users with a broaden outline for a creation and visualization of multi-camera scenarios. Image Based Visual Servoing Using Takagi-Sugeno Fuzzy Neural Network Controller has been proposed by Miao et. al. [9]. In their study, a T-S fuzzy neural controller based IBVS method was proposed. Eigenspace based image compression method is firstly explored which is chosen as the global feature transformation method. Inner structure, performance and training method of T-S neural network controller are discussed respectively. Besides that, the whole architecture of TS-FNNC is investigated. For robotics arm visual servo, this issue has been formulated as a function of object feature Jacobian. Feature Jacobian is a complicated matrix to compute for real-time applications. For more feature points in space, the issue of computing inverse of such matrix is even more hard to achieve.

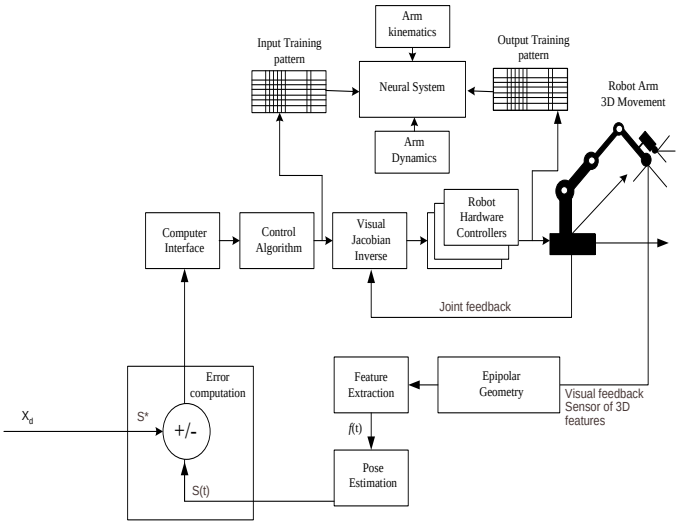

Fig. (2) : Neural system based Visual servo

2. Double Camera Scene Analysis Epipolar Geometry

In this section, we shall consider an image resulting from two camera views. For two perspective views of the same scene taken from two separate viewpoints O_1 and O_2, this is illustrated in Fig .1. Also we shall assume that (m_1 and m_2) are representing two separate points in two the views. In other words, perspective projection through O_1 and O_2, of the same point X_w, in both image planes Λ_1 and Λ_2. In addition, by letting (c_1) and (c_2) be the optical centers of two scene, the projection E_1 (E_2) of one camera center O_1 (O_2) onto the image plane of the other camera frame Λ_2 (Λ_1) is the epipole geometry. We can expressed such an epipole geometry in homogeneous coordinates in terms $\tilde{E}_1$ and $\tilde{E}_2$:

$$\tilde{E}_1 = \begin{pmatrix} E_{1x} & E_{1y} & 1 \end{pmatrix}^T \text{ and}$$
$$\tilde{E}_2 = \begin{pmatrix} E_{2x} & E_{2y} & 1 \end{pmatrix}^T \quad (1)$$

One of the main parameters of an epipolar geometry is the fundamental Matrix H (which is $\Re \in 3\times 3$). H conveys most of the information about the relative position and orientation (t, R) between the two different views. Moreover, the fundamental matrix H algebraically relates corresponding points in the two images through the Epipolar Constraint. For instant, let the case of two views of the same 3-D point X_w, both characterized by their relative position and orientation (t, R) and the internal, hence H is evaluated in terms of K_1 and K_2 (extrinsic camera parameters), [8] :

$$H = K_2^{-T}[t]_x R K_1^{-1} \quad (2)$$

In such a case, a 3-D point (X_w) is projected onto two image planes, to points (m_2) and (m_1), as to constitute a conjugate pair. Given a point (m_1) in left image plane, its conjugate point in the right image is constrained to lie on the epipolar line of (m_1). The line is considered as the projection through C_2 of optical ray of m_1. All epipolar lines in one image plane pass through an epipole point. This is the projection of conjugate optical centre : $\tilde{E}_1 = \tilde{P}_2 \begin{pmatrix} c_1 \\ 1 \end{pmatrix}$ Parametric equation of epipolar line of $\tilde{m}_1$ gives $\tilde{m}_2^T = \tilde{E}_2 + \lambda P_2 P_1^{-1} \tilde{m}_1$. In image coordinates this can be expressed as :

$$u = [m_2]_1 = \frac{[\tilde{e}_2]_1 + \lambda[\tilde{v}]_1}{[\tilde{e}_2]_3 + \lambda[\tilde{v}]_3} \quad (3)$$
$$v = [m_2]_2 = \frac{[\tilde{e}_2]_2 + \lambda[\tilde{v}]_2}{[\tilde{e}_2]_3 + \lambda[\tilde{v}]_3} \quad (4)$$

here $\tilde{v} = P_2 P_2^{-1} \tilde{m}_1$ is a projection operator extracting the i^{th} component from a vector. When (c_1) is in the focal plane of right camera, the right epipole is an infinity, and the epipolar lines form a bundle of parallel lines in the right image. Direction of each epipolar line is evaluated by derivative of parametric equations listed above with respect to (λ) :

$$\frac{du}{d\lambda} = \frac{[\tilde{v}]_1[\tilde{e}_2]_3 - [\tilde{v}]_3[\tilde{e}_2]_1}{([\tilde{e}_2]_3 + \lambda[\tilde{v}]_3)^2} \quad (5)$$
$$\frac{dv}{d\lambda} = \frac{[\tilde{v}]_2[\tilde{e}_2]_3 - [\tilde{v}]_3[\tilde{e}_2]_2}{([\tilde{e}_2]_3 + \lambda[\tilde{v}]_3)^2} \quad (6)$$

The epipole is rejected to infinity once $[\tilde{E}_2]_3 = 0$. In such a case, direction of the epipolar lines in right image doesn't

depend on any more. All epipolar lines becomes parallel to vector $\left(\left[\tilde{E}_2\right]_1 \quad \left[\tilde{E}_2\right]_2\right)^T$. A very special occurrence is once both epipoles are at infinity. This happens once a line containing (c_1) and (c_2), the baseline, is contained in both focal planes, or the retinal planes are parallel and horizontal in each image as in Fig. (1). The right pictures plot the epipolar lines corresponding to the point marked in the left pictures. This procedure is called rectification [8]. If cameras share the same focal plane the common retinal plane is constrained to be parallel to the baseline and epipolar lines are parallel.

3. Neural Net Based Image-Based Visual Servo Control (ANN-IBVS)

Over the last section we have focused more in single and double camera scenes, i.e. representing the robot arm visual sensory. In this section, we shall focus on Image-Based Visual Servo (IBVS) which uses locations of object features on image planes (epipolar) for direct visual feedback. For instant, re-consider Fig. 1, and Fig. 2, where it is desired to move a robotics arm in such away that camera's view changes from (initial) to (final) view, and feature vector from (ϕ_0) to (ϕ_d). Here (ϕ_0) may comprise coordinates of vertices, or areas of the object to be tracked. Implicit in (ϕ_d) is the robot is normal to, and centered over features of an object, at a desired distance. Elements of the task are thus specified in image space. For a robotics system with an end-effector mounted camera, viewpoint and features are functions of relative pose of the camera to the target, $({}^c\xi_t)$. Such function is usually nonlinear and cross-coupled. A motion of end-effectors DOF results in complex motion of many features. For instant, a camera rotation can cause features to translate horizontally and vertically on the same image plane, as related via the following relationship :

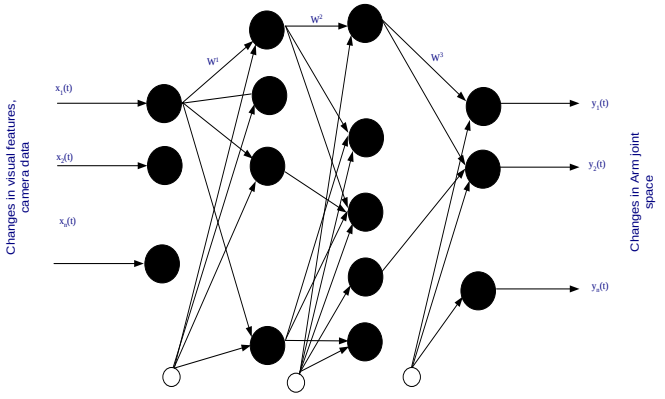

Fig. (3) : Learning neural system

$$\phi = f({}^c\xi_t) \tag{7}$$

Equ (7) is to be linearized. This is to be done around an operating point :

$$\delta\phi = {}^f J_c({}^c x_t)\delta\, {}^c x_t \tag{8}$$

$${}^f J_c({}^c x_t) = \frac{\partial \phi}{\partial {}^c x_t} \tag{9}$$

In Equ (9), ${}^f J_c({}^c x_t)$ is the Jacobian matrix, relating rate of change in robot arm pose to rate of change in feature space. Variously, this Jacobian is referred to as the feature Jacobian, image Jacobian, feature sensitivity matrix, or interaction matrix [10]. Assume that the Jacobian is square and non-singular, then :

$${}^c\dot{x}_t = {}^f J_c({}^c x_t)^{-1}\dot{f} \tag{10}$$

from which a control law can be expressed by :

$${}^c\dot{x}_t = [K][{}^f J_c({}^c x_t)^{-1}](f_d - f(t)) \tag{11}$$

will tend to move the robotics arm towards desired feature vector. In Equ (11), K^f is a diagonal gain matrix, and (t) indicates a time varying quantity. Object posture rates ${}^c\dot{x}_t$ is converted to robot end-effector rates. A Jacobian , ${}^f J_c({}^c x_t)$ as derived from relative pose between the end-effecter and camera, $({}^c x_t)$ is used for that purpose. In this respect, a technique to determine a transformation between a robot's end-effector and the camera frame is given by Tsai and Lenz [11] . In turn, an end-effector rates may be converted to manipulator joint rates using the manipulator's Jacobian [12], as follows :

$$\dot{\theta}_t = {}^{t6}J_\theta^{-1}(\theta)\,{}^{t6}\dot{x}_c \tag{12}$$

$\dot{\theta}_t$ represents the robot joint space rate. A complete closed loop equation can then be given by :

$$\dot{\theta}_t = K\,{}^{t6}J_\theta^{-1}(\theta)\,{}^{t6}J_\theta^f J_c^{-1}\,{}^c x_t(f_d - f(t)) \tag{13}$$

For achieving this task, an analytical expression of the error function is given by :

$$\varphi = Z^+\varphi_1 + \gamma(I_6 - Z^+Z)\frac{\partial \varphi_2}{\partial X} \tag{14}$$

Here, $\gamma \in \Re^+$ and Z^+ is pseudo inverse of the matrix Z, $Z \in \Re^{m\times n} = \Re(Z^T) = \Re(J_1^T)$ and J is the Jacobian matrix of task function as $J = \frac{\partial \varphi}{\partial X}$. Due to modeling errors, such a closed-loop system is relatively robust in a possible presence of image distortions and kinematics parameter variations of the Puma 560 kinematics. A number of researchers also have demonstrated good results in using this image-based approach for visual servoing. It is always reported that, the significant problem is computing or estimating the feature Jacobian, where a variety of approaches have been used [12]. The proposed IBVS structure of Weiss [13,14], controls robot joint angles directly using measured image features. Non-linearities include manipulator kinematics and dynamics as

well as the perspective imaging model. Adaptive control was also proposed, since ${}^{f}J_{\theta}^{-1}({}^{c}\theta)$, is pose dependent. In this study, changing relationship between robot pose, and image feature change is learned during the motion via a learning neural system. The learning neural system accept s a weighted set of inputs (stimulus) and responds. The four-layer feedforward neural network with (n) input units, (m) output units and N units in the hidden layer, is shown in the Fig. (3).

Fig. (3). exposes a one possible neural network architecture that have been used. In reference to the Fig. (3), every node is designed in such away to mimic its biological counterpart, the neuron. Interconnection of different neurons forms an entire grid of the used ANN that have the ability to learn and approximate the nonlinear visual kinematics relations. The used learning neural system composes of four layers. The input, output layers, and two hidden layers. If we denote ${}^{w}v_{c}$ and ${}^{w}\omega_{c}$ as the camera's linear and angular velocities with respect to the robot frame respectively, motion of the image feature point as a function of the camera velocity is obtained by :

$$\dot{\gamma} = -\frac{\alpha\lambda}{{}^{c}p_{c}} \begin{bmatrix} 0 & 0 & \frac{{}^{c}p_{x}}{{}^{c}p_{z}} & \frac{{}^{c}p_{x}\,{}^{c}p_{x}}{{}^{c}p_{z}} & -\frac{{}^{c}p_{x}\,{}^{c}p_{x}}{{}^{c}p_{z}} & {}^{c}p_{x} \\ 1 & -1 & \frac{{}^{c}p_{y}}{{}^{c}p_{z}} & \frac{{}^{c}p_{x}\,{}^{c}p_{x}}{{}^{c}p_{z}} & -\frac{{}^{c}p_{x}\,{}^{c}p_{x}}{{}^{c}p_{z}} & -{}^{c}p_{x} \end{bmatrix} \begin{bmatrix} {}^{c}R_{w} & 0 \\ 0 & {}^{c}R_{w} \end{bmatrix} \begin{bmatrix} {}^{w}v_{c} \\ {}^{w}\omega_{c} \end{bmatrix} \tag{15}$$

Instead of using coordinates ${}^{x}P_{c}$ and ${}^{y}P_{c}$ of the object feature described in camera coordinate frame, which are a priori unknown, it is usual to replace them by coordinates (u) and (v) of the projection of such a feature point onto the image frame.

4 Simulation: A Case Study

In this section the presented visual servoing is verified and discussed. The simulated system is presented in Fig. (2). During simulations the task has been performed using 6-DOF Puma manipulator with 6 revolute joints and a camera that can provide position information of the robot tip and the target in the robot workplace. The robot direct kinematics is given by the set of equations of Puma 560 robotics system, as documented in [15]. Kinematics and dynamics equations are already well known in the literature. For the purpose of comparison, the used example is based on visual servoing system developed by Rives [1]. The robotics system are has been servoing to follow an object that is moving in a 3-D working space. Object has been characterized by (8-features) marks, this has resulted in 24, $\Re \in^{8\times3}$ size, feature Jacobian matrix.

INITIAL PHASE: FREE RUNNING SYSTEM, ANN DESIGN, AND LEARNING :

The foremost ambition of this visual servoing is to drive a 6-DOF robot arm, as simulated with Robot Toolbox [14], and equipped with a pin-hole camera, as simulated with Epipolar Geometry Toolbox, EGT [8], from a starting configuration toward a desired one using only image data provided during the robot motion. For the purpose of setting up the proposed method, Rives algorithm has been run a number of time before hand. In each case, the arm was servoing with different object posture and a desired location in the working space.

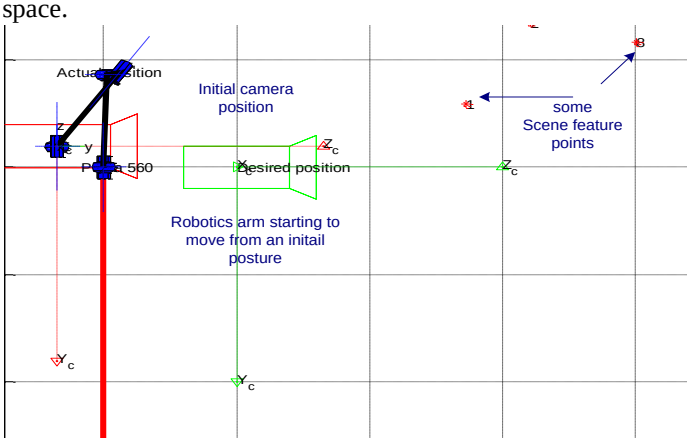

Fig. (4) : Top view: Actual object position and desired position.

Large training patterns have been gathered and classified, therefore. Gathered patterns at various loop locations gave an inspiration to a feasible size of learning neural system. Four layers artificial neural system has been found a feasible architecture for that purpose. The net maps 24 (3×8 feature points) inputs characterizing object cartesian feature position and arm joint positions into the 6 differential changes in arm joints positions. The network is presented with some arm motion in various directions. Once the neural system has learned with presented patterns and required mapping, it is ready to be employed in the visual servo controller. Trained neural net was able to map nonlinear relations relating object movement to differentional changes in arm joint space. Object path of motion was defined and simulated via Rives Algorithm, as given in [1], after such large number of running and patterns, it was apparent that the learning neural system was able to capture such nonlinear relations. Execution starts primary while employing learned neural system within the robotics dynamic controller (which is mainly dependent on visual feature Jacobian). In reference to Fig. (2), visual servoing dictates the visual features extraction block. That was achieved by the use of the Epipolar Toolbox. For assessing proposed visual servo algorithm, simulation of full arm dynamics has been achieved using kinematics and dynamic models for the Puma 560 arm. Robot Toolbox has been used for that purpose. In this respect, Fig. (4) shows an aerial view of actual object posture and the desired one. This is prior to visual servoing to take place. The figure also

indicates some scene features. Fig. (5) shows the Robot arm-camera servoing and approaching towards a desired object posture. ANN was fed with defined pattern during arm movement. Epipolars have been used to evaluate visual features and the update during arm movement. Fig. (6) shows error between the Rives Algorithm and the proposed ANN based visual servo. Results suggest high accuracy of identical results, indicating that a learned neural system was able to servo the arm to desired posture. Difference in error was recorded within the range of (2.5×10^{-7}) for specific joint angles. Finally, Fig. (7) show migration of the eight visual features as seen over the camera image plan. Just the once the Puma robot arm was moving, concentration of features are located towards an end within camera image plane.

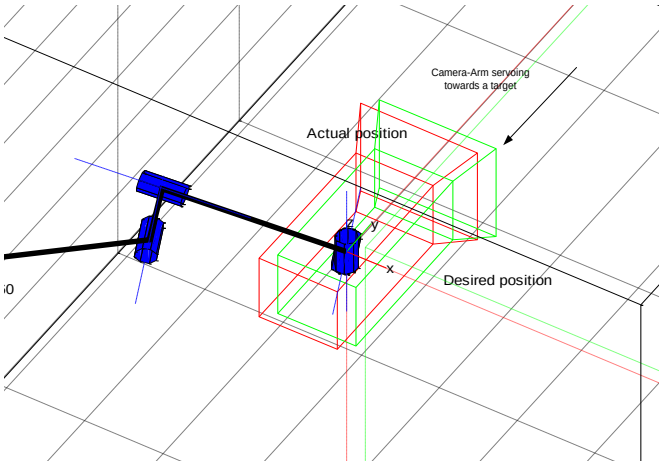

Fig. (5) : Robot am-camera servoing towards a desired object posture.

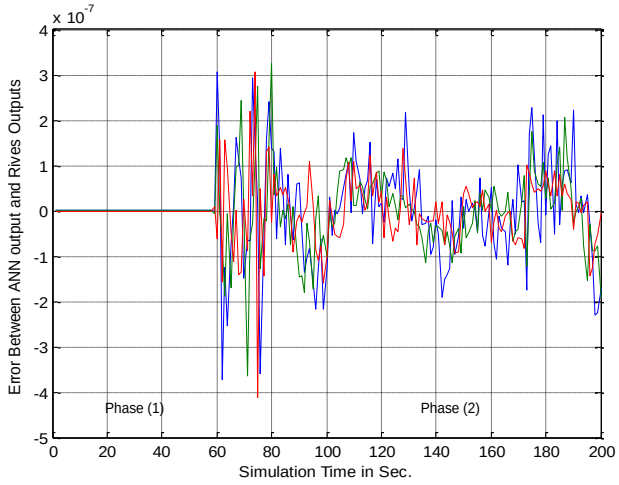

Fig. (6) : Error between the Rives Algorithm results and the proposed ANN based visual servo

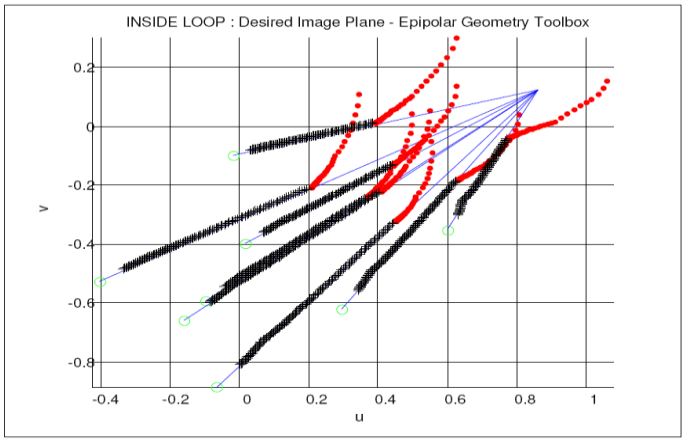

Fig. (7) : Migration of eight visual features, as seen over the camera image plan.

5 Conclusions

This article has been focused towards approximating complicated nonlinear kinematics and feature Jacobian matrices relating a robotics arm system movement in reference to an object displacement, as profoundly appear in closed loop visual servos systems. The presented approach avoids " heavily computed " kinematics relations. That was achieved whilst using a leaning artificial neural system, resulting in reduced computation time, usually a cumbersome for real-time applications. In addition, the proposed methodology depends on mergence of three MatLab-based Toolboxes together, the Robotics Toolbox, ANN toolbox, and the Epipolar Geometry Toolbox. While learning closed-loop visual and kinematics relations, a multi-layer neural net structure has been used for that purpose. The proposed methodology has proven to be an effective approach of approximation, and has reduced computational time usually needed to update visual feature Jacobian matrix as robotics system in motion.

Abstract-*This paper focuses on the design and implementation of the analytical hierarchy process (AHP) using Fuzzy inference techniques. This AHP-FUZZY approach is a multi-criteria combination system. The nature of the AHP-FUZZY approach is pair-wise comparison, which is expressed by the fuzzy inference techniques, to achieve the weights of the attributes. The hierarchy structure of the AHP-FUZZY approach can greatly simplify the definition of decision strategy and represent the multiple criteria explicitly, and the fuzzy inference technique can handle the vagueness and uncertainty of the attributes and adaptively generate the weights for the system. Based on the AHP-FUZZY approach, a simulation system is implemented in the route guidance system and the process is analyzed.*

Keywords: fuzzy inference, analytical hierarchy process

1 Introduction

Route choice mechanism is the key technology of the route guidance system providing path planning strategy for the travelers. However, most of the route guidance systems usually give the shortest distance path or shortest time path based on the historical average traffic data, which easily cause traffic congestion. Therefore, optimum route choice based on the static and dynamic traffic information can provide optimum path for travelers and alleviate traffic congestion. Due to the complexity of the route choice attributes, it is hard to realize the pair-wise comparison between different attributes.

In the past few years, much research has been done to study the route choice algorithm, the mainly used algorithms are as follows: fuzzy logic algorithm and genetic algorithm [1], fuzzy neural algorithm [2], fuzzy logic-ant colony [3], analytical hierarchy process (AHP) using quantifier-guided ordered weighted averaging (OWA) procedure [4]. The fuzzy logic based system is widely used mainly because of its capacity to handle vagueness and it is also easy to combine with other methods to adaptively choose the optimum route. OWA is a kind of multi-criteria aggregation procedure which was developed in the context of fuzzy set theory and is composed of two weights: the weights of criterion importance and order weights. The order weights decide the optimum route choice of road network, while the AHP proposed by Saaty (1980) is based on the additive weighting model. The AHP can decompose the decision problem into a hierarchy of sub-problems composed of several criterions and the importance of weights is associated with their criterions. This approach is of great importance for spatial decision problems that can not complete pair wise comparisons of the alternatives [5]. However, due to the vagueness and uncertainty of traffic attributes and route decisions, a crisp, pair-wise comparison of AHP can not capture the vagueness of traffic attributes. Thus, fuzzy logic is introduced into the AHP structure to compensate the deficiency of AHP.

This paper is outlined as follows: Section II gives an introduction to the AHP approach in a spatial decision-making context. Section III presents the AHP procedures using fuzzy inference techniques. Section IV presents an implementation of the approach and the results analysis. Some conclusions are given in Section V.

2 The AHP approach

The AHP approach is a flexible and yet well structured methodology to analyse and solve complex decision problems by structuring them into hierarchical framework [6]. It can be realized by three steps: (1) developing the AHP hierarchy, (2) pair-wise comparison of elements of the hierarchical structure, (3) constructing an overall priority rating.

2.1 The AHP hierarchy

For the first step of the AHP procedure, it is to decompose the decision problem into several sub-problems, represented by the hierarchy structure tree, which consists of goal, objectives, attributes and alternatives (Figure 1.). Accordingly, the spatial-decision problem is related to a set of defined alternatives, a set of evaluation criteria and its associated weights.

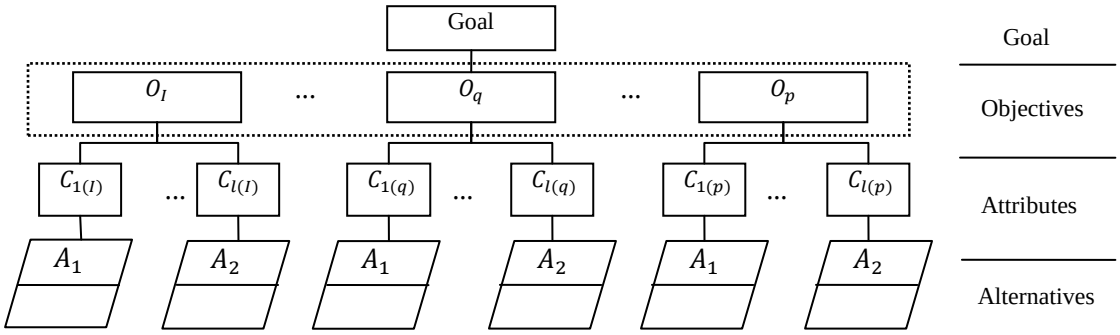

Figure 1. The hierarchy structure of AHP approach

The spatial decision problem is decomposed into a set of p objectives O_q for $q = 1,2,\dots,p$. The objectives are measured in terms of the underlying attributes, and a set of n attributes C_j for $j = 1,2,\dots,n$, corresponded with the p objectives. In addition, a subset of attributes in terms of the q th objective is denoted by $C_{k(q)}$ for $k = 1,2,\dots,l; l \le n$. The weights of objectives and attributes can be denoted by $w_q = [w_1, w_2, \dots, w_p]$ and $w_{k(q)} = [w_{1(q)}, w_{2(q)}, \dots, w_{3(q)}]$ respectively, where $w_q \in [0,1], \sum_{q=1}^{p} w_q = 1$, and $w_{k(q)} \in [0,1], \sum_{k=1}^{l} w_{k(q)} = 1$. The performance of the alternatives is related to attributes C_j is denoted by a set of standardized criterion values: $X = [x_{ij}]_{m\times n}$; $x_{ij} \epsilon [0,1]$ for $j = 1,2,\dots,n$.

2.2 Pair-wise comparisons

The pair-wise comparison as the second step of the AHP procedure is the basic measurement mode employed in the AHP procedures, which can greatly reduce the conceptual complexity of a problem since only two components are considered at any given time.

The decision hierarchy tree of AHP can provide the selection and ranking of alternatives by pair-wise comparison according to related criteria. The pair-wise comparison matrices are based on the alternatives, $A_1, \dots, A_m$, in terms of each criteria being considered. A pair-wise matrix for an expert i with respect to criterion k can be denoted as:

$$A_i^k = \begin{matrix} \\ A_1 \\ \vdots \\ A_m \end{matrix} \begin{matrix} \begin{matrix} A_1 & \dots & A_m \end{matrix} \\ \begin{bmatrix} a_{11}^{k,i} & \cdots & a_{1m}^{k,i} \\ \vdots & \ddots & \vdots \\ a_{m1}^{k,i} & \cdots & a_{mm}^{k,i} \end{bmatrix} \end{matrix} \quad (1)$$

Each a'_{11} denotes the strengths of preferences that the user believe alternative i over alternative j.

Each pair-wise matrix in the form of $m \times m$, whose elements are a'_{11}s, is a square positive reciprocal matrix:

$$a_{ij} = \frac{1}{a_{ji}} \text{ and } a_{ii} = 1.00 \ \forall i, j = 1, \dots, m \quad (2)$$

Therefore, the ratio either under or above the principal diagonal of the matrix are enough to complete the matrix by taking the reciprocals of the given elements. Each a_{ij} could be regard as an estimate of the weight of the alternative i, w_i, to alternative j, w_j:

$$a_{ij} = \frac{w_i}{w_j} \quad (3)$$

Then,

$$w_i = a_{ij} w_j \quad (4)$$

2.3 The weights of the criterions

After the pair-wise comparison matrix is obtained, the next step is to summarize preferences so that each element can be assigned a relative importance. It can be achieved by computing the weights and priorities, $w = [w_1, w_2, \dots, w_p]$ for p objectives and $w_{(q)} = [w_{1(q)}, w_{2(q)}, \dots, w_{l(q)}]$ for attributes associated with the qth objective.

The weights can be achieved by normalizing the eigenvector with respect to the maximum eigenvalue of the pair-wise comparison matrix. The normalized eigenvector consists of an iterative process; first the matrix $\hat{A}$ is calculated by normalizing the columns of A:

$$\hat{A} = [a_{qt}^*]_{p\times p}, \quad (5)$$

Where $a_{qt}^* = \frac{a_{qt}}{\sum_{q=1}^{p} a_{qt}}$, for all $t = 1,2,\dots,n$.

The vector of ω can be given:

$$w_q = \hat{a}_{qt(z)}^*, \text{ for all } q = 1,2,\dots,p. \quad (6)$$

By the simple rule, the attributes weights can be calculated:

$$a_{kh(q)}^* = \frac{a_{kh(q)}}{\sum_{k=1}^{l} a_{kh(q)}}, \text{ for all } h = 1,2,\dots l. \quad (7)$$

$$w_{k(q)} = \hat{a}_{kh(q)}^*, \text{ for all } k = 1,2,\dots,l. \quad (8)$$

2.4 The priority rating

Finally the weights can be given by aggregating the relative weights of objectives and attribute levels, which can be done by a sequence of multiplications of the matrices of relative weights at each level of hierarchy. The global weights of each criterion, w_j^g are calculated as follows:

$$w_j^g = w_q \times w_{k(q)} \quad (9)$$

For the overall evaluation results, R_i of the ith alternative is calculated as follows:

$$R_i = \sum_{j=1}^{n} w_j^g x_{ij} \quad (10)$$

Where x_{ij} is associated with the attributes value.

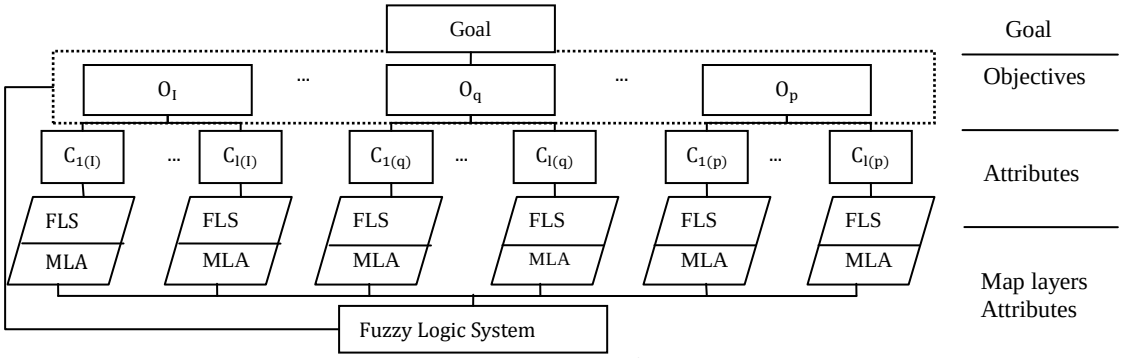

Figure 2. The hierarchical structure of AHP-FUZZY system

3 The Ahp-fuzzy system

3.1 The FUZZY model

FLS[7] is a process of mapping an input space onto an output space using membership functions and linguistically specified rules. The process of fuzzy inference involves Membership Functions, Logical Operations, and If-Then Rules. Fuzzy Logic theory with expert knowledge can represent the inference procedure explicitly using a set of fuzzy if-then rules, which offer a high degree of transparency into the system being modeled. With the inputs and output defined, it needs to specify a set of rules to define the model. The rules of approximate reasoning which can be used to describe the route choice are if-then rules. After the inputs are fuzzified and the degree of each part of the antecedent is satisfied for each rule, the logical operations can help the logical verbal rules. Finally, defuzzification process can help resolve a single output value from the set.

3.2 The AHP-FUZZY model (Figure 2.)

Consider a directed graph $\vec{G} = (V, E)$ with a origin point $o \in V$ and a destination $d \in V$. A denotes the set of all acyclic routes from the origin point o to destination point d on $\vec{G} = (V, E)$. For each road segment of road network $e \in E$, criteria is defined, then the multi-criteria structure is imposed on the road network.

The purpose of this paper is to give the least cost route decision considering both the traffic density of road segments of each intersection and the overall cost of O/D pairs. Supposing that there are a set of m alternatives, that is, m adjacency road segments for each node, which can be denoted by A_i for $i = 1,2,\dots,m$. The alternatives are to be evaluated by a set of p objectives O_q, where $q = 1,2,\dots,p$. The objectives are measured in terms of the underlying attributes. Thus, a set of n attributes associated with the p objectives can be denoted by C_j, where $j = 1,2,\dots,n$, while a subset of attributes associated with the qth objective is denoted by $C_{k(q)}$, for $k = 1,2,\dots,l; l \le n$. There are two sets of weights, $w_q = [w_1, w_2, \dots, w_p]$ and $w_{k(q)} = [w_{1(q)}, w_{2(q)}, \dots, w_{3(q)}]$ are assigned to the objectives and attributes, respectively. The weights have the following properties: $w_q \in [0,1]$, $\sum_{q=1}^{p} w_q = 1$, and $w_{k(q)} \in [0,1]$, $\sum_{k=1}^{l} w_{k(q)} = 1$. Based on the basic knowledge of AHP approach, the fuzzy logic approach is employed to improve its performance. For the weights of the objectives and weights, they are not constant values any more, which will be decided by the fuzzy logic rules. Combining with the above weights, the global weights of each criterion, w_j^g are calculated as follows: $w_j^g = w_q \times w_{k(q)}$, while the performance of alternatives A_i with respect to attributes C_j represented by a set of standardized criterion values: $X = [x_{ij}]_{m \times n}$; for $x_{ij} \in [0,1], j = 1,2,\dots n$. The final evaluation results of the ith alternative can also be calculated as follows: $R_i = \sum_{j=1}^{n} w_j^g x_{ij}$, where x_{ij} is associated with the attributes value.

4 Implementation of Ahp-fuzzy approach

4.1 Illustration of implementation process

Traditionally, the movements of vehicles are considered as isolated moving units in the route guidance system. However, a car driving on the road is influenced by the whole road network including static and dynamic

information. Generally, distance and travel time are usually considered as the main factors to decide the route selection neglecting the traffic density which can represent the traffic load capacity and the intensity of travelers' comfort. Basically, travelers usually want to get to their destination at least cost. Thus, there are three main criteria considered in this route guidance system for k routes given by the route search algorithm, as follows:

- Travel distance: 0 denotes the routes with the shortest distance. In contrast, 1 denotes the longest route. The attribute value for other routes can be decided by a linear scale.

- Travel time: 0 denotes the least time, while 1 denotes the largest time value. Again, the attribute value for other routes can be decided by a linear scale.

- Travel congestion: 0 denotes no congestion, while 1 denotes the worst situation.

It can be noticed that each driver wants to get to their destination at least cost, that is, those attribute scores are close to zero.

Therefore, the hierarchy structure also consists of objectives, attributes and alternatives (Figure 3.). The overall goal is to achieve the least cost path. The objectives are decided by three criterions: (i) distance, (ii) time, (iii) density. The weights of the objective are decided by these three criterions:

$$w_q = [w_1, w_2, w_3],$$

Where w_q denotes the weights of three criterions respectively, $q = 1,2,3$.

The weights of the attributes are decided by the pair-wise comparison of alternatives:

$$w_{k(q)} = [w_{1(q)}, w_{2(q)}, \dots, w_{3(q)}],$$

Where $w_{k(q)}$ is in terms of the weights of the alternatives corresponding to one single attribute. $k = 1,2,3$. In order to simply the illustration, only three alternative routes are considered.

As mentioned in Section III, the fuzzy inference system is introduced into the AHP approach to quantify the weights of objectives and attributes. The nature of the fuzzy inference system is the formal mathematical formulation represented by the fuzzy rule statements.

As to the weights of the objectives w_q, the traveling cost composed of travel distance and travel time, is influenced by the traffic on the roads. Moreover, the cost of road segment is greatly influenced by the road load capacity, that is, traffic density. Thus, the fuzzy rules can be given according to the intensity of traffic density. The first fuzzy rules are described as follows:

- If the traffic density is low, then the weight of distance is high, that is, the time weight is low (For the free traffic flow, the cost of traffic is totally decided by the shortest path.

- If the traffic density is high, then the weight of time is high, that is, the distance weight is low (For time periods of traffic congestion, the cost of traffic is totally decided by the least time path).

- If the traffic density is medium, then the weight of distance is medium, that is, the time weight is medium. As to the value of the weights, it can be generated by the fuzzy membership function and defuzzification process.

For the weights of the attribute $w_{k(q)}$, is in terms of the weights of the alternatives corresponding to one single attribute. $k = 1,2,3$.

1) If the degree of the attributes (distance, time, density) is low, then the weight of the attributes is low.

2) If the degree of the attributes (distance, time, density) is medium, then the weight of the attributes is medium.

3) If the degree of the attributes (distance, time, density) is high, then the weight of the attributes is high.

Based on the fuzzy rules and the membership functions of fuzzy sets, the criterion weights w_q and $w_{k(q)}$ are generated by the defuzzyfication process. The global weights of each criterion, w_j^g are calculated as follows: $w_j^g = w_q \times w_{k(q)}$. The final evaluation results of the ith alternative can also be calculated as follows: $R_i = \sum_{j=1}^{n} w_j^g x_{ij}$, where x_{ij} is associated with the attributes value.

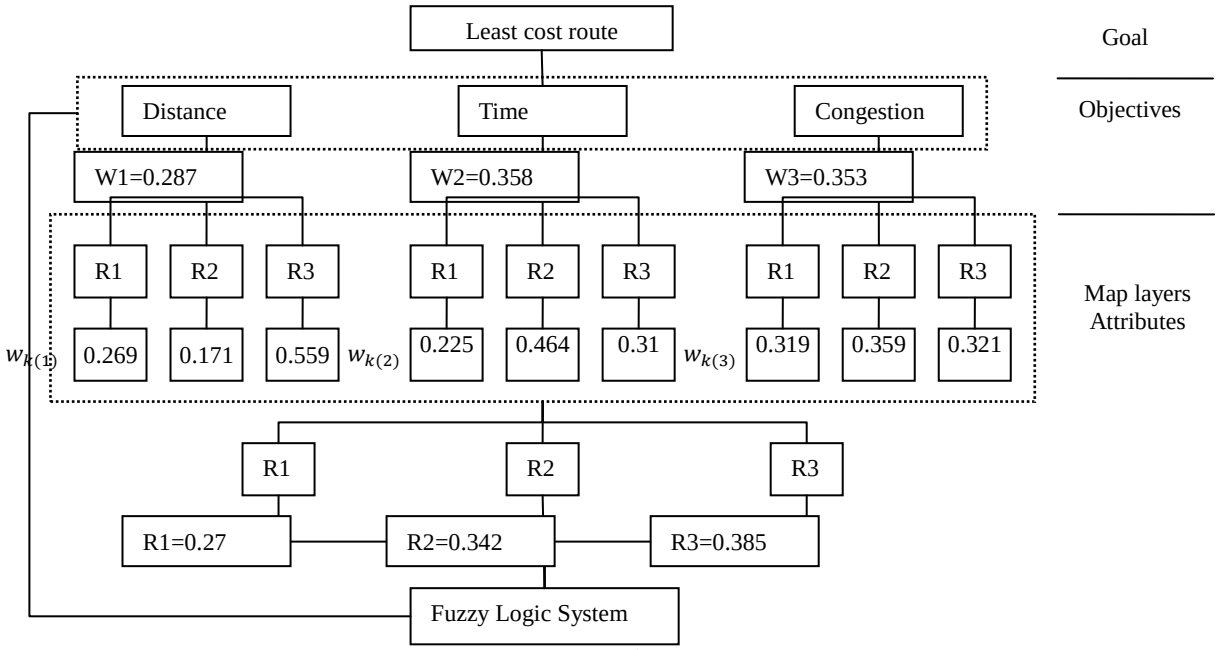

Figure 3. The implementation of AHP-FUZZY system

4.2 Result analysis

In order to demonstrate the process of the AHP-FUZZY approach, a simulation is implemented in Sydney and a random orientation and destination is selected for the study. Based on the real-time traffic information, three available routes are given as the route alternatives for pair-wise comparison and an illustration example is given in Figure 3.

TABLE 1. PAIR-WISE COMPARISON MATRIX OF THE OBJECTIVE ATTRIBUTES

	Distance	Time	density	weight
Distance	1	0.8	0.81	0.287
Time	1.25	1	1.01	0.358
Density	1.23	0.98	1	0.353

TABLE 2. PAIR-WISE COMPARISON MATRIX OF ALTERNATIVES CORRESPONDING TO THE DISTANCE

	A1	A2	A3	weight
A1	1	1.57	0.48	0.269
A2	0.64	1	0.3	0.171
A3	2.07	3.26	1	0.559

The pair-wise comparison of the objectives and attributes can be achieved by the fuzzy inference techniques. Table1 and Table2 show the pair-wise comparison of the objectives and attributes. From Equation(9), it can easily get the global weights of the alternatives. The evaluation results can also be given by the Equation(10).

TABLE 3. RESULTS COMPARISON FOR ROUTE CHOICE METHODS

Route choice methods	**Distance**	**Time**	**cost**
Shortest distance	18.5km	85min	0.2934
Least time	21.85km	44min	0.1542
Least cost	20.26km	48min	0.1278

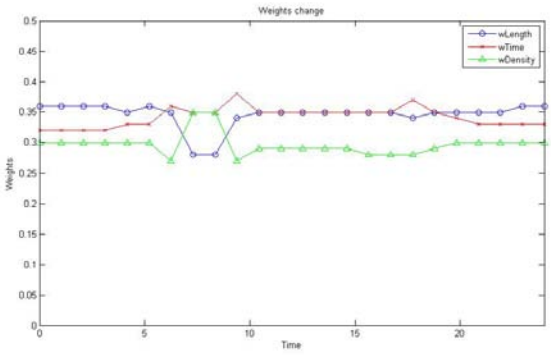

Figure 4. Traffic attributes changes during the whole day

Figure 4 shows that the weights change less during off-peak hours, while there are great gaps during peak hours. For the off-peak hours, the traffic is usually free flow traffic and the AHP-FUZZY approach usually chooses the shortest path for the travelers. During the peak hours, for the different road segments, they have different traffic density, thus the weights of traffic attributes are different from each other. The results denote that the AHP-FUZZY approach can adaptively change their weights based on the real time information.

In order to validate the AHP-FUZZY model providing optimum path, we compare the least cost path with the shortest path and least time path. During off-peak hour, shortest path or least time always comes with the least cost, there is no need to compare them during off-peak hour. Thus, the comparison results focus on the peak-hour traffic. The results for three route choice methods at 8:00am are shown in Table 3. From Table 1, it shows that the shortest distance path has the longest time and the least time path has the longest distance, while the least cost path has the medium distance and medium time. From study the traffic volume data on these three routes, it shows that traffic volume on shortest distance path has heavy traffic jams, while the least time waste too much

cost on the road distance. Based on the study of traffic data on routes of shortest distance path and least time path, it can be shown that the least cost path is more optimum and it can also balance the traffic flow on the roads without betray the cost requirements.

5 Conclusion

In this paper, an AHP-FUZZY approach for route guidance system is proposed. The AHP-FUZZY approach is a multi-criteria combination system developing the hierarchy structure and adaptively generating the weights based on the two step fuzzy rule system, which can greatly simplify the definition of decision strategy and represent the multiple criteria explicitly. In addition, for the two step fuzzy-rule system, the former one can adaptively generate different weights of attributes (distance, time and density) based on the traffic density during the whole time periods of day, and the letter one can realize the dynamic route selection based on the real time traffic information. The simulation experiment has been done on the road network in Sydney. The simulation results show that this AHP-FUZZY approach can adaptively adjust the weights of the objectives to get the least cost path for the different time periods of day.

Abstract – *artificial bee colony algorithm is a new swarm intelligence algorithm. It is inspired from natural bee swarm intelligence concepts to solve the optimization problems. This paper proposes a framework for artificial bee colony algorithm. This framework is problem independent. The usage of this framework in any optimization problem is the goal of this research. This reusability is presented as a part of this paper.*

The paper introduces the artificial bee colony algorithm. Afterwards, a description of the framework will be provided. Detailed view of the framework and how to be used are shown. The experiments are stated after that. A conclusion is presented at the end of this paper.

Keywords: *Artificial Bee Colony Algorithm, Generic Artificial Bee Colony Framework (GABCF), Problem Independent Artificial Bee Colony Implementation.*

1 Introduction

The solution techniques of the optimization problems could be categorized into: combinatorial optimization techniques and approximate optimization techniques. The combinatorial optimization techniques find the optimal solution of the problem. Approximate optimization techniques target finding a solution that satisfies the user constraints and needs. This solution maybe very close to the optimal solution and also may not be close, this is not the main concern in such techniques. Swarm -based optimization algorithms are kind of the approximate techniques. Swarm intelligence algorithms contain ant colony, bee colony, cockroach, etc [2].

Artificial bee colony (ABC) algorithm is a simulation of real bee colony and its foraging behaviors. ABC is introduced in 2005 for the first time [1]. In this paper, we provide a framework that implements ABC algorithm using Java programming language. This framework called "Generic Artificial Bee Colony Framework" (GABCF). Previously, each time the researcher uses ABC algorithm for a new problem, he had to implement it again to be compatible with the problem nature. The presented framework (GABCF) in this paper is problem independently designed and implemented. The framework separates the ABC algorithm workflow/intelligence from the problem specific implementation. The framework performs this separation by providing interfaces and abstract classes as integration gates. The user could implement only a small problem's related section to have the ABC framework works with his problem dynamically.

In section 2, ABC algorithm is presented. The framework details, diagrams, and specifications are presented in section 3. The experimental work in this research is how to use this proposed framework in problem solving, this point is described in section 4. A conclusion is conducted at the end of this paper in section 5.

2 Artificial Bee Colony (ABC) Algorithm

Artificial bee colony is an algorithm that simulates the swarm intelligence integration of bees' colony in foraging natural life. The actual bees' colonies categorize the bees in foraging activities into the following types:

- Worker (Employee) bees group.
- Onlooker bees group.
- Scout bees group.

From natural bees' point of view, each group of bees has a specific role. The worker bees use the real nectar sources in foraging process. The workers collect the nectar from these sources and return to the hive. Worker bees do a waggle dance when return to the hive. The dance describes the evaluation of the food source and its geographic location.

After the worker bees dance in front of the hive, there is a group of bees (onlooker bees) monitoring their dancing to choose resources from the workers findings. This selection is based on the worker bees' sources fitness evaluation function. After the onlookers choose a subset of the resources, the onlookers go to these sources and search in their neighbors to find a better food sources. After that the onlookers return to the hive with their findings.

Simultaneously there are a group of bees called (scout bees), these bees look always for abandoned food sources exploring. Scout bees explore new areas by finding random nectar source

(create random solution in the artificial algorithm) and returning this information back to the hive.

By mapping these natural activities to the artificial bee colony algorithm, the worker bees catch a valid solution of the problem. Onlooker bees select solutions based on the fitness value of them. They search in the surrounding solutions to find a better solution. Scout bees create random solutions per iteration to simulate the real scout bees' activities.

By this step, a cycle in bee colony foraging is completed. At the beginning of the new cycle, the worker bees select new sources for the new iteration (cycle) from all the available sources (old worker sources, onlookers' findings and scout discovered sources).

There are four mandatory parameters for ABC algorithm: worker bees count, onlooker bees count, scout bees count, maximum cycle number (MCN). These parameters are mandatory for ABC to be able to do its logic. The framework gets these parameters through communication gates described in the next section.

Onlookers bees are selecting the sources depends on the sources (solutions) fitness. The selection use a probability of source selection, this probability is [2, 3]:

$$Pi = fit\ i / \sum fitn \qquad where\ n=1\ to\ SN \qquad (1)$$

Where fit_i is the fitness value of the solution number (i) and (SN) is the count of the food sources. The count of food sources is equal to the number of worker bees.

In GABCF, the framework uses this probability selection equation for the onlooker's bees sources allocation.

Some researches go to that: the worker bees also do a local search activity in the neighbor areas but with very small scale, then onlooker bees do the search with a wider scope than worker bees. GABCF provides the flexibility to the user in enabling this feature or disabling it. Figure 1 presents ABC algorithm steps.

1: Initialize Population
2: **repeat**
3: Place the employed bees on their food sources
4: Place the onlooker bees on the food sources depending on their nectar amounts
5: Send the scouts to the search area for discovering new food sources
6: Memorize the best food source found so far
7: **until** requirements are met

Figure 1: ABC algorithm description.

"Requirements are met" mentioned in figure 1 is the exit condition of ABC algorithm. It could be an acceptable solution fitness value, and also it could be the number of cycles [4, 5]. Maximum cycle number (MCN) is the used exit criteria in the generic artificial bee colony framework.

3 Generic Artificial Bee Colony Framework (GABCF)

Generic artificial bee colony framework is problems independent framework. It separates the workflow of ABC algorithm from the actual problems' details. As described in the next diagrams, the framework contains the ABC algorithm logic, and some interfaces and definitions that should be implemented (by the user) to make the GABCF works with his problem adaptively.

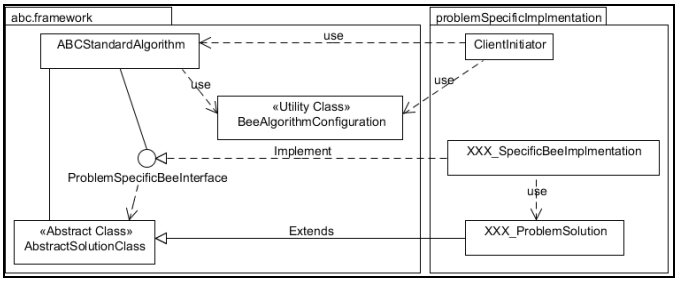

Figure 2: High level class diagram.

As described in figure 2, GABCF contains three integration gates with the user:

- "ABCStandardAlgorithm" class.
- "ProblemSpecificBeeInterface" interface.
- "AbstractSolutionClass" class.

More descriptions of these components are described in figure 3, and figure 4 in a detailed form.

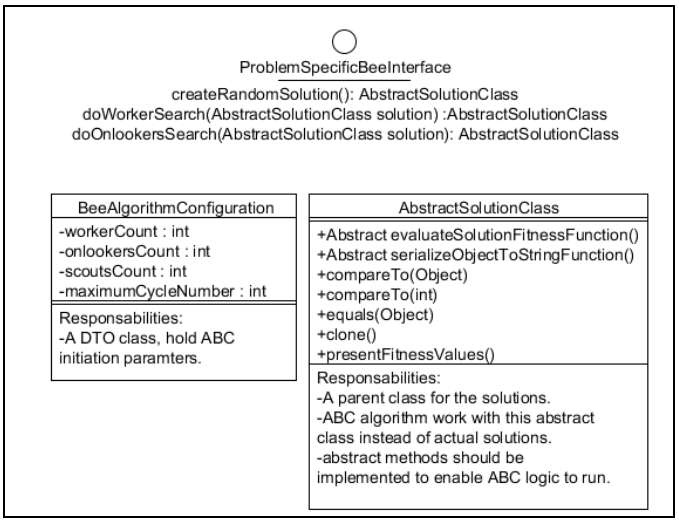

Figure 3: Low level class diagram.

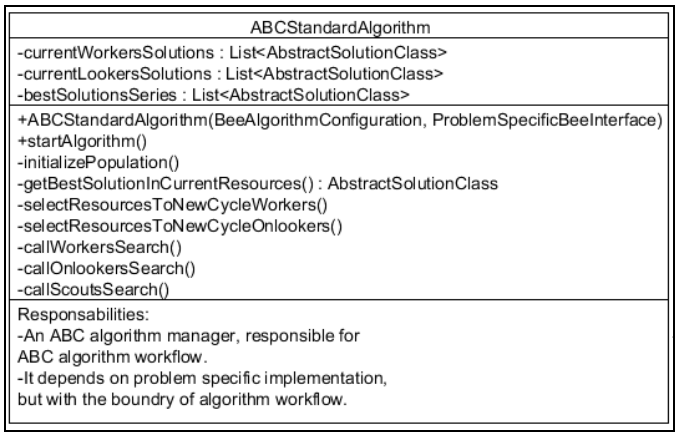

Figure 4: Low level class diagram – part 2.

In the following points, the description of each component is provided:

- "BeeAlgorithmConfiguration" class:
  It is a configuration class that has the needed parameters for ABC algorithm. These parameters are: worker bees count, onlooker bees count, scout bees count and maximum cycle number (MCN).

- "ABCStandardAlgorithm" class:
  It is the starting point of the algorithm. This class needs a configuration object described above and the problem specific implementation which provided by the user of the framework. This class contains the ABC algorithm work flow. The only public methods in "ABCStandardAlgorithm" class are the constructor and "startAlgorithm()" methods. "startAlgorithm()"is the real starting point of the algorithm execution.

- "ProblemSpecificBeeInterface" interface:
  Each problem has its search space specifications. For example if we use GABCF in travelling salesman (TSP) problem, the search space is the valid routes that could solve the problem. In this interface, there are three declared functionalities:

  a) Create random solution: which is used in the initial generation creation and in scout bees' work.

  b) Do the worker bees search: depends on each problem, the user could provide a worker bee search action to be executed during ABC algorithm lifecycle. This search should run using the method parameter (solution). If the user of the framework doesn't want search activities to be done by the worker bees, he could return the method parameter as it is into the function output without any changes.

  c) Do the onlooker bees search: depends on each problem, the user could provide an onlooker bee search action to be executed during ABC algorithm lifecycle. This search should run using the method parameter (solution). Theoretically, onlooker search action should be on a wider scale than worker bees' action, but this depends on the user implementation logic.

- "AbstractSolutionClass" class:
  This is a parent class for the solutions. Each problem has its solutions format, but the user problems' solution class should extend this abstract parent. The only two methods that should be implemented according to the problem nature are:

  a) "evaluateSolutionFitnessFunction", the user should implement this method to evaluate the solution fitness value according to the problem details.

  b) "serializeObjectToStringFunction", this method is serializing the solution object to a string format to be compared by the framework in equality conditions. This string represents the solution and should be considered as a hash code of the solution which should not return the same value except for the typical solutions content.

After discussing the detailed image of the framework components, figure 5 presents the sequence flow of the work starting from the initiation of the algorithm by the user until returning the best fetched solution to the caller. The sequence diagram presents first cycle actions. Other cycles do the same sequence of actions excluding the initial generation creation.

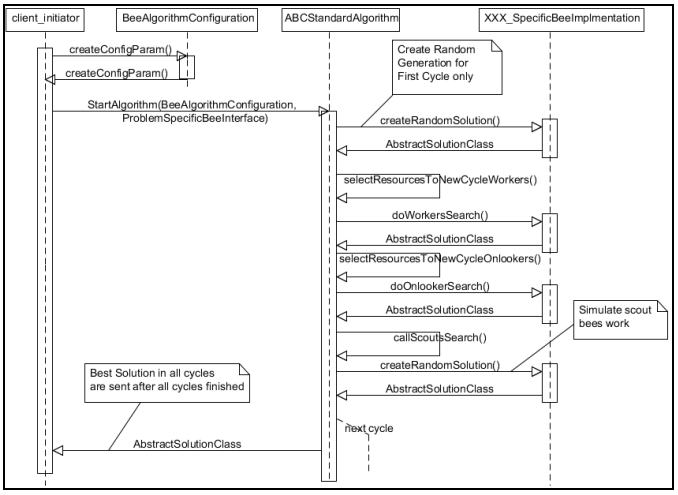

Figure 5: GABCF sequence diagram for iteration 1.

As described in figure 5, the workflow of the framework starts by the client when bee algorithm configurations object creation. In this step, the user set the needed parameters of the GABCF framework. These parameters are the ABC algorithm parameters that described in the previous section. Afterwards, the GABCF uses the specific problem implementation to run the ABC algorithm workflow. The ABC algorithm starts from initial generation creation, select the sources for the worker bees for the current iteration, run the worker search logic, select the onlooker bees' sources, run the onlooker bees

search, and run the scout bees search to complete the available sources to be ready for the next cycle enrollment. Figure 6 presents the other iterations flow. This flow in figure 6 is applied starting from iteration 2 to the last iteration.

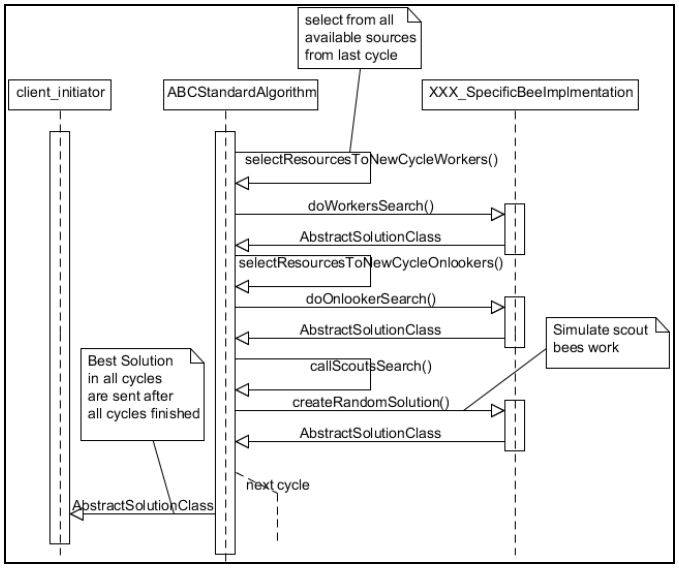

Figure 6: GABCF sequence diagram for other iterations.

4 Experiments

In this section, the paper presents experimental usage of GABCF in solving traveling salesman problem (TSP). This section mainly provides the actual activities of the GABCF user to be able to run the complete solution for his problem (TSP). As described in the previous section, the user of GABCF has to implement "ProblemSpecificBeeInterface" interface, and "AbstractSolutionClass" class.

```
public class TSPSolution extends AbstractSolutionClass {

    private List<Cities> route=new ArrayList<Cities>();// like A, B,C, A

    @Override
    public int evaluateSolutionFitnessFunction()
    {
        int length=0;
        for (int i = 0; i < route.size()-1; i++) {
            length+=Math.sqrt(
                    Math.pow(route.get(i).getCityX()-route.get(i+1).getCityX(),2) +
                    Math.pow(route.get(i).getCityY()-route.get(i+1).getCityY(),2) );
        }
        return length;
    }

    @Override
    public String serializeObjectToStringFunction()
    {
        String output="";
        for (int i = 0; i < route.size(); i++) {
            output+=route.get(i).getCityName()+"-";
        }
        return output+evaluateSolutionFitnessFunction();
    }
```

Figure 7: TSP solution class implementation.

As presented in figure 7, the user creates problem's solution extending "AbstractSolutionClass". The created class implements two abstract parent methods. The first one is "evaluateSolutionFitnessFunction", which should evaluate the solution fitness function according to the problem nature. The second one is "serializeObjectToStringFunction" which should serialize the solution object into string, just to act like the hash code during the objects comparison.

The second needed class is the implementation of "ProblemSpecificBeeInterface" interface. TSP implementation of this interface is presented in figure 8.

The needed functions implementation sample is presented in figure 8. The user implements a function that creates a random solution. This function is used in the first generation creation and in scout bees search. Other two functions search in the search space according to the problem nature, one for worker search scope and the other one for onlooker search scope. If the user in any search function (worker for example) returns the parameter as is, so the user implicitly cancels this search activity.

```
public class TSPSpecificBeesImplmentation implements ProblemSpecificBeeInterface {

    public AbstractSolutionClass createRandomSolution() {
        TSPSolution solution = new TSPSolution();
        //TODo the logic that create random solution;
        return solution;
    }

        public AbstractSolutionClass doWorkerWork(AbstractSolutionClass solution) {
        if (!(solution instanceof TSPSolution)) {
            return null;
        }
        TSPSolution newSolution = new TSPSolution();
        //Clone solution to tspSolution variable (to avoid any reference problem)
        //using tspSolution variable, do the search in worker scale (small)
        //and return the best solution in very close neighbors
        return newSolution;
    }

    public AbstractSolutionClass doOnlookersWork(AbstractSolutionClass solution) {
        if (!(solution instanceof TSPSolution)) {
            return null;
        }
        TSPSolution newSolution = new TSPSolution();
        //Clone solution to tspSolution variable (to avoid any reference problem)
        //using tspSolution variable, do the search in looker scale (wide scale somehow)
        //and return the best solution in very close neighbors
        return newSolution;
    }

    public TSPSpecificBeesImplmentation() {
        loadCitiesFromFile();// TSP problem specific implementation
    }
```

Figure 8: TSP specific problem implementation class.

5 Conclusion

Generic Artificial Bee Colony Framework (GABCF) is the proposed framework that implements artificial bee colony algorithm. The value of GABCF demonstrated in its separation between ABC algorithm details and any specific problem implementation. It implements the workflow of ABC algorithm. It provides interfaces that should be implemented by the user of the framework, by implementing these interfaces the framework will adapt and run on the user specific problem details. GABCF is applied for TSP, and some bioinformatics problems without any modifications of the framework. It just needs implementing small parts related to the problem specification components (parts which are described in the paper). Using the framework saves a lot of time in reaching a final executable solution for the problems due to the proposed reusable work provided in the framework. The usage of the framework for TSP problem is described with sample of code in this paper.

The profit of GABCF (saving the development time) is vary from problem to another due to the complexity of the problem, so this research doesn't provide a mathematical representation of this saved time, but the paper provide a sample of using the GABCF and proof its usefulness in a subjective way.

Finger-Knuckles Biometric OAuth as a Service (FKBoaS)

Ibrahim Abd-elatief Ahmed [1], Gouda I. Salama[1], and Ibrahim I. Emam[1]
[1]Computer Science, Arab Academy for Science Technology & Maritime Transport, Cairo, Egypt

Abstract - *the need for providing delicate authentication-based systems via biometric-based methods is increasing by the time. This importance is even more sustained for customer-oriented applications, especially the web-based systems. Having this authentication mechanism provides user friendly solutions for login that help the users to avoid thinking about memorizing different passwords or having to have periodic passwords changes*.

Keywords: Knuckles, HAAR, and SURF

1 Introduction

Nowadays, proof of identity is required in several places in our life [1]. This could be done by using other approaches such as user/pass requests or by asking for some personal documents, such as Social Insurance Number, Health Card, or so on [2]. These identification measures are often enough to identify persons. However, in case of having these identification measures stolen, there is no way to prevent the identity theft [3].

Therefore, the identification must provide a linkage between these metrics and the person being identified [4]. This could be done using some biological and/or behavioral measures from the identifier (such as finger and voice, which are the most popular ways to have this linkage)[5]. Therefore, using these biometric means is more reliable as they confirm the real presence of the person being identified [6].

Finger-back surface has not been in the focus of hand-based authentication researches, although the finger knuckles bending has highly unique pattern formation compared to other comparators, which means that it can be used as a valid feature to provide biometric-based identification[7].

The biometric hand-based authentication has proven significant reliability and users' acceptance, as it provides different extraction features (internal/external to distinguish between different entries) [8]. However, it becomes more challenging for large scale systems [9]. Specially, this requires extracting additional features to ensure the distinction between different users [10]. We use "Fingers' Knuckles" as a significant feature to be extracted to enhance the hand-based authentication process. In this context, we automate a feasible method to extract knuckle from the finger-back (hand dorsum) surface.

As well as the biometric authentication, we could even add an extra layer to optimize this authentication approach. This can also involve applying an oAuth application template for the signing process, and having a threshold-based process to evaluate the authentication process.

The previous finger knuckles researches provided good results with effective finger knuckles feature extraction [11]. However, these researches focused on specific equipments (mostly expensive ones) with a static environment [12]. Only few researches provided dynamic settings using cost-effective devices (such as RGB camera) to provide authentication systems [13]. Nevertheless, it has a lot of inflexibilities of having strict placement of hands in front of the camera. Having dynamic settings and environments can face several problems [14]. For example, there is a need to provide a separation between hand and any unrecognized backgrounds [15]. Also, it must provide consistent translation, scale invariance, and rotation of the Regions of Interests (ROIs), regardless of the captured images general features (such as blurriness or lighting)[16],[17].

In that research, we provide a novel approach based on or web camera to overcome all of the challenges that we can face with dynamic settings and environments. It provides a cutting edge technique to replace fingerprint biometric identifier with finger knuckles. For instance, the users will only need to show their knuckles against their web camera or their laptops integrated camera in order to get authenticated right away. On the other hand, in the normal fingerprint authentication way, you are entitled to scan your finger with a certain position and make sure that it is too straight so the system will be able to scan it well, and also avoid any other external variables such as having a sweaty fingers or unclean fingerprint scanners.

In wide-scale systems, the authentication main target is to identify a user among a large set of other existing identities in the system, or other connected systems and environments [18]. Thus, we need to have an indexing technique to reduce the number of identities to be processed by the identification algorithm [19]. A knuckle indexing technique on closed set of identifications can be applied, and based on minutiae and SURF features in order to enhance the performance of data retrieval and identification [20].

We will start first with showing an overview for the system and how it works. Then, we will show the different preprocessing operations that we apply when receiving inputs. After that, the feature extraction followed by the data retrieval process will be clarified. Then, the classification process will be illustrated in details and how we can classify different retrieved data.

2 System Overview

The system consists of two tiers which are client (User Interface), and Server. The server tier has a frontend server (Application Server) and a backend server (Biometric Server), which utilize OAuth protocol.

The client tier could be an intranet user accessing the system internally through a web camera, while, the front server is used to handle different web-based transactions. On the other hand, the Biometric Server is used to handle the user authentication processes including the users' enrollment database.

The user does his common online transactions through the front server. Once, the user is promoted to do a secure transaction (such as a payment), they are redirected to the Biometric Server, which starts handling the authentication process. The process starts by asking the user to input their authentication values using input devices (such as scanners) in order to authenticate them before starting to handle his secure transactions. Suppose that is the first time the user uses the system, then the backend server establishes an entry for the user in the database, extract different features moments, and store them in the secure server database. Figure1 shows an abstract view of the secure transaction process, and figure 2 shows a deployment view of the system.

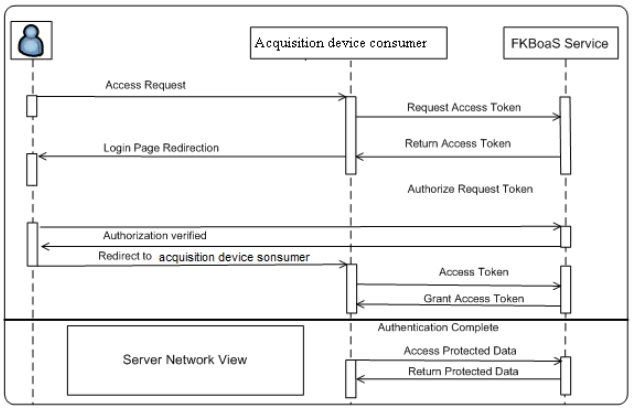

Fig. 1 Biometric Server OAuth flow.

This solution provides experimentation results based on biometric fusion rules and identifiers using web camera.

Web camera is used as a cost-effective acquisition device hosted in a cloud web service, and can be easily linked to other servers. The authentication process requires the user to show their dominant hand to the web camera and wait until the web camera captures the required details. This process requires the user to have the three gaps between the fingers visible, as they are used to extract the Region of Interest (ROI) from the fingers knuckles in addition to the depth map. The verification process consists of preprocessing, feature extraction, clustering and retrieval, and classification. It starts with the image acquisition, which goes through image preparation and mapping processes. After that, we extract the region of interests, and their SURF and Minutiae key points in order to extract features. Then, apply some curvature equations before proceeding the matching process, and taking decision whether to accept the acquired finger knuckle or not.

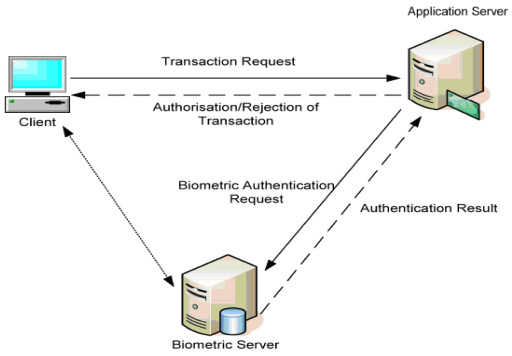

Fig. 2 Server Network Flow.

3 Preprocessing

This stage is about preparing the image for being processed by applying different image filters to enhance the picture [21]. For that, four preprocessing tasks are required prior to extracting features. These tasks are image reconstruction [22], finger features extraction, and disparity map estimation [23]. We will discuss these tasks after applying different images filters. The Image preparation procedure consists of the following ordered steps:

1. Collect the Stereo Pairs as structured samples
2. Apply a Histogram Equalization on the image [24].
3. Apply a low pass filter to remove noise [25].
4. Apply a non-linear filter [26].
5. Extract depth maps to construct illuminated image.

3.1 Structured Sampling and Image Reconstruction

We have to collect a series of images because of the small variations between the hand positions and movement, based on the radiance function properties. Then, we have to segment these captured images into regions with concave or convex behavior in order to provide sampling strategies for radiance reconstruction. This requires determining the inflection point on two orthogonal axes that pass through the surface of the captured hand. After that, an adaptive subdivision is applied on these orthogonal axes in order to produce two unidimensional segments lists. Finally, the produced image will be illuminated and ready for the next process.

3.2 Disparity Map Estimation

As we lack for raw depth map that shows the z-value differences, we use stereo pairs images to calculate the surface curvature. After that, we apply Kurt Konolige's matching

stereo correspondence algorithm in order to calculate the pixels differences between two captured images [28]. This algorithm uses the sliding sums of absolute differences sifted by variant pixels amount ranges between minimum disparity up to the summation of minimum disparity and number of disparities. The algorithm computes disparity on a pair of images (Width and Height) using the following formula:

$$o(W \times H \times numberOfDisparities) \quad (1)$$

The results will be merged to the raw disparity map with precedence to inputs.

Procedure to Extract Disparity Map Estimation

1. Collect the Stereo Pairs (pair of available images).
2. Apply the Block Matching Stereo Correspondence algorithm to find the possible correspondences.
3. Construct a simple Q-Matrix to rectify the image.
4. Reproject the image with z-value to provide a set of vertices.
5. Construct the disparity map.
   a. It calculates the Gaussian and Mean curvatures and provide the z-value for each pixel.
   b. It merges the constructed map with the raw depth map.

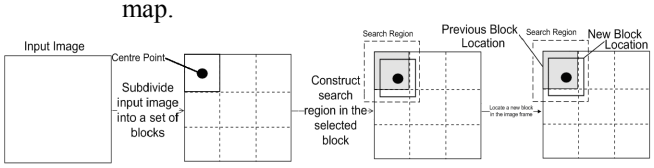

Fig. 3 Block Matching Stereo Correspondence

4 Feature Extraction

The features are extracted by examining the structural information contained in the distribution of knuckle minutiae and SURF key points [29].

These features are then clustered using K-Means [30]. This clustering is used to identify groups of samples that behave similarly and dissimilarly, such as malicious and non-malicious activity [31]. In the next phase of identification, Naïve Bayes is used for validating the identity of the group [32]. K-Mean clustering is a cluster analysis method that is used to partition observations in a set of k clusters belongs to the cluster nearest mean. This clustering process results on a set of Voronoi cells in a data space partitioning [33].

4.1 SURF Feature Extraction

The extracted ROIs for finger knuckles have low definition and their grayscale values can change very easily in the space. This makes it more difficult to detect stable points even with algorithms such as Harris or Different of Gaussian (DoG) [34].

4.1.1 Fast-Hessian algorithm as a key point's detector

In this context, the Fast-Hessian key point detector algorithm is accurate and has good performance [35]. If we have a point in an image, the Hessian matrix in that point can be defined at a given scale as follows:

$$H(p,s) = \begin{bmatrix} L_{xx}(p,s) & L_{xy}(p,s) \\ L_{xy}(p,s) & L_{yy}(p,s) \end{bmatrix} \quad (2)$$

In that matrix, the value of each element is the Gaussian second order derivative convolution $\frac{\partial^2}{ax^2} g(s)$ in a point . Using box filters, we can apply the Gaussian second order partial derivative in the directions of y and xy. In figure 4 the regions in gray are equal to zero. A box filter is and , in order to maintain high efficiency on images.

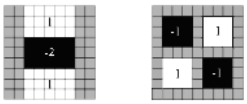

Fig. 4 Knuckle Minutiae Box Filter.

We then apply non-maximum suppression in a range of $3 \times 3 \times 3$ neighborhood in order to locate the points of interest. Figure 5 provides an example of detected Finger Knuckles points ROI images using Fast-Hessian.

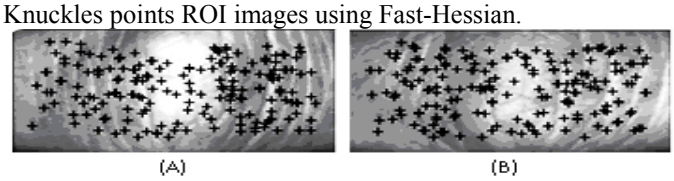

Fig. 5 SURF Keypoints.

4.2 SURF (Speeded Up Robust Feature) Descriptor

Key points must be unique compared to each others and this is provided by SURF. In SURF, a key point can be described based on its dominant orientation on the surrounding regions. Extracted key points are surrounded by circular constructed regions, which are used to compute the dominant orientation. The computation is applied on both horizontal and vertical directions using Haar wavelet responses, and calculated by adding a wavelet space θ (value 60^o in our case) to the Haar wavelet response. The result of that summation is the maximum dominant orientation for the key points' description, and it is its rotation invariant for the image rotation as well as the dominant orientation.

4.3 SURF descriptor components

Descriptor extraction constructs are an aligned centered square around the points of interest on the dominant orientation. That square region is divided into smaller squares of size of 4×4 and the Haar response is applied to each square on both axes. The summation of these responses on both sides is used as feature attribute to form the first feature vector. The polarity intensity changes information is the absolute

summation of responses on both axes on a four-dimensional vector V So, we compose a 64-length SURF descriptor for the key-point from all 4×4 sub regions as follows:

$$V = \{\sum d_x, \sum d_y, \sum |d_x|, \sum |d_y|\} \quad (3)$$

4.4 D. Index Space Model Creation

A triplet $\vec{t}_i$ has nine-fold consisting of ridge curve and geometric agglomeration features. It is presented as 9-dimensional, where $\vec{t}_i = \{\alpha^i, \beta^i, \gamma^i, k_1^i, k_2^i, k_3^i, \lambda_1^i, \lambda_2^i, \lambda_3^i\}$ and it can be viewed as a single entry in hyperspace. So, each knuckle image has a collection of points reside in that 9-dimensional index space model. For a new set of trained knuckle images, a new space model is created with unsupervised clustering on the generated 9-dimensional entities of these trained images, which results on a number of clusters shown in its centroid.

When a knuckle input y is authorized, it is divided into a set of triplets mapped into the 9-dimenstional space, and assigned to a unique cluster c_j, where j is the minimum distance rule, and it can be calculated as:

$$j = \arg \min_{k=1}^{k} \left\| t_i - \vec{\mu}_k \right\| \quad (4)$$

, where $\|\cdot\|$ is the norm of a each side, and means that this process is applied on each cluster and repeated for each entry. This provides us a list of all knuckles identities $\{y_{j1}, y_{j2}, ..., y_{jn}\}$ in that cluster, which have at least one triplet assigned.

Figure 6 shows the model map population process:

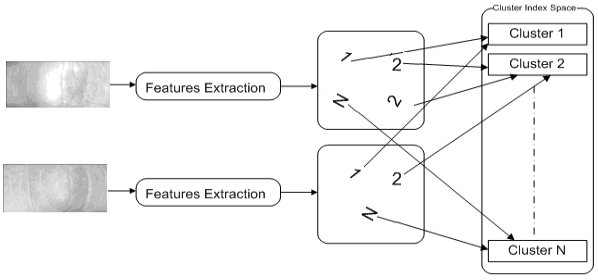

Fig. 6 Mapping finger knuckles in the database, and put similar patterns into clusters

4.5 K-means Data Clustering

Clustering is the process of partitioning data into subsets (defined as clusters) to classify the entries that share specific properties [36] It is used as a first step to enable different static analysis processes on the images, such as image analysis, pattern recognition, etc [36] The clustering can be supervised if the data collected samples are labeled by class membership; otherwise, it is an unsupervised clustering [37] In the unsupervised clustering algorithms, clustered objects are divided into a number of k partitions based on specific attributes from the generated data from Gaussian distributions [38], [39] The $k-means$ algorithm is used to minimize the variance of the intra class and squared error function following this formula:

$$E = \sum_{i=1}^{k} \sum_{x_i \in C_i} \left\| x_j - \vec{\mu}_i \right\| \quad (5)$$

Where k is the number of clusters, j a number of points x_j in a set of clusters C_i, and μ_i their centroid. The algorithm $k-means$ of is commonly used as it provides quick retrieval when it is run several times to cluster the data set available. However, it can result on unexpected results when data is not clustered totally, so, it is better to make sure that a number of clusters are pre-set first [40].

4.6 Knuckle Clustering and retrieval

When executing a query, the system divides the triplets in a 9-dimentionals points based on these extracted features. Each directive point $\vec{t}_i$ is mapped into a cluster $c_{\pi i}$ where πi is $1 \le \mu \le k$ using the minimum distant rule. Each target cluster can be associated with the executed query, and their top N-identifiers occur frequently in that target for further matching processes.

5 Classification using Naïve Bayesian Network

K-Means is used to identify groups of samples that behave similarly and dissimilarly such as malicious and non-malicious activity in the first stage while Naïve Bayes is used in the second stage to classify all data into correct class category. Naïve Bayesian Network (NBN) probabilistic classifier applies strong independence assumptions using Bayes theorem [41] NBN classifiers are trained using supervised learning set in a Bayesian network. It encodes a distributed set of variables $\{x_1, x_2, ..., x_n\}$,as a set of Conditional Probability Distributions (CPDs) and directed acyclic graph. The encoding process asserts that each node must be independent of each descendents. Each node has its corresponding CPD that provides different state probabilities, with all combinations of its patents [42].

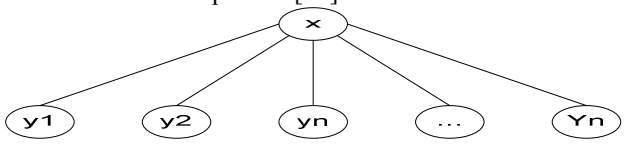

Fig. 7 Naive Bayesian Network Schema

Assume that we have a number n of input attributes $X = \{x_1, x_2, ..., x_N\}$. Thus, the total possibility (product) of this input can be written as:

$$P(x) = p(x_1) \times p(x_2) .... \times p(x_n) \quad (6)$$

It is considered independent with or without conditions in a fixed class (y), and its probabilities are estimated as follows:
Conditional probability (which is the Naïve Bayesian Classifier basis):

$$P(y \mid x) = P(y) \times P(x \mid y) / P(x) = P(y) \times (P(x_i \mid y) / P(x_i)) \quad (7)$$

Relative probability:

$$P(x \mid y) = P(x_1 \mid y) \times P(x_2 \mid y) .... P(x_N \mid y) \quad (8)$$

5.1 Fusion Decision Network

It is a majority network used to resolve uncertainties in the statistical probabilities by processing the input data and its classifier modules output in order to provide final decision [43] However, if a set of three modules provides three different classification results, the output result will be indecision [44] This requires at least two modules to have the same classified class in order to get a correct output result [45].
The applied methods for feature extraction are directly fusible. Thus, we need to apply feature length normalization or mage resizing in case the decision of the feature level is used. This requires applying an appropriate strategy for the decision level, in order to avoid having complicated system computations result eventually on performance degradation. The feature extraction generates a distance probability for each knuckle area $P^{k1}(x, y)$, and $P^{k2}(x, y)$

Thus, each knuckle has the same feature extraction process applied and ready for fusion. Each two subjects are matched through fusing decision level that requires combining the distance between their knuckle areas (k_1, k_2).

For instance, for a subject P, two feature codes x_{k1}^{p}, and x_{k2}^{p} are extracted, and for a subject Q, two other features x_{k1}^{Q}, and x_{k2}^{Q} are extracted. The two distances between these two subjects are calculated as:

$$d_{k1} = d(x_{k1}^{p}, x_{k1}^{Q}) \quad (9)$$

$$d_{k2} = d(x_{k2}^{p}, x_{k2}^{Q}) \quad (10)$$

Then, the total distance between the two subjects are calculated based on a weighted combination of two distances as:

$$d(P,Q) = \alpha(d_{k1} + d_{k2}) \quad (11)$$

In this equation, is a weighting factor and can be calculated as follows [46]:

$$\alpha(x, y) = \frac{1}{1 + \sigma v(x, y)} \quad (12)$$

In which v is the value of the image variance, and σ is used as a tuning parameter to distribute α as much as possible in a normalized range [0,1] in a formal manner [46].

6 Results

The used database for testing consists of a set of images and PolyU FKP database, in where each entry has k-images for each knuckle area; k-image consists of raw and depth image. It also includes FKP database after extracting offline depth image.

6.1 Performance of Classification

Classification performance is measured based on the error and accuracy rates. Error rate is the ratio between the number of misclassified knuckles, and the total number of test samples:

$$\text{Error Rate} = \frac{\text{Number of misclassified Knuckles} \times 100}{\text{Total number of test samples}} \% \quad (13)$$

On the other hand, the accuracy rate is simply the remained portion of the classified knuckles after subtracting the error rate:

$$Accuracy = 100\% - \text{Error Rate} \quad (14)$$

The error rate is generally described as the function of the searchable percentage of the database, which is referred to as penetration rate, and computed as:

$$\text{Penetration Rate} = \frac{\text{Number of accesses knuckles} \times 100}{\text{Total number of knuckles samples}} \% \quad (15)$$

TABLE I
MODAL BIOMETRICS PERFORMANCE

Knuckle Area	Accuracy (%)
Lk_1	99.63
Lk_2	99.84
Rk_1	99.36
Rk_2	99.79
$Lk_1 + Lk_2 + Rk_1 + Rk_2$	100

This is a summary for the accuracy of knuckle areas, using the proposed fusion approach. We can observe from the table that as high as 100% accuracy was achieved for fussed knuckle areas. The performance of identification for single knuckle area is significantly lower than that fused. Inclusion of skeletal structure of knuckle for classifying each shape to a specific region result could also improve the system accuracy.

7 Conclusion

In this research, we managed to clarify that we can use knuckle as a reliable biometric identifier that do not require expensive equipments or special arrangement. In addition, it does not force the users to provide data inputs in certain ways such as direction of fingers. Also, the user does not need to have extra cognitive thinking to remember the password or being asked to change the password periodically. Not only this, but also it maintains higher security level given that it will ensure that the person must be present in order to have a successful login.
We obtained reliable results compared to other knuckle identification researches, and the same time, we do not need to use special equipment, and instead, we use any web camera.

This means that the application can be used on different ranges.
However, in this paper, we have not applied results on a wide-scale database that covers different other cases and metrics such as aging, skin color, different races, etc. This is in addition, to other variables such as fatness, skin, injuries, etc. This will require applying different traces and geometrical features on difference races with different color skins, and hand sizes. Thus, for the future, including skeletal structure of knuckle for classifying each shape (to a specific region result) will result on more reliable, and accommodates other circumstances such as aging and injuries.

Abstract— *The paper presents a method to estimate the velocity of the dynamic obstacles using the range-based scene flow vectors. These scene flow vectors are computed using differential flow technique which uses the range intensity gradients. Then the velocity of the dynamic obstacle is estimated effectively using a single camera unit i.e. Photonic Mixer Device (PMD) camera. The method is tested and validated with different scenarios and the results are discussed.*

Keywords: 3D Scene flow,PMD camera, motion detection, velocity estimation

1. Introduction

Historically, the path planning problem has been studied much less for cluttered environment. This may be because of the entire information of the environment will change along with the dynamic obstacles, so the complexity and uncertainty increase greatly in dynamic environments. Uncertainty is an important factor in the field of dynamic path planning because of the partial knowledge about the obstacles. So, motion estimation plays an important role in path planning techniques.

Most of the researchers are now working on stereo camera system because of the estimation errors and somewell known ambiguities (aperture problem) occur in the single camera, since the images from the single camera are the three-dimensional information projected to the camera's image plan. The distance information between the camera and the obstacle is lost completely. These two dimensional motion vectors are obtained using sparse techniques [Bauer et al., 2006], dense optical flow techniques [Bruhn et al., 2005].

These stereo cameras offer an additional information to reconstruct the three dimensional orientation. From the research work of [Wedel et al., 2011], the triangulation of stereo camera results in ambiguities. One of the challenges of 3D scene flow estimation using stereo cameras is that the two-view stereo problem at two different time steps, and the optical flow problem for each of the cameras. The intensity based image processing techniques are mainly based on grey scale or color in the images which is obtained from the conventional cameras. The main disadvantages of these techniques are that the image processing becomes inadequate in low illumination conditions and when the objects and the background look similar to each other [Yin, 2011].

In this paper, we use a single PMD camera which provides range information. The combined Lucas/Kanade and Horn/Schunck techniques [Bruhn et al., 2005] are utilized to calculate the scene flow. The distance moved by the obstacle is computed by the mean value of the consecutive segmented range frames. Then the velocity of the obstacle is estimated

The paper is organised as follows. Section II provides the methodology for velocity estimation. In Section III, the experimental results are discussed. Section IV summarises the work.

2. Methodology

2.1 PMD Camera

We are using Photonic Mixer Device (PMD) camera, a time-of-flight (TOF) camera in this work, in figure (1). A time of flight camera is a system that works with the TOF principles [Weingarten et al., 2004], and resembles a LIDAR scanner. In the TOF unit [Lange, 2000], a modulated light pulse is transmitted by the illumination source and the target distance is measured from the time taken by the pulse to reflect from the target and back to the receiving unit. PMD cameras can generate the range information, which is almost independent of lighting conditions and visual appearance, and a grey scale intensity image, similar to conventional cameras. The coordinates of the obstacle with respect to the PMD camera are obtained as a 200 by 200 matrix, each element corresponding to a pixel. It provides fast acquisition of high resolution range data. As the PMD range camera provides sufficient information about the obstacles, it is proposed to estimate the trajectory of the moving obstacles. These TOF camera provide a 3D point cloud, which is set of surface points in a three-dimensional coordinate system (X,Y,Z), for all objects in the field of view of the camera.

Fig. 1: PMD Camera

2.2 Scene Flow

Scene Flow [Vedula et al., 2005] is the three-dimensional velocity fields of points in the world; just as optical flow is the 2D motion field of points in an image. Any optical flow is simply the projection of the scene flow onto the image plane of a camera. If the world is completely non-rigid, the motions of the points in the scene may all be independent of each other. One representation of the scene motion is therefore a dense three-dimensional vector field defined for every point on every surface in the scene.

In order to compute the $3D$ motion constraint equation, the derivatives of the depth function with respect to the other world coordinates have to be computed. For instance, the dynamic object at (x, y, z) at time t is moved by $(\delta x, \delta y, \delta z)$ to $(x + \delta x,\ y + \delta y,\ z + \delta z)$ over time δt. The $3D$ Motion Constraint Equation (1) is obtained after performing 1^{st} order Taylor series expansion [Barron and Thacker, 2005].

$$R_x V_x + R_y V_y + R_z V_z + R_t = 0 \tag{1}$$

where, $\vec{V} = (V_x, V_y, V_z) = (\delta x/\delta t, \delta y/\delta t, \delta z/\delta t)$ is the $3D$ volume velocity, $\nabla R = (R_x, R_y, R_z)$ are the $3D$ spatial derivatives and R_t is the $3D$ temporal derivative. It is the analogue of the brightness change constraint equation [Spies et al., 2002] used in optical flow calculation.

2.3 Differential Flow Technique

Differential techniques can be classified as local and global. Local techniques involve the optimization of a local energy, as in the Lucas and Kanade method. The global techniques determine the flow vector through minimization of a global energy, as in Horn and Schunck. Local methods offer robustness to noise, but lack the ability to produce dense optical flow fields. Global techniques produce 100 percent dense flow fields, but have a much larger sensitivity to noise. The combined differential approach involves applying a locally implemented, weighted least squares fit of local constraints to a constant model for flow velocity, which is combined with the global smoothness constraint. The velocity estimates can be minimised by equation (2).

$$\begin{aligned} E^2 &= \int_D (W_N^2(\nabla R.\vec{V} + R_t)^2) \\ &+ \alpha^2 \left(\|\nabla V_x\|^2 \|\nabla V_y\|^2 \|\nabla V_z\|^2\right) dxdydz \end{aligned} \tag{2}$$

$A^T W^2 A$ is calculated as (3)

$$A^T W^2 A = \begin{pmatrix} \sum W^2 R_x^2 & \sum W^2 R_x R_y & \sum W^2 R_x R_z \\ \sum W^2 R_x R_y & \sum W^2 R_y^2 & \sum W^2 R_y R_z \\ \sum W^2 R_x R_z & \sum W^2 R_y R_z & \sum W^2 R_z^2 \end{pmatrix} \tag{3}$$

The velocity estimates can be solved through an iterative process.

$$V_x^{n+1} = V_x^n - \frac{W_N^2 R_x (R_x V_x + R_y V_y + R_z V_z + R_t)}{\alpha^2 + W_N^2 (R_x^2 + R_y^2 + R_z^2)} \tag{4}$$

$$V_y^{n+1} = V_y^n - \frac{W_N^2 R_y (R_x V_x + R_y V_y + R_z V_z + R_t)}{\alpha^2 + W_N^2 (R_x^2 + R_y^2 + R_z^2)} \tag{5}$$

$$V_z^{n+1} = V_z^n - \frac{W_N^2 R_z (R_x V_x + R_y V_y + R_z V_z + R_t)}{\alpha^2 + W_N^2 (R_x^2 + R_y^2 + R_z^2)} \tag{6}$$

where, the average of previous velocity estimates (V_x^n, V_y^n, V_z^n) are used along with the derivates estimates to obtain the new velocity estimates (V_x^{n+1}, V_y^{n+1}, V_z^{n+1}).

2.4 Velocity Estimation

The distance travelled by the obstacle between the two consecutive frames in three dimensional coordinates is given by the equation (7). In three-dimensional Euclidean space, the distance D_{ab} is

$$D_{ab} = \sqrt{(X_a - X_b)^2 + (Y_a - Y_b)^2 + (Z_a - Z_b)^2} \tag{7}$$

The estimated velocity of the obstacle is calculated in the equation (8).

$$EstimatedVelocity(mm/s) = \frac{D_{ab}(mm)}{t(sec)} \tag{8}$$

where,

- D_{ab} is the distance between two points (X_a, Y_a, Z_a) and (X_b, Y_b, Z_b) in mm.
- t is the time interval between two frames in sec.

The velocity error is the difference between the mean value of the estimated velocity and the actual velocity.

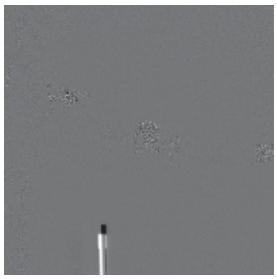
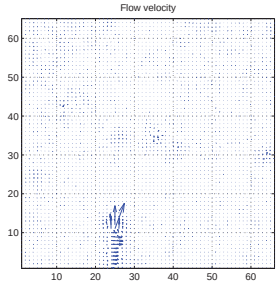
(b) $Frame-4$



(c) $Magnitudeimage$



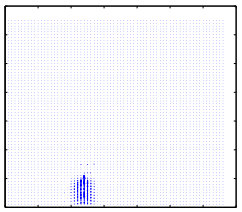
(d) $FlowVectors$

Fig. 4: 2D Range Flow Vectors

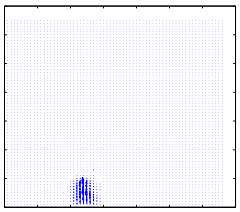
3. Experimental Results

The proposed technique is tested by various experiments. As the PMD camera can provide three dimensional coordinates (X,Y,Z), they are used for reconstructing 3D scene flow. The camera is mounted on the Pioneer 3DX Mobile Robot. The dynamic obstacle is allowed to move at different known velocities in the Field of View (FOV) of the camera as illustrated in figure 2. The pixels of range information are processed at different known time periods.

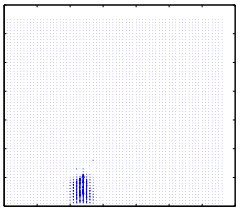
In Figure 3, the sequences of the frames are taken at different time period (t = 0.5, 1 ,1.5, 2 sec) where the obstacle is moving diagonally away from the camera. The obstacle's position in the world coordinates can be calculated in the two frames.



(a) Range Flow X-Coordinates



(b) Range Flow Y-Coordinates



(c) Range Flow Z-Coordinates

Fig. 5: 3D Range Flow Vectors

The 2D flow vectors are computed using combined Lucas/Kanade and Horn/Schunck techniques between Frame1 and Frame4 as shown in figure 4. The three dimensional coordinates which are obtained from the PMD camera, are used to estimate the scene flow vectors. These flow vectors along X, Y, Z coordinates are illustrated in figure 5.

The distance between the mean value of two segmented frames i.e. $F_1(X_a, Y_a, Z_a)$ and $F_4(X_b, Y_b, Z_b)$ are then calculated using the equation (7). The experiments are performed in different velocities at different time frames. The table (1) compares the actual velocity with the estimated velocity. And the result shows the velocity can be estimated within a percentage error of 5%.

Table 1: Estimated Velocity

$ActualVelocity$ (mm/sec)		$EstimatedVelocity$ (mm/sec)	$Error$ (%)
600	t=0.5 sec	601.5	0.25
	t=1.0 sec	587.5	2.08
	t=1.5 sec	590.5	1.58
	t=2.0 sec	580.4	2.66
1200	t=0.5 sec	1211	0.92
	t=1.0 sec	1158	3.5
	t=1.5 sec	1257	4.57
	t=2.0 sec	1180	1.67
1800	t=0.5 sec	1838	2.11
	t=1.0 sec	1708	5.11
	t=1.5 sec	1701.2	5.488
	t=2.0 sec	1749	2.83

4. Conclusion

In this paper, we have presented a range-based differential technique for velocity estimation using scene flow information. As the PMD camera gives suffient information about the obstacles, it can integrated with a Pioneer mobile robot to develop an online efficient dynamic path planning in a cluttered environment. Experimental results have shown encouraging results. Our future work will focus on prediction of the dynamic obstacle's trajectory using the estimated velocity.

Optimizing Frequency Resolution Muti-tone Detection Using the WDFT

Ohbong Kwon and Aparicio Carranza
Computer Engineering Technology,
New York City College of Technology, Brooklyn, NY, U.S.A.

Abstract— In this letter we investigate how to optimize the frequency discrimination of multi-tone signals based using the warped discrete Fourier transform (WDFT). Compared to a conventional DFT or FFT, which has a uniform frequency resolution across the entire baseband, the frequency resolution of the WDFT is non-linear and externally controlled. This feature can be used to overcome the multi-tone signal detection limitations of the DFT/FFT. The letter demonstrates that by intelligently controlling the frequency resolution of the WDFT, multi-tone signals can be more readily detected and classified. Furthermore, the WDFT can be built upon an FFT enabled framework, insuring high efficiency and bandwidths.

Keywords—Spectral analysis, Frequency discrimination, Warped discrete Fourier transform (WDFT), Spectral leakage

I. INTRODUCTION

Multi-tone signal detection and discrimination is a continuing signal processing problem. The applications include dual-tone multi-frequency (DTMF) systems, Doppler radar, electronic countermeasures, wireless communications, OFDM-based radar exciters, to name but a few. Traditional multi-tone detection systems are based on a filterbank architecture that use an array of product modulators to heterodyne signals down to DC, and then processes the down-converted array of signals with a bank of lowpass filters. The output of the filterbank is then processed using a suite of energy detection operations to detect the presence of tones and multiple tones [1]. The capability of such a system to isolate and detect multiple narrowband signals is predicated on the choice of initial modulating frequencies and post-processing algorithms. Other approaches to the problem are based on multiple signal classification (MUSIC) algorithms, least mean-square (LMS) estimators, and DFT derivatives such as Goertzel algorithm [2]. The approach taken in this paper is to explore the use of another DFT derivative called the *warped discrete Fourier transform* or *WDFT* [3, 4].

II. FFT - THE ENABLING TECHNOLOGY

The discrete Fourier transform (DFT) is indisputably an important signal analysis tool, finding applications in virtually all engineering and scientific endeavors. Generally, the preferred implementation of the DFT is the venerable Cooley-Tukey fast Fourier transform (FFT) algorithm. An N-point DFT $X[k]$, $0 \le k \le N$-1, of a length-N time-series $x[n]$, $0 \le n \le N$-1, is defined by:

$$X[k] = \sum_{n=0}^{N-1} x[n] e^{-j2\pi kn/N}, \quad 0 \le k \le N-1. \qquad (1)$$

For spectral analysis applications, the DFT provides a uniform frequency resolution $\Delta = 2\pi / N$ over the normalized baseband $\omega \in [-\pi, \pi]$. That is, the DFT's frequency resolution Δ is uniform across the entire baseband. This fact historically has limited the role of the DFT in performing acoustic and modal (vibration) analysis, applications that prefer to interpret a signal spectrum using logarithmic (octave) frequency dispersions. Another application area in which a fixed frequency resolution is a limiting factor is multi-tone signal detection and classification. It is generally assumed that if two tones are separated by 1.6Δ (1.6 harmonics) or less, then a uniformly windowed DFT/FFT cannot determine if one tone or multiple tones are present at a harmonic frequency due to spectral leakage, which obscures the spectral separation between adjacent DFT harmonics [4]. This problem is exacerbated when data widows are employed (*e.g.*, Hamming window). This condition is illustrated in Fig. 1. In Fig. 1(a), two tones separated by one harmonic (i.e., Δ) are transformed. The output spectrum is seen to consist of a single peak, losing the

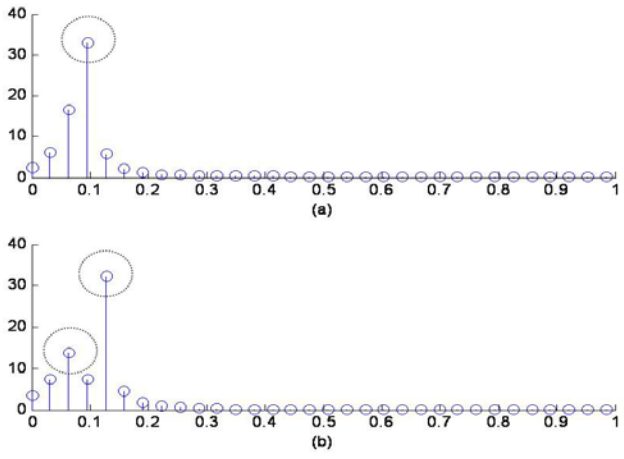

Figure 1: Magnitude spectrum for two tones using a 64-point DFT. (a) Two tone separated by one harmonic. (b) Two tones separated by two harmonics.

identification of each individual input tone because their main lobes get closer and eventually overlap. In the other case reported by Fig. 1(b), the two tones being transformed are separated in frequency by two harmonics (i.e., 2Δ). The presence of two distinct tones is now self-evident.

III. THE WDFT

The WDFT is a derivative of the familiar DFT filterbank [6]. It differentiates itself from the standard DFT filterbank in that it contains an additional pre-processed stage. The WDFT can be developed in the context of multi-rate and polyphase signal processing theory [7]. A polyphase multi-rate filter architecture, shown in Fig. 2, was used to implement a WDFT [8]. In Fig.2, the filter function $A(z)$ is as a pre-processing all-pass filter. For the case where $A(z) = 1$, the design degenerates to a traditional uniform DFT filterbank [6, 7]. For the case where $A(z) = 1$ and the polyphase terms $P_i(z) = 1$, the architecture shown in Fig. 2 becomes an N-point DFT.

Formally the N-point WDFT, reported in Fig. 2 for $P_i(z) = 1$, is defined in terms of a DFT and pre-processing the all-pass filtered data, filtered by $A(z)$, where:

$$A(z) = \frac{-a + z^{-1}}{1 - az^{-1}} \tag{2}$$

where " a "is real and is called the *warping control parameter*. For stability reasons, "a" ranges between -1 and 1.

To motivate the behavior of a WDFT, consider the experiment reported in Fig. 3. The uniform resolution DFT case ($P_i(z) = 1$ and $a = 0$) is compared to the non-uniform resolution case ($P_i(z) = 1$ and $a = \pm 0.3$). The ability of locally control the frequency

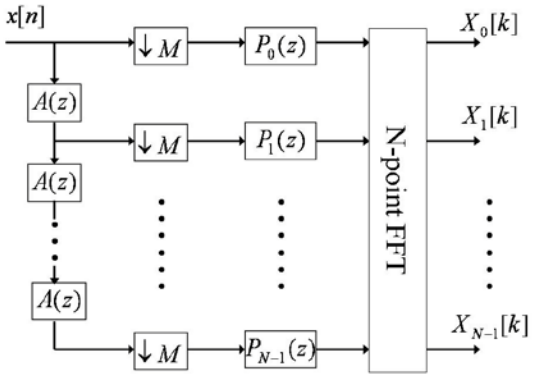

Figure 2. Polyphase multi-rate FFT Filterbank.

resolution of the WDFT is clearly demonstrated. In addition, if a lowpass subband shaping filter polyphase filter ($P(z) = \Sigma z^{-i} P_i(z)$) is employed (*e.g.*, approximate ideal lowpass FIR), then additional control can be exercised over the shape and frequency selectivity of the WDFT spectrum.

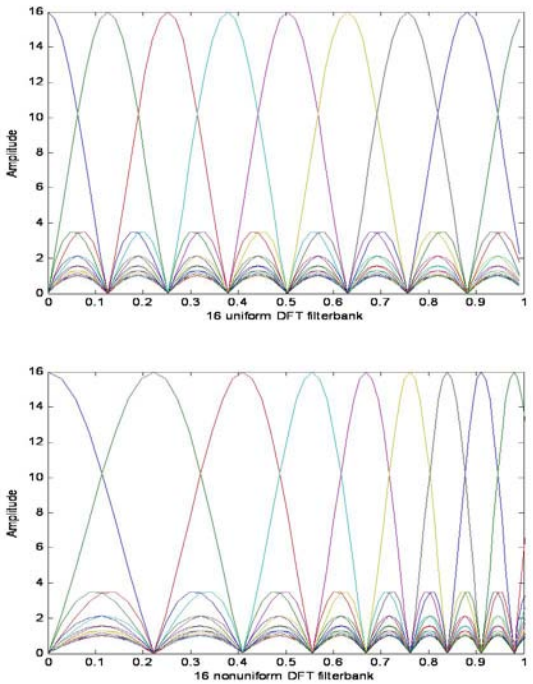
Concentrating on the WDFT case where $P(z) = 1$, it may be recalled that the standard z-transform of an N-point input time series $x[n]$, namely

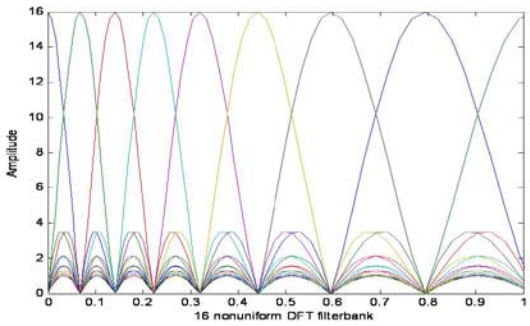
$$X(z) = \sum_{n=0}^{N-1} x[n] z^{-n} . \tag{3}$$

The warping filter converts the input into:

$$\overline{X}(z) = \sum_{n=0}^{N-1} x[n] A(z)^n . \tag{4}$$

Recall that the conventional DFT of $x[n]$, namely $X[k]$, produces





$\overline{\omega}$ corresponds to normalize baseband in [0,π].

16-channel non-uniform FFT spectrum for a= 0.3 (bottom left).

Figure 3: WDFT Experiment.

a spectrum given by:

$$X[k] = X(z)\big|_{z=e^{j2\pi k/N}},\ 0 \le k \le N-1 \qquad (5)$$

where $X[k]$ is evaluated at $z= e^{j2\pi k/N}$, a point the uniformly resolved locations on the periphery of the unit circle in the z-domain. The WDFT coefficients, $\overline{X}[k]$, are similarly obtained by uniformly sampling $\overline{X}(z)$ at points on the unit circle in the z -domain, namely:

$$\overline{X}[k] = \overline{X}(z)\big|_{z=e^{j2\pi k/N}},\ 0 \le k \le N-1. \qquad (6)$$

The conventional uniform frequency resolution DFT, defined by $z = e^{j\omega}$, has harmonic frequencies located at frequencies $\omega = 2\pi k/N,\ k \in [0,\ldots,N-1]$. The center frequencies of an N-point WDFT spectrum are located at the warped frequencies $\overline{\omega}$ where $z = e^{j\overline{\omega}}$, which are associated to ω through the non-linear frequency warping relationship

$$\tan\left(\frac{\overline{\omega}}{2}\right) = \left(\frac{1-a}{1+a}\right)\tan\left(\frac{\omega}{2}\right). \qquad (7)$$

Equation (7) establishes a non-linear frequency warping relationship that is controlled by the real parameter "*a*". A positive "*a*" provides higher frequency resolution on the high frequency region and a negative value of "*a*" increases frequency resolution in the low frequency region (see Figure 3).

The effect of the warping relationship is demonstrated in Fig. 4 which compares a DFT ($a = 0$) to WDFTs for a = -0.071, a = -0.23 and a = -0.4 for the case where two tones are present separated by a single DFT harmonic. It is easily seen that by intelligently choosing the control parameter "*a*" the locally imposed frequency resolution can be expanded or contracted. To enhance the system's frequency discrimination, the frequency resolution should be maximized in the local region containing the input signals. As such, an intelligent agent will need to assign the best warping parameter "*a*" strategy, one that concentrates the highest frequency resolution in the spectral region occupied by the multi-tone process.

The next section describes the outcome of a preliminary study that compares two criteria and two search algorithms and develops an "intelligent" frequency resolution discrimination policy that can be used to improve multi-tone detection.

IV. OPTIMIZATION OF FREQUENCY RESOLUTION

To optimize the choice of the warping parameter "*a*", $|a|<1$, an intelligent search algorithm or agent is needed. An initial search strategy is being evaluated and enabled using optimal single-variable search techniques, a Fibonacci search [1] [9] and a modified Golden Section search [2]. The search process is expected to iterate over a range of values of "*a*" that places a high local frequency resolution in the region occupied by multi-tone activity. To find the best warping parameter "*a*", two criteria of optimization and cost functionals have been singled out for focused attention. The search methods iteratively restrict and shift the search range so as to optimize spectral resolution within a convergent range. The direction of the search is decided by the value of the cost functional at two points in the range.

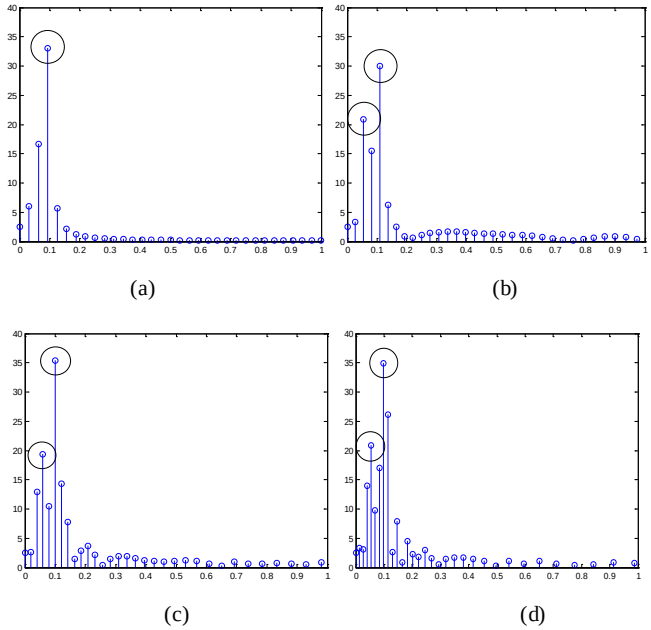

Figure 4. Magnitude spectrum for two tones with 64-point WDFT with (a) a = 0, (b) a = -0.071, (c) a = -0.23, and (d) a = -0.40.

Two criteria studied to date are developed below.

A. Criterion #1

$$\Phi_1(\overline{\omega}) = \max_k\left[\overline{X}[k]\right] - \sum\left[\overline{X}[k]\big|_{\overline{\omega}_b}\right] \qquad (8)$$

where $\overline{\omega}_b$ is a frequency within the search interval and $\Phi_1(\overline{\omega})$ is designed to reward a local concentration of spectral energy and penalize more sparsely populated section of the spectrum. The optimal operating point corresponds to a warping parameter "*a*" that maximizes the local spectral resolution in a region of signal activity.

B. Criterion #2:

$$\Phi_2(\overline{\omega}) = \sum\left[\sigma - \overline{X}[k]\right] \qquad (9)$$

where σ is the threshold used to suppress leakage and $\Phi_2(\overline{\omega})$ is designed to reward the local concentration of spectral energy.

[1] The Fibonacci search technique is a method of searching a sorted array using a divide and conquer algorithm that narrows down possible locations with the aid of Fibonacci numbers.

[2] The Golden Section search is a technique for finding the extremum (minimum or maximum) of a unimodal function by successively narrowing the range of values inside which the extremum is known to exist.

Table 1
Comparison of the warping parameter

Criterion	*Criterion #1*		*Criterion # 2*	
Search Method	Fibonacci search	M. Golden section search	Fibonacci search	M. Golden section search
Warping parameter	a = -0.1087	a = -0.0721	a = -0.0996	a = -0.1381
Elapsed time (sec.)	t = 0.749252s	t = 0.888743s	t = 0.736151s	t = 0.751035s

V. RESULTS AND COMPARISON

The letter reports on a multi-tone signal discrimination study conducted using two search methods, namely a Fibonacci search and a modified Golden Section search algorithm. Both are iterative methods that restrict and shift the searching range so as to determine an optimal operating point within a frequency range. Studies based on these criteria involved presenting to the WDFT frequency discriminator of two sinusoidal tones located at 0.157 and 0.314 rad/s. The search method was charged to find the "best" warping parameter. The comparison of results is shown in Table 1 and the evidence of this activity can be seen in Fig. 5. To compare the temporal efficiency of each case, Table 1 also shows elapsed time needed to execute a search using MATLAB. The two tones, separated by one harmonic, were unresolved with 64-point DFT but resolved with 512-point DFT at the expense of increased complexity (see Fig. 5 (a) and (b), respectively). In Fig. 5 (c)-(e), however, the two tones are seen to be present using 64-point WDFT. To calibrate the WDFT spectra, the locations of the actual two tones are also shown. Comparing the outcomes, a Fibonacci search was found to be the fastest and most effective in finding the "best" warping parameter using either search criteria. *Criterion #1* resulted in frequency resolution with a bigger variation according to search methods, while *Criterion #2* facilitated the optimization of the local resolution and identified the two tones closer to the actual locations of the tones.

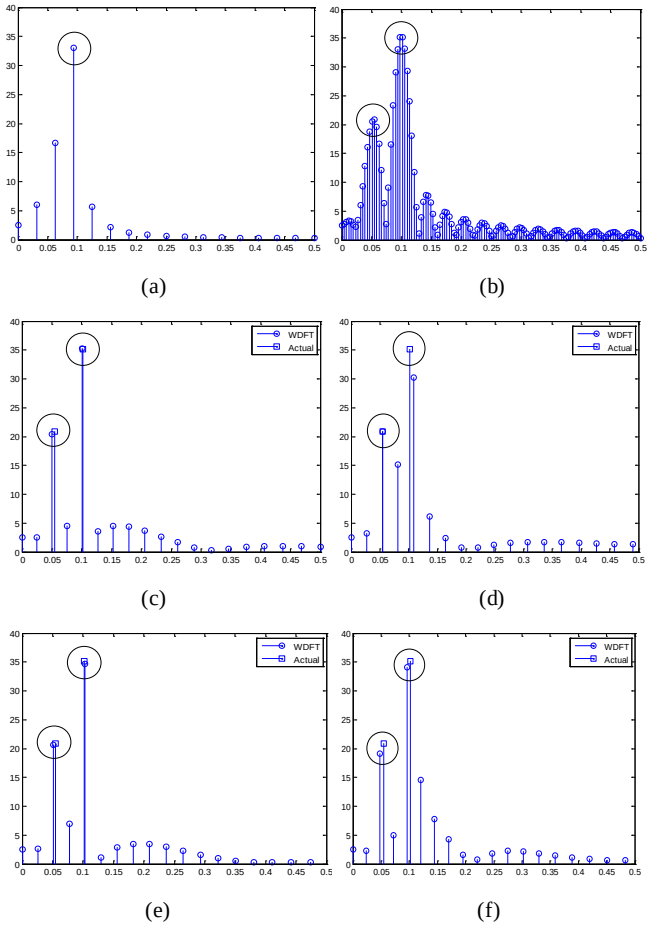

Figure 5. (a) Magnitude spectrum for two tones with (a) 64-point DFT (a = 0) and (b) 512-point DFT (a = 0) and magnitude spectrum for two tone detection with 64-point WDFT with (c) a = -0.1087, (d) a = -0.0721, (e) a = -0.0996 and(f) a = -0.1381.

VI. CONCLUSION

We have studied and shown that multi-tone processes can be successfully discriminated using the WDFT. The study demonstrates that the local frequency resolution can be selectively enhanced in regions of interest using the reported search techniques. Overall, the WDFT is found to be a very capable transform which can provide selective high spectral resolution at low complexity. Studies continue in this area, processing more complex signal cases.

Abstract - *This paper is for the study of feature analysis of the correlation of brain waves between channels in the stimulation of the 5 senses (sight, hearing, touch, smell, taste). In the existing studies, feature analysis of brain waves in response to stimulation of the human senses has been made by single sense stimulation or double sense stimulation, but, study with stimulation of all 5 senses is still not yet satisfactory. In this paper, the brain waves in response to stimulation of the 5 senses in the behavior of eating food are collected and analyzed for the analysis of the features of brain waves. From time-based data and frequency elements, features of correlation in brain waves between channels are extracted. The overlapping rates between the stimulation sections, between experimenters, and between frames consisting of channels with high correlation coefficients are calculated. In the experiment, 65 sections (32 stimulation sections, 33 break sections) of a brain wave database (DB) about the stimulation of the 5 senses were collected and analyzed for 9 men and 2 women. In the results of the experiment, the stimulation is distinguishable for each sense.*

Keywords: EEG, Five senses stimulus, Analysis of correlation characteristics

1 Introduction

Recently, the study of Brain Computer Interfaces (BCI) has been active. Users' intensions and emotional conditions can be detected in brain waves measured through the scalp, and the electrical activity of brain cells show differences according to the mental conditions of an individual, which can be used for BCI. Human Interfaces based on brain waves have been used for medical treatment, games, training for mental concentration, robot control, and mind recognition [1, 2]. Human beings recognize situations through 5 senses (sight, hearing, touch, smell, taste). Humans become aware of their situation through the senses. In addition, interaction between humans and objects as well as with other humans takes place by means of the senses. Thus, analyses of brain wave characteristics in response to human sensory stimulation of have been conducted. In the existing studies, the feature analysis of brain waves in response to the stimulation of human senses has been done with the stimulation of a single sense [3-9] or two senses [10], but study with the stimulation of 5 senses has been dissatisfactory. Expanding on these studies, the features of brain waves in response to the stimulation of all 5 senses are analyzed by extracting correlation features in the brain waves. A DB of brain waves measured in response to the stimulation of all 5 senses during the behavior of eating food was collected and analyzed. In Chapter 2, we will examine existing research on sense stimulation. In Chapter 3, we explain our proposed correlation feature analysis method. Chapter 4 describes our experiments. Chapter 5 discusses the conclusion of this study.

2 Existing Studies

The feature analysis of brain waves for single sense stimulation [3-9] and two senses at the same time [10] has been conducted in previous studies. In addition, brain waves with visual stimulation using correlation coefficients have been analyzed [4, 5]. The method for feature analysis of brain waves acquires brain wave data when senses are stimulated, and extracts time-based data and frequency elements in each channel (each area of the scalp) from the acquired brain wave data and analyzes them. Brain wave data is induced from the scalp, passes through an amplified circuit and filter. Then the brain wave data is transmitted to an analog-to-digital (AD) converter and sent to a smart phone or PC for analysis. In existing studies, frequency element analyses of brain waves are commonly classified as Delta (1~3Hz), Theta (4~7Hz), Alpha (8~13Hz), Beta (14~30Hz), and Gamma (31~50Hz), and are analyzed for features.

3 Correlation Feature Analysis Method of Brain Waves between Channels

The feature analysis of brain waves in response to the stimulation of 5 senses was made by correlation feature extraction from brain waves between channels. A portable brain wave acquisition device was developed in a previous study [11]. Analog brain wave voltage signals in the range of 0.017uV~1.101uV are amplified by a factor of 2,225 to transform them into digital values and are transmitted to a smart phone. This device acquires the brain wave data for the 14 channels and takes 128 samples per second. AD-transformed brain wave data is changed to voltage values (0-

2.5V) by deducting an offset average value from each channel voltage value, and removing the DC element. A correlation coefficient is used to calculate the time-based data and 7 kinds of frequency elements. The frequency data are classified as Delta (1~3Hz), Theta (4~7Hz), Alpha (8~13Hz), Beta (14~30Hz), Gamma (31~50Hz), 51~59Hz, and 1~59Hz. There are 91 x 8 kinds of correlation coefficients between the 14 channels for a total of 728. The correlation coefficient is treated as a frame unit (1 unit is 128 samples). If the quantity is less than 128 in the last frame of each section, it is disregarded. Equation (1) is used to calculate the correlation coefficient.

$$r_{i,j} = \frac{\sum_{n=1}^{N}(X_{i,n} - \overline{X}_i)(X_{j,n} - \overline{X}_j)}{\sqrt{\sum_{n=1}^{N}(X_{i,n} - \overline{X}_i)^2 \times \sum_{n=1}^{N}(X_{j,n} - \overline{X}_j)^2}} \quad (1)$$

M : *The Number of EEG Channels*

$i = 1,2,\cdots,M-1$

$j = i+1, i+2,\cdots,M$

$X_{i,n}$ is data at time n sample of section i (channel), and $\overline{X}_i$ is average value over N samples of a section (channel) of data. X_i and X_j are different channels. $r_{i,j}$ is a normalized covariance value divided into the multiply standard deviation of the two variables X_i, X_j by covariance. The range has the value $-1 \le r_{i,j} \le +1$. In case of $r_{i,j} = +1$, there is a perfect positive correlation between the two variables. In case of $r_{i,j} = -1$, there is a perfect negative correlation between the two variables. In case of $r_{i,j} = 0$, the two variables are perfectly independent.

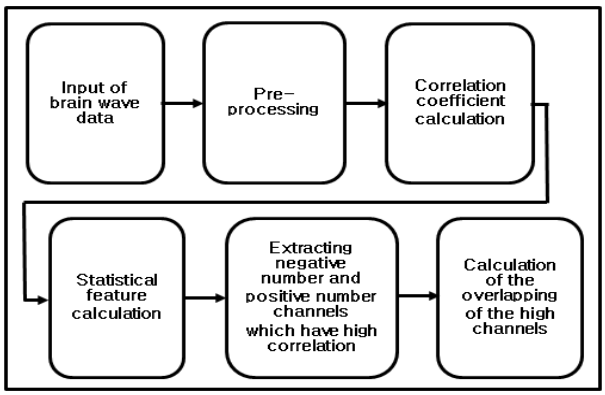

Figure 1. Block diagram of correlation feature analysis of brain waves between channels.

The statistical feature calculation calculates 5 kinds of feature values (mean, variation, standard deviation, maximum value, minimum value) of 8 kinds of correlation coefficients. There are a total of 3,640 feature values between the channels.

In the calculation of the overlapping rate of channels with high correlation in each section, the overlapping rate of all 65 sections in the brain wave DB is calculated once per test. The 240 channels which have high correlation in each section are judged in regard to whether they are the same or not. A block diagram of correlation feature analysis of brain waves between channels is shown in figure 1.

The method of correlation analysis is as follows.

1) Brain wave data is input: 14 channel brain wave data.
2) Pre-processing: AD conversion data are changed to voltage values.
3) Correlation coefficient calculation: The correlation coefficients of time-based data and 7 kinds of frequency elements are calculated (91 correlation coefficient between 14 channels, 91 x 8 kinds of correlation coefficients for a total of 728 coefficients.)
4) Statistical feature calculation: 5 kinds (mean, variation, standard deviation, maximum value, minimum value) of feature values about 8 kinds (time-based data and 7 kinds of frequency elements), (8 kinds x 91 correlation coefficient between channels x 5 kinds feature value, calculate 3,640 whole feature value between channels).
5) Extracting negative number and positive number channels which have high correlation: Extract 3 positive number and negative number channels which have high correlation from 5 kinds of feature values about 8 kinds of correlation coefficients between channels. Extract 48 from a whole feature value between 3,640 channels (8 x 91 x 5 matrix).
6) Calculation of the overlapping of the high channels: Judge whether the channels with high correlation are the same or not (compare 48 extracted features between channels).

4 Experiments and Results

4.1 Using the device

We used a portable electroencephalography (EEG) acquisition system developed in a previous study [11]. Figure 2 shows the portable EEG signal acquisition system interfaced with an Android device. This EEG device amplifies brain wave signals 2,225 times. It has an HPF cut-off frequency of 0.58Hz, an LPF cut-off frequency of about 58,94Hz, and 16-bit/128 per second sampling activities in AD conversion.

(a) (b)

Figure 2. The portable EEG signal acquisition system using an Android device: (a) portable EEG device, (b) EEG demonstration (interfacing between the portable EEG device and smart phones).

4.2 EEG Measurement Points

The lower regions behind the ears are where the EEG measurements are taken. The 14 measurement points are denoted as F7, AF3, FC5, F3, T7, P7, O1, F8, AF4, FC6, F4, T8, P8 and O2, and they are placed according to the international 10-20 electrode system. The gyro X-axis and Y-axis are assigned to channels 8 and 16, respectively. Figure 3 shows the points of EEG measurement.

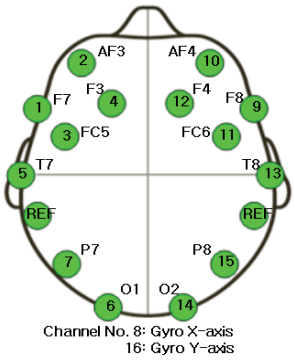

Figure 3. The points of EEG measurement.

4.3 The Experimental Conditions and Results

In this study, brain waves in response to stimulation of the 5 senses during the behavior of eating food were collected and analyzed. Correlation features between channels regarding the time base energy and frequency elements were also extracted and analyzed. The subjects of the experiment were 9 men and 2 women between the ages of 23~36, and the experiment was executed in 65 sections (32 stimulations, 33 break and rest periods). The experimental conditions were as follows:

1) The experimental place was a quiet laboratory, and the experiment was done with the subject sitting in a chair in front of a table, and the laboratory was well ventilated with an open window.

2) The food was a beef hamburger (Lot***** brand). The diameter was about 4 inches and the materials included buns, beef patty, mayonnaise, and beef sauce, weighing 154g and containing 390 kcal.

3) The experiment was composed of one subject, one experimenter, and another experimenter to give verbal instructions (e.g. "close your eyes") to the subject, who acted according to the decided scenario.

4) Auditory stimuli were made by a hamburger advertisement (the contents of the advertisement make people have the desire to eat a hamburger: beef ~ burger, burger, burger ~ Wow! Beef or shrimp which will ignite flame from man's heart)

5) The conditions of the scenario to collect the brain wave DB are to add stimulation of each sense, one by one, with minimized 5 sense stimulation, and to make the applied stimulation distinguished. There were break and rest sections between the stimulation sections to distinguish the stimulation sections from each other. Table 1 shows the type of 5 senses stimulation in the behavior of eating food. The brain wave DB was collected by dividing the total 65 sections into 4 sets. Each stimulation was about 10sec ~ 30sec, and the breaks were about 30sec ~ 40sec. The breaks were done with open eyes and restful sitting. The brain wave DB collection scenario is shown in Figure 4.

Table 1. The type of 5 senses stimulation in the behavior of eating food.

Figure 4. The scenario of brain wave DB collection (ex: No1 set)

4.3.1 Experiment 1

This experiment was done to analyze the overlapping rate between stimulation sections, which consist of channels with high correlation coefficients. For the correlation feature values of brain waves between channels of 65 sections (32 stimulation sections and 33 break sections) per one subject, the overlapping rate of the channels which had high

correlation in each section were calculated. The average overlapping rates were obtained for 32 stimulation sections and 33 break sections each. From the results of the experiment, the average overlapping rate of 32 stimulation sections for 11 people was 13.05%, and the average overlapping rate of 33 beak sections was 17.67%. The average overlapping rate of the total 65 sections was recorded as 15.36.

4.3.2 Experiment 2

This experiment was done to analyze the overlapping rate between experimenters. The analysis was done on channels with high correlation coefficients. From the results of the experiment, the average overlapping rate of al 65 sections was recorded as 7.17%. Between sensory stimuli on the same cross-section overlapping of subjects were lower than the correlation between EEG channels.

4.3.3 Experiment 3

This experiment was done to analyze the overlapping rate between frames, and was done on channels with high correlation coefficients. From the results of the experiment, the average overlapping rate of al 8 kinds was recorded as 18.71%.

4.3.4 Experiment 4

We were recognition experiments from 1 person (subject 11). 65 kinds of candidate models of recognition were used for the high-correlation channels from each section of the average correlation coefficients. This experiment changed the extracting negative number and the positive number channels which have high correlation. 3 to 30 of positive number and negative number channels which have high correlation from 1 kind of feature values about 8 kinds of correlation coefficients were extracted. 48 to 488 from a whole feature value between channels 728 (8 x 91 x1 matrix) were extracted. In the results of the experiment, 26 extracting numbers showed the highest correlation. The total average rate was recorded as 60.14%.

4.3.5 Experiment 5

We were recognition experiments from 11 people. 26 positive number and negative number channels were extracted, each of which has high correlation from 1 kind of feature value on 8 kinds of correlation coefficients. From the results of the experiment, the average rate of recognition was recorded as 59.89.

5 Conclusion

A study on correlation feature analysis of brain waves between channels related to the stimulation of five senses was performed in this paper. To analyze correlation features of brain waves related to the stimulation of five senses, brain waves were collected, and a correlation feature analysis experiment was performed on the brain waves between channels from the collected brain wave DB. In the results of the experiment, when stimulating the five senses, the overlapping rate of correlation features of the brain waves between channels was found to be low, thus, it seems that the stimulations could be distinguishable from each other. It seems that the method for extracting correlation features of brain waves between channels presented in this study could be used for technology based on brain waves for recognition of the five senses. In the future, the study of figure analysis of brain waves related to the stimulation of the five senses during movement behaviors will be needed.

Abstract - *Human Computer Interaction (HCI) is one of the key focuses in gaming industry. Its computer side interactions can be traced back since 1963 when Ivan Sutherland suggested interacting with the objects on the screen directly with a light-pen. Few years later, mice were suggested to be the replacement for the expensive light-pen and have been the most popular interactive device till now. Touch-screen technology and recognition-based user interface (RBUI) are also gaining its popularity in the recent gaming industry. However, the above mentioned technologies interact with virtual objects in two dimensional (2D) output screens which constraint the mobility of the players to only front side of the screens. Deployment of Augmented Reality (AR) in gaming industry will solve this problem by providing true three dimensional (3D) immersive experiences and 6 degree-of-freedom to the players. In this paper, we introduce ARPuzzle, an AR version of jigsaw puzzle, which provides mobility freedom to the players and focus on interactions between two virtual objects.*

Keywords: Augmented Reality, Human Computer Interaction, Recognition-Based User Interface.

1 Background

Human Computer Interaction (HCI) is one of the key focuses in gaming industry. HCI contains two main components, i.e. human side and computer side interactions. Our main discussion is on the computer side. HCI can be traced back since 1963 when Ivan Sutherland first suggested manipulating the visible objects on the computer screen directly with a light-pen pointing device in his doctoral dissertation [[1]]. Meanwhile, HCI researches on other devices were also carried out and gained successful results. Mice were developed as a commercial device by Xerox PARC [[3]] mainly as replacements for the expensive light-pens. Since then, mice have become the most popular pointing device of personal computers. Its popularity remains till now, though various other pointing devices like joysticks, touchpad, trackball, pointing stick, were suggested. Recently there is a trend to change the pointing habit from using physical input device to touch-screen technology, however, mice-supported screens are still strong in market acceptance compare to touch screen, in view of its cost effectiveness. The latest technology deployed in gaming industry which excites the players is recognition-based user interface (RBUI) that involves input-output of gestures, handwriting, speech, etc. Though RBUI is not new in discussions and researches, this technology gained its popularity around the globe when Nintendo released its *wii* version in 2006, to control the avatar remotely via accelerometer and optical sensing technology [[4]]. We anticipate the next interactive application which will stir a craze in the gaming industry is Microsft's Kinect for Xbox 360, which is based on PrimeSense light-coding technology for motion and depth detection. Unlike Nintendo *wii*, Kinect for Xbox requires no external controller device, i.e. the player is the controller [[5]]. Nevertheless, both games display the avatars, i.e. three dimensional (3D) virtual objects, on two dimensional (2D) screens. The players' mobility freedoms are partially achieved as they can walk around but still confined to the front side of the screen. Comparatively, Augmented Reality (AR) is a better choice in game developments, as AR can help to achieve true 3D immersive experiences and provide the players with six degree-of-freedom when interacting with the 3D virtual objects. AR uses pattern recognition technology to display virtual objects in the real environment on a fiducial marker. In our project, we have developed an AR game called ARPuzzle which is the AR version of a jigsaw puzzle. In the first version of ARPuzzle, we concentrate on the interactions between the virtual puzzle blocks and its pushing rod. Our final objective of ARPuzzle is to be able to deploy RBUI technology to use hand gesture to interact with the virtual puzzle blocks, in real environment.

2 ARPuzzle Overview

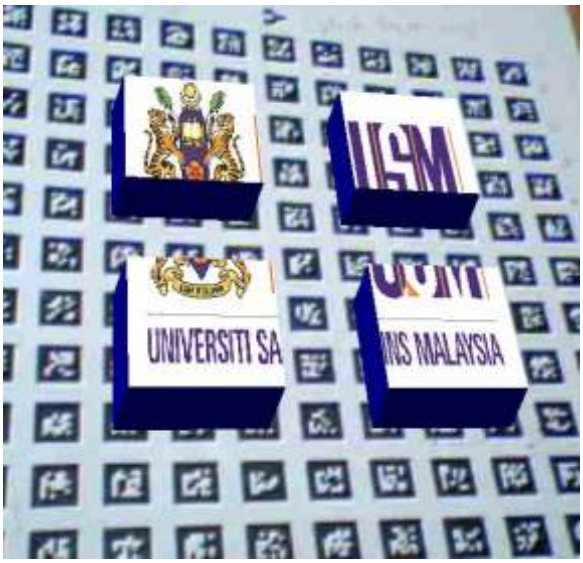
ARPuzzle is a user interactive game developed on ARTag for its strength to provide higher accuracy on marker detection by using arrays of markers, after reviewing a set of common AR tools available [[6]]. The first version of ARPuzzle contains four puzzle blocks shaped in square prism. The top faces of the four blocks form an image of Universiti Sains Malaysia (USM) logo once the puzzle is solved. When the virtual puzzle blocks were first displayed, it was scattered on *base0* marker (Fig. 1a), the puzzles can be moved by using the virtual pushing rod displayed on *toolbar0* marker (Fig. 1b).

The side faces of the blocks are colored in blue to create the depth illusions. When the puzzle blocks are formed correctly, the side faces of all the puzzles will be changed to red, to indicate the puzzle has been solved.

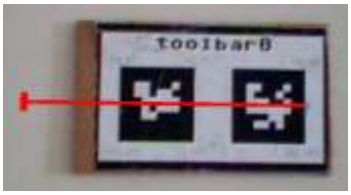
2.1 Components of ARPuzzle

There is no special equipment required as we plan to make ARPuzzle a common game which can be played anytime, anywhere. A laptop or PC running MS windows, a PC camera and two ARTag markers labeled *base0* and *toolbar0* are required. Though a PC camera is enough, a head mounted display (HMD) is encouraged while playing the game to obtain the full mobility of the players. The ARTag markers are available together with the game in PDF format, which can be printed out by the players.

The *x*- and *y*-coordinates of ARTag's *base0* marker range from –80 to +80 in both directions. The *x*- and *y*-coordinates of the *toolbar0* marker range from 0 to 40 and 0 to 100 respectively. When detected, *toolbar0's* coordinates are calculated and transformed to *base0* marker's coordinates to check if an interaction between the markers is established [[7]].



Base0 marker with the virtual puzzle blocks



Toolbar0 marker displaying the virtual pushing rod.

Fig. 1. ARTag markers used in ARPuzzle

2.2 Structure of each puzzle block

Each puzzle block is divided into four right-angle triangles according to +45°, +135°, -135° and -45° labeled as A, B, C and D. Thus, A, B, C and D are formed within angles -135° and -45°, -45° and +45°, +45° and +135°, -135° and +135° respectively (Fig. 2.).

The right-angle vertices of the four triangles meet at the centre of the puzzle piece. When the pushing rod's tip is detected at region A, B, C or D, the piece moves up, left, down and right respectively (Fig. 3.).

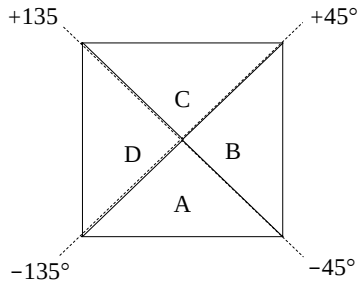


Fig. 2. Division of a puzzle piece into four right-angle triangles.

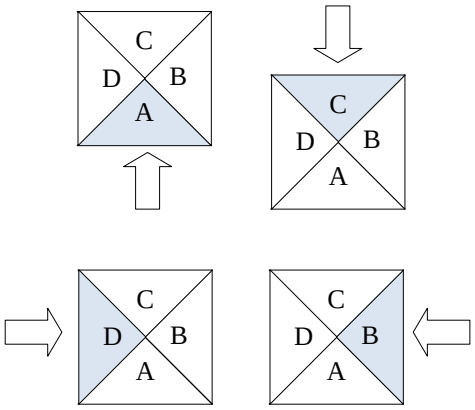

Fig. 3. Moving directions of the blocks when the tip of the pushing rod is detected. Shaded areas denote the detected areas and its moving direction is showing by the arrows.

2.3 Movement validity check when the virtual objects are interacting

While moving the puzzle blocks, we need to ensure that the blocks are not overlapping each other. The *x*- and *y*-distances between centers of two blocks are calculated. When checking the validity of the movements, the *x*- and *y*-distances are checked against the width of the blocks. Further, the positions of x_1 compare to x_2, y_1 compare to y_2 are also checked to decide the direction of the movement; given the center coordinates of the stagnant and moving puzzle blocks are (x_1, y_1) and (x_2, y_2) respectively. The validity of the movements is stated in Table 1.

3 How ARPuzzle work

ARPuzzle starts by displaying *base0* marker within the field of view of the camera. Four virtual puzzle blocks will be displayed on the marker. The blocks are scattered amongst themselves. The first version of the ARPuzzle scatters the four blocks at an ordered distance (Fig. 1a.). By pushing the blocks in four directions, i.e. up/down/left/right, from their positions, a full image of USM logo will be formed. The first version of ARPuzzle focuses on interactions between two virtual objects. A virtual pushing rod appears on the *toolbar0* when it is displayed within the camera's FOV. When the pushing rod is detected on one of the A, B, C and D region (Fig. 2), the puzzle blocks moves according to Fig. 3 and Table 1. Fig. 4 displays a half-done puzzle. When the four pieces of jigsaw puzzle combined together and become a big cube, its color turned red and it indicates the end of the game (Fig. 5).

Table 1. Validity check of two blocks during the movement. The stagnant block is assigned the center coordinates with (x_1, y_1). The piece which we want to move is assigned the center coordinate with (x_2, y_2).

		$\lvert y_1 - y_2\rvert$ < width		$\lvert y_1 - y_2\rvert$ = width		$\lvert y_1 - y_2\rvert$ > width	
		$y_1 < y_2$	$y_1 > y_2$	$y_1 < y_2$	$y_1 > y_2$	$y_1 < y_2$	$y_1 > y_2$
$\lvert x_1 - x_2\rvert$ < width	$x_1 < x_2$	Error	Error	Down-move invalid	Up-move invalid	valid	valid
	$x_1 > x_2$	Error	Error	Down-move invalid	Up-move invalid	valid	valid
$\lvert x_1 - x_2\rvert$ = width	$x_1 < x_2$	Left-move invalid	Left-move invalid	valid	valid	valid	valid
	$x_1 > x_2$	Right-move invalid	Right-move invalid	valid	valid	valid	valid
$\lvert x_1 - x_2\rvert$ > width	$x_1 < x_2$	valid	valid	valid	valid	valid	valid
	$x_1 > x_2$	valid	valid	valid	valid	valid	valid

Fig. 4. The two bottom blocks of the puzzle are formed.

Fig. 5. The edge of the completed puzzle is turned to red.

4 Conclusion and Future Work

ARPuzzle is a new development for AR game mainly focusing on the interaction between two virtual objects. Much work remains to be done. In our following versions, we shall deploy RBUI to recognize finger gesture to move the puzzle block. Further, fine-tuning on the appearance of the puzzle and provide blocks with irregular shape are in the development pipeline.

A probability based defuzzification method for fuzzy cluster partition

Thanh Le[1], Tom Altman[1], Katheleen J. Gardiner[2]
[1]Department of CSE, University of Colorado Denver, Denver, CO, USA
[2]Department of Pediatrics, University of Colorado Denver, Aurora, CO, USA

Abstract– *Fuzzy C-Means (FCM) is an unsupervised clustering method that has been used extensively in data analysis and image segmentation. The defuzzification of the fuzzy partition of FCM is usually done using the maximum membership degree principle which may not be appropriate for some real-world applications. In this paper, we present a new algorithm that generates a probabilistic model of the fuzzy partition and applies the model to classification of data objects. We show that our method outperforms four popular defuzzification methods on uniform and non-uniform artificial datasets as well as on real datasets.*

Availability: *The test datasets and the method software are available online at http://ouray.ucdenver.edu/~tnle/fzpbd.*

Keywords: *fuzzy c-means, classification, fuzzy partition, Bayesian based model.*

1 Introduction

Cluster analysis and image segmentation are important in a variety of scientific and industrial applications. They are used to group data objects based on the similarities of their properties. Data objects within a cluster are closely related to each other and can be discriminated from data objects within other clusters. Fuzzy C-Means (FCM) [1] is an unsupervised method that has been successfully applied to feature analysis, cluster analysis, classifier design, and futures analysis in fields such as astronomy, geology, medical imaging, target recognition, image segmentation, and economics. Unlike hard clustering methods, which force data objects to belong exclusively to one cluster, FCM allows data objects to belong to more than one cluster with varying degrees of fuzzy set membership. However, the fuzzy partition of FCM needs to be defuzzified for crisp classification information of the data objects. A popular approach to this problem is to use the maximum membership degree principle (MMD) [2, 9, 12]. This may be inappropriate in some applications because FCM membership is computed using distance between the data object and cluster center. Use of membership degree can assign marginal objects of a large cluster to the immediately adjacent small cluster. This is illustrated in Figure 1, where if a data object is in the gray rectangle, it may be incorrectly assigned to cluster 3 instead of cluster 2.

Recent solutions include that of Chang et al. [4] who proposed using spatial information to adjust the membership status of every data point using the membership status of its neighbors. In a similar approach, Chiu et al. [3] used spatial information to determine the distance between the data point and cluster center. However, these methods require definition of neighborhood boundaries. Genther et al. [7] proposed defining spatial information by the clustering structure, not the neighborhood, to compute the distance from the data point to cluster center.

A common limitation of methods that use spatial information in computing membership degree is that they have to scale between the actual position information of the data point and its spatial information. In addition, while use of spatial information is appropriate for image segmentation, it may not work with generic data cluster analysis because it is difficult to define neighborhood boundaries.

In this study, we propose a method that uses the fuzzy partition and the data themselves to construct a probabilistic model of the data distributions. The model is then applied to produce the classification information of data points in the dataset.

This work was supported in part by the Vietnamese Ministry of Education and Training (TL).

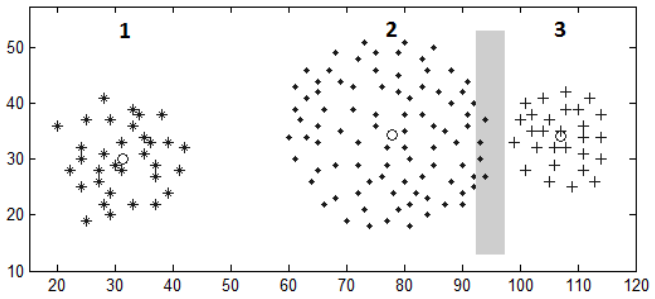

Figure 1: ASET4 - an artificial dataset with three clusters of different sizes

2 Methods

2.1 Fuzzy C-Means algorithm (FCM)

Let $X = \{x_1, x_2, \ldots, x_n\} \in R^p$ be a set of data objects x_i, i=1..n, and for a given c, $2 \le c < n$, the Fuzzy C-Means algorithm (FCM) divides X into c clusters by minimizing the objective function:

$$J_m(U,V) = \sum_{i=1}^{n}\sum_{k=1}^{c} u_{ki}^m d^2(x_i, v_k) \rightarrow \min \qquad (1)$$

where $u_{ki} \in [0,1]\ \forall k,i$,

$$\sum_{k=1}^{c} u_{ki} = 1 \forall i\ , \qquad (2)$$

and m, $1 \le m$, is the fuzzifier factor, V, $V = \{v_1, v_2, \ldots, v_c\}$ is a set of c cluster centers, $U = \{u_{ki}\}_{i=1..n,k=1..c}$ is a partition matrix and $d^2(.)$ denotes the Euclidean norm.

Minimizing J_m with respect to (2), we obtain an estimated model of U and V as:

$$u_{ki} = \left(\frac{1}{d^2(x_i, v_k)}\right)^{\frac{1}{m-1}} \Bigg/ \sum_{l=1}^{c}\left(\frac{1}{d^2(x_i, v_l)}\right)^{\frac{1}{m-1}}, \qquad (3)$$

$$v_k = \sum_{i=1}^{n} u_{ki}^m x_i \Big/ \sum_{i=1}^{n} u_{ki}^m\ . \qquad (4)$$

2.2 Defuzzification of fuzzy cluster partition

Defuzzification, in fuzzy cluster analysis, is a procedure to convert the fuzzy partition matrix U into a crisp partition which is then used to determine the classification information of the data objects.

Maximum membership degree principle

A popular approach for defuzzification of fuzzy partition is application of the maximum membership degree principle (MMD). The data object x_i is assigned to the class of v_k if and only if its membership degree to cluster v_k is the largest, that is

$$u_{ki} = \max_{l=1..c}\{u_{li}\}\ . \qquad (5)$$

If the dataset is non-uniform, this approach may make incorrect cluster assignments, in particular of marginal data objects of large clusters, as illustrated in Figure 1. Common approaches to resolve this problem use spatial information in membership degree computation.

Fuzzy clustering based method

Genther, Runkler and Glesner [7] proposed a defuzzification method based on fuzzy clustering (FCB) that used fuzzy cluster partition in membership degree computation. For each data object x_i, i=1..n, an estimated value, $\mu(x_i)$, is computed using the fuzzy partition. The set of estimated values of X, $\{\mu(x_i)\}_{i=1..n}$ is then used to compute the estimated value of v_k, w_k, k=1..c, as:

$$w_k = \sum_{i=1}^{n} u_{ki}^m \mu(x_i) \Big/ \sum_{i=1}^{n} u_{ki}^m\ . \qquad (6)$$

In FCB, distance, d_F, between the data object and cluster center, is computed using both the actual and the estimated information as:

$$d_F(x_i, v_k) = \sqrt{\frac{\alpha d^2(x_i, v_k)}{\max_{j,l}\{d^2(x_j, v_l)\}} + \frac{\beta d^2(\mu(x_i), w_k)}{\max_{j,l}\{d^2(\mu(x_j), w_l)\}}}\ . \qquad (7)$$

$d_F()$ is used, instead of d(), to compute the membership degree. The problem with this is selection of the values for α and β that scale the actual and estimated parameters in the distance measure.

Neighborhood based method (NBM)

In NBM, Chuang et al. [4] proposed adjusting the membership status of every data point using the membership status of its neighbors. Given a cluster v_k, k=1..c, a data point, x_i, i=1..n, receives an additional amount of membership degree from its neighbors:

$$h_{ki} = \sum_{x_j \in NB(x_i)} u_{kj}\ . \qquad (8)$$

The partition matrix U is then revised as in (9).

$$u_{ki}^{NB} = \frac{(u_{ki})^p \times (h_{ki})^q}{\sum_{l=1}^{c} (u_{li})^p \times (h_{li})^q} \quad (9)$$

NBM uses the spatial information in membership degree computation, but requires definition of neighborhood boundaries and the values of p, q which weight the position and spatial information.

Spatial FCM (sFCM)

In sFCM, Chiu et al. [3] used spatial information in computing the spatial distance, d_S, between the data point and cluster center:

$$d_S(x_i, v_k) = \frac{1}{NB} \sum_{j=1}^{NB} \left[(1 - \alpha_j^i) d(x_i, v_k) + \alpha_j^i d(x_j, v_k) \right], \quad (10)$$

where NB is the number of neighbors of every data point, α_j^i is the weighted factor of x_j, a neighbor of x_i, defined as:

$$\alpha_j^i = 1 / \left(1 + \exp(\Delta_j^i / \sigma_i)\right), \quad (11)$$

where $\Delta_j^i = d(x_j, x_i)$. sFCM uses $d_F()$, instead of d(), to compute the membership degree, and updates cluster centers, $\{ v_k^S \}$, k=1..c, as follows:

$$v_k^S = \sum_{i=1}^{n} u_{ki}^m \left[\frac{1}{NB} \sum_{j=1}^{NB} (1 - \alpha_j^i) x_i + \alpha_j^i x_j \right] \Big/ \sum_{i=1}^{n} u_{ki}^m \cdot \quad (12)$$

sFCM requires the number of neighbors, NB, to be specified a priori.

3 The fzPBD algorithm

To generate classification information, we propose fzPBD, a novel probability based method for defuzzification of fuzzy cluster partition, using the fuzzy partition and Bayesian probability to generate a probabilistic model of the data distributions, and applies the model to produce the classification information. To create a probabilistic model of the data distributions using fuzzy partition, we used the method of Le et al. [8].

Possibility to probability transformation

Given a fuzzy partition matrix U, the vector $U_k = \{u_{ki}\}_{i=1..n}$, k=1..c, is a possibility model of the data distribution of v_k on X. Assume P_k is the probability distribution of v_k on X, where $p_{k1} \geq p_{k2} \geq p_{k3} \geq \ldots \geq p_{kn}$. We associate with P_k a possibility distribution U_k of v_k on X [5] such that u_{ki} is the possibility of x_i, where

$$\begin{aligned} u_{kn} &= n \times p_{kn} \\ u_{ki} &= i(p_{ki} - p_{k,i+1}) + u_{k,i+1}, \ i = n-1,...1. \end{aligned} \quad (13)$$

Reversing (13), we obtain the transformation of a possibility distribution to a probability distribution. Assume that U_k is ordered the same way with P_k on X: $u_{k1} \geq u_{k2} \geq u_{k3} \geq \ldots \geq u_{kn}$,

$$\begin{aligned} p_{kn} &= u_{kn} / n \\ p_{ki} &= p_{k,i+1} + (u_{ki} - u_{k,i+1}) / i. \end{aligned} \quad (14)$$

P_k is an approximate probability distribution of v_k on X, and $p_{ki} = P(x_i|v_k)$.

Probabilistic model of the data distributions

Central Limit Theorem– *The distribution of an average tends to be normal, even when the distribution from which the average is computed is decidedly non-normal.*

In real datasets, for a cluster v_k, the data points usually come from different random distributions. Because they cluster in v_k, they tend to follow the normal distribution of v_k estimated as follows,

$$\sigma_k = \sum_{i=1}^{n} p_{ki} \| x_i - v_k \|^2, \quad (15)$$

$$P_n(x_i \mid v_k) = \left((2\pi)^{1/n} \times \sigma_k \times e^{\frac{\|x_i - v_k\|^2}{2\sigma_k^2}} \right)^{-1}. \quad (16)$$

Defuzzification of fuzzy partition

We use the probabilistic model as in (15) and (16) for defuzzification of the fuzzy partition. The data object x_i is assigned to the class of v_k, where

$$P(v_k \mid x_i) = \max_{l=1..c} \{P(v_l \mid x_i)\} \quad (17)$$

Because $P(v_k|x_i) = P(x_i,v_k)/P(x_i) = P(x_i|v_k)*P(v_k)/P(x_i)$, then

$$P(v_k \mid x_i) = \max_{l=1..c} \{P(x_i \mid v_l) \times P(v_l)\}, \quad (18)$$

where $P(v_l)$, l=1..c, the prior probability of v_l, can be computed using the method of Soto et al. [10].

fzPBD algorithm

- Input: An optimal fuzzy clustering solution,
  - c: optimal number of clusters.
  - $V = \{v_i\}$, i =1..c: the cluster centers.
  - $U=\{u_{ki}\}$, i=1..n, k=1..c: the partition matrix.
- Output: The classification of $x_i \in X$, i=1..n.

Steps

1. Convert the possibility distributions in U into probability distributions using (13) and (14).
2. Construct a probabilistic model of the data distributions using (15) and (16).
3. Apply the model to produce the classification information for every data point using (18).

4 Experimental results

Datasets

To evaluate the performance of fzPBD, we used four artificial datasets generated using an infinite mixture model method [11]. Datasets ASET1, ASET2 and ASET3 have well-separated clusters of similar size. The number of clusters and data dimensions of these dataset are (5,2), (5,3) and (11,5) respectively. ASET4 is more complex, containing three clusters that differ in size and density (Figure 1). For the real datasets, we used the Iris, Wine and Glass datasets from the University of California Irvine (UCI) Machine Learning Repository [6]. The classification structures in these datasets are known.

Performance measures

We use two measures to evaluate algorithm performance. The compactness cluster validity index is defined as:

$$\text{compactness} = \sum_{k=1}^{c}\sum_{i=1}^{N_k} d(x_i, v_k), \qquad (19)$$

where N_k is the number of data points assigned to cluster v_k, k=1..c. Smaller compactness means better cluster partition. The overall performance is measured by the number of data objects that are misclassified. The cluster label of each data object is compared with its actual class label. If any do not match, then a misclassification has occurred.

We compared fzPBD with four defuzzification algorithm methods: MMD, FCB, NBM, and sFCM [2-4, 7, 9, 12]. For each dataset, the following values of the fuzzifier factor, m were used: 1.25, 1.375, 1.50, 1.625, 1.75, 1.875 and 2.0. The number of clusters, c, was set to the known number of clusters. The FCM algorithm was run 3 times and the best fuzzy cluster partition was selected to test all the algorithms. We repeated the experiment 100 times and averaged the performance of each algorithm using the two measures.

ASET1 and ASET2 datasets

ASET1 and ASET2 each contain five well-separated clusters of the same sizes. ASET1 and ASET2 are in two-dimensional and three-dimensional data space, respectively. Performance of all algorithms is shown in Figures 2 and 3. fzPBD, MMD and sFCM generated no misclassification across multiple levels of m.

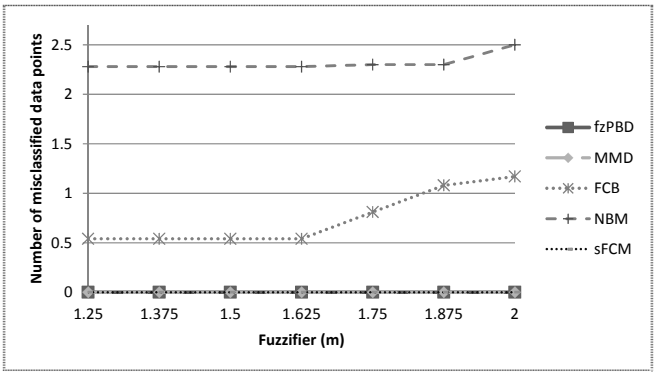

Figure 2: ASET1 dataset

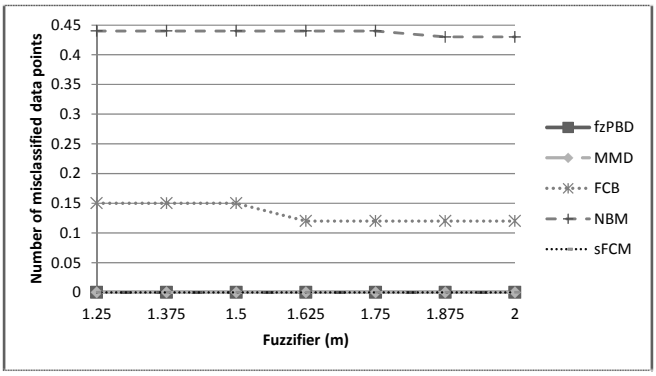

Figure 3: ASET2 dataset

ASET3 dataset

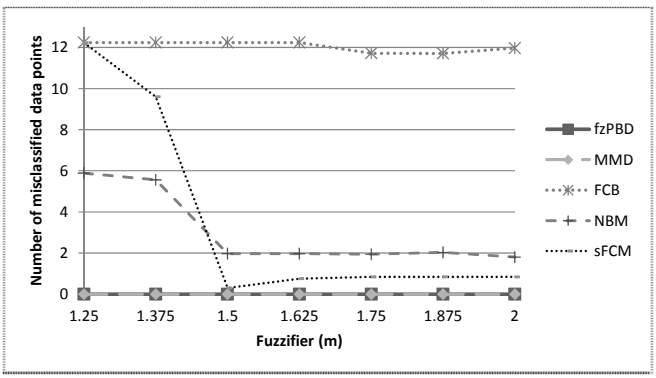

Figure 4: ASET3 dataset

ASET3 contains 11 well-separated clusters in a five-dimensional data space. Results are shown in Figure 4. fzPBD and MMD performed best. Table 1 shows that they also had the smallest compactness measures across multiple levels of m.

Table 1

ASET3: Compactness measure

Algo.	Fuzzifier factor m						
	1.25	1.375	1.5	1.625	1.75	1.875	2.00
fzPBD	0.39	0.39	0.39	0.39	0.39	0.39	0.39
MMD	0.39	0.39	0.39	0.39	0.39	0.39	0.39
FCB	4.52	4.52	4.52	4.52	4.53	4.54	4.54
NBM	12.85	11.28	8.73	8.72	8.72	8.72	8.72
sFCM	4.94	3.2	0.45	0.49	0.49	0.5	0.5

ASET4 dataset

This dataset is non-uniform with three clusters in a two-dimensional data space (Figure 1). Results are shown in Figure 5. fzPBD outperformed all the other algorithms.

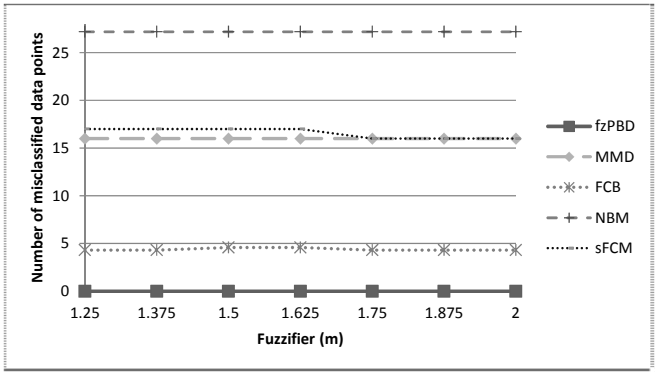

Figure 5: ASET4 dataset

IRIS dataset

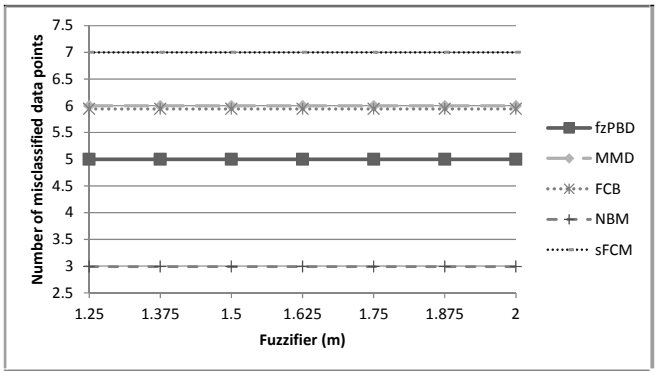

Figure 6: IRIS dataset

The IRIS dataset contains three clusters corresponding to the three classes of Iris flowers. Results are shown in Figure 6. NBM outperformed other algorithms. fzPBD performed lightly less well, however Table 2 shows that, compared with NBM, fzPBD had smaller compactness measures across multiple levels of m.

Table 2

IRIS: Compactness measure

WINE dataset

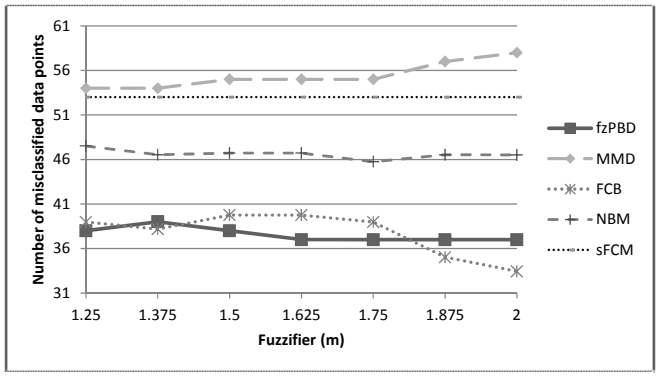

Figure 7: WINE dataset

The Wine dataset contains information on 13 attributes of the three classes of wines. Results are shown in Figure 7. fzPBD and FCB performed better than other algorithms. fzPBD performed better than FCB with the fuzzifier factor levels less than 1.8. However, Table 3 shows that fzPBD performed better FCB across multiple levels of m.

Table 3

GLASS dataset

The Glass dataset contains information on nine attributes of six classes of glass used in building construction. Results are shown in Figure 8. fzPBD significantly outperformed all the other algorithms.

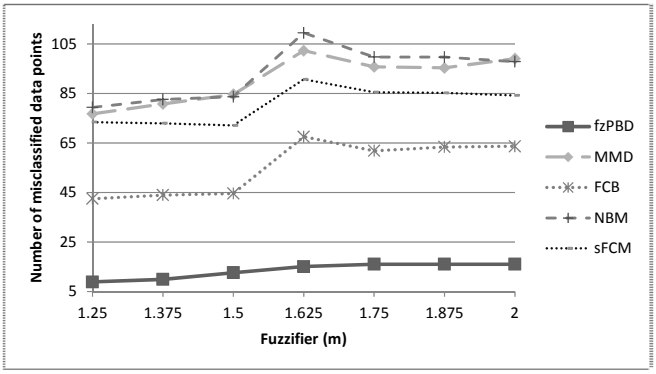

Figure 8: GLASS dataset

5 Conclusions

fzPBD is a novel defuzzification algorithm that uses a Bayesian based approach to generate a probabilistic model for a given fuzzy partition and then uses the model to produce classification information for the data objects. fzPBD outperformed other methods on both artificial and real datasets, particularly on the datasets with clusters that differed in size. fzPBD is therefore appropriate for real-world datasets, where the data densities are not uniformly distributed. In future work, we will exploit this Bayesian probabilistic model to generate classification information at different ranks with application to microarray data analysis.

Abstract – *With the increasing popularity of social media over the last few years, terrorist groups have flocked to the popular web sites to spread their message and recruit new members. As terrorist groups establish a presence in these social networks, they do not rely on direct connections to influence sympathetic individuals. Instead, they leverage "friend of a friend" relationships where existing members or sympathizers bridge the gap between potential recruits and terrorist leadership or influencers. As anti-Western propaganda flows through these social networks, homegrown terrorists and lone wolf terrorists have been inspired to commit acts of terrorism. These terrorist social networks in social media can be uncovered and mapped, providing an opportunity to apply social network analysis algorithms. Leveraging these algorithms, the main influencers can be identified along with the individuals bridging the gap between the sympathizers and influencers.*

Keywords: terrorism, terrorist networks, social media, influence, social network analysis

1 Introduction

Terrorists use a number of methods to indoctrinate and radicalize new followers. With the growth of the Internet and the explosion in popularity of social networking sites all over the world in recent years, terrorist groups have significantly increased their global reach. They are now able to spread propaganda and recruit half way around the world from the convenience of an Internet cafe. Terrorist groups and their members have made a concerted effort to increase their presence on social media sites like Facebook and Twitter to go along with their existing Internet presence on web sites, forums, and message boards. However, it is their new found presence on social media sites that allows them to identify and target individuals that are particularly influenced by their propaganda. By reaching out to disillusioned individuals, they attempt to create new followers. The ultimate goal is to indoctrinate and radicalize these people so they feel compelled to commit acts of terrorism.

The individuals that have become indoctrinated with terrorist ideology have been heavily influenced during their use of social media. This has especially been the case with homegrown terrorists that have committed acts of terrorism in Western countries. Although they never had direct access to the terrorist ideology or training camps, they were exposed to it through relationships developed on social media sites and subsequently influenced. However, it was not necessarily the direct connections within their social networks that were the heavy influencers pedaling terrorist ideology. Often, it comes from individuals they are not directly connected to, but someone they encounter through a direct connection or "friend." Through a "friend of a friend," a disenchanted individual can quickly become enamored with the anti-Western culture. Consequently, it is important to identify these at risk individuals, the influencers, and the bridge between them. A variety of social network analysis methods can be used to identify these actors within a social network. This paper will explore terrorists' use of social media and the phenomenon of "friend of a friend" influence. Furthermore, it will discuss social network analysis techniques aimed at discovering these entities within social networks.

2 Terrorists' Use of Social Media

Over the last ten to fifteen years, the presence of terrorist groups online has greatly increased. In 1998, there were only 15 web sites associated with terrorist groups on the Internet [1]. By 2005, there were more than 4,000 [1]. Up until recent years, terrorists have limited themselves to more covert means of communication on the Internet such as password-protected forums for communicating and disseminating propaganda to support their causes. There was a shift in the way terrorists conduct operations. In an effort to adapt with current technology trends and reach larger audiences with their message, they have taken up the use of social networking sites. These sites also provide a number of other benefits as terrorists attempt to spread their propaganda. With that being said, terrorist groups are using social networking sites as a new medium for recruitment, radicalization, and planning.

In December 2008, pro-jihad contributors to the "al-Fajola Islamic Forums" urged Al-Qaeda supporters to "invade" Facebook by creating sympathetic groups to spread the Salafi-Jihadi message [1]. This movement had almost immediate results. In December 2009, Pakistani authorities arrested five young American Muslims as they were attempting to join Al-Qaeda [2]. Groups such as Lashkar-e-Taiba and Lashkar- e-Jhangyi used Facebook and YouTube to recruit them [1]. In regards to this incident, a high-ranking Department of Homeland Security (DHS) official said, "Online recruiting has exponentially increased, with

Facebook, YouTube, and the increasing sophistication of people online" [2].

There are many motivating factors behind the migration of terrorists to social networking sites. Terrorists have always utilized the latest technology to support their cause. Examples include the use of complex encryption programs for communications and altering computer games to mimic real life missions and attacks. As a result, their use of social networking sites is a natural progression of their technology-oriented tactics. Terrorist organizations have also moved to social networking sites out of self-perseveration [3]. Traditional web sites hosted by an ISP are prone to monitoring, attacks, and subject to shutdowns. Terrorist web sites are always targeted by the United States and its allies. Patriotic hacktivists also target the web sites using distributed denial of service (DDoS) attacks. For example, in June 2011, a hacker named "The Jester" shut down http://www.alijahad.com [3]. If they use a Facebook page, there is a very low probability someone would execute a DDoS attack against Facebook's web site. That is even assuming they can locate the page in question. The use of social networking sites provides terrorists with free web hosting where they can upload content anonymously, reliably, and at no cost [4].

Social networking sites are attractive to terrorists and their groups because they have features to control access to the page [5]. Instead of the site being open to the public, the page owner can set it to private. Then the owner must approve someone's request for access or invite them to join the page. This provides the opportunity to vet an individual thoroughly before granting them permission to view the content of the group's page or participate in a discussion forum [5]. Additionally, the owners can monitor the content posted on the pages. This provides a unique environment for terrorists where they control the content and access to it while also reaching large audiences.

The most important reason terrorist organizations are taking to social networking sites is to recruit, indoctrinate, and radicalize new members that can support their cause. "The Internet is the enabler that acts as a catalyst for the radicalization lifecycle" [6]. Without the use of the Internet and social networking sites, the perpetuation of Al-Qaeda's message would be severely stifled [6]. However, the radicalization process that used to take months now takes weeks or even days [6]. With the help of the Internet, terrorists are able to communicate across the globe instantly. They are targeting mainstream social networking sites because they are more accessible to sympathizers than the hardcore forums [7]. After the indoctrination of sympathizers, they are steered to the terrorist forums where some will finally join the front lines of the jihad [7].

3 Friend of a Friend Influence

A "friend of a friend" is described as an individual that has a friendly relationship with the friend of a person, but that person has no direct relationship to that individual. Figure 1 depicts the friend of a friend relationship between nodes A and C in the social network. C is a friend of A's friend B, and vice versa. A and C are not directly connected, but a path exists between them through C. Although there is no direct

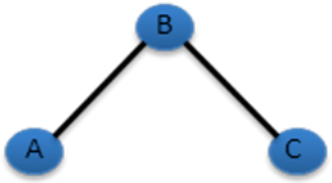

Figure 1. A friend of a friend relationship between A and C

connection between the person and the friend's friend, this is still an important relationship. Each person can exert a certain amount of influence on one another using the common friend as an intermediary. Ideas, information, behavior, and even feelings can spread through this social network. In addition, when the flow of information and ideas are strong enough, the three individuals will form a triad. In fact, social theory even argues there is a strong propensity for people to form these triads. Once this direct connection is formed between the two individuals that were not previously directly connected, ideas, information, and behavior are free to flow back and forth. The triad formed by A, B, and C is shown in Figure 2. This is the exact social phenomenon that terrorists are looking to exploit when using social media sites in an effort to build their virtual networks.

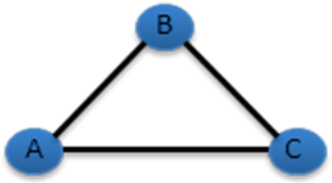

Figure 2. A triad formed between A, B, and C

4 Terrorists' Use of Friend of a Friend Relationships on Social Media Sites

Initially, the terrorists' first attempts at infiltrating social media sites like Facebook consisted of "Facebook raids" or campaigns aimed at disseminating their propaganda through existing Facebook channels [8]. Although this was spreading their message, it did very little in the way of adding followers and building their virtual networks. Their subsequent efforts have been to establish a permanent presence on Facebook by creating groups and virtual communities affiliated with terrorist web sites [8]. This allows the terrorists to bridge the gap between sympathizers and leadership. This is where the friend of the friend relationship starts to take root. To reach out to the Facebook users they are trying to recruit, terrorists are creating Facebook pages and coordinating communication between Facebook and the web sites. The terrorists operating on Facebook befriend sympathizers on the fringe and begin pedaling their anti-Western sentiment. This forms the structure seen in Figure 1 and starts the information flow from terrorist leaders and web sites to the sympathizer.

Information also flows back through this channel as sympathizers are often afforded the opportunity to interact with leadership through the intermediary. The flow of information will continue as the sympathizer becomes indoctrinated and radicalized, eventually leading to the individual becoming vetted and accepted as one of them. They then gain access to the password protected forums and web sites and are allowed to interact directly with leadership, effectively closing the triad and forming the structure depicted in Figure 2. This is the best case scenario terrorist groups hope for when targeting social media sites for new members. There are many examples that show terrorist groups attempting to reach out to sympathizers on social media sites. Some are clear cases that illustrate a concerted effort to bridge the gap between leadership and sympathizers and others show individuals that have been radicalized through these means and motivated to carry out acts of terror.

Many consider the Facebook page Jihad Al-Ummah to be one of the most important terrorist pages on Facebook and one of the most authoritative sources on the Internet outside of the actual forums [8]. The page is closely associated with the Shumukh Al-Islam forum and is a hub for jihadi material [8]. It distributes content from terrorist sites and serves as a liaison between Facebook users and those same sites [8]. The Jihad Al-Ummah Facebook page contains videos, announcements, articles, and other jihadist media right after it appears on the Shumukh forum [8]. To facilitate the material's dissemination through Facebook, they will tag friends of the page in the posts [8]. This brings the newly posted material to the attention of friends of the page or friends of the friends as they are updated on their friend's Facebook activity. For example, the Shumukh forum announced an open question and answer session with Sheikh Abu Walid Al- Maqdisi, leader of a Gaza based jihadi group [8]. Jihad Al-Ummah's Facebook page also announced the session and collected questions written by friends of the page [8]. Those who ran the Facebook page then passed on the questions to the Shumukh forum for answering. The friend of a friend relationship is being exploited by connecting friends of the Jihad Al-Ummah Facebook page to leadership in an effort to influence sympathizers. Utilizing Facebook in this manner for communications allows terrorist organizations to insulate leadership while also providing access for sympathizers.

The same type of activity is also reflected on Twitter. Twitter pages are set up to notify followers of updates on terrorist web sites and blogs. The Twitter page serves as the intermediary between sympathizers and the terrorists behind these web sites and blogs. The Taliban attempts to use Twitter in this manner. They leverage a system called TwitterFeed that automatically updates a Twitter page to reflect web site or blog updates [9]. Anytime there is a new addition to the web site, a link to the update is tweeted. This instantly updates followers who receive the tweet. The followers are now able to go directly to the site to view the update, bridging the gap between the propaganda and sympathizers.

Utilizing these communication patterns in social media, terrorists groups have inspired homegrown terrorism and driven seemingly normal individuals to act in support of their cause. For example, Taimour al-Abdaly appeared to be an average family man. He was a former DJ from Great Britain that was married with three children. However, much more sinister intentions were developing underneath his outwardly appearance. In December 2010, on a suicide mission, he blew himself up in Stockholm, Sweden, injuring two others.

As it turns out, he was a member of a virtual terrorist network constructed through social media. After the fact, when researchers explored Taimour's social media activity, they determined there were only three degress of separation between him and Samir Khan [7]. Khan was one of Al-Qaeda's top media operatives before being killed in Yemem as the target of a U.S. drone attack in September 2011. Figure 3 shows the friend of friend relationships that existed between them with Tamiour's friend being friends with several of Khan's friends [10]. Khan and his friend were not the only

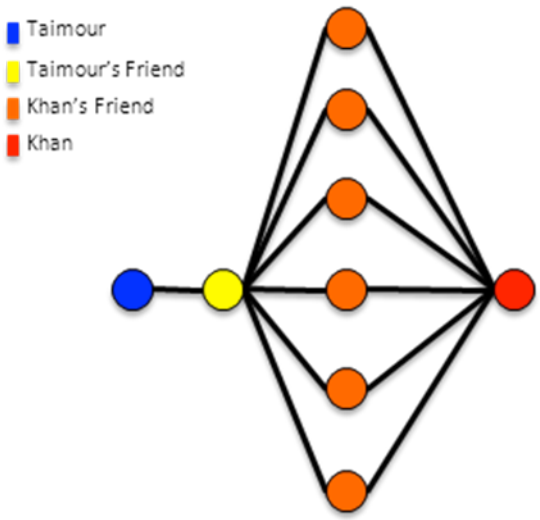

Figure 3. Subset of Taimour's Social Network

individuals who Taimour encountered online. His social media exploits also extended to YouTube where he would frequently view YouTube videos that consisted of violence and anti-Western propaganda. In fact, he was connected to Mohammed Gul, who was sentenced to jail in February 2011 in Britain for posting extremist Islamic material on the Internet. Taimour labeled four videos posted by direct associates to Gul as his favorites on YouTube [11].

Another individual that was heavily influenced by their involvement in virtual terrorist networks is Arid Uka, who opened fire on U.S. soldiers in Frankfurt, Germany, killing two and wounding another two. On Facebook, Uka had 127 friends that included extremists such Salahudin Ibn Ja'far [12]. Ja'Far openly identified with Germans involved in terrorist activity and was strongly linked as a friend and subscriber of two YouTube accounts known for posting extremist propaganda [13]. Uka was also Facebook friends with a German jihadist group using the name "Dawaffm De" that was friends with "AzeriJihadMedia," a jihadist media organization, on YouTube [14]. Uka was never a known member of any terrorists groups and was not under any type

of surveillance before his attack [15]. He was simply immersed in this online terrorist social network. Given his connections to extremists and their connections to others, it is clear that anti-Western propaganda flowed through this network and heavily influenced him. So much so that he decided to commit an act of terrorism and murder two U.S. soldiers.

5 Using Social Network Analysis to Detect Friend of a Friend Activity

It is clear that in online terrorist social networks influence is flowing through friends and between individuals who are not even directly connected, radicalizing extremist sympathizers with no physical connections to terrorist groups. Since a specific behavior has been established with these virtual networks, we can begin to use social network analysis methods to disrupt the flow of influence and try to prevent individuals from becoming indoctrinated with extremist ideals. Mapping the relationships between members of these online terrorist communities creates a social network. Various social network analysis methods can then be used to identify the different individuals that are a part of these types of relationships.

If there is an individual that is a part of a social network and feared to be a terrorist sympathizer, their ego network analysis will identify the individuals with whom they are connected to and influenced by. Ego network analysis consists of analyzing an individual within a social network and all the nodes the individual is connected to at some path length [16]. According to social theory, influence works at distances with up to three intermediaries [3]. Identifying all persons with a path length of 2 from ego produces a list of all of their friend of a friend relationships. This could go on to path lengths of three and four to identify further influencers and intermediaries. Figure 3 is essentially a subset of Taimour's ego network, depicting the people he is connected to with path length three or less. The people found to be on the end of these paths are potential influencers while those found in between are the intermediaries passing it along. Ego-networks can also be examined for structural holes. A structural hole refers to a tie that is absent [16]. For example, the network depicted in Figure 1 has a structural hole between A and C while Figure 2 contains no structural holes. Social network analysis software such as UCINET analyzes ego networks for structural holes. Identifying structural holes may lead to the discovery of friend of a friend relationships in which influence is flowing from terrorist leadership to sympathizers.

Betweenness centrality measures the ratio of shortest paths an individual is present upon. Individuals with a high betweenness centrality hold a very important position in a social network. By being present on the shortest path between two individuals, they have the opportunity to serve as a broker of information by passing it along or affecting it in some way. In the friend of the friend relationship, they serve as the intermediary connecting two individuals that would otherwise be disconnected. For example, in Figure 1, B would score a high betweenness centrality for being on the shortest path between A and C. By calculating the betweenness centrality for an entire social network, the individuals with the highest betweenness values are identified. By the pure definition of betweeness centrality we know that these individuals must be connecting others who are not directly connected. As a result, by using betweenness centrality, we identify the individuals in the friend of a friend relationships that are passing information and influence between terrorist leadership and sympathizers in social networks.

Community detection algorithms detect groups that exist within social networks and help reveal network structure. Most community detection algorithms work by measuring the density between sets of nodes and identifying groups or communities where the density of those nodes within the group is greater than that of nodes outside the group. As a result, communities of individuals are identified where the members of the community are more connected to each other than any other people in the network. For example, the subset of Taimour's social network shown in Figure 3 could be identified as a group in a large social network. We see that there are several connections between the intermediaries that serve as friends of friends and Khan himself along with Taimour's connection to this group. Depending on how the parameters are set for the community detection algorithm, many different types of groups may be identified. They could identify groups of sympathizers, intermediaries, leadership, or mix of all three. Essentially any pocket of increased connectivity. When examining social networks, it is important to identify these groups because the increased connectivity between the individuals will indicate some type of coordinated activity. For example, a group of sympathizers may be communicating on social media and actively seeking information and propaganda relating to the terrorist cause. A group of intermediaries whose job it is to bridge the gap between these sympathizers and leadership may also be identified. Community detection algorithms are valuable to the examination of social networks to identify these pockets of activity in a larger network so they can be further investigated.

6 Conclusion

Given the popularity and widespread use of social media sites across the world, terrorist groups have targeted the sites as new grounds for spreading their propaganda and recruiting new members. Targeting social media sites provides terrorists groups with a number of benefits over their traditional recruiting efforts. They are able to reach many more people essentially anywhere in the world, given free web hosting to upload content, have the ability to control access, and social media pages are less prone to attack. Once the terrorists gain a foothold on social media sites, they look to build virtual online terrorists networks where influence and ideas can flow from existing members to potential recruits. They leverage friend of a friend relationships where indirect connections allow influence and propaganda to make its way from leadership and web sites to sympathizers who may be inclined

to join their cause. Although the sympathizers may not be directly connected to the main influencers, the information and ideas still flow through intermediaries to reach them. Mainly, it is the friends that sympathizers make on social media sites that are responsible for delivering the propaganda. This social phenomenon has been exhibited as extremist groups hold question and answer sessions with leadership through Facebook and use Twitter posts to keep followers updated on the latest activity. It has also shown direct results by inspiring lone wolf terrorists. Taimour al-Abdaly injured two others while blowing himself up in Stockholm. Arid Uka acted against U.S. soldiers, murdering two and injuring another two. Later research showed these individuals were heavily immersed in virtual terrorist networks. They had friends that were connected to radical terrorists and consumed anti-Western material as it made its way to them on Facebook and YouTube. By targeting this type of behavior on social media sites, social network analysis can be used to identify these relationships. Using techniques such as ego network analysis, betweenness centrality, and community detection algorithms, the sympathizers, intermediaries, and leadership that constitute these friend of a friend relationships can be identified. Locating these relationships is extremely important so actions can be taken to disrupt the flow of influence and propaganda and prevent the existing terrorist groups from inspiring lone wolf terrorists.

MISAAC: Instant messaging tool for Ciberbullying Detection

Perla Janeth Castro Pérez[1], **Christian Javier Lucero Valdez**[1], **María de Guadalupe Cota Ortiz**[1], **Juan Pablo Soto Barrera**[1], **Pedro Flores Pérez**[1]
[1] Universidad de Sonora, Blvd. Luis Encinas y Rosales S/N, 83000 Colonia Centro, Hermosillo, Sonora, México.

Abstract - The efforts of education authorities to find ways to identify problems related to bullying, still have not considered ciberbullying, and have not taken the necessary measures to maintain proper control of the problem through computer applications. In this paper are proposed a security model based on agents, which can analyze the messages exchanged between children (ages 9 to 13) through chats that are used in classrooms, and emit warnings about the threats, which may be considered to address such problems. The information generated can be used for the detection of cyberbullying and offer psychological support to those that may be formed as aggressors, preventing that this behavior becomes a disease that could be avoided at an early age.

Keywords: Pattern recognition, Agent, Security, Ciberbullying.

1 Introduction

The problem of cyberbullying is defined by the fact that a person is abused, threatened or harassed through electronic means, and has recently generated great controversy, since this type of violence may increase as advances the use of new technologies [1, 2].

Because there are several forms of cyberbullying, this paper proposes a model based on the architecture of ARSEC-AMS agents [3] to detect threats and verbal abuse to which a child is usually exposed, taking into account the behavior of the aggressors and techniques of content analysis of messages exchanged through chats [4-6].

It is important to mention that the content analysis is applied to the spanish language, so that in the experimental examples section the analyzed sentences are presented in that language, since the result does not have the same structure or the same meaning in other languages.

Moreover, this paper is organized as follows: introduction, description of the model, components of content analysis, implementation of the architecture ARSEC-AMS, experimental tests, and finally is presented the conclusions and bibliographical references.

2 Model

This model focuses on the detection of threats and aggressions to which a child is exposed on having interacted with others through instant messaging, applying content analysis techniques to measure the dangerousness of the message. Moreover, it is used the software agent technology based on the architecture ARSEC-AMS [3] that allows to implement computer security concepts.

2.1 Content analysis

The analysis of content is a set of technologies that allow distinguishing the symbolic semantics of the messages regarding the mode of production, these messages generally do not have a single meaning, since in occasions they change their semantics according to the context in which they are in relation to the rest of the information. [4-6]

In the process of analysis, the aim consists of realizing an inspection of the sentences that are exchanged in the instant messaging application, and identify those that represent a threat to the user who receives them, and registered as evidence to determine if the user is a person likely to carry out his threats. For this task we designed a dictionary of keywords, some of which are used in sentences that constitute a threat, as well as the words that can not represent an attack by themselves. As support for the content analysis it was identified two components or modules that help to detect if the statement is a threat to another person. These components are the lexical analyzer (tokenizer) and the content analysis.

2.1.1 Lexical analyzer

The lexical analyzer also known as tokenizer is a program that separates the words of the sentence analyzed in tokens, which are compared with the content of a dictionary that corresponds to a previously selected set of sentences for testing. With the obtained result it is possible to recognize if the word belongs to the set of verbs, adjectives or nouns. Later, the set of analyzed words will serve to identify patterns that will match with some type of registered threat.

Before comparing the tokens with the designed dictionary, they are processed in a sub-module for exchange of characters, which purpose is to consider those written in words misspelled, idioms or abbreviations, in order to have the word in a neutral state by applying a procedure that allows identifying the principal core of the word. To obtain each token in a neutral state certain characters are replace by others, which are previously identified with base in the specifications of *Table 1* that are used in place of characters in the words that are analyzed, where it is presented the letters or syllables according to their cataloguing and character replacement.ion.

Table 1. Words replacement

Replacement	Letters or syllables
0	b,v
1	ce,ci,si,se,zi,ze
2	d,de
3	g,j
4	i,y,ll
5	ca,co,cu,ka,ko,ku
6	qui,qi,ki,que,qe,ke,q,k
7	t,te
8	u,w
9	x,cs,xh,cc,sh,zh
*****	sa,so,su,za,zo,zu
^	s,es
+	pe,p
-	R
It is omitted	First letter 'h'

It is necessary to mention that the way of assigning the replacement characters does not have preferential order, nevertheless, on having replaced some characters or syllables in the application they do have preference for exchange, since in certain cases would alter the token in a neutral state and the difficulty of cataloguing it as a key word.

2.1.2 Knowledge programming

After being labeled or tokenized the selected words of the sentence are evaluated in the module of knowledge programming through predicates or rules of prolog type; in order to determine whether they match aggression patterns or threats that were emitted by the user responsible of the analyzed message.

The components of the knowledge programming and the lexical analyzer provide a rapid and accurate way to analyze messages, and give the possibility to evaluate information as a human being does.

2.2 ARSEC-AMS architecture

The proposed model is based on the architecture ARSEC-AMS [3] (*Figure 1*), which takes into account the use of four modules: reactive, deliberative-cognitive, security and control of blackboard, in such a way that the signs that are received in the agent system via sensors are filtered by an interpreter which is responsible for acting in a coordinated way and track the set of actions required to achieve the correspondent objectives, applying this in the model to detect the danger of exchanged messages through a system of Instant Messaging (IM). A wide reference of the previously architecture mentioned is described in [3].

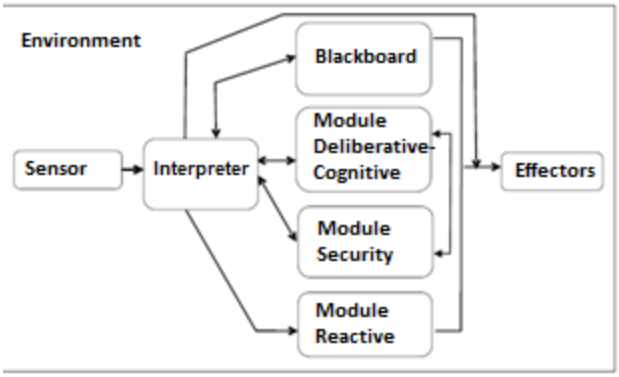

Figure 1. ARSEC-AMS architecture

2.3 Agent model

The agent model proposed in the architecture ARSEC-AMS defines a hierarchy of agents, which is described below:

- *Coordinator agent*: is the software agent responsible of the flow of transactions that allow to apply security levels in the system and in the work of local and network agents, in addition is in charge of analyzing the content of the messages to determine if they are

evidences, and if necessary alert users that exceed a certain number of incidences of evidences.

- *Local Agent:* is the software agent that reviews and tokenize the messages of the users locally.
- *Network Agent:* is the agent responsible of the messages sent by the user and get them already encrypted to the system.

To show the control that the agents will have in the system it was included the sequence diagram for the content analysis in order to model the functioning of the application (*diagram 1*).

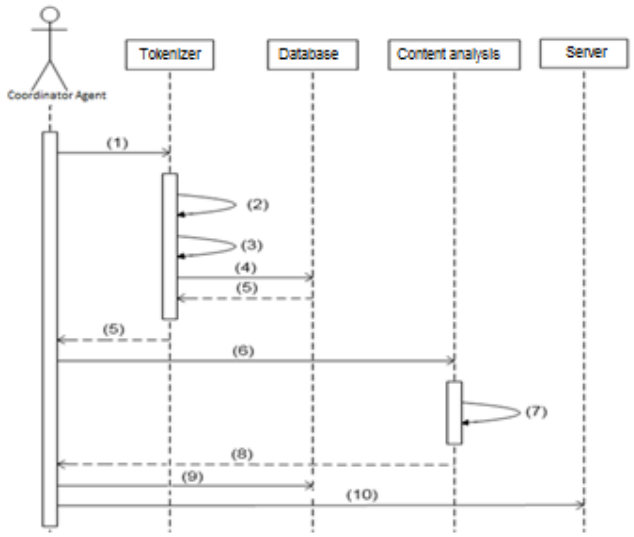

Diagram 1. Content analysis process

Next are detailed the steps that realized the coordinating agent in *diagram 1*:

(1). Passes the original message

(2). Divides the message into lexical components (tokens)

(3). Codifies lexical components (exchange of characters)

(4). Searches for neutral words in the dictionary

(5). Returns keywords

(6). Sends keywords

(7). Finds patterns that match threats of cyberbullying

(8). Returns the dangerousness of keywords

(9). Stores user information and the original message

(10). Displays an alert message

3 Experimental tests

To determine the proper functioning of the application were taken sentences with certain degree of dangerousness called evidences and common sentences that can be misinterpreted by a system as described herein. Following are some common sentences and evidences:

Common sentences

- "Voy a pegar lo que recortamos en el cuaderno."
- "Hiciste la tarea sobre la matanza de Tóxcatl."
- "El cuento del zorro es muy interesante."

Evidence sentences

- "Te voy a pegar estúpido."
- "Vamos a matarte."
- "Eres una zorra."

.

In previous examples, underlined words, which can have different meanings, depending on the context of the sentence, so that sometimes are part of a sentence may be considered threatening and sometimes can be part of phrases that are considered normal.

It is noteworthy that the evidences have certain degree of dangerousness; therefore they are categorized into low and high levels. Evidences of high level are phrases, which meaning is a threat to another user, while the low level evidences are aggressions. According to the number and level of evidences is how the coordinating agent can determine the state in which the user is, cataloguing it in three levels, denoting it as 'semaphore of users' and the levels are red, yellow and green. The red level corresponds to a user who must be observed; the yellow one corresponds to users who not necessarily have reach a level of threat, but that his sentences have already certain trend to do it; the green level is for users who do not represent any danger.

As an example, next is the procedure applied to a previously misspelled phrase selected to determine whether it is a phrase that can be used as evidence:

"TE BOOOOI A PEGAR, HIMBÉCIL"

The following is an example of how the sentence is processed above:

The phrase is converted into lowercase letters:

"te booooi a pegar himbécil"

Vowels with accents are replaced by vowels without accents:

"te booooi a pegar himbecil"

Omit repetitions:

"te boi a pegar himbecil"

Replacement according to Table 1, character interchange:

"7 0o4 a +3a- 4m0e1l"

Note: It can be observed that the number of characters has decreased omitting the spaces in the original sentence. The number of characters is 22 in the original sentence, while the replacement sentence has 15. Obtained the words in neutral form, they are compared with the words contained in the dictionary, resulting in two verbs "0o4" (voy), "+3a -" (pegar), plus an adjective "4m0e1l" (imbécil), naming them key words.

The keywords are evaluated in the predicates type Prolog, obtaining as result that the sentence is an evidence of high level.

The coordinator agent records the evidence and reviews the history of the user to determine in what level of the semaphore is positioned. Following *Table 2* shows different cases that may occur depending on the user status and considering that he did an incidence of high level.

Table 2. States of user (Semaphore)

User state	Previous evidences		New State
	High	Low	
Green	0	1	Green
Yellow	2	6	Red
Red	5	10	Red

When cataloging through the semaphore allows early detection of cases of users that merit attention from school authorities and are given appropriate treatment.

4 Conclusions

With the proposed model it is intended to help detect early cases of cyberbullying avoiding cases of threats and aggressions that may be suffering the child or the young person in school. The fact that there is a children interest to use tools based on information technologies and communications, makes them feel part of the technological wave which nobody wants to be left behind. These tools give course to communication channels that are not exempt from threats or aggressions by users to people with low self-esteem and high levels of vulnerability. By the above, it is important that schools classrooms where computers are used, are applied to detect forms of cyberbullying problems through systems like the one proposed in our model, where an agent system can analyze in real time messages that are exchanged through chats.

Leveraging Layered Network Analysis for Intuitive Decision-Making

Peter M. LaMonica and Craig S. Anken
Air Force Research Laboratory, AFRL/RIEA
525 Brooks Road, Rome, NY 13441-4505

Abstract - *Current analysis and decision-making relies too heavily on a single source of data. This can be attributed to a myriad of reasons such as failure to standardize and normalize diverse data, inability to define a common ontological mapping between datasets, and even an unawareness that related additional data exists. However, in reality many datasets can be interconnected through nodes and/or edges and together can collectively provide much greater situation awareness to the user. Fusing multiple diverse datasets together for collective exploitation is referred to as layered network analysis and provides a more intuitive approach to analysis and decision-making. The purpose of this article is to conceptually define how layered network analysis can advocate and provide an intuitive decision-making environment in knowledge discovery and decision support systems. Further, this approach can be applied to numerous domains that address the data-to-decision problem.*

Keywords: Layered network analysis, intuition, decision-making, situation awareness, knowledge discovery, and data to decisions.

1 Introduction

Decision makers in various domains are constantly hampered by information overload from numerous diverse sources. This places tremendous strain and burden on the decision maker to manually derive mental correlations to determine how these diverse data sources are connected and related. Even more troublesome is deriving patterns over space and time across these different data types. While this is an extremely difficult manual process, the vast majority of this data does not exist independently, as much of it is related and connected across networks of data. This was the reasoning behind developing the Layered Network Analysis model [1] for combining heterogeneous relational data types to improve situation awareness. Layered Network Analysis provides a foundation for users to think intuitively by quickly allowing them to understand how data is connected and related. Allowing users to better understand the data will provide greater situation awareness [2] and intuitive decision-making capabilities. This research will provide detail on Intuitive Decision-Making by Klein and the Layered Network Analysis model, and discuss how these two approaches can work together to improve decision-making.

2 Intuitive Decision-Making

Klein [3, 4, 5, 6] claims that the vast majority of decisions made are driven by personal intuition. This is a great contrast and departure from the traditional decision-making models that leverage analytical and statistical methods. Klein proves that intuition is used more accurately than analysis of a situation – in order to make a decision.

Throughout his research on intuitive decision-making, Klein developed a model that demonstrates the process that users go through. Klein's Recognition-Primed Decision Model can be seen in Figure 1 [3]. This process begins when a user experiences a situation that demonstrates cues. The user determines if this situation is typical based on what has been observed. If this is not a typical situation, the user looks for features to diagnose the situation to determine any relevancies to past situations. If this is a typical situation, the user seeks to recognize four by-products: cues, expectancies, plausible goals, and typical actions.

If this is a situation that is typical yet the expectancies are anomalistic, then the user needs more data to further clarify and diagnose the situation. Otherwise, the user evaluates the action that has taken place and also conducts mental simulation where the user relies on mental models to determine potential outcomes. If these models do not seem to work (possibly due to an underlying difference in the situation – e.g. different terrain), the user may slightly modify existing models to project future outcomes. Otherwise, the user determines how the situation can progress and determines a course of action that can be implemented successfully.

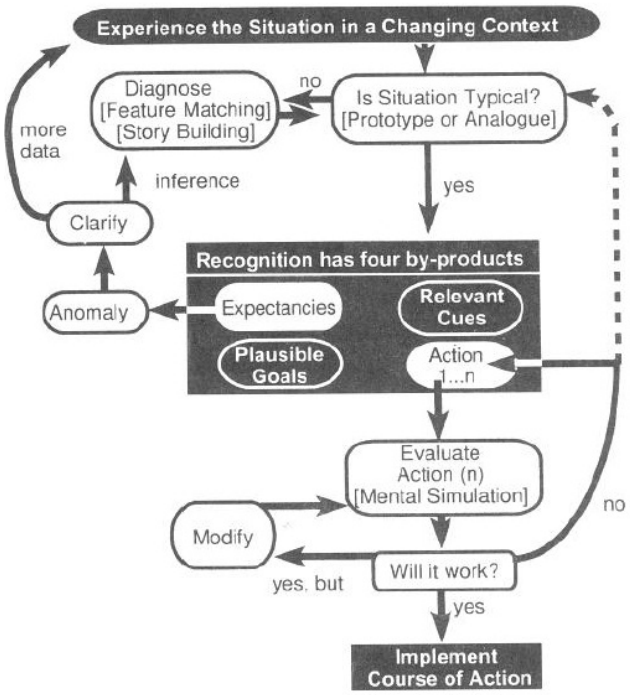

Figure 1. Recognition Primed Decision model [3]

The Recognition-Primed Decision Model is highly relevant in multiple user domains ranging from firefighters to United States Naval commanders. Klein [3] conducted a series of studies across various domains to test the Recognition-Primed Decision Model. One study explored United States Navy AEGIS command and control (C2) commanders. AEGIS is an integrated United States Naval weapons system that uses radar and software systems to guide and track weapons. This work was done in coordination with the Office of Naval Research and Klein wanted to learn how these officers had responded and made decisions in conflicts. In this case, the time pressure was severe and the skill level of the officers was generally high. However, the situations changed rapidly and there were very few courses of action available. The officers had clear guidelines with official rules of engagement. Over 78 decision points that Klein studied in this case, the Naval officers used Recognition-Primed Decision-making 95% of the time. These officers claimed that in 95% of the cases, they had not compared any options and the course of action selected was not a novel one. The commanders justified their selection to use intuition decision-making because of typically suffering from various issues such as relevance to a past event/scenario (known patterns), a lack of time, and a lack of specific scenario data (uncertain, unknown, or incomplete data).

In another study, Klein looked at how teams use the Recognition-Primed Decision Model. Klein worked with command and control teams at the Army brigade level at Fort Hood. The teams were working through training exercises on decision-making. Klein [3] initially thought that a team structure might reduce the rate of recognition-primed decision-making because when a team makes decisions, the team typically comes to consensus, which involves considering alternate courses of action. However after analyzing the complete training session tapes (five hours in duration) and the 27 decision points, only one of those points showed evidence of comparing options (demonstrated a 96% use of recognition-primed decision-making). This was startling to Klein since typically Army planners are taught to develop a set of courses of action that typically includes a minimum of three options.

In a different domain, Klein [3] studied how urban fireground commanders make their decisions. Fireground commanders rely on visual and audio cues to determine how to approach a fire. For example, if a fire starts on the lower floors of an urban building and there are no visual signs of smoke from the outside of a building, then this means a fire is just starting. However, if smoke is pouring from the eaves of the roof, then the fire has risen from the lower floors to the roof of the building. This puts the fireground commander into search and rescue mode to get all occupants out of the building as soon as possible. This demonstrates how fireground commanders are required to make quick, accurate decisions based on cues of what they recognize in real-time. Figure 2 depicts other studies that Klein conducted with many of them demonstrating high levels of recognition-primed decision-making.

Study	Number of Decision Points	Decision Points Handled Using RPD Strategy (%)
1. Urban fireground commanders	156	80
2. Expert fireground commanders	48	58
Novice fireground commanders	33	46
3. Tank platoon leaders	110	42
4. Wildfire incident commanders	110	51
Functional decisions	79	56
Organizational decisions	31	39
5. Design engineers	51	60
6. Battle command teams	27	96
7. AEGIS commanders	78	95

Figure 2. Frequency of Recognition Primed Decision-Making Across Domains [3]

2.1 An Intuition Example

The following scenario will further reinforce the application of the Recognition Primed Decision Model and took place during the Persian Gulf War in 1992. This is used by Klein [3] to demonstrate and compare intuition to analysis. The HMS Gloucester is a British destroyer and is on watch

during an airraid of Kuwait. United States Navy A-6 aircraft that had specific targets to take out in Kuwait City was conducting the airraid. During this mission, the Gloucester was monitoring the airspace for retaliation by Iraq when it noticed a blip on the radar screen.

A US Navy A-6 aircraft flew at approximately 600-650 knots when returning from a bomb run and typically flew at 2,000 to 3,000 feet. When the pilots would make a bomb run, their radars were typically off as well as their 'Identify Friendly or Foe' mechanism, as these were two ways to be easily detected by the enemy. In this particular mission, the allied forces were conducting an airraid near a known Iraqi silkworm missile site. The silkworm missile flew at approximately 600-650 knots, was about the same size as the American A-6 aircraft, but it flew at roughly 1,000 feet of altitude. The radar used on the British ship could only work over water and not on land due to high amounts of ground clutter and noise. Further, the British radar could only work vertically first, then once it detects a target it takes an additional 30 seconds to track it horizontally to determine its altitude.

In this case, the British officer immediately claimed that the blip on the screen was a silkworm missile aimed for the Gloucester and not a friendly American aircraft. The British officer ordered for a missile to be fired and the blip was taken out. Instantaneously, the commander ordered for reasoning behind the officer's determination. The officer did not have time to wait for the horizontal radar to sweep and determine altitude. How did this officer know that this was a missile and not an aircraft? Initially, the officer could not explain how he determined that it was a missile and not a friendly aircraft.

The British officer later discussed the scenario with Klein and told Klein that he knew the Iraqis were getting desperate and this attack was the Iraqi's last chance to use their missiles in an attempt to disrupt allied forces. With all these factors considered, he immediately knew that this was a silkworm missile aimed at the Gloucester. The officer said he knew he only had seconds left to live if he had not ordered to fire at the silkworm missile. The officer turned out to be correct – the blip on his radar was in fact an Iraqi silkworm missile and this missile would have done significant damage if not catastrophic to the Gloucester if the officer had not acted on his intuition.

Klein noted several key factors about this scenario and why intuitive decision-making is more agile and accurate. In the end, it was the officer's mental model that saved his life, as well as his fellow troops. It was the combination of radar, location, and knowledge of the situation that collectively determined the action of the officer. Klein [2] argues that if the officer had relied on the analysis of metrics and the hard sensor data alone, then his decision probably would not have been the same.

3 Layered Network Analysis

Layered Network Analysis is a novel term that was defined by LaMonica and Waskiewicz [1] and refers to the fusion of previously disconnected data in a common operating picture allowing the user to explore and exploit the interconnected data in a unified state. Layered Network Analysis can be used to discover patterns within and across layers, discover previously unknown nodes and edges, and allow users to focus on multiple data types within a specific time and space.

The intent is to understand the structure and dynamics of network data as this data is of vital importance to decision makers. Current analysis of network data occurs primarily within one or two particular domains and relies on the user to infer and derive links between data sources. However, to fully understand the network environment, decision makers must be able to investigate interconnected relationships of many diverse network types simultaneously as they evolve spatially and temporally. No single data network exists in a vacuum as networks are interconnected through space and time. It is imperative to understand that no single network exists independently of others. Each layer represents a diverse network data type and these layers can be connected through nodal and edge similarities as is depicted in Figure 3 below.

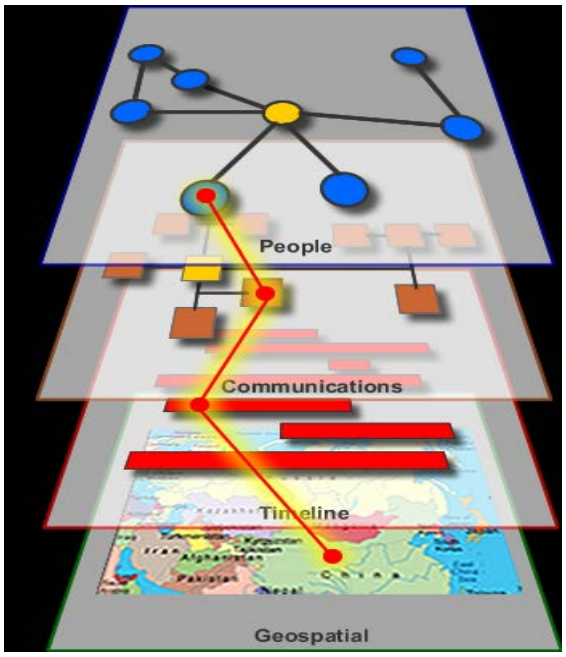

Figure 3. Layered network analysis

Layered Network Analysis is meant to be an approach to this data problem that users can interrogate and shape for their mission. Layered Network Analysis can assemble previously disconnected, multi-modal networks (e.g. social networks, financial transactions, computer networks) in a common battlespace picture providing the user with timely situation awareness, understanding and anticipation of threats, and support for effective decision-making in diverse environments. Combining numerous networks requires various data transformation techniques such as data association, alignment, and entity resolution.

The ultimate goal of this research is to allow a decision maker to have all network data in a layered network application where they can correlate and analyze activity and time occurrence in related networks to understand and potentially predict when a major event of interest is about to happen and where to expect it. Thus, Layered Network Analysis will allow users to apply network analysis methods (e.g. centrality measures, group detection algorithms) via visualization technology to the collective network.

The concept behind layered network analysis is derived from social network analysis and link analysis techniques. The collective network is layered because it would consist of many interconnected networks that were previously disparate. It is also multi-modal because the network will incorporate many different entity types (e.g. people, organizations, locations, objects). Having this data in a collective network will allow users to apply techniques derived from traditional SNA and link analysis measures. In addition, this may introduce new areas of research for metrics, entity resolution and pattern learning as the user will ultimately have to analyze data of multiple types.

There are many reasons behind a layered network analysis approach. First, an underlying unified network model is necessary that will allow multimodal and multi-dimensional layered network analysis to be possible [7]. This framework would serve as the connecting language and translation mechanism between the heterogeneous data networks. This would allow any network in any domain to be mapped and connected. Ultimately, users would analyze and visualize these collective networks. Further, the user would be able to select which layers he/she would want to view and focus the collective network based on space and time. This will drastically reduce complexity and any potential scalability issues with this approach. It will also deliver the appropriate data to the user based on his/her current situation.

Once the data is in a common network, new network analysis metrics can measure the importance of entities, groups, and their relationships across networks. Previously, traditional social network analysis metrics are designed to analyze only social relations [8]. Also, prior SNA metrics do not analyze attribute data, rather they measure connectivity (how well each node is connected to other nodes in the network). Thus, it is unclear how these metrics will be applicable. In addition, new threat patterns will need to be developed per given scenarios that can operate across networks, time, and entity types. The end user has previously done this manually.

At present, the research team is focusing on developing an approach to apply social network analysis metrics based on specific measures (e.g. eigenvector centrality, group detection) and visualization technology to the collective network. At this initial stage in the research, the team has identified two risks with this approach – scalability and visualization. However, the researchers feel that these two risks can be mitigated by providing only the data that user needs for his/her scenario. This can be accomplished either through selecting which data sources the user needs or through group detection algorithms to determine subgraphs related to the user's scenario.

3.1 Significance

Developing a layered network approach to network analysis will eliminate the current stovepipes and manual association that exist today. This approach would create an environment where users can visualize and analyze how numerous networks (entities and their relationships) are interconnected. This will allow the user to have all network data in a layered network application where they can correlate and analyze activity and time occurrence in related networks to better understand the battlespace. From this information, the user would be able to derive the most influential nodes and relationships, discover groups, and learn and predict the behavior of how these different network types interact and influence each other.

From the way that nodes and edges can connect these diverse network datasets (subgraphs) this can immediately allow users to learn and understand relationships in and across databases that they never knew existed. This can also help to infer new relationships, help uncover unknowns, and identify new groups and patterns across networks. Entities and relationships that were lost or unknown in one database could be discovered in another. Also, information and new patterns can be conveyed between data networks. Collectively this will enable users to act and predict by aiding in threat detection and prediction, provide informed course of action selection, and have a solid understanding to make a decision and act.

4 Application

Data-to-Decisions is one of seven science and technology (S&T) priorities of the Secretary of Defense [9]. The goal of this initiative is to shorten the cycle time from data

gathering to decision-making to address the challenge of insuring that the right, relevant and actionable information is provided to achieve the desired effect. With the increasing availability and relevance of open source information, the need to discover and identify threat signatures in complex, incomplete, imprecise and potentially contradictory large datasets has become a critical issue.

Recently, Lieutenant General David Deptula (now retired and the former Air Force Director of Intelligence) recognized that the armed services are 'swimming in sensors and drowning in data.' [10] The addition of new sensing capabilities are emerging and are delivering significantly much more data that can currently be processed. Because the current intelligence collection and analysis process is overwhelmed by the volume of information it must process to generate, analyze, and understand networks of interest, there is a disconnect between the output requirements and the inputs available for analysis [9]. As a result, the process results in high information loss, incomplete analysis and poor situation awareness and understanding.

Decision makers have a clear recognition that the detection and understanding of enemy networks is a critical factor in the building of situational awareness. However, developing the ability to be fully aware of enemy social networks is a challenging task. The results of the research outlined in this paper are aimed at assisting decision makers gather and fuse the most complete knowledge and understanding of geospatial, temporal and social events. This will enable the decision maker to assemble previously disconnected information about networks in a common battlespace picture, providing timely situation awareness, understanding and anticipation of threats, and support for effective decision-making in diverse environments. It will also help remove the burden of making mental correlations of observations and conclusions the user has drawn from one domain as additional information is made available from other domains.

Layered Network Analysis is an intuitive way to think – take for example the scenario about the W2-Glouscter ship. The British officer put together multiple data to come to his conclusion, decision, and action all in seconds.

The following meteorological example clearly demonstrates the power and applicability of Layered Network Analysis. Assume a severe thunderstorm that is demonstrating tornadic attributes. A meteorologist does not solely rely on one particular data type to analyze this potentially catastrophic event. For example, Doppler radar will tell the meteorologist where the storm is, precipitation, and where the storm is moving over time. However, the meteorologist needs more information to make an accurate forecast. Therefore the meteorologist will focus on various inputs, in addition to Doppler radar such as wind speed/direction, barometric pressure, temperature, cloud cover, etc. A key point is that each data type is different from every other data type; however when focused on a specific space and time, the data is all related and connected. The meteorologist depends on this data to make an accurate forecast and prediction of where the thunderstorm will move, how fast, and what severity it may have. This example also demonstrates how a user could focus on what is relevant to his/her current situation. The meteorologist is immediately focused on this localized thunderstorm and will likely analyze localized weather data, as opposed to developing a longer forecast (e.g. five day forecast) where the meteorologist will analyze more global trends.

5 Conclusion

Layered Network Analysis tools can provide a core piece to the Processing, Exploitation and Dissemination (PED) process helping automate the tedious process associated with the detection, recognition and understanding of enemy entity-relation networks. The Layered Network Analysis approach has shown promise in helping users quickly go from data-to-decisions by finding patterns in very large databases and facilitating the connection of bits of information into patterns that can be evaluated and analyzed. The technical area encompasses how people combine, interpret, store, and retain information, providing a quantitative evaluation of events that enhances a decision maker's ability to judge, appraise, and determine the relevance of emerging situations. The technology area is focused on providing the Air Force and its component units with the capabilities needed to achieve a higher level of enemy network comprehension [11]. Identifying relationships in large, dynamic, multi-modal layered graphs requires the development and integration of novel technologies. Layered Network Analysis will allow users to identify and detect emerging threats from large collections of data spatially and temporally. The result will be a dramatic improvement in situational awareness across multiple domains and significantly advance the current state-of-the-art network analysis capabilities by having an accurate and complete multi-dimensional understanding of the layered, dynamic network environment. Lastly, the Layered Network Analysis approach will provide an intuitive, logical process to decision-making that is agile and accurate.

ABSTRACT

A Communication network is used to facilitate communication among different parties. Though any network topology can be designed to implement a communication network but for a given problem we can choose a network topology which maximizes the reliability of communication network. This problem has many applications in telecommunications, electricity distribution, gas pipelines and computer communication industry. Since this problem belongs to an optimization problem, many authors have applied evolutionary techniques however there is still a need to apply optimization algorithm effectively so that this problem can be solved in minimum time. This paper makes such an attempt to solve this problem by using a memetic Algorithm.

Keyword: Network, Reliability, Cost and Multi-Objective Optimization

I. INTRODUCTION

Topological optimization of networks is an important problem in many fields such as telecommunications, electricity distribution, gas pipelines and computer communication. This refers to design an optimal network topology for one or more objective functions (network delay, bandwidth utilization, reliability, cost etc.). Since optimization problems are NP hard problems, many nature inspired algorithms have been applied for solving this problem. GA and Tabu search are the basis of many research proposal [3,4,5,13]

There have been several notable attempts in the literature to solve this optimization problem. Jan et al. [1] applied branch and bound technique to minimize cost of links of a network with a minimum network reliability constraint, this is computationally tractable for fully connected networks up to 12 nodes .Using a greedy heuristic, Agrawal et al.[2] maximized the reliability of a network . Jos´e Manue et al[3] optimize the budget of network topology. Bassam Al-Bassam et al.[4] has done the reliability optimization . Anup Kumar [5] optimized the diameter of network topology. Ventetsanopoulos and Singh [6] used a combination of heuristic search and branch bound to find most reliable network. Atiqullah and Rao [7] and Pierre et al. [8] used simulated annealing to find optimal designs for networks. Koh and Lee [9] used tabu search to find telecommunication network design that require some nodes (special offices) having more than one link while other others (regular offices) required only one link, while also using this link constraint as a surrogate for network reliability.

Although many methods are available yet there is a need to apply optimization algorithm effectively so that this problem can be solved in minimum time. This paper makes such an attempt to solve this problem by using a combination of local search and a variant of genetic algorithm [14].

The primary goal of this paper is to design a topology which has maximum reliability and satisfies the given cost constraints. The paper is organized into five sections. Section 2 presents some background on Genetic Algorithm and its variant .Section 3 describes step by step application of memetic algorithm For solving Problem. In Section 4, we discuss experimental results of the proposed algorithm. Finally, in Section 5 concludes the paper.

II. BRIEF HISTORY OF GENETIC ALGORITHM

Genetic algorithms are search algorithms which work according to the principle of natural selection on a population and behave according to the principle of 'Survival of the fittest'. More precisely genetic algorithm is a family of computational models inspired by evolution. At each generation, a new set of solutions are created by the process .Selection of the individual is done according to their fitness value in the solution space .This process leads to the evolution of populations of individuals that are better suited to their environment than the individuals that they were created from, just as in natural adaptation.

These algorithms encode a potential solution to a specific problem on a sample chromosome-like data structure and apply recombination operators to these

structures so as to preserve critical information related to the problem. Genetic algorithms are often viewed as function optimizers although the range of problems to which genetic algorithms have been applied is quite broad.

Genetic algorithms search for optimum value by using three operators.

A. Selection Operator

It is a genetic operator that chooses a chromosome from the current generation's population for inclusion in the next generation's population. Before making it into the next generation's population, selected chromosomes may undergo crossover or mutual depending upon the probability of crossover and mutation) in which case the offspring chromosome(s) are actually the ones that make it into the next generation's population.

This is achieved in following steps

a) Identify good solutions in population.
b) Make multiple copies of good solutions.
c) Eliminate bad solutions from the population so that multiple copies of good solutions can be placed in the population.

Some common methods [10, 11] for selection are:

a) Tournament Selection
b) Proportionate Selection
c) Ranking Selection

B. Crossover Operator

The chromosomes are exchanged between these two parents and offspring are produced. In general crossover operator recombines two chromosomes so it is also known as recombination. Crossover is intelligent search operator that exploits the information acquired by the parent chromosomes to generate new offspring. If both the parent has same genetic structure then offspring are just copies of the parent irrespective of cutting point but if parent have different genetic structure then offspring are different then parent. Thus, crossover is sampling process, which samples new points in search space. Generally crossover probability is very high like 1.00, 0.95, 0.90 etc.

Parents	01010101 11110000
Offspring	01010000 11110101

A number of variations on crossover operations are proposed and the simplest form is a single-point crossover. The parents are randomly selected based on the above mentioned selection scheme. A crossover point is randomly selected and the portions of the two chromosomes beyond this point are exchanged to form the offspring's. Some common methods for crossover are

a) Single point crossover
b) Uniform crossover[12]

C. Mutation Operator

The need for mutation is to maintain a good diversity of 1s and 0s in the population. After reproduction, crossover, and mutation are applied to the whole population, one generation of a GA is completed. The need for mutation [12] is to keep diversity in the population

III. PROPOSED APPROACH

Earlier in previous work, K.K.Mishra et al [14], have proposed a novel genetic algorithm by changing the crossover operator of genetic algorithms. The details of this algorithm had been taken from paper [14]. In genetic algorithm, we do not concentrate on the fitness value of parents involved in crossover. Also we randomly choose a cross site and as such we cannot predict the nature of generated children by traditional genetic algorithm. In our method we will concentrate on fitness of both the parents involved and will generate good children .We will not choose the cross site randomly .We will decide that site using the fitness of parents. Our crossover operator is based on the biological nature of crossover .In nature when parents (male, female) perform crossover children share the properties of parents. We will use the same basic for generating children. Let we are performing crossover operation between two parents P1 and P2 having the fitness value f1 and f2 and each of length L (chromosome length). We assume that fitness of male is always greater than female and cut point is to be determined by Male. We will calculate the crossover point by calculating ((f1/(f1+f2))*L) and ((f2/(f1+f2))*L) (If f1 is the fitness of male chromosome) and rounding off this to say variable C1 and C2. On the basis of this value C1, we will cut parents chromosomes at these sites and generate two children. The value C1 will always be less than L. Similarly we repeat the same process for C2 and generate two mutated children. We then perform binary tournament selection and select best mutant. Now we will show that application of this crossover and mutation will not affect randomness of genetic algorithm. As we are unaware about the nature of fitness value associated with each population, so fitness values will appear as random values associated with the parents and this operator will generate random values of children. So this operator will preserve the randomness of genetic algorithm][14].

III.I. APPLICATION OF MEMETIC ALGORITHM FOR SOLVING PROBLEM

In order to optimize the reliability of the network topology, we have used memetic algorithm. Since random initialization may cause infeasible solution. At initial stage prime's algorithm is used to generate initial population for the problem which perform a local search for a set of good solution then this variant of G.A has been applied to generate most reliable topology.

III.I.I. STATEMENT OF THE PROBLEM

As discussed in [13] the statement of problem can be explained as follows. A probabilistic graph G = (N, L, p) can be used to represent communication network. Where N and L are the set of nodes and links that corresponds to the computer sites and communication connections, respectively. The networks are assumed to have bi-directional links and, therefore, are modeled by graphs with undirected links. It is further assumed that the graph has no parallel (i.e. redundant) edges. Redundant links can be added to improve reliability, and the approach described here could be modified straightforwardly to include redundancy. The optimization problem is

$$\text{Minimum } Z = \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} c_{ij}x_{ij}$$

Maximize R(x)

Where $x_{ij} \in \{0, 1\}$ is decision variable, c_{ij} is the cost of (i, j) link, R(x) is the network reliability.

The other problem assumptions are:

1. The location of each network node is given.
2. Nodes are perfectly reliable.
3. Each c_{ij} and p are fixed and known.
4. Links are either operational or failed.
5. The failures of links are independent.
6. No repair is considered.

III.I.II. NETWORK DESIGN USING MEMETIC ALGORITHM

Input: A Set of network topology is generated by primes algorithm and this work as initial population.

Output: network topology that achieves maximum reliability for the network.

Begin

STEP 1: Create an initial population by applying prime's algorithm at initial stage $N(P_0)$ (set of chromosomes are generated by assigning binary strings to edges(if present assign 1 else 0)) and then fitness (reliability) of each chromosome is calculated

STEP 2: Generate off spring population Q_t by using binary tournament selection recombination and mutation operator.

STEP 3: Create offspring population Q_{t+1} from P_{t+1} by using the tournament selection, crossover and mutation operators.

STEP 3.1: Tournament Selection: For each population generated randomly, randomly pick two members from Q_t and a tournament is done between two based on fitness function f(x).Winners are further propagated for crossover.

STEP 3.2: Crossover: Two strings are crossed based on the crossover point (jcross).

In proposed approach, crossover point=jcross=(f1(x)/f1(x)+f2(x))*Length (chromosome).

STEP3.3: Mutation: point=jcross=(f2(x)/f1(x)+f2(x))*Length(chromoso me). Perform tournament selection and pick best one.

These processes ultimately result in the next generation population of chromosomes that is different from the initial generation. Generally the average fitness will have increased by this procedure for the population.

STEP 4: Repeat steps 3 until a network with required reliability has been reached.

IV. EXPERIMENTAL RESULTS:

We have compared the results of proposed approach with the results produced by ga[13].It can be seen that networks generated by proposed approach has better reliability as compared to other approach. For calculating reliability two connectivity repair algorithm has been used.

initial parameters of the graph is shown below the no. of nodes:5

V. CONCLUSIONS

Experiments prove that the results generated by the proposed approach are good. Generation of unreliable network has been avoided by the use of local search. This local search produces good population at initial population. When this population is supplied to the proposed algorithm it has produced better results. Comparisons are shown in graph 1 to 4.

Abstract - *We present an ensemble of artificial neural networks to predict the severity of chronic cystic fibrosis within an individual by comparing against fifty patients ranked ordinally by increasing disease severity. The neural networks were programmed using Matlab and trained to minimize the sum-of-squared-error between the networks' rankings and the fifty actual rankings. The training data was subjectively but professionally ranked by one of us (DJC). Variables were chosen from the data collected in the UCSD cystic fibrosis clinic to use as input parameters for the networks. The resulting data matrix was then used by an ensemble of neural networks in training, validation and testing to ultimately produce a prediction of the chronic severity of cystic fibrosis within a patient. Between any two patients, the networks were able to correctly identify the more severe case 86% of the time. The goal was to capture Dr. Conrad's severity index, implied by the ranked set provided, to use on patients outside of that data set in assessing their chronic disease severity. The resulting neural networks have the potential to provide a useful diagnostic tool for physicians treating CF patients.*

Keywords: Machine learning, neural networks, cystic fibrosis

1 Introduction

We set out to develop an ensemble of artificial neural networks (ANNs) to predict chronic disease severity within cystic fibrosis patients as an experienced pulmonary physician would. ANNs are a form of machine learning algorithm based on the functionality and structure of a biological neural network, as observed in the brain. Used to observe complex trends and patterns in a set of data, they are capable of applying sets of non-linear equations to inputs to achieve a desired outcome. These equations can be reproduced to apply to further data, which gives rise to the predictive capabilities that this project utilizes.

2 Materials and Methods

The data were collected from patients cared for in the UCSD Adult Cystic Fibrosis Clinic (ACFC). Fifty patients were selected and ordinally ranked by Dr. Douglas J. Conrad, director at the ACFC, in order of increasing disease severity ranking 1 to 50 as a training cache for the ANNs. The 50 patients and their corresponding 14 variables were compiled as a matrix, along with their actual rankings, and imported to Matlab. Such variables included results from lung function tests (FEV1, FVC, FEV1/FVC), physical descriptions (age, height, weight, gender, BMI) and longitudinal regression values based on FEV1 vs. time graphs (m, b, r^2, se_m, se_b). For each patient, only the best FEV1 value from the previous year was considered.

2.1 Programming the ANN

To obtain the artificial neural networks, a progression of training, validating and testing steps were taken to develop the ability to predict with an acceptable amount of error. In training, each network is supplied with a set of data as inputs, and through a series of equations, returns an answer. Once the tested outputs of the network accurately reflect the answers provided in the training data, the ANNs can then be used to classify future data.

For an ANN to follow the trends in cystic fibrosis data, the variables were run through a series of equations, deemed "layers." Four matrices of random numbers were generated, two representing weights and two being biases. Let *w1* and *w2* denote the weight matrices, *b1* and *b2* the biases, and *in* represent the vector of one patient's inputs. The layout of a single-hidden layer ANN is as follows:

$$hidden\ layer = squash((in \times w1) - b1) \quad (1)$$

$$CF\ severity = (hidden\ layer) \times w2 - b2 \quad (2)$$

$$squash(x) = \frac{1}{1+e^{-x}} \quad (3)$$

Once the severity has been run through the above layers for each patient, the ANN returns its predicted severity, and the error is calculated between its prediction and the actual answer. The weights and biases are adjusted using Matlab's fminsearch optimization function, and after each adjustment, the squared error was calculated between the ANN outputs and the actual provided patient severity. Fminsearch is set to repeat these adjustments until a minimum in the total calculated error is found. However, if the entire set of 50 patients were to be used in training a network, there would be no unknowns upon which to test its accuracy. For this reason, only thirty of the fifty patients, or 3/5 of the original data set, were randomly selected and used to train each ANN.

The remaining 20 patients are randomized and split evenly into validation and testing groups. In validation, the purpose is to halt the fminsearch function once a network begins to over-train. Between the fminsearch iterations of the training set, the squared error is calculated and recorded for the ten validation patients. Once the weights and biases have become overly specific for the training set, the validation error will halt the network training (Figure 2). The test set for the network is recorded along with the adjusted parameters.

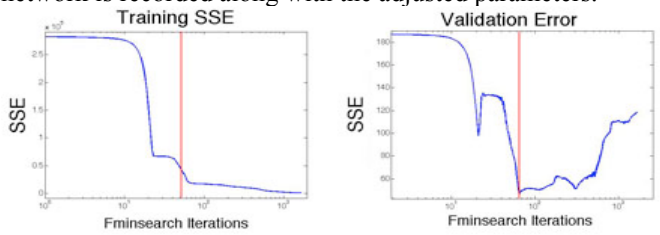

Figure 2. Training and Validation Errors for an ANN

2.2 Testing

A set of twenty networks' parameters and test sets was compiled. Each patient defined to be in a test set was run through the layers using the corresponding network's weights and biases, and averaged with the other participating networks. Thus, each ANN only "voted" on the severity of inputs that were not used in its training or validation processes. The averaged output consists of fifty patients, to be compared against the actual severities provided on the original fifty-patient datasheet.

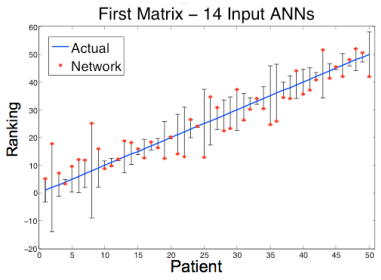

Figure 3. Voting of 14-input ANNs

2.3 Subsequent Inputs

Following the testing of the original networks, the importance of the 14 training variables was determined. Using the computational program R and the randomForest toolbox, FVC, FEV_1, and obstruction ratio were found to hold the strongest predictive power for CF severity. A new ensemble of 50 ANNs were trained and tested using only the FVC, FEV_1, and obstruction ratio as training features (See figure 5A).

A new dataset was then assembled including several new inputs. Multiproduct and powerproduct attempt to place emphasis on age, and were generated from the equations:

$$multiproduct = Age \times FEV1\% \quad (4)$$

$$powerproduct = FEV1\% \times e^{\frac{Age}{10}} \quad (5)$$

Other variables included the Brasfield score and its components. The randomForest toolbox predicted multiproduct, FEV1, FVC, powerproduct, obstruction ratio, and the overall Brasfield score as the most important variables of the new set (Table 1). An ensemble of ANNs were trained from these six variables and tested for their performance. For each of the 3 sets of inputs, the R^2 values were calculated (see Table 2). The ranking accuracy was defined by the ability of the ANNs to identify the more severe case of CF for any two patients.

First Inputs	Node Purity	Second Inputs	Node Purity
FVC	3018.8	Multiproduct	2308.5
FEV1	1960.8	FEV1	1217.0
Obstruction Ratio	1086.6	FVC	960.5
Age	616.3	PowerProduct	832.5
BMI	593.3	Obstruction Ratio	622.3

3 Conclusions

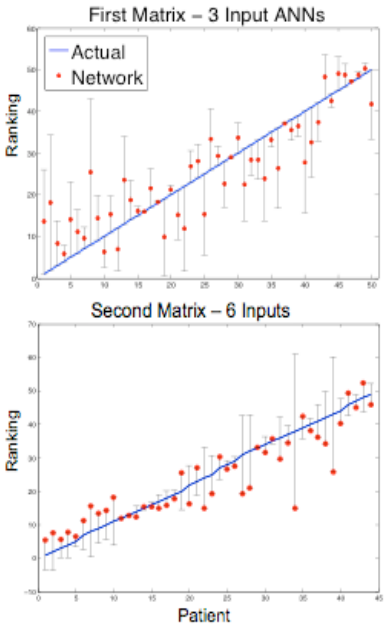

Figure 5. Voting of 3-Input and 6-Input ANNs

Matrix	Inputs	Train Time (min)	R^2	Ranking Accuracy (%)
1	14	360	.8261	86.67
1	3	10	.7845	85.14
2	6	30	.8109	88.48

Table 2. ANN Voting Results

The ensembles of neural networks were all able to train from the provided inputs and accurately vote upon unseen CF patients, as shown in Table 2. The variables FEV1, FVC, and obstruction ratio appeared to hold the greatest ability to train the ANNs from the original list of inputs. Of the second list of inputs, the Brasfield Index, multiproduct, and powerproduct were also found to be useful in ANN training. Future directions include expanding the parameters used, comparing the accuracies of multiple networks using the different inputs, obtaining rankings from other CF experts, and integrating the developed neural networks into a comprehensive GUI interface application being developed by the SDSU Cystic Fibrosis Group.

This work was made possible by NSF grant UBM 0827278 to A.M. Segall and P. Salamon. We thank the SDSU UBM and Cystic Fibrosis Groups for their guidance and many helpful discussions.

A Transient Current Based Transmission line Protection Using Neuro-Wavelet Approach in the Presence of Static Var Compensator

Abstract *- The SVC (Static Var Compensator) based on voltage source converter (VSC) is used for voltage regulation in transmission and distribution system. The SVC can rapidly supply dynamic VARs required during system faults for voltage support. The apparent impedance is influenced by the reactive power injected or absorbed by the SVC, which will result in the under reaching or over reaching of distance relay. This paper presents simulation results of the application of distance relays for the protection of transmission systems employing flexible alternating current transmission controllers such as SVC. The complete digital simulation of the Static Var Compensator within a transmission system is performed in the MATLAB/Simulink environment using the Power System Block set (PSB). This paper presents an efficient method based on wavelet transforms, fault detection, classification and location using ANN technique which is almost independent of fault impedance, fault distance and fault inception angle .*

Keywords: *Distance relay, Flexible alternating current transmission controllers, SVC, power system protection.*

1 Introduction

The performance of a power system is affected by faults on transmission lines, which results in interruption of power flow. The quick detection of faults and accurate estimation of fault location, helps in faster maintenance and restoration of supply resulting in improved economy and reliability of the power supply. Wavelet Transform (WT) is an effective tool in analyzing transient voltage and current signals associated with faults both in frequency and time domain. Chul-Hwan Kim, et al [1] have used Wavelet Transforms to detect the high impedance arcing faults. Joe-Air Jiang, et al [2] has used Haar Wavelet to detect dc component for identifying the faulty phases. The distance protection schemes using WT based phasor estimation are reported in [3]&[4].

Some research has been done on the performance of the distance relay for a transmission system with different FACTS[5-6] devices. The impact of SVC on the performance to the type of the FACTS controller[10,11], the application for which it is used for and its location in the power system. The question of whether the existing transmission line distance protection relays would perform well with the installation of shunt FACTS controllers in the transmission line has been recently investigated and reported in [8]-[9]. The results of these investigations have shown that midpoint shunt FACTS compensation can affect the distance relays with regards to impedance measurement, phase selection and operating times. It has been reported also the observation of the over-reaching and under- reaching phenomena in the presence of a midpoint SVC controllers.

Due to fast developing communication techniques, it is possible to develop communication-aided high-speed digital protection scheme, which suits the EHV transmission. Even better performance can be achieved using two terminal synchronized sampling of signals. The Global Position System (GPS) based algorithms with better performance and accuracy have been proposed. There is always a need to develop innovative methods for transmission line protection. In this paper, Wavelet Multi Resolution Analysis is used for detection, classification and location of faults on transmission lines. Detail D1 coefficients of current signals using Bior1.5 wavelets at both the ends are used to detect, classify and location of fault.

This paper presents an efficient method based on wavelet transforms both fault detection, classificationand location using artificial Neural network, which is almost independent of fault impedance, fault location and fault inception angle of transmission line fault currents with FACTS controllers.

2 Wavelet Analysis

Wavelet Transform (WT) is an efficient means of analyzing transient currents and voltages. Unlike DFT, WT not only analyzes the signal in frequency bands but also provides non-uniform division of frequency domain, i.e. WT uses short window at high frequencies and long window at low frequencies. This helps to analyze the signal in both frequency and time domains effectively. A set of basis functions called Wavelets, are used to decompose the signal in various frequency bands, which are obtained from a mother wavelet by dilation and translation. Hence the amplitude and incidence of each frequency can be found precisely. Wavelet Transform is defined as a sequence of a

function {h(n)}(low pass filter) and {g(n)}(high pass filter). The scaling function φ(t) and wavelet ψ(t) are defined by the following equations φ(t) = √2∑ h (n) φ(2t-n), ψ(t) = √2∑ g (n) φ(2t-n) Where g(n) = $(-1)^n$ h(1-n) A sequence of {h(n)} defines a Wavelet Transform. There are many types of wavelets such as Haar, Daubachies, and Symlet etc. The selection of mother wavelet is based on the type of application. In the following section a novel method of detection and classification of faults using Multi Resolution Analysis of the transient currents associated with the fault is discussed.

3 System Under Study

Figure-1 shows the single line diagram of the system considered along with the various blocks of the proposed scheme. Two 200-km parallel 500kV transmission lines terminated in two 9000-MVA short-circuit levels (SCLs) sources and the angle difference 20^0 with 60HZ.The 100MVA and FACTS controller is installed in the middle of the second transmission line.

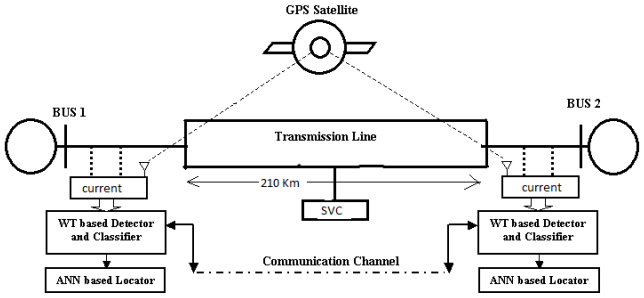

Fig.1.Power system model with SVC Controller

A 300-Mvar Static Var Compensator (SVC) regulates voltage on a 6000-MVA 500-kV system. The SVC consists of a 500kV/16-kV 333-MVA coupling transformer, one 109-Mvar thyristor-controlled reactor bank (TCR) and three 94-Mvar thyristor-switched capacitor banks (TSC1 TSC2 TSC3) connected on the secondary side of the transformer.

4 Detection and classification of Faults

Wavelet Multi Resolution Analysis is used for detection, classification and location of faults on transmission lines. Detail D1 coefficients of current signals at both the ends are used to detect and classify the type of fault. The three phase currents of the local terminal are analyzed with Bior.1.5 mother wavelet to obtain the detail coefficients ($D1_L$) over a moving window of half cycle length. These $D1_L$ coefficients are then transmitted to the remote end. The detail coefficients received from the remote bus ($D1_R$) are added to the local detail coefficients ($D1_L$) to obtain effective D1 coefficients ($D1_E$). The Fault Index ($\mathbf{I_{f1}}$) of each phase is then calculated as $I_{f1} = \Sigma \left| D1_E \right|$.

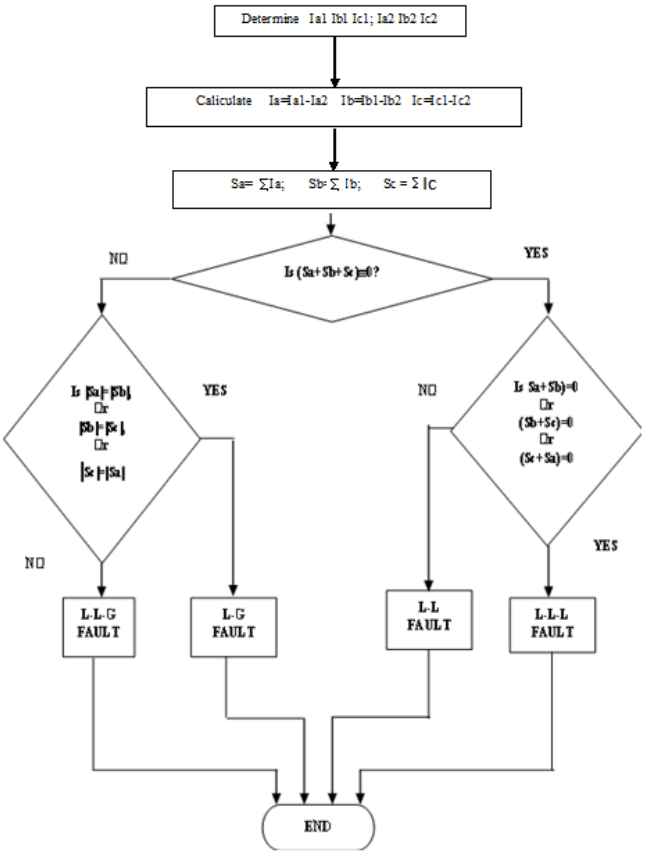

Fig 2. Flow chart for the fault classification

The types of faults considered in the analysis are L-G, L-L-G, L-L, L-L-L, faults. The simulations show that fault inception angle has a considerable effect on the phase current samples and therefore also on Wavelet transform output of post-fault signals. As the waves are periodic, it is sufficient to study the effect of inception angle in the range of 0^0 to 180^0. The complete flow chart for the fault classification is as shown in Figure 2.

5 Estimation of Fault Location

Subsequent to detection and classification of fault, estimation of fault location is carried out using ANNs [12-13]. For this purpose the three phase currents of the local terminal are decomposed with Bior1.5 mother wavelet over a half cycle window are obtained. This is done concurrently with the decomposition D1 used for fault detection and classification to speed up estimation of fault location.

For an LG, LLG and LLLG fault, D1 decomposition of any one faulty phase can be used to estimate fault location. . The details of the ANN architecture descibed as follows :

Input layer : Detail D1 coefficients of current signals using Bior1.5 wavelets at both the ends are used location of fault.
Number Layers : two
Number of neurons : 18
Transfer function : Log-Sigmoid

	80	80.19	-0.19	0.009
	120	123.544	-3.544	1.77
	160	159.84	0.158	-0.008
	200	191.318	8.682	-4.34

The fault index of three phase currents for transmission line is shown in Figure-3 and the fault index of three phase currents with SVC controllers are placed at middle of the transmission line shown in Fig 4. It is observed that the fault index of faulty phase is large compared to those of healthy phases. Thus the number of faulty phases is determined by comparing the Fault Index (I_{f1}) with a Fault Threshold (T_{f1}).The proposed algorithm has been tested for all types of faults, considering variations in fault locations and fault incidence angles (θ) in the range 0-180^o. This scheme is proved to be effective in detecting and classifying various types of faults. Fig 5-a,b,c shows the variation of three phase currents D1 Coefficients of Phase A, Phase B &Phase C for LG,LLG&LLLG fault on transmission line without SVC Controller. Figu 6-a,b,c shows the variation of D1 coefficients for LG,LLG and LLLG transmission line with SVC Controller. Table. I shows the fault distance location analysis

7 Conclusions

Wavelet based multiresolution analysis approach can be successfully applied for effective detection and classification and location of faults in transmission lines. Fault detection and classification can be accomplished with in a half a cycle using detail coefficients of currents at both the ends. Fault location can be estimated with a fair degree of accuracy from the approximate decomposition of phase voltages and currents of local end using ANNs. The proposed protection scheme is found to be fast, reliable and accurate for various types of faults on transmission line fault currents with FACTS controllers, at different locations and with variations in incidence angles

Learning the Size of the Sliding Window for the Collocations Extraction: a ROC-based Approach

Fethi Fkih[1] **and Mohamed Nazih Omri**[1]
[1]MARS Research Unit, Faculty of Sciences of Monastir,
University of Monastir, Monastir, Tunisia

Abstract - *In the statistical terminology field, the collocations extraction from specialized textual corpus is done by computing the joint frequency of a given pair of words inside a sliding window of fixed size. The choice of the window size, which provides the best performance to the system of collocations extraction, remains a problem in this area. In this paper, we propose an efficient approach based on ROC curves for the automatic learning of the window size used for the collocations extraction.*

Keywords: collocation extraction, sliding window, window size, ROC curves, Area Under Curve

1 Introduction

The knowledge extraction from text documents is an important task in the Natural Language Processing (NLP) field. Such knowledge can be used in several applications such as machine translation, document classification, automatic indexing, construction of linguistic resources, etc.

In this paper we will focus on the extraction of a particular kind of knowledge, i.e. word collocations, which are characterized by specific linguistic and statistical properties. Indeed, the extraction of collocations requires two main tasks: recognizing interesting collocations in the text; classifying them according to classes predefined by the expert.

The techniques used for the collocations extraction are often based on the calculation of the joint frequency of a pair of words within a sliding window of fixed size. The choice of the ideal window size (for a given knowledge field) is considered as a problem in the terminology extraction field. However, we don't find in the literature any exact rules to justify this choice. So, it's interesting to propose a new technique for the window size learning based on empirical studies using ROC curves.

The remainder of this paper is structured as follows. Section 2 presents the theoretical basis of the statistical approach for collocations extraction. Then, we propose our approach based on the ROC curves technique. Finally we conclude with an exposition of the obtained results.

2 Collocations extraction: state of the art

In this section, we present an overview of the terminology extraction field through a statistical approach. Next, we introduce the problematic of the window size choice.

2.1 Definition

In the statistical approach, collocation is considered as a sequence of words (n-gram) among millions of other possible word sequences. In Church and Hunks work [1], a collocation as defined is a pair of words that appear together more often than expected. Benson in [2] defines collocation as an arbitrary and recurrent word combination. Smadja in [3] consider that these definitions don't cover some aspects and properties of collocations that affect a number of machine applications. So, he enriches these definitions by four properties:

- Collocations are arbitrary: collocations are difficult to produce for second language learners; it's difficult to translate a collocation word-for-word.
- Collocations are domain-dependent: they are related to the treated knowledge area (medical, biologic, etc.).
- Collocations are recurrent: these combinations are not exceptions; they are very often repeated in a given context.
- Collocations are cohesive lexical clusters: the presence of one or several words of the collocations often implies or suggests the rest of the collocation

The remainder of this paper, we adopt this definition. Subsequently, we present the techniques used for collocations extraction.

2.2 Statistical approach for collocations extraction

The collocations extraction technique is based on a simple principle: if two words frequently appear together, then there's a chance that they form a meaningful lexical sequence (or a pertinent term). In practice, we calculate a score that measures the attachment force between two words in a given text. If this force exceeds a threshold fixed a priori, we can judge in this case that the couple can form a pertinent term.

Before calculating the words joint frequency we must, first, reduce them to a canonical form. Stemming (or lemmatization) can solve the terminological variation problem. The terminological variation can be graphical, inflectional or otherwise. In fact, terminology variation can disrupt the results if we consider two variations of the same token as two different units. Example, the lexical units "acids" and "Acid" are reduced to their canonical form "acid" that will accumulate the frequencies sum of all its variations.

Next, we apply on the text a common statistical technique presented by Kenneth Church in [1]. This technique consists in moving a sliding window of size *T* over the text (see Figure 1).

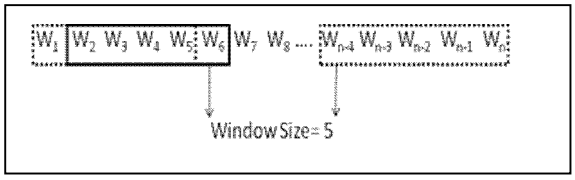

Figure 1. Example of a sliding window of size 5

For each pair of lemma (w_1,w_2), (w_1,w_2),…, (w_1,w_T) we increment it's occurrence frequency in the corpus. We associate with each couple (w_i,w_j) a contingency table (see table1).

Table 1. Contingency table

	w_j	$w_{j'}$ with $j' \neq j$
w_i	*a*	*b*
$w_{i'}$ with $i' \neq i$	*c*	*d*

- *a* = occurrences number of the pair of lemma.
- *b* = occurrences number of the pair of lemma where a given lemma appears as the first item of the pair.
- *c* = occurrences number of the pair of lemma where a given lemma appears as the second item of the pair.
- *d* = occurrences number of the pairs of lemma that don't contain one of the two lemma.

In the literature, we find several statistical criteria to determine the reattachment force between two words in a text. These measures are used initially in biology domain to detect possible relationships between events that occur together. We cite, inter alia, the mutual information and the likelihood (*Loglike*).

According to Fano [4] and Shannon [5], if two points *x* and *y* have respectively the probabilities *P(x)* and *P(y)* then their Mutual Information is defined by (1):

$$I(x,y) = \log_2 \frac{P(x,y)}{P(x)P(y)} \quad (1)$$

Mutual information compares the probability of observing *x* and *y* together (the joint probability) with the probabilities of observing *x* and *y* independently (chance) [1].

This measure is adapted to calculate the connection force between two words w_i and w_j, using our notation (Table 1) the formula becomes (2):

$$I(w_i, w_j) = \log_2 \frac{a}{(a+b)(a+c)} \quad (2)$$

The likelihood (*Loglikelihood*) (3) is distinguished from other measures by the consideration of cases where no occurrences appear [6]. This measure is frequently used in the terminology extraction field as in [7], [8] and [9].

$$\begin{aligned} \text{Loglike} = {} & a\log(a) + b\log(b) + c\log(c) + d\log(d) - \\ & (a+b)\log(a+b) - (a+c)\log(a+c) - \\ & (b+d)\log(b+d) - (c+d)\log(c+d) + \\ & (a+b+c+d)\log(a+b+c+d) \end{aligned} \quad (3)$$

Roche in [10] defines a new measure (Occ_L) that combines likelihood with joint occurrence (4).

$$Occ_L = Loglike + a \quad (4)$$

Based on experimental studies, Roche in [11] has proved that Occ_L measure admits a higher discriminative ability than other measures and offers, therefore, the best result. That's why; we choose this measure to extract collocations in our work.

The frequencies calculation in the statistical approach is based on the sliding window technique. Then, the window size choice is a necessary task to ensure better performance

for the term extraction. Therefore, we do a survey on the related works.

2.3 How to choose the appropriate size of the sliding window?

In the domain of terminology extraction based statistical approach, we confront a main problematic: in a given knowledge field, what's the ideal window size for the collocations extraction? Practically, we find in the literature a several window sizes used for extraction. Kenneth Church shows that window size choice varies with the type of information to extract. Small windows will identify fixed expressions (idioms) and named entities (person names, dates, company names, etc...). By cons, larger windows sizes will identify semantic concepts [12].

For terminology extraction, Kenneth Church proposes a window size of 5 words [1]. According to Church, this size is a good compromise, one side, it is large enough to show some semantic relationships between words, and on the other hand, it is not too large to lose the relationships that demand a certain strict adjacency between words.

Frank Smadja in [3] uses in her system (Xtract) a window of size 6. It tries to detect possible collocations by exploring the near neighbors of the target word (five neighbors before and five after the word). He considers that two words co-occur if they are in a single sentence and if there are fewer than five words between them.

In conclusion, the choice of the size of the sliding window for the extraction of collocations remain (until now) without clear justification. Therefore, we propose our approach based on ROC curves for assistance in decision making of the window size most appropriate for a given knowledge field.

3 Learning the size of the sliding window: a ROC-based approach

In the context of the statistic approach, we propose an approach based on ROC curves. Practically, we want to help choose the window size which offers to the system an optimal discriminative ability.

3.1 ROC curves

Bradely in [13] is the first to use the ROC curves for evaluation and comparison of learning algorithms. Mathieu Roche [11] used ROC curves for learning statistical measures used for terminology extraction.

ROC (Receiver Operating Characteristic) is used to measure system performance. Its methodology is based on statistical decision theory; its goal is to measure the performance of a binary classifier, i.e., a system that aims to categorize entities into two distinct groups based on one or many of their characteristics. Graphically, the ROC curve shows the rate of correct classifications (called true positive rate) as a function of the number of incorrect classifications (false positive rate) for a set of results provided by the system to be evaluated. The area under the ROC curve (AUC) is considered as an important criterion for evaluating the system.

In our case, our system (*S*) classifies collocations into two classes: relevant and irrelevant collocations. Collocations correctly classified by the system in the class "relevant" are called "true positives"; collocations misclassified are called "false positives". Collocations correctly classified by the system in the class "irrelevant" are called "true negatives"; collocations misclassified are called "false negatives". The relevance of the extracted collocations is reviewed by a domain expert (researcher, linguist, engineer…) who will decide whether collocations admit sense or not. The ultimate goal of our technique is to maximize the rate of true positives and the rate of false positives, also is to minimize the rate of false positives and the rate of false negatives.

Subsequently, we can build the following table:

Table 2. Basic measures of performance of diagnostic tests

	Relevant collocations	**Irrelevant collocations**
Collocations evaluated as relevant by the system	True Positives (TP)	False Positives (FP)
Collocations evaluated as irrelevant by the system	False Negatives (FN)	True Negatives (TN)

We define the following terms [14]:

- Sensitivity (also known as Fraction of True Positives): proportion of positive collocations detected by the test. In other words, the sensitivity allows measuring how much the test is effective when used on positive collocations. The test is perfect for positive collocations when sensitivity is 1, equivalent to a random draw when sensitivity is 0.5. If it is below 0.5, the test is cons-efficient.

  Sensitivity (*Se*) is defined as: $Se = TP/(TP+FN)$.

- Specificity (also known as Fraction of True Negatives): proportion of negative collocations detected by the test. Specificity allows measuring how well the test is effective when used on

negative collocations. The test is perfect for collocations negative when the specificity is 1, equivalent to a random draw when specificity is 0.5. If it is below 0.5, the test is cons-efficient.

Specificity (*Sp*) is defined as: *Sp= TN/(TN+FP).*

- Area Under Curve (AUC): is considered it as an important criterion for system evaluation, is equal to the probability that a randomly selected positive case will receive a higher score than a randomly selected negative case [15].

Graphically, the ROC curve represents the sensitivity (*Se*) as a function of fraction of false negatives (*1-Sp*).

Our idea is to evaluate system performance by varying the size of the sliding window and finally to choose the window size which ensures optimum performance for the system, i.e., the window size that maximizes the true positives and the true negatives rate.

3.2 Experimental study and results evaluation

3.2.1 Corpus description

During this work, we used an extract from the medical corpus MEDLARS[1] (75 documents) for the experimentation phases. An expert in the medical field (university professor in medicine) manually prepared a list of relevant terms extracted from the corpus. This list contains 225 technical terms in the medical field. Examples of terms existing in the list: *fetal plasma, maternal level, diabetic syndrome, histological examination, nucleic acid*, etc.

Cleaning the corpus is a necessary task to remove all empty words such as articles (*the, a, an, some, any*), conjunctions (*before, when, so, if*, etc...), Pronouns (personal, relative, possessive and demonstrative) and punctuation. Indeed, these words have high frequency in text documents without having a real terminology importance. So it is essential to remove them to avoid hampering the statistical computing and don't induce, subsequently, a noise in the results.

The lemmatization task is performed by "TreeTagger[2]" a part-of-speech tagger having an acceptable performance.

3.2.2 Results evaluation

We apply the sliding window technique on the corpus. Each time, we vary the window size starting with 2 until reaching 10. For each window size, we get a list of collocations ordered by descending order of their Occ_L value. Table 3 contains the first 11 collocations from a list obtained by the use of a window of size 5.

Table 3. Sample of collocations extracted by a window of size 5

Collocation		Occ_L
Fatty	acid	66.488
non-esterified	fatty	28.720
Chronic	hepatitis	28.578
Nephrotic	syndrome	28.359
non-esterified	acid	28.248
Day	life	22.892
Active	hepatitis	22.352
Maternal	plasma	22.002
Maternal	level	21.810
Maternal	fetal	21.632
Blood	glucose	19.700

So, we get 9 lists collocations ordered in descending order (a list for each window size). For each list, we select the top 400 collocations (hereinafter referred to as list-S). List-S contains collocations evaluated as relevant by the system; the other collocations (not belonging to list-S) are evaluated by the system as irrelevant. A collocation belonging to the list-S is seen as a true positive (*TP*) if it belongs to the expert list, else it is considered as false positive (*FP*). A collocation not belonging, at the same time, to the expert list and the list-S is counted as true negative (*TN*). A collocation not belonging to the list-S but it belongs to the expert list is considered as a false negative (*FN*).

Using XLSTAT[3], a statistical and data analysis software, we plot the following ROC curves (Figure: 2, 3, 4, 5, 6, 7, 8, 9 and 10):

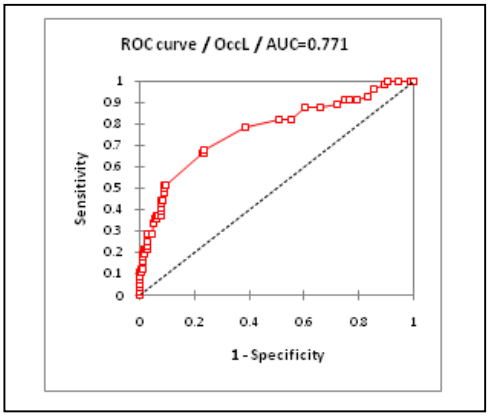

Figure 2. ROC curve corresponding to the window of size 2

[3] http://www.xlstat.com/fr/

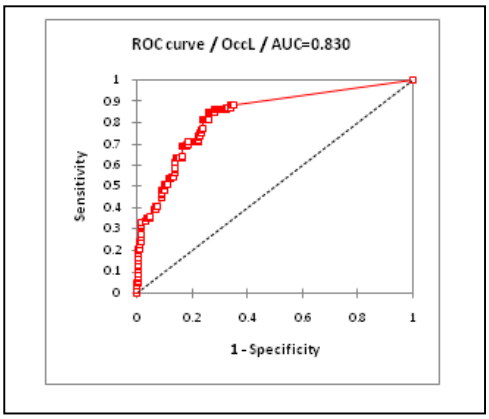

Figure 3. ROC curve corresponding to the window of size 3

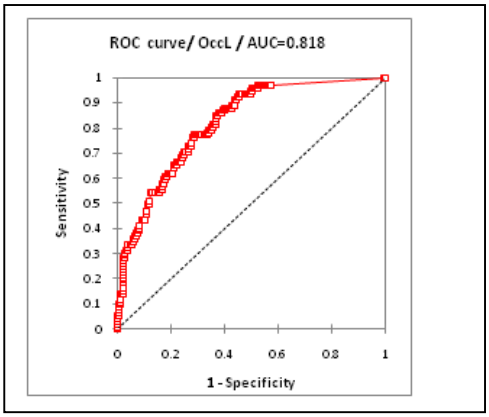

Figure 4. ROC curve corresponding to the window of size 4

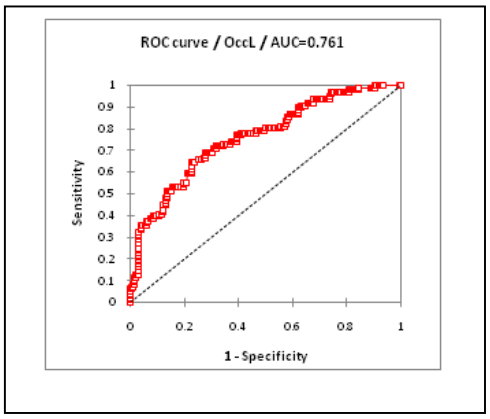

Figure 5. ROC curve corresponding to the window of size 5

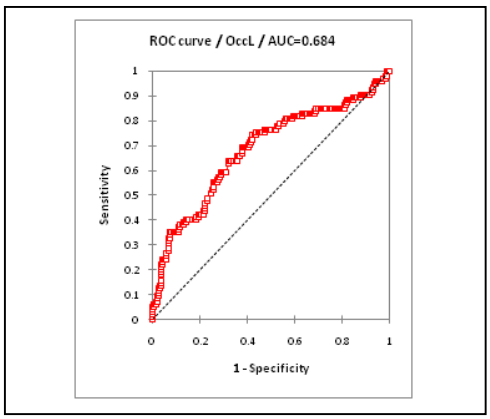

Figure 6. ROC curve corresponding to the window of size 6

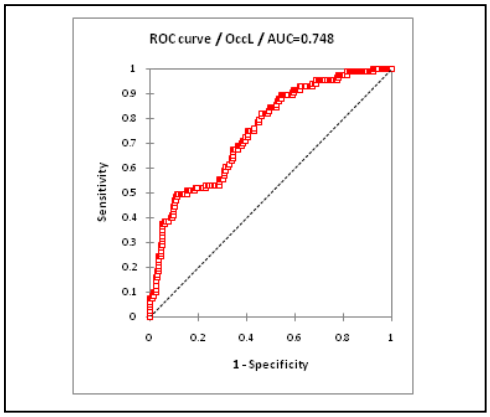

Figure 7. ROC curve corresponding to the window of size 7

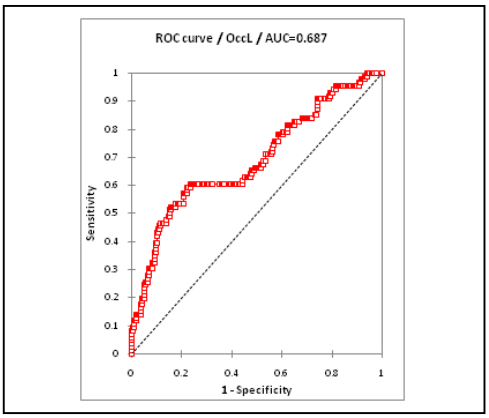

Figure 8. ROC curve corresponding to the window of size 8

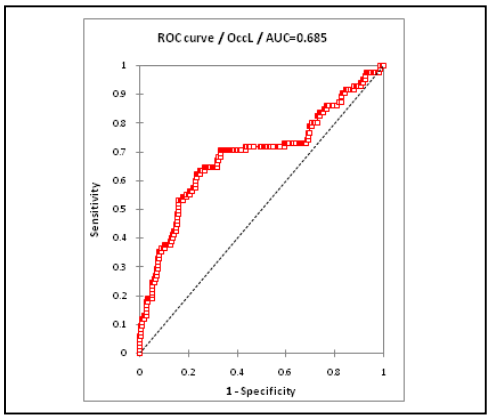

Figure 9. ROC curve corresponding to the window of size 9

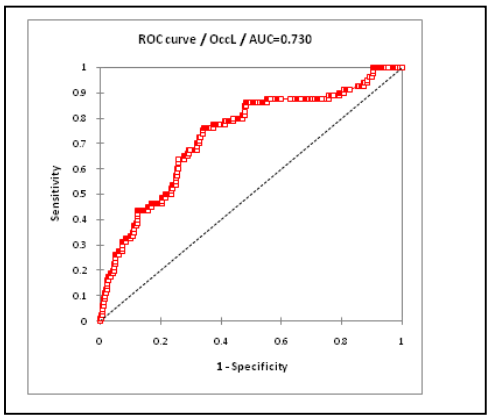

Figure 10. ROC curve corresponding to the window of size 10

To evaluate the 9 ROC curves obtained (see Figure: 2, 3, 4, 5, 6, 7, 8, 9 and 10), we use the Area Under Curve (AUC) as a performance indicator. We recall that the AUC informs about the probability that the test results allows to provide a correct judgment, for two different classes (relevant and irrelevant) of collocations.

As well, when the test is perfectly discriminative, the area under the curve (AUC) is 1. This means that, given two collocations (relevant and irrelevant) the test distinguishes, in 100% of cases, between relevant and irrelevant collocation.

Conversely, when the test is not discriminative, the probability of distinguishing between the relevant and the irrelevant collocation is 50% (chance). In this case, the area under the ROC curve is 0.5.

In the table (Table 4) we sort the windows by their AUC values, greater to the smaller.

Table 4. AUC for each window size

Window Size	3	4	2	5	7
AUC	0.830	0.818	0.771	0.761	0.748
Window Size	10	8	9	6	
AUC	0.730	0.687	0.685	0.684	

According to the table 4, we can classify the results into three groups:

1. Windows having an AUC between 0.8 and 1: The windows of size 3 and 4 have the highest AUC values that exceed (0.8). We can conclude that these window sizes are the more suitable for collocations extraction. The majority of extracted collocations are idioms, named entities and nominal group.
2. Windows having an AUC between 0.7 and 0.8: the majority of windows (2, 5, 7 and 10) belong to this group, which has a medium discriminative capacity, but they are useful for extracting collocations which refers to deep semantic relationships.
3. Windows having an AUC less than 0.7: this group includes windows of size 8, 9 and 6. These window sizes weaken the discriminative power of the system and reduce the importance of testing.

For collocations extraction from a textual corpus of medical field, a window of size 4 can be a good compromise between “fixed” and “semantic” collocations.

4 Conclusion

In this paper, we proposed an approach based on ROC curve for learning the size of the sliding window used in the statistical approach for the extraction of collocations. The choice of the window size, the most appropriate for a given knowledge field, is still a problem without a clear and precise solution. So it's original to propose a practical solution based on experimental studies to circumvent this problem.

Our approach based on ROC curves showed the influence of the various choices of window size on the overall performance of collocations extraction system, to avoid the sizes that weakens the discriminative power of the system and favored the one which gives the optimal discriminative power.

Abstract- *The advancement of the digital forensic investigation requires a new design, improved mechanism and processes. Forensic experts are faced with growth in data. Huge amount of data has expanded and grown in recent years attempts to consume the storage space available. The problem created by this trend is that our ability to analyse and filter data hasn't grown at nearly the same pace. Computing resources are improving, distributed computing field has made major contribution for improvement. By coding tools that can harness the resources of computers. The aim of the research is to identify the main application areas in which agent application has been successfully used currently and to recognise the importance of building digital forensic tool with intelligent agent techniques.*

Keywords- Agent, Intelligent Agent, Autonomy, Automated Tools, Digital Forensic

1. Introduction

Intelligent agent is a new concept for developing software appliactions. Currently, agents are the focus of intense interest on the part of many fields of computer science and artificial intelligence. Agent are used in an increasingly wide variety of applications, from email filters to large open, complex mission criticl system such as air traffic control, in both system the key abstraction used is that of an agent (Jennings and Wooldridge, 1998). Russell and Norvig (2010) describe an agent as anything that can perceive its environment through sensors and act upon that environment through actuators. For instance a human agent has eyes, ears for sensors and hands, legs, for actuators, a robotic agent might have cameras and infrared range finders for sensors and various motor for actuators. A typical example is Letizia, an intelligent agent used for reading documents off the World Wide Web (WWW). Most of the time when the user is accessing the WWW, the computer is idle, waiting for instructions from the user to retrieve a new document. Letizia uses this otherwise idle time to look for other documents somehow related to the document being read, so that the user, after having read the document, will get suggestions for other documents that might be of interest. Letizia thus bases its searching on the contents of relatively recently read documents (Lohani and Jeevan, 2007). Wallace (1997) defined Intelligent Software Agent as software that uses Artificial Intelligence (AI) in the pursuit of the goals for its clients. AI is the limitation of human intelligence by mechanical means. In the terms of this research the word agent generally indicates intelligent agent (IA).

According to Williams (2004) an agent is anything that can perceive its environment through sensors and act upon that environment through effectors. The criterion that is used to evaluate and draw conclusion whether an agent is successful or not is performance measure and a critical success factor is based on how an agent could perform a particular task. The intrinsic part of an agent is being autonomous, adaptive and cooperative in the environment which it operates. The most desirable attribute of an agent is autonomous meaning the agent should not be under the control of another agent (Ademu et al, 2012). The aim of the research is to identify the main application areas in which agent application has been successfully used currently and to recognise the importance of building digital forensic tool with agent technology.

2. Properties of Intelligent Agent

Agent is a computer system put in some environment, that is capable of autonomous action in this environment on order to meet its design objectives (Jennings and Wooldridge, 1998). The system should be able to act without the direct intervention of humans or other agents and should have control over its own

actions and internal state. In drawing a correlation between the notion of autonomy with respect to agents and encapsulation with respect to object oriented systems. An object encapsulates some state, and have some control over this state so that it can only be modified through the methods that the object provides. Agent encapsulate state in the same way but it can also be thought that agent encapsulate behavior in addition to the state but object cannot encapsulate behavior. Due to this distinction (Jennings and Wooldridge, 1998) do not think of agents as invokig actions or methods on agent rather they think of them requesting actions to be performed. The authors identified intelligent agent as a computer system that is capable of flexible autonomous action in order to meet its design objectives. The properties of intelligent agent are:

- **Autonomy:** The agent possesses the capacity to act independently from its user, both in chronological terms and in the sense of adding intelligence to the user's instructions, and exercising control over its own actions (Williams, 2004).

- **Reactivity:** The agent senses in and acts in its own surroundings. The agent also reacts to changes in the surroundings that are the result of its own actions (Bradshaw, 1997).

- **Proactivity:** This refers to the agent's ability to exhibit goal-directed behaviour and take initiatives by itself to get closer to the defined goal, out of an external instruction by its user (Russell and Norvig, 2010). It can predict, or at least make good guesses about the consequences of its own actions, and in this way use its reactivity to come closer to its goal. This should happen simultaneously, and on a periodical basis, which makes their use of enormous help in saving time.

- **Adaptability:** The agent's capacity to learn and change according to the experiences accumulated. This has to do with the feature of having memory, and learning. An agent learns from its user, from the external world and even from other agents, and progressively improves in performing its tasks, independently from external instructions (Lohani and Jeevan, 2007).

- **Continuity:** An agent doesn't necessarily work only when its owner is sitting by the computer, it can be active at all times. It is thus a temporally continuous process (Lohani and Jeevan, 2007).

- **Social ability:** An agent is social software, which interact to other agents to do its job. It can be talking to other similar agents to exchange information, or it can talk to other kinds of agents to request and offer services. Communication with the owner is also important. It is through this the agent is praised or punished for its work, and the owner can give further directions to the agent for how it can do its job better (Herman, 1997).

- **Flexibility:** The agent works proactively, that is directed by goals, but how it goes about to reach these goals may vary. As opposed to a script that performs the same sequence of commands each time it is run, an agent can do the same job in many different ways, depending on the situation and the surroundings (Lohani and Jeevan, 2007).

- **Cooperation:** The notion of cooperation with its user also seems to be fundamental in defining an agent, different from the one-way flow of information of ordinary software; intelligent agents are therefore true interactive tools (William, 2004).

3. Classification of Agent

According to (Jennings and Wooldridge, 1998) agent can be classified by the type of the agent, by the technology used to implement the agent, or by the application domain itself. For the purpose of this research, agent application will be classified as follows:

3.1 Classification by the Type of Agent

Nienaber and Barnard (2005) classified an agent into two namely, stationary agents and mobile agents. A stationary agent can be seen as autonomous software that permanently resides on a particular host. Example of such an agent is one that performs task on its host

machine such as accepting mobile agents, allocating resources, performing specific task etc. A good example of stationary agent is Clippie, the Microsoft Office Assistant where its settings are for programs in Microsoft Office Suite. A mobile agent is a software agent that has the ability to transport itself from one host to another in a network. The ability to travel allows a mobile agent to move to a host that contains an object with which the agent wants to interact, and then to take advantage of the computing resources of the object's host in order to interact with that object. An example of a mobile agent is a flight booking system where a logged request is transferred to a mobile agent that on its part negotiates the web seeking suitable flight information quotations as well as itineraries.

3.2 Classification by Agent Application Domain

- **Commercial Application**

Shopping Assistant: Shopping Assistant uses intelligent agent technology to help the internet shopper to find the desired item quickly without having to browse from one page to the other. A good example is the trading and negotiation agent which negotiate with other agents to buy or sell shares on behalf of their users and the auction agent at EBay (Patel et al, 2010).

Information Management Agents: These agents help to selectively retrieve appropriate information (Bradshaw, 1997). For instance instead of hiring help desk consultant of helping the customers search through the internet for an answer, with intelligent agent, the customer describes the problem and the agent automatically searches the appropriate databases e.g. CD-ROM, or Internet then present a united answer with the most likely first. The diversity of information available to us has increased, the need to manage this information has also grown. The large volume of information availabel throught he internet and World Wide Web (WWW) represents a very real problem. Even though an end user is required to constantly direct the management process there is need for such searches to b carried out by agents, acting autonomously to search the web on behalf of some users this is so important in the digital forensic investigation Ademu, et al, 2011).

Intelligent agent has been proposed in some distributed application as a useful mechanism. Intelligent agent is very applicable in digital forensic investigation. As Solomon and Lattimore (2006) mentioned, in many digital crimes, the procedures of accomplishing forensic are neither consistent nor standardized, instead there are some elementary guidelines for specific situations. Rekhis et al (2009) mentioned that digital investigation should integrate the use of formal techniques that are useful to develop results and proof that should not be disapproved and avoid errors that could be introduced by manual interpretation. There is need to consider the development of automated tools for collection and analysis of digital evidence before presentation.

Web Browser Agent: This is an intelligent agent which helps keep track of what website is visited and customizes ones view of the web by automatically keeping a bookmark list, ordered by how often and how recent one visit the site. It also let you know by notifying you when sites you like are updated, and it could also automatically download pages for browsing offline. A good example is the IBM web browser intelligent, web spider which is used for collecting data to build indexes to be used by a search engine.

Data Mining – This is where information-specific agents provide a context for data searches in vast databases or other information sources (like the web for example) from which cooperating intelligent personal agents will extract a selection of useful information. This field is one of the fastest-evolving ones at the moment given the explosive growth of the amount of accessible information via networks and communications Ralha (2009).

Broker agents: Another types of agent that act as mediators or facilitators by matching user requests against information or known solutions in databases or provided by database agents (Lohani and Jeevan, 2007).

3.3 Classification by Technology used to implement the Agent

Interface Agent: Interface agent emphasize autonomy and learning in order to perform tasks for their owners. Interface agents support and provide proactive assistance to a user learning to use a particular application such as a spreadsheet or an operating system (Jennings and Wooldridge, 1998). The user's agent observes and monitors the actions taken by the user in the interface, learns new short-cuts and suggests better ways of doing the task.

Personal assistant agents: This is an agent that contains personalized learning algorithms developed for a single, specialized application or task. Information filters for browsing tasks belong to this class of agents (Bradshaw, 1997).

Network management – This is where collaborative agents collect and exchange local information on network statistics in order to achieve automation and optimization of decisions on network administration tasks like routing, access, service provisions, monitoring and statistical evaluation, within a global view (Ralha, 2009).

4. Intelligent Agent applied to Digital Foresic Investigation

The New Technologies Inc. (NTI) developed an intelligent Filter program known as the Filter_1 which has the ability to make binary data printable and to extract potentially useful data from a large volume of binary data (Middleton, 2004). The intelligent filter program or Filter_1 tool help to reduce the size of the bitstream files without sacrificing useful information. IP Filter is possibly the most interesting and useful of the Forensic Utilities. It was developed by NTI to help law enforcement track down and investigate child pornography cases. It has a simple DOS user interface and is used in almost the same way as the Filter_1 (Stephenson, 2002). The difference is that it searches for instances of email addresses, Web URLs, and graphic or Zip file names. TextSearch Plus is a utility for searching a disk for text strings. It can search both allocated space and unallocated space (slack space). When used to search the physical disk, it can be used against any file system. TextSearch Plus makes an excellent tool for parsing very large logs in an internet backtracing investigation. It uses fuzzy logic and is designed to process a large amount of data in a relatively short time.

Rekhis et al (2009) developed a system for digital investigation of network security incident using techniques known as intrusion response probabilistic cognitive maps that are constructed to analyse the attacks performed against the network. In their work the authors emphasized that focusing merely on restoring the system as disadvantageous, valuable information and traces that allow understanding the attack could be removed, if the compromised system is formatted or reinstalled, this weakness point up the need for conducting a post - incident digital forensic investigation. And in dealing with the problem faced with collecting and analysing of large amount of data, digital forensic investigation should reconcile both the expertise of the incident response team and the use of formal reasoning techniques, this allows the better filtering of the data to be analysed and source of evidence to be explored and also validate the result of the formal techniques by the incident response team before presenting them. The recommendation by this authors relates to this present research where emphasizes is made for intelligent and reasoning techniques to be applied to digital forensic.

Conclusion

The research identifies the current state of the art in applied agent system. Agents where classified into types, application domain and technology used. The research discussed a wide variety of agent application. This research has pinched from different literature in order to discuss the rapidlly evolving area of software agents and emphasized on the importance of building digital forensic tool with intelligent agent techniques.

Neural Network Based Modeling and Fuzzy Control of A Chemical Plant for Automatic Gas Yield Control

Su-Yeon Jeong[1] , Bok-Jin Oh[1] , and Doo-Hyun Choi[2]
[1]School of Electronics Engineering and Computer Science, Kyungpook National Univ, Daegu, S. Korea
[2]School of Electronics Engineering, Kyungpook National Univ, Daegu, S. Korea

Abstract — *In this paper, a rectifying tower of a chemical plant is modeled using neural networks and human experts in charge of production control are modeled by fuzzy logic. The neural network models and fuzzy controllers are interconnected for automatic O2 production simulation. Standard multilayer perceptron architecture and backpropagation learning algorithm are used to model a rectifying tower. Real data gathered from operating rectifying tower are used to train and test the neural network models. Two widely used increase and decrease cases of O2 production quantity from 3,000 to 5,000 Nm3/h in rectifying tower is selected in this study. After implementing neural network based rectifying tower, fuzzy logic is used to model human experts and used as a controller instead of human experts. Through experiments using 35 real increase and decrease cases of gas production quantity, the neural network models and fuzzy controller show some possibility to mimic complex real plants and verify that those can be used as useful tools to train unskillful engineers and novices in chemical plants.*

Keywords – rectifying tower; chemical plant; artificial neural network; Fuzzy system; modeling and control

1 Introduction

There are so many plants in a steel company. One of them is chemical plants that are in charge of providing high purity oxygen and nitrogen gases needed to producing steel production. Oxygen and nitrogen production plants are one of the huge energy consuming facilities in steel companies. Efficient production control of chemical plants saves much energy and reduces manufacturing cost as a result. Currently, human experts are controlling production levels of chemical plants between 3000 and 5000Nm3/h considering energy consumption and gases' necessities of other plants in steel companies. The control algorithms of gas production quantity is different from experts to experts and the consumption of energy is different each other and each time. It is necessary to standardize the control process of gas production in order to get effective production control and reduce energy consumption substituting current control paradigm depending on individuals' experience and insights.

There are many approaches to model and control complex real plants having many uncertainties and ambiguities using soft computing algorithms such as neural networks, fuzzy logic, evolutionary algorithms, etc. Some of them use MLPs to model nonlinear systems [1-4] and some try to use fuzzy logic as control algorithms [5-7]. Combination of both neural networks and fuzzy logic systems is also suggested to model and control chemical contents [8-9]. In this paper, neural networks are used to model rectifying towers and fuzzy logic is used to model human experts. The neural network models can be substituted with real plants for training unskillful engineers and fuzzy controllers may be substituted with human experts or used for monitoring human mistakes.

This paper is organized as follower. A chemical plant and a rectifying tower are overviewed and the principle of Claude type gas production is introduced. Proposed artificial chemical plant and fuzzy controller is summarized in section III. Neural network based rectifying tower modeling and its modeling performance is explained in section IV. In section V, fuzzy controllers and simulation result using real data are explained.

2 Overview of a Chemical plant and a rectifying Tower

In 1902, Georges Claude, a French engineer and inventor, devised the Claude system for liquefying air. The system enabled the production of liquid nitrogen (N), oxygen (O_2) and argon (Ar). The system produces liquid air through the processes of air inhaling – air compression – heat exchange – expansion engine – rectifying column. Fig. 1 shows the Claude system.

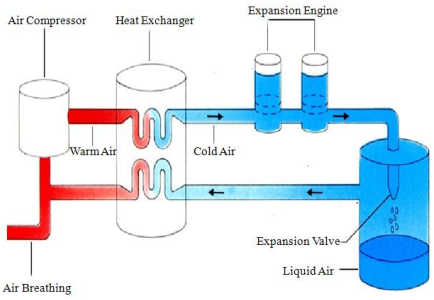

Fig. 1. The Claude system for liquid air production [1].

This study tried to model a rectifying tower in chemical plants and a human expert in charge of controlling the chemical plant. The chemical plant of attention is a high-purity liquid oxygen (O_2), argon (Ar) and nitrogen(N) gas production plant. The plant is built based on the Claude system similar to Fig. 1 and additional processes are used to enhance production efficiency. At first atmospheric air is inhaled and then the inhaled air passes through air filters to reduce dust in the air. Air compressor compresses the air and then heat exchanger using water decreases the air temperature again. Absorber is used to eliminate unnecessary constituents such as moisture, CO_2, carbon, hydrogen, etc. Expansion turbine is used to decrease further the air temperature to near absolute zero degrees. Finally, rectifying towers are used to get liquid gases of N, O_2 and Ar. Fig. 2 shows the block diagram of an O_2 and N production plant. This paper is focused to control of a rectifying tower based on fuzzy inference engine.

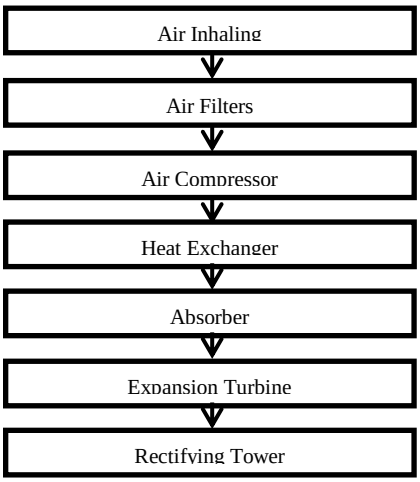

Fig. 2. Block diagram of liquid gas production sequences [1].

3 Overview of the proposed Chemical Plant modeling and Controller

The final goal of this paper is implementing fuzzy controller of a chemical plant using soft-computing algorithms. In order to do this a rectifying tower, the most important process of gas production, is modeling using standard multilayer perceptrons (MLPs) and backpropagation (BP) learning algorithm. Then we tried to model human experts having skills of increase and decrease of gas production using fuzzy systems. The fuzzy models are used as a controller of rectifying tower and directly control the quantity of gas production. Fig. 3 shows the block diagram of neural network modeling and fuzzy control of rectifying towers. Fig. 3(a) shows the block diagram of rectifying tower modeling using neural networks. After modeling process, that is, neural network learning has been finished, the rectifying tower can be replace using neural network models of the rectifying tower as shown in Fig. 3(b). After then the model is used as an education tools for unskillful engineers. To make a fuzzy controller for controlling the quantity of gas production, human experts should be modeled at this time. The human experts use rules based on their experiences and handed down information. These rules are rough and incomplete in general and it is hard or sometimes impossible to model using strict computational tools. We try to apply the fuzzy system to model these rules of human experts. Fig. 3(c) shows the block diagram of modeling of human experts and Fig. 3(d) shows replaced version of chemical plants. Rectifying towers can be replaced to neural networks and human experts to fuzzy controllers using well modeled neural networks and fuzzy controllers. Those may be good educational tools for novices in chemical plants.

4 Neural network modeling of a Rectifying tower

To model a rectifying tower, MLPs are selected and standard BP algorithms are used as their learning algorithms. The real operating data for most frequently used ranges of 3000 and 5000 Nm^3/h increases and decreases of production are used to train neural networks. For 3000 and 5000 Nm^3/h increases and decreases, 30 sequences are gathered. Among the sequences, 27 sequences are used for learning and 3 sequences are used for test. Among many sensing and control data of a rectifying tower 27 data is selected as inputs and outputs of neural networks by analyzing operation history during past 6 months. 27 data include 22 inputs and 10 outputs. In 22 inputs, 5 inputs are fed back from outputs to inputs. All the input data are normalized 0 to 2. Table I summarized every inputs and outputs used rectifying tower modeling in the experiments. Signals used as both input and output are represented using italic font. "(Set)" represents control signals used by human experts. Fig. 4 shows average learning error and final error is 0.0107 after 50,000 iterations. Fig. 5 shows a modeling result for 5000 Nm^3/h decrease of production quantity. In Fig. 5, solid line represents the data from real rectifying tower and dashed line does the data from neural network models.

5 Fuzzy based controller for increase and decrease of production quantity

Fuzzy system is used to model human experts as mentioned in section III. Several best operation histories of increase and decrease of production quantity are selected with human experts actually working in the chemical plant. Also, several control signals are selected based on data mining of operation history during past 6 months which are same as the period used in rectifying tower modeling. Rules provided by human experts and data mining is used as rule base for fuzzy systems and membership functions are designed for each input and output data. To defuzzify, center of mass (COM) is used after aggregating each rules' outputs. Fig. 6 shows some of the membership functions on sensor data, O_2 Output, N Output, and Lower Air Quantity. Outputs of fuzzy controller are O_2 Output (Set), N Output (Set), Lower Air Quantity (Set), and Lean Liquid Quantity (Set) and these data are used as control signals for the rectifying tower. Fig. 7 shows the result of 5000 Nm^3/h decrease of production quantity using a fuzzy controller and neural network models of a rectifying tower. Solid line represents real output and dashed line represents simulation result. It is obvious that the controller and models can be used in real situation.

6 Conclusion

A fuzzy based controller to control the production quantity of high purity O_2 and N is implemented in this paper. To implement the controller, at first, a rectifying tower is modeled using neural networks using a real data gathered from a rectifying tower on the job during past six months. Total 30 periods of production increase and decrease is selected for training and testing of neural network models with the aid of human experts. The performance of the modeling of rectifying tower is verified using trained data and the other data which is not used to train the neural networks. Then a human expert controlling the production of O_2 and N is also modeled using fuzzy system since the human experts use their experience based rules even though they do not recognize. After composing a fuzzy controller the neural network model for the rectifying tower is interconnected to the fuzzy controller. The performance of the implemented fuzzy controller is tested using 21 production increase period and 14 production decrease periods. Several results for neural network modeling and fuzzy based control are presented in the section IV and V. Small errors exist in the result and so more rules and real data from the site is needed to make elaborate fuzzy controller and neural network models. Even though some minor errors exist it is better than unskillful engineers and in near future human experts may be substituted with soft computing controllers.

Parallel Texts Alignment Strategies

E. B. Kozerenko
Institute of Informatics Problems of the Russian Academy of Sciences, Moscow, Russia

Abstract - *The paper focuses on the problems of design and development of the linguistically motivated mechanisms for parallel texts alignment and grammatical (functional semantic) matches extraction for design of statistical language portraits to be further incorporated into the hybrid models of machine translation. By hybrid models we mean those employing both statistical and rule-based mechanisms within one framework for natural language processing. Our approach consists in the use of the starting ("seed") grammar to be further enriched by the matches discovered in parallel texts. The seed grammar is used featuring the cognitive and functional characteristics of phrase structures. The grammar formalism employed is the Cognitive Transfer Grammar based on the transfemes (bilingual phrase structures).*

Keywords: Alignment, Syntax, Semantics, Phrase Structure, Hybrid Machine Translation, Parallel Texts

1 Introduction

The problem of parallel texts alignment is considered in this paper in connection with the task of developing linguistically sound mechanisms for the learning components of machine translation and knowledge extraction systems. The present state of research and developments in the field of natural language processing is characterized by the "hybridization" of approaches and models. There can be two ways of bringing the stochastic and symbolic paradigms together: either augment an existing formalism with statistical data, or introduce linguistic expertise, i.e. syntax and semantics into statistical mechanisms. Introduction of statistics into the rule-based systems allows to capture the dynamics and variety of language forms and meanings generated in the process of speech activity, and linguistic knowledge in statistical frameworks serves as the means of their "intellectualization".

The objective of our parallel texts studies is to extract the phrase structures conveying the same meaning in different laguages for enhancing the seed grammar component for the tasks of machine translation and for multilingual knowledge extraction from domain-oriented texts. The seed grammar we use features the cognitive and functional characteristics of phrase structures. The grammar formalism employed is the Cognitive Transfer Grammar (CTG) [1] based on the *transfemes* (bilingual phrase structures). The CTG formalism captures the paradigmatic characteristics of the languages under study, i.e. *language* as a *system*, while the parallel texts we align are the realization of *speech, i.e. language* as *activity*. This activity is characterized by syntagmatics and dynamics. Considering the syntagmatic features of the parallel texts under study we focus on sentences as the basic unit of study.

For sentence and word alignments we turn to statistical tools. So, the first step is employment of instruments for sentence alignment to obtain the sentence-aligned parallel corpora. The next step is the word-based alignment which conjectures as to what word of a source sentence corresponds to what word of the target sentence. The word-based alignment methods range from simple 1:1 correspondence establishment to more sophisticated methods attempting to capture some structural differencies in the aligned texts. A further step is phrase-based alignment, however the term *phrase* in statistical alignment does not mean a well-formed non-terminal of any grammar formalism, but rather an arbitrary sequence of words. An overview of statistical alignment methods is presented in section 4.

Major problems in parallel texts alignment and consequently in training statistical language processing tools are caused by the existence of transformations in the source and target sentences which result from the action of specific mechanisms of each particular natural language to describe the referential situation. These phenomena are studied and described in translation theory and linguistics as interpretational transformations. Our efforts are directed at discovery of the most typical and relevant transformations in the parallel texts under study and enriching the typology of transformations already represented in the seed CTG formalism. Thus, we have to design and employ such strategies and instruments that provide maximal adequacy for language structures representation and extraction.

In our research and development we make certain difference between the task of machine translation by transfer method which is performed at the level of syntactic structures with functional semantic motivation [1] which we call *transfemes* and the task of multilingual knowledge extraction based on the interlingua representation mechanism of extended semantic networks (ESN). Hence, we employ two types of alignment strategies:1) transfeme-based alignment; 2) concept-based alignment. The former is founded on the notion of *transfeme* and the latter rests on the concept of *entities* and *links* of the ESN knowledge-based approach. These strategies are presented in sections 2 and 3. The related works are discussed in sections 4 and 5. The functional semantic alignment methods supplied with examples and statistics are given in section 6. The paper is concluded by section 7 containing further research directions.

2 Transfeme-based alignment

A *transfeme* is a unit of cognitive transfer establishing the functional semantic correspondence between the structures of the source language and the structures of the target language.

Definition. Transfeme is a unit of cognitive transfer, the translatable meaningful integral structure of mental-lingual plane taken in the unity of its categorial and functional characteristics that establishes semantic correspondence between text and speech segments belonging to different language levels and systems.

For the alignment of parallel texts the *transfemes* are given as the rewrite rules in which the left part is a nonterminal symbol, and in the right part there are aligned pairs of chains of terminal and nonterminal symbols belonging to the source and target languages :

$T \to \langle \rho, \alpha, \sim \rangle$, (1)

where T is a nonterminal symbol, ρ and α are chains of terminal and nonterminal symbols which belong to the Russian and English languages, and $\sim$ is a symbol of correspondence between the nonterminal symbols occuring in ρ and the nonterminal symbols occuring in α. In the course of parallel texts alignment on the basis of the Cognitive Transfer Grammar (CTG) [1] the derivation process begins with a pair of the linked starting symbols S_ρ and S_α, then at each step the linked nonterminal symbols are rewritten pairwise with the use of the two components of a single rule.

The objectives of parallel texts alignment are as follows :

- extract the phrase structures conveying the same meaning in different laguages – *transfemes ;*
- enhance the seed grammar component for the tasks of machine translation and for multilingual knowledge extraction ;
- develop the *typology of matches*, explore the contextual characteristics of *transfemes* and crosslingual matches.

Of primary concern for our research are the interpreters' transformations existing in parallel texts, and the typology of these transformations has been designed comprising the statistics as to the preferences of particular structures (matched configurations of tokens sequences) for each language under study (Russian, English and French). Of special interest for us is the situation of the categorial shift in translating a syntactic pattern. The category of a syntactic pattern, i.e. phrase structure, is determined by the category of the head word of this phrase structure. Thus, when transfer employs conversion, and the category of the head word shifts to another category, the whole structure is assigned the feature of the new category. Thus a Nominal modifier of a Nominal Phrase becomes an Adjective in translation; a Verbal unit acting as a Verbal modifier becomes an Adverbial clause containing the Finite Verbal form, etc.

We observed 34 major types of transformations, the most statistically relevant being verbal – nominal transformations; nonfinite – finite verbal transformations; passivization with various methods of passivization expression in Russian, English and French. We explored the synonymous ways of conveying the same functional semantic meanings, this phenomenon is frequently addressed as paraphrasing.

We consider morphological-syntactic features of the conversed verbs and nouns:

e.g. *read – reading (chitat'- chtenie – Russian)*

In our studies we focus on functional semantic (transfeme) alignment. The results of alignment are employed for developing the linguistic knowledge base to be used in machine translation. The object of our research is the high quality phrasal transformations extraction from bilingual corpora. We also consider monolingual phrasal and sentential synonyms, transformations, including nominalization, passivization, dative shift, and topicalization.

The *dynamic* alignment is realized in *matches* and is based on Semiotic (Categorial) Grammar mechanism [2,3].

The whole alignment process we employ is carried out in two stages : the preliminary alignment and the functional transfer alignment. The preliminary alignment includes sentence alignment, word alignment, sub-trees alignment, structures alignment and and concordances formation. For preliminary alignment the following instrumental systems are employed: sentence alignment - ABBYY aligner [4]; word alignment - Verbalizator (tokenizer), Berkeley aligner [5]; sub-trees alignment - Cognitive Dwarf [6]; structures alignment and concordances formation: Sketch Engine [7].

The functional semantic stage of alignment is based on the notions of *Transfeme* and *Match*, it is also called a Transfeme-based alignment.

Definition. Transfeme is a paradigmatic unit, i.e. relating to *Language*, Match is a syntagmatic unit, i.e. a unit of *Speech* (*Discourse*), thus *transfemes* are realized in *matches*.

The functional semantic alignment consists in

- head-driven structures establishment,
- head words alignment.

The formalism employed for the functional semantic alignment is Cognitive Transfer Grammar (CTG) [1],

$$G_{CT} = \{T_{L_1}, T_{L_2}, N_{L_1}, N_{L_2}, P_{CA}, P_{CT}, S_{L_1}, S_{L_2}, M, D\} \quad (2)$$

where T_{L_1} and T_{L_2} are the sets of terminal symbols of the languages L_1 and L_2, N_{L_1} and N_{L_2} are the sets of non-terminal symbols of the languages L_1 *and* L_2, P_{CA} and P_{CT}, are the sets of the analysis and transfer rules respectively, M is the function of establishing the correlations between the structures of the languages L_1 and L_2, D is the function assigning the probability values to each rule from the sets P_{CA} and P_{CT}.

• Transfeme is a paradigmatic unit, i.e. relating to *Language*, Match is a syntagmatic unit, i.e. a unit of *Speech* (*Discourse*).

A *match* can be broader than a *tranfeme* and often comprises the context. The core unit of the CTG formalism is the *Transfemes Lexicon* which belongs to the set of non-terminal symbols.

3 Concept-based alignment of parallel texts

The *concept-based* alignment of parallel texts is aimed at entities and links alignment in parallel texts for developing multilingual knowledge bases to be further used in analytical intelligent systems for knowledge processing. The instrument employed for this type of alignment is the Semantix processor. The process of concept-based alignment consists in entities alignment, actions (predicates) alignment and links alignment. For entities alignment phrases with nominal heads are matched in parallel texts; for the links alignment genitive and of- phrases are aligned. In the process of actions (predicates) alignment verbal phrases are aligned taking into account finite-nonfinite and verbal-nominal transformations.

The concept-based alignment mechanism is based on the extended semantic networks (ESN) [8] which have the sufficient expressive power for presenting the highly embedded structures of natural language and plays the role of an *interlingua*. The basic structural element of the ESN is the named N-ary predicate, called "fragment". ESN is the development of this type of networks in the direction of the descriptive power increase with the retention of uniformity. The ESN basis is the set of vertices (V), from which the following elementary fragments are comprised: *V0(V1,V2,...,Vk/Vk+1), where V0,V1,V2,...,Vk,Vk+1 V, k > 0.*

This fragment represents a *k*-ary relation. The fragments are assigned their roles. The vertex V0 corresponds to the name of relation, the vertices V1, V2,…, Vk correspond to the objects which are linked by the relation, and the vertex Vk+1 separated by the line (/) from the entire structure corresponds to the vertex of connection. The Vk+1 is called a C-vertex, and all these elements form the extended semantic network (ESN).

The whole set of language objects are given in the form of predicate-argument structures. The uniformity of language presentations is a very important factor, and in the process of analysis of natural language sentences the unification grammar is used. With this approach the words and the constructions, which perform the role of predicates in the sentence, serve as the "support" elements, and the result of the analysis of a sentence is one "extended" predicate, which corresponds to the predicate of a sentence (i.e. to the basic verb in the tensed form or to another basic predicate expression). The government models and transformation features are given in the vocabulary entries of verbs:

e.g. *shoot the ducks from the rifle – strelyat' utok iz ruzh'ia/ strelyat' po utkam iz ruzh'ia*

shooting the ducks from the rifle – strel'ba po utkam iz ruzh'ia / strelyaiuschii po utkam iz ruzh'ia/ strelyaia po utkam iz ruzh'ia / strelyaiuschii po utkam iz ruzh'ia/ strelyaia po utkam iz ruzh'ia /

The transformations result in the shift of the government models. Special attention in our research is given to the cases of nominalization and changes from prepositional government models to those without prepositions: *strelyat' po utkam - shoot the ducks.*

Hence, the concept-based alignment is the process of multilingual knowledge extraction and subject knowledge base population resulting in subject domain expert systems.

4 Statistical approaches to alignment of parallel texts overview

The statistical approaches to parallel texts alignment are aimed at establishing the most probable alignment *A* for the two given parallel texts *S* and *T*:

$$\arg\max_A P(A \mid S,T) = \arg\max_A P(A,S,T) \qquad (3)$$

For estimation of the probability values indicated in this expression the most frequently used methods present the parallel texts in the form of aligned sentence sequences $(B_{1,\dots,}B_K)$. The probability of each sequence is independent from the probabilities of other sequences, and it depends on the sentences in the given sequence only [9]. Then

$$P(A,S,T) \approx \prod_{k=1}^{K} P(B_k) \qquad (4)$$

This method takes into account the length of sentences in the source language and in the target language measured in symbols. The longer sentence in one languages will correspond to the longer sentence in the other language. This approach gives stable results for similar languages and literal translation. The more finely tuned mechanisms of matching are provided by the methods of lexical alignment. Thus in [10] the method of alignment by means of creating the model for consecutive word-by-word translation is presented. The best alignment result will be the one which maximizes the probability of a corpus generation with the given translation model. For the alignment of the two texts *S* and *T* they should be split into the sequences of sentence chains. A chain contains zero or more sentences in each of the two languages, and the sequence of chains covers the whole corpus

$$B_k = (S_{a_k},\dots,S_{b_k};t_{c_k},\dots,t_{d_k}) \qquad (5)$$

Then the most probable alignment $A = B_1,\dots,B_{m_A}$ of the given corpus is determined by the following expression, and the chains of sentences do not depend on each other:

$$\arg\max_A P(S,T,A) = \arg\max_A P(L)\prod_{k=1}^{m_A} P(B_k), \quad (6)$$

where $P(L)$ denotes the probability of the L chains being generated. The translation model employed in this approach is extremely simplified and does not take into account the factor of the word order in a sentence and the possibility of the fact that a word in the source text can correspond to more than one word in the text of translation. In this model the word chains are used, and they are limited to the 1:1, 0:1 и 1:0 matches. The translation model based on the word-by-word alignment (we employ this model for the Russian and English parallel texts) will be as follows:

$$P(r \mid e) = \frac{1}{Z}\sum_{a_1=0}^{l}\ldots\sum_{a_m=0}^{l}\prod_{j=1}^{m} P(r_j \mid e_{a_j}), \quad (7)$$

where e is a sentence in English; l is the length of e expressed in words; r is a sentence in Russian; m is the length of r; r_j is the j-th word in r; a_j is the position in e, with which the r_j is aligned; $P(w_r \mid w_e)$ is the probability of translation, i.e. the probability of the w_r appearing in the Russian sentence if the corresponding w_e occurs in the English sentence, and Z is the normalization constant.

For a particular alignment m probabilities of translations are multiplied, and the individual translations are independent one from another.

However, there are certain structural differencies between these languages, and in translation there can be considerable transformations. If the languages under consideration are structurally different, the methods are used oriented at the introduction of grammar knowledge, for example, the alignment methods based on the words that belong to particular parts of speech [11] are employed. In this case the auxiliary words are not taken into account. For the employment of these methods the part of speech tagging of the parallel texts should be performed. It is necessary to take into account various transpositions of words, omissions, insertions, and the alignments between different language levels: when a word in the source text corresponds to a phrase in the target text, and the opposite situation. The most general definition of the word-based alignment is given in [12]. Suppose the two word chains are given, one in the source text (for example, in Russian – r) $r_1^J = r_1,\ldots,r_j,\ldots,r_J$, and the other one is in the target language (English – e) $e_1^I = e_1,\ldots,e_i,\ldots,e_I$, and for these chains it is necessary to establish the alignment. The alignment between the two chains of words is a subset of a Cartesian product of the positions of words, i.e. the alignment A is defined as follows:

$$A \subseteq \{(j,i): j = 1,\ldots,J; i = 1,\ldots,I\}. \quad (8)$$

In machine translation based on statistical methods an attempt is made to construct a model of the translation probability $P(r_1^J \mid e_1^I)$, which describes the correlation between some chain r_1^J in the source language and the chain e_1^I in the target language. In statistical texts alignment model $P(r_1^J, a_1^J \mid e_1^I)$ a "hidden" alignment a_1^J is introduced which describes the mapping from the source position j into the target position a_j. The correlation between the translation model and the alignment model is given in the following way:

$$P(r_1^J \mid e_1^I) = \sum_{a_1^J} P(r_1^J, a_1^J \mid e_1^I). \quad (9)$$

The alignment a_1^J can contain the alignments $a_j = 0$ with the empty word e_0 for the words of the source language which had not been aligned with any word in the source language. On the whole the statistical model depends on the set of unknown parameters θ which are extracted from the training data set in the course of learning. The following presentation is used to express the dependence of the model on the set of parameters:

$$P(r_1^J, a_1^J \mid e_1^I) = p_\theta(r_1^J, a_1^J \mid e_1^I) \quad (10)$$

For detection of the unknown parameters θ a training corpus of parallel texts is given containing S sentence pairs $(\mathrm{r}_s, \mathrm{e}_s): s = 1,\ldots,S$. For each pair (r s (the alignment variable is designated by $a = a_1^J$. The unknown parameters are established by means of maximization of the parallel texts similarity in the corpus:

$$\theta = \arg\max_\theta \prod_{s=1}^{S}\sum_{\mathrm{a}} p_\theta(\mathrm{r}_s, \mathrm{a} \mid \mathrm{e}_s). \quad (11)$$

As a rule the maximization for such models is performed on the basis of the expectation maximization algorithm [13] or the similar ones. Such algorithm is useful for the solution of the parameters estimation problem, but it is not indispensable for the statistical approach. Hence despite the fact that there exist a large number of alignments for a given pair of sentences, it is always possible to find the best alignment:

$$a_1^J = \arg\max_{a_1^J} p_\theta(r_1^J, a_1^J \mid e_1^I). \quad (12)$$

The alignment a_1^J is also called the Viterbi alignment for the pair of sentences (r_1^J, e_1^I). The estimation of the Viterbi alignment quality is performed by means of comparison with some reference alignment carried out manually. The parameters of statistical alignment models are optimized with the consideration of the maximal likelihood criterion which does not always reflect the quality of alignment.

5 Related work

The problem of paraphrasing is very topical and it is considered in the works of the leading computational linguistics research teams [14,15,16,17,18,19]. The paraphrase model described in the work [17] was trained using the Europarl corpus. The authors used ten parallel corpora between English and (each of) Danish, Dutch, Finnish, French, German, Greek, Italian, Portuguese, Spanish, and Swedish, with approximately 30 million words per language for a total of 315 million English words. Automatic word alignments were created for these using Giza++ [19]. The English side of each parallel corpus was parsed using the Bikel parser [20]. A total of 1.6 million unique sentences were parsed. A trigram language model was trained on these English sentences using the SRI language modeling toolkit [21]. The toolkit supports creation and evaluation of a variety of language model types based on N-gram statistics, as well as several related tasks, such as statistical tagging and manipulation of N-best lists and word lattices.

Paraphrase extraction using bilingual parallel corpora was proposed by Bannard and Callison-Burch [22] who induced paraphrases using techniques from phrase-based statistical machine translation [23]. Furthermore, by introducing *complex syntactic labels* instead of solely relying on non-terminal symbols in the parse trees, the authors were able to keep the broad coverage of the baseline method. Syntactic constraints significantly improve the quality of this paraphrasing method. The paper [24] presents a novel approach to paraphrasing with bilingual parallel corpora, the author demonstrates that a significantly higher performance can be achieved by constraining paraphrases to have the same syntactic type as the original phrase. The paper proposed constraints on paraphrases at two stages: when deriving them from parsed parallel corpora and when substituting them into parsed test sentences, the author introduced syntactic constraints by labeling all phrases and paraphrases (even non-constituent phrases) with CCG-inspired slash categories. The author did not formally define a synchronous grammar, nor discuss decoding, since his presentation did not include hierarchical rules. Synchronous grammar rules for translation are extracted from sentence pairs in a bixtext which have been automatically parsed and word-aligned. Extraction methods vary on whether they extract only minimal rules for phrases dominated by nodes in the parse tree, or more complex rules that include non-constituent phrases [25].

A key motivation for the use of syntactic paraphrases over their phrasal counterparts is their potential to capture meaning-preserving linguistic transformations in a more general fashion. A syntactic paraphrasing system intuitively should be able to learn well-formed and generic patterns that can be easily applied to unseen data.

6 Transformations in parallel texts alignment

For developing the *typology of transformations* we consider the following Simultaneous Interpretation Techniques (SIT):

1) Full translation of lexical grammatical forms (LGF) *completely correspond to each other both in the source and the target languages as to their form, function and meaning*

(2) Null translation (LGF is used differently)

(3) Partial translation (several content functions)

(4) Functional substitution (functional identity of different LGF)

(5) Assimilation (LGF combinability features differ)

(6) Conversion (substituting a form of one category by a form of another category)

(7) Antonyms employment (is used for eliminating a conflict between lexical and grammatical combinability of LFG)

The transformations in focus are singled out on the basis of their counts in parallel texts, these are:

Nominalization (35% in the English-Russian language pair);

Passivization (18-24% in the Russian-English direction);

Adjectival – Adverbial structures (12-14% in both directions;

Subject – Object transformations (28% in both directions).

Consider some examples:

Indirect Object → Subject

Ser'oznymi raznoglasiyami byla otmechena vstrecha storon – Serious disagreements arose during the meeting of the sides

Direct Object → Subject

Novuiu planetu nazvali v tchest' ieio otkryvatelia – The new planet was named after its discoverer.

Prepositional phrase → Subject

Na vstreche dogovorilis' – The meeting reached the conclusion.

Regular semantic shifts are as follows:

Substituting a predicate of action by the predicate of state.

He is a member of the college team. (A predicate of state).

On igraet v studencheskoi komande. (He plays in the students' team. A predicate of action).

Functional motivation of phrase structures is represented in the set of non-terminals with their counts in a text, e.g.:

("Objective infinitive", 400.0)

("Objective be-infinitive", 600.0)

("Subjective infinitive with participlePast",600.0)

("Subjective infinitive with adjective", 600.0)

("Subjective participle", 600.0)

We employ match typing and statistical portraits of transformations. The Russian language is about 35% more "nominative" than English:

In vacuum molecules have large space in which to move (V)

V vakuume molekuly imeiut bol'shoe prostranstvo dlia dvizhenia. (Rus.-translit)

dlia dvizhenia - for movement

in which to move (V) → *dlia dvizhenia* (N)

The most productive types of verbal-nominal transformations correlate with the following functional values

- Adverbial modifier of purpose and of consequence, expressed by infinitive (58%),
- Composite predicate with the infinitive (be + infinitive) (51%).

This statistics is taken into account in the multivariant cognitive transfer rules. The matches, or *events* comprise well-formed nonterminals and dynamic syntactic contexts represented in categorial grammar (SUG) notation [2,3]. For disambiguation procedures Vector spaces of events are employed. The main technique of phrase matching is heads alignment which is carried out at present semiautomatically, and the fully automated procedure is under development:

phrase head elements are aligned and structures are compared). It is important to emphasize that *Transfeme* is a paradigmatic unit, i.e. relating to *Language*, *Match* is a syntagmatic unit, i.e. a unit of *Speech* (*Discourse*). Transfeme is realized in Matches.

We distinguish two types of Matches: the direct matches without transformation M^d and the matches employing transformations M^t. M^d display direct correspondence of categorial features of head elements of the matched structures (S_s and S_o), i.e. a noun in the source text will correspond to the noun in the objective text, and the phrase structures will be similar, e.g. a NP in the source text will correspond to the NP in the objective text.

M^t will employ transformations, e.g. a noun in the source text will correspond to a verbal element in the objective text, and the phrase structures will differ,

e.g. NP → VP

Match strategies are employed taking into account the possible transformations $M^t_{s\to o}$, where *M* is *Match*, *t* is *transformation*, *s* is a *source* language, *o* is an *objective* language; $S^{CT}_M = \sum M^t_{s\to o}$ forms the space of cognitive transfer matches (S^{CT}_M).

The goal of semantic alignment is the establishment of matches (rules) for training data collections of the machine learning components for the machine translation systems based on statistical and symbolic approaches.

Examples of the English – Russian texts alignment:

The second step of the above described process is conducted in the presence of a metal catalyst.

NP (Subj) PP VP (Passive) PP (English).

Vtoruju (Adj, F, Sg, Acc) stadiju (N, F, Sg, Acc) vysheopisannogo (N, F, Sg, Acc) sposoba (N, M, Sg, Gen) provodiat (V, Pl, 3-d Person, Pres) v (P) prisutstvii (N, Neutr, Sg, Prep) metallicheskogo (Adj, M, Sg, Gen) katalizatora(N, M, Sg, Gen) .

NP(Accusative) NP(Gen) VP (Person Undefined – Plural) PP (Russian).

The transformation will be as follows :

NP (Subj) PP VP (Passive) PP →

NP(Accusative) NP(Gen) VP (Person Undefined – Plural) PP

134 types of matches were established classified into Cognitive Transfer Spaces (CTS)	
Primary Predication	Orientation
Secondary Predication	Partition
Nomination and Relativity	Determination
Modality and Mood	Existentiality
Connectivity	Negation
Attributiveness	Reflexivity
Metrics and Parameters	Emphasis
	Dispersion

Machine learning methods [26,27] provide the system ability to extract meanings that are expected to be heared or read in a given context. Therefore, it is natural to apply statistical data extracted from large amounts of existing textual information and use it to calculate the probability of a certain meaning in a specific context.

The success of a probabilistic model depends, among other things, on an adequate definition of *event.* A common type of event in probabilistic NLP is the occurrence of one or more words in a specific context. Here *word* usually means not a word-form (i.e. a character string as it appears in a text) but rather a stem or *lemma*. The context is in turn defined as an ordered set of adjacent words on both sides of each word occurrence and the length of such context window is usually set to an arbitrary integer value. While equating a stem with a lexical unit *(lexeme)* may be a reasonable if not ideal way of representing meanings, the definition of context commonly used in statistical NLP is a clear oversimplification, which obscures important linguistic relationships. It is indeed reasonable to assume that the probability of a word having a specific sense depends on other words located in its proximity. However, this "bag of words" approach hides underlying complexities that require more precise discovery procedures.

7 Conclusions

In this paper the English-Russian language pair is considered, however our experiments show that major conclusions hold for Byelorussian and Ukrainian languages that are closely related to Russian, as the syntactical transformation processes are similar in these languages. Introduction of statistics into the rule-based systems allows to capture the dynamics and variety of language forms and meanings generated in the process of speech activity.

Functional and cognitive motivation of the seed grammar rules increases the precision of matches by 23% - 42% depending on the text type (the evaluation of human experts). Further developments will comprise the French and German languages and will focus on the texts of scientific and economic domains

***Abstract*—This paper proposes a new index for the relevance of terms extracted from domain corpora. We call it term frequency, disjoint corpora frequency (*tf-dcf*), and it is based on the absolute term frequency of each term tempered by its frequency in other (contrasting) corpora. Conceptual differences and mathematical computation of the proposed index are discussed in respect with other similar approaches that also take the frequency in contrasting corpora into account. To illustrate the efficiency of the *tf-dcf* index, this paper evaluates the application of this index and other similar approaches.**

I. Introduction

The automatic extraction of terms from texts is a well mapped task, but the automatic choice of which extracted terms are relevant for a specific domain is a much more defiant task. Finding the most relevant terms for a domain, *i.e.*, the domain concepts, is an important step for knowledge engineering tasks such as ontology learning from texts [1].

Some classical linguistic-based work in this area suggest the use of distributional analysis [2] to associate terms and then, establish which of them are good concept candidates. A different approach, but yet following the same idea of inferring concepts from term association, is made by Chemudugunta *et al.* [3], where the identification of concepts is made through pure statistical measures tempered by previous inserted human information. Titov and Kozhevnikov [4] work also follows this line of research by inferring semantic relations among terms in order to identify different terms representing a same concept in sets of small documents (weather forecasts) with no linguistic annotation.

The work of Bosma and Vossen [5] presents a similar effort to establish term relevance measures considering a multiple corpora resource. This work proposes different relevance measures of terms to each corpus, but, Bosma and Vossen's relevance measure of a term in a given corpus do not affect the relevance of this same term in other corpora. In fact, the methodology proposed in their work access WORDNET [6] in order to validate the term candidates according to their measures, but also to establish relations (hypernym, hyponym, meronym, *etc.*) among them.

In opposition to these efforts, this paper proposes an approach that is not linguistic-based, but it relies only the on statistical information gather from the domain corpus to establish a numerical measure to term relevance in this corpus. Therefore, this paper approach is aligned with works that take into account the term frequency on documents to compute a relevance index to establish how representative a term extracted from a corpus will be for the domain represented by this corpus. Some examples of such statistical-based approaches are the works of Dunning in 1993 [7] which proposes the use of log likelihood ratio, Manning and Schultz in 1999 [8] which proposes a composition of *tf-idf* (term-frequency, inverse document frequency [9] adapted for term relevance in a corpus), and other initiatives based on computing indexes from one specific corpus only.

However, our claim is that those typical indices fail to rule out those terms which are not particularly relevant to a target domain. The basic idea behind approaches like the one in our paper is the assumption that a term relevance to a specific domain can only be established by comparison with corpora from other domains, called contrasting corpora.

One of the first examples of similar previous work like our own was the work of Chung in 2003 [10]. But recently, more sophisticated versions were proposed by Park *et al.* in 2008 [11] with domain specificity index, by Kit and Liu in 2008 with termhood index [12], and by Kim *et al.* in 2009 with term frequency, inverse domain frequency index [13]. These approaches brought some quality to the term extraction, as was verified by the works of Teixeira *et al.* [14], as well as, Rose *et al.* [15].

Similar to our proposal, all these previous works followed the same principle to compute a relevance index that is directly proportional to the term absolute frequency in the corpus and inversely proportional to the term absolute frequency in other corpora. The main difference among these similar previous works [11], [12], [13] and our own is the specific formula to weight the influence of other corpora frequency.

This paper first contribution resides in drawing a panorama of options of indices to express the relevance of extracted term from a domain corpus, focusing on indices that take into account also corpora of other domains (contrasting corpora). Some experiments illustrate the benefits of approaches using contrasting corpora over traditional indices.

Secondly, and most important, this paper contributes with the proposal of a new relevance index, called *tf-dcf*, that is, according to our experiments, superior to the other indexes based on contrasting corpora. This contribution is enhanced by the analysis of the *tf-dcf* behavior against different options of contrasting corpora.

It is not the goal of this paper to analyze techniques to improve the quality of term extraction itself, since we assume that a previously performed extraction provides a set of extracted terms. It is also out of the scope of this paper to analyze how many terms should be considered concepts of a domain. Our purpose is to present arguments and experiments showing that the proposed index is effective to rank extracted terms according to their relevance for the domain, thus allowing to identify domain concept candidates.

This paper is organized as follows: Section II describes the existent statistical measures that are compared to our proposed *tf-dcf* index; Section III presents our paper main contribution, which is the proposal of a term relevance index based on the inclusion of a "disjoint corpora frequency" (*dcf*) component; Section IV evaluates the existing and proposed indices. Finally, Conclusion stress the contributions and limitations of this paper, leading to the proposition of future works.

II. Existing measures for relevance estimation

The most elementary way to establish the statistical relevance of terms extracted from a domain specific corpus is to compute the absolute frequency of terms, *i.e.*, how many times each term occurs in the corpus. Obviously, this simple approach is very fragile, since not necessarily a very frequent term is relevant for the domain. This fact is specially noticeable with simple extraction methods, although even sophisticated linguistic-based methods also suffer from using such simple criteria.

For example, pure statistical methods require the adoption of a list of highly frequent grammatical words (*stop list*). Without a stop list, any pure statistical method delivers terms with very low significance such as prepositions and usual expressions. However, it might be very difficult to establish an exhaustive stop list in advance for different domain and genre.

The use of term frequency as relevance measure is a little less harmful for extraction methods taking into account linguistic information. For example, the syntactic annotation of a corpus allows the extraction procedure to avoid terms that are unsuitable for concept names, such as verbs and pronouns. In fact, more sophisticated linguistic analysis, as the identification of noun phrases, may improve significantly the quality of extraction, but even in these cases the use of term frequency do not prevent the incorrect extraction of common expressions which are not domain specific. For example, the quite common expression "*future work*" may be found in several academic texts, but it is hardly considered a defining concept to any scientific domain.

Nevertheless, the starting point of all sophisticated indices is the simple absolute frequency. Assuming, $tf_{t,d}$ as the number of occurrences of term t in document d, and $\mathcal{D}^{(c)}$ the set of all documents belonging to the corpus c referring to a specific domain, the absolute term frequency of a term t in corpus c is expressed by:

$$tf_t^{(c)} = \sum_{\forall d \in \mathcal{D}^{(c)}} tf_{t,d} \tag{1}$$

A. Term frequency and inverse document frequency - tf-idf

An alternative for plain term frequency is to take into account the frequency of the term among documents. The seminal work of Spärck-Jones [9] shows the importance to consider frequent terms, but also non-frequent ones in order to retrieve documents. These ideas lead to the well-known Robertson and Spärck-Jones probabilistic model to term relevance to specific documents [16]. Croft and Harper [17], and later Robertson and Walker [18], proposed formulations to a popular index that takes positively into account the term frequency (*tf*), *i.e.*, the number of occurrences of a given term t in a document d; and also considers negatively the number of documents of the corpus where term t appears at least once, *i.e.*, the inverse document frequency (*idf*).

This index, called *tf-idf* has many formulations, *e.g.*, [19], [20], [8], but in this paper we will consider the formulation adopted by Bell *et al.* [21]. The *tf-idf* index is mathematically defined for each term t to each document d belonging to a corpus c that has at least one occurrence of t as follows:

$$tf\text{-}idf_{t,d} = \underbrace{(1 + \log(tf_{t,d}))}_{tf \text{ part}} \times \underbrace{\log\left(1 + \frac{\mid \mathcal{D}^{(c)} \mid}{\mid \mathcal{D}_t^{(c)} \mid}\right)}_{idf \text{ part}} \tag{2}$$

where $tf_{t,d}$ is the number of occurrences of term t in document d; $\mathcal{D}^{(c)}$ is the set of all document of a given corpus c; and $\mathcal{D}_t^{(c)}$ is the subset of these documents where t appears at least once.

Observing equation (2) it is possible to observe the term frequency (*tf*) and the inverse document frequency (*idf*) parts. The *tf* part considers the logarithmic frequency of the term, since the variation of term occurrences of terms approaches an exponential distribution, *i.e.*, a term t that occurs 10 times is not 10 times more important than a term t' that appears only once. Nevertheless, term t is an order of magnitude more important than term t'. The *idf* part represents a value that varies from $\log(2)$ for a term that appears in all documents, until $\log(1+ \mid \mathcal{D}^{(c)} \mid)$ for a document that appears in only one document.

The idea behind *tf-idf* formulation is that a term t is more relevant as a keyword for a document d if it appears many times in this document and very few times (or ideally none) in other documents. This is an important distinction for information retrieval. The popularity of this index is justified mostly because it prevents frequent terms spread in many documents to be considered more relevant than they should. Indeed, *tf-idf* is an effective measure to identify the defining terms of documents, because it spots terms that are good for document indexation.

The use of *tf-idf* to establish relevance of terms to domain corpora was proposed by Manning and Schütze [8]. According to these authors, a possible index to express the relevance of a term t in a corpus c is expressed by:

$$tf\text{-}idf_t^{(c)} = \sum_{\forall d \in \mathcal{D}_t^{(c)}} tf\text{-}idf_{t,d} \tag{3}$$

B. Term domain specificity - tds

The first initiatives to consider the relevance of terms to a domain corpus taking into account contrastive generic corpus, or corpora, include the works made by Chung in 2003 [10] and Drouin in 2004 [22]. However, at the authors best knowledge, it is the work of Park *et al.* [11], in 2008, one of the first formulations of an index to express term relevance to a specific domain. In that work, such index is called *domain specificity*, and it is expressed as the ratio between the probability of occurrence of a term t in a domain corpus c and the probability of this same term in a generic corpus. Park *et al.* definition of term t domain specificity to a specific domain corpus c, considering a generic domain corpus g was expressed as:

$$tds_t^{(c)} = \frac{p_t^{(c)}}{p_t^{(g)}} = \frac{\frac{tf_t^{(c)}}{N^{(c)}}}{\frac{tf_t^{(g)}}{N^{(g)}}} \tag{4}$$

where $p_t^{(c)}$ express the probability of occurrence of term t in corpus c; and $N^{(c)}$ is the total number of terms in corpus c, *i.e.*, $N^{(c)} = \sum_{\forall t'} tf_{t'}^{(c)}$.

C. Termhood - thd

Following the approach to consider, besides the domain corpus of interest, a contrasting corpus, the work of Kit and Liu in 2008 [12] proposes an index called termhood. This index, as for Park *et al.*'s term domain specificity, follows the idea that a term relevant to a domain is more frequent in the corpus domain than in other corpora. The main difference brought by this work is to consider the term rank in the corpus vocabulary (the set of all terms in the corpus), instead of the term absolute frequency. Kit and Liu definition of term t termhood index for a corpus c, a generic domain corpus g (called background corpus by them) was expressed by:

$$thd_t^{(c)} = \underbrace{\frac{r_t^{(c)}}{\mid V^{(c)} \mid}}_{\text{norm. rank value in } c} - \underbrace{\frac{r_t^{(g)}}{\mid V^{(g)} \mid}}_{\text{norm. rank value in } g} \tag{5}$$

where $V^{(c)}$ is the vocabulary of corpus c, *i.e.*, $\mid V^{(c)} \mid$ is the cardinality of the set of all terms in the corpus c, and $r_t^{(c)}$ is the rank value of term t expressed as $\mid V^{(c)} \mid$ for the more frequent term, $\mid V^{(c)} \mid -1$ for the second most frequent, and so on until the less frequent term as $r_t^{(c)} = 1$.

Observing the termhood index we can see it as the difference between the normalized rank value of the term in the domain corpus c and the generic domain corpus g. Actually, the division of the rank value by the vocabulary size is intended to keep the normalized rank value within the interval $(0, 1]$, with a value equal to 1 to the more frequent term, and the other terms decaying, according to their frequency, asymptotically toward 0.

As a result, the termhood index will be whitin the interval $[1, -1]$, having the more frequent term in c having a value equal to 1, if it does not belong to vocabulary $V^{(g)}$, until a value -1 for the more frequent term in g, if it does not belong to vocabulary $V^{(c)}$.

D. Term frequency, inverse domain frequency - TF-IDF

Recently, Kim *et al.* [13] have proposed in 2009 another index to rank term relevance considering the original idea of the *tf-idf* index, which was to identify whereas a term is suitable to represent a document. In such way, Kim *et al.* did not actually proposed a new index, but instead, they proposed the use of the same *tf-idf* formulation, but considering the set of documents of a corpus as a single document. To avoid confusion, we will refer to this index with the acronym *TF-IDF* in uppercase, to differentiate it from the term frequency, inverse document frequency (*tf-idf*).

The *TF-IDF* index for term t at corpus c, considering a set of corpora $\mathcal{G}$ as proposed by Kim *et al.* is numerically expressed by:

$$TF\text{-}IDF_t^{(c)} = \underbrace{\frac{tf_t^{(c)}}{\sum_{\forall t'} tf_{t'}^{(c)}}}_{TF \text{ part}} \times \underbrace{\log\left(\frac{\mid \mathcal{G} \mid}{\mid \mathcal{G}_t \mid}\right)}_{IDF \text{ part}} \tag{6}$$

where $tf_t^{(c)}$ is the term frequency of term t in corpus c; $\mathcal{G}$ is the set of all domain corpora; and $\mathcal{G}_t$ is the subset of $\mathcal{G}$ where the term t appears at least once.

It is important to notice that the basic formulation of *tf-idf* used as inspiration by Kim *et al.* proposal is not as robust as the one of Bell *et al.* (Eq. 3). For instance, if a term t appears in all corpora, the *IDF* part of Eq. 6 will become 0, and therefore, such term t will have a *TF-IDF* index also equal to 0, *i.e.*, it will be considered less relevant than any other term, regardless its number of occurrences. Another important difference between Equations 3 and 6 is that Bell *et al.*'s (Eq. 3) uses the log of absolute term frequency in the *tf* part, while Kim *et al.*'s (Eq. 6) considers directly a relative term frequency.

III. Proposed Index

The goal of all indices presented in the previous section is to obtain higher numeric values for terms that are relevant to a given domain, or for more recent knowledge engineering tasks [14], [15], terms that are suitable candidates for concepts of an ontology. The raw term absolute frequency (Eq. 1), obviously indicates a relevance, since a term that is very frequent is likely to be important to the domain. Also the *tf-idf* (Eq. 3) index can be an indicative of relevance, since terms that are very distinctive to some documents of the corpus are also likely to be representative of the domain.

The *tds* (Eq. 4), *thd* (Eq. 5) and *TF-IDF* (Eq. 6) indices have better chance to identifying concepts of a domain because they use contrasting corpora. Nevertheless, these indices adopt different approaches that reveals distinct empirical initiatives to tackle the concept identification problem.

The first difference is how these indices take the occurrences of terms in the domain corpus into account. The *tds* (Eq. 4) and *TF-IDF* (Eq. 6) indices compute a relative frequency of the term, since the term probability ($p_t^{(c)}$) for *tds* and the *tf* part for *TF-IDF* are computed as the absolute frequency divided

by the total number of terms in the domain corpus. The *thd* (Eq. 5) index, however, computes a normalized rank value, that, even though being computed according to the absolute frequency, delivers a linear relation[1] among all terms.

The second difference resides in the effect brought by the occurrence of terms in contrasting corpora. The *tds* (Eq. 4) index penalizes the terms that occurs in the contrasting corpora by dividing its probability in the domain corpus by the probability in the contrasting corpora. The *thd* (Eq. 5) index also penalizes the terms that occurs in the contrasting corpora, but in this case it subtracts the normalized rank value in the domain corpus by the normalized rank value in the contrasting corpora. The approach for *TF-IDF* (Eq. 6) index is quite different, since it rewards the terms that are unique to the domain corpus by multiplying the relative frequency by the log of the number of corpora. Such reward decreases as the term appears in other contrasting corpora, until it drops to 0 when the term appears in all corpora. It is important to notice that this reward decreases proportionally to the number of corpora, but it is independent to the number of term occurrences in contrasting corpora.

We propose a new index to estimate the term relevance to a domain following the same idea of contrasting corpora, but we propose differences in the way term occurrences in the domain corpus are taken into account, and most of all, in the effect brought by occurrences in the contrasting corpora. Specifically, we propose a representation to this effect called "disjoint corpora frequency" (*dcf*), which is a mathematical way to penalize terms that appear in contrasting corpora proportionally to its number of occurrences, as well as the number of contrasting corpora in which the term appears.

A. Term frequency, disjoint corpora frequency - tf-dcf

Our proposal, like other contrasting corpora approaches, is based on a primary indication of term relevance and a reward/penalization mechanism. The basis of *tf-dcf* index is to consider the absolute frequency as the primary indication of term relevance. Then, we choose to penalize terms that appear in the contrasting corpora by dividing its absolute frequency in the domain corpus by a geometric composition of its absolute frequency in each of the contrasting corpora. The *tf-dcf* index is mathematically expressed, for term t in corpus c, considering a set of contrasting corpora $\mathcal{G}$, as:

$$\textit{tf-dcf}_t^{(c)} = \frac{\textit{tf}_t^{(c)}}{\prod_{\forall g \in \mathcal{G}} 1 + \log\left(1 + \textit{tf}_t^{(g)}\right)} \tag{7}$$

The choice of absolute frequency as primary indication of term t relevance for corpus c, instead of using a relative frequency (like *tds* and *TF-IDF*) or term rank (like *thd*), aims the simplicity of the measure for two main reasons:

- We do not consider that there is a need for linearization brought by the use of the term rank, as for *thd* index, nor there is a need to make explicit the normalization according to the corpus size, as for *tds* and *TF-IDF*; In fact, any normalization according to the corpus size still remain possible after the *tf-dcf* computation;
- We consider that keeping a relation with the absolute term frequency preserves the index intuitive comprehension, since the *tf-dcf* index numeric value will be smaller (if the term appears in the contrasting corpora) or equal to *tf* (if the term does not appear in the contrasting corpora).

The geometric composition of absolute frequencies in the contrasting corpora chosen to express the penalization, *i.e.*, the divisor in Eq. 7, tries to encompass the following assumptions:

- The number of occurrences of a term in each of the contrasting corpora is distributed according to a Zipf law [23], and to correctly estimated this importance, a linearization of this number of occurrences must be made;
- A term that appears only in the domain corpora should not be penalized at all, *i.e.*, terms that do not occur in the contrasting corpora must have the divisor equal to 1; and
- A term that appears in many corpora is more likely to be irrelevant to the domain corpus, than those terms that appears in fewer corpora.

Because of the first assumption, we choose to consider a log function to compute the absolute frequency in each contrasting corpora ($\textit{tf}_t^{(g)}$). This decision follows the same principle adopted in the original proposition of *tf-idf* measure proposed by Robertson and Spärck-Jones [16].

The second assumption made us adapt this log function with the addition of value 1 inside and outside the log function in order to deliver a value equal to 1 when the number of occurrences of a term in a contrasting corpora is equal to 0. This decision follows the same principle adopted to the Bell *et al.* [21] to express their formulation of *tf-idf* measure.

Finally, the third assumption led us to employ the product of the log of occurrences in each contrasting corpora. The product represents that the importance of occurrences grows geometrically as it appears in other corpora. In fact, according to our formulation a term is more likely to be irrelevant for a domain corpus when it appears few times in many multiple contrasting corpora, than if it appears many times in just few contrasting corpora. Additionally, the product is compatible with the idea to have a divisor equal to 1 when a term appears only in the domain corpus.

IV. Practical Results

The practical application of the proposed index is meant to illustrate its effectiveness and some basic characteristics of *tf-dcf* according to the contrasting corpora used. The experiments were conducted over Brazilian Portuguese corpora, using a linguistic-based term extraction tool to provide terms and their number of occurrences. Nevertheless, corpora in any language submitted to any kind of extraction could be employed without any loss of generality.

[1]It is important to recall, that the distribution of absolute frequency values is likely to follow a Zipf law [23], *i.e.*, the most frequent term is likely to have twice the number of occurrences as the second, three times the number of occurrences of the third, and so on.

A. The chosen corpora

The chosen test bed was one corpus from Pediatrics domain [24] with 281 documents from The Brazilian Journal on Pediatrics. This corpus (PED) was chosen because of the availability of reference lists of relevant terms.

Four other scientific corpora were used as support for definition of specific Pediatrics terms. These corpora have approximatively 1 million words each and their domains are: Stochastic modeling (SM), Data mining (DM), Parallel processing (PP) and Geology (GEO) [25]. Tab. I summarizes the information about these corpora.

Table I
CORPORA CHARACTERISTICS.

		documents	sentences	words
Pediatrics	PED	281	27,724	835,412
Stochastic Modeling	SM	88	44,222	1,173,401
Data Mining	DM	53	42,932	1,127,816
Parallel Processing	PP	62	40,928	1,086,771
Geology	GEO	234	69,461	2,010,527

B. Extraction tools

The extraction procedure of terms and their frequencies was made by a two step process. First the documents were annotated by the Portuguese parser PALAVRAS [26]. Then the PALAVRAS output, *i.e.*, a set of TigerXML files, was submitted to ExATOlp term extractor [27].

PALAVRAS and ExATOlp joint application delivers high quality term lists, since the extracted terms are noun phrases found in the corpus and their frequencies. The extracted noun phrases were filtered according to ExATOlp heuristic rules aiming the output of noun phrases as meaningful as possible. These heuristics goes from simple exclusion of articles, but also quite ingenious ones like detection of implicit noun phrases[2] [28].

C. Extracted terms and reference lists

The extracted terms were divided in two lists, bigrams and trigrams. Single terms and those with more than three words were not considered in the evaluation, since they were not included in the hand-made reference list constructed by terminology laboratory TEXTECC (http://www6.ufrgs.br/textecc/).

The reference lists were produced by a careful and laborious process that involved terminologists, domain specialists (Pediatricians) and academic students. These lists are available for download at TEXTECC website and they have been used for practical applications including glossary construction, translation aid, and even ontology construction. These reference lists are composed by 1,534 bigrams and 2,660 trigrams and they can also be consulted at http://ontolp.inf.pucrs.br/ontolp/downloads-ontolplista.php.

The full extracted term lists delivered by PALAVRAS and ExATOlp for the Pediatrics corpus were composed by 15,483 distinct bigrams and 18,171 distinct trigrams. To each of these lists the computed indices were:

- *tf* the absolute term frequency (Eq. 1);
- *tf-idf* the term frequency, inverse document frequency (Eq. 3) with the basic formulation from Bell *et al.* [21] aggregated with the sum proposed by Manning and Schütze [8] to be used as an example of index not using contrasting corpora;
- *tds* the term domain specificity (Eq. 4) proposed by Park *et al.* [11];
- *thd* the termhood (Eq. 5) proposed by Kit and Liu [12];
- *TF-IDF* the term frequency, inverse domain frequency (Eq. 6) proposed by Kim *et al.* [13]; and
- *tf-dcf* the term frequency, disjoint corpora frequency (Eq. 7) proposed in the previous section of this paper.

D. The impact of different measures on frequent terms

Observing in detail some terms in the extracted lists it is possible to have a better understanding of the effect of each index, and, therefore, the benefits brought by *tf-dcf* as relevance index. Tab. II presents the top ten frequent terms, *i.e.*, the ten terms with more absolute occurrences in the Pediatrics corpus. In this table it is shown the number of occurrences of the term in each corpora, *i.e.*, Pediatrics (PED), Stochastic modeling (SM), Data mining (DM), Parallel processing (PP) and Geology (GEO). Additionally, the last column (ref. list) indicates wether the term belongs ("IN") or not ("OUT") to the reference list.

Table II
OCCURRENCES FOR FREQUENT TERMS FROM PEDIATRICS CORPUS.

term in Portuguese	(translation)	PED	SM	DM	PP	GEO	ref. list
aleitamento materno	(breast feeding)	306	0	0	0	0	IN
recém nascido	(new born)	299	0	0	0	0	IN
faixa etária	(age slot)	234	0	6	0	0	IN
presente estudo	(current study)	188	4	1	0	67	OUT
leite materno	(mother's milk)	163	0	0	0	0	IN
idade gestacional	(gestacional age)	144	0	0	0	0	IN
ventilação mecânica	(mechanical ventilation)	138	0	0	0	0	IN
via aérea	(airway)	120	0	0	0	0	IN
pressão arterial	(blood pressure)	112	0	0	0	0	IN
sexo masculino	(male sex)	109	7	8	0	0	OUT

The same ten more frequent terms are also shown in Tab. III with the values for the six presented indices, as well as their rank according to each of them. For example, in the third row of Tab. III, the term "faixa etária" ("age slot" in English) belongs to the reference list and it is ranked as the third term in the lists sorted with the term frequency (*tf* - Eq. 1) and with the term frequency, inverse document frequency (*tf-idf* - Eq. 3). In the lists sorted with the other indices this term is ranked as the $13{,}281^{th}$ (for *tds* - Eq. 4), the fourth (for *thd* - Eq. 5), the sixth (for *TF-IDF* - Eq. 6), and the fifteenth (for *tf-dcf* - Eq. 7).

Observing the rank differences between the lists sorted with the term frequency (*tf* - Eq. 1) and the term frequency, inverse document frequency (*tf-idf* - Eq. 3), we noticed an important

[2]Implicit noun phrases are, for example, "sick children" and "healthy children" that can be extracted from the sentence "Sick and healthy children can be treated.".

Table III
ANALYSIS OF FREQUENT TERMS FROM PEDIATRICS CORPUS.

term in Portuguese (translation)	*tf* Eq. 1	*tf-idf* Eq. 3	*tds* Eq. 4	*thd* Eq. 5	*TF-IDF* Eq. 6	*tf-dcf* Eq. 7
aleitamento materno (breast feeding)	306 1^{st}	199.18 1^{st}	1.00 1^{st}	1.00 1^{st}	0.0027 1^{st}	306.00 1^{th}
recém nascido (new born)	299 2^{nd}	184.98 2^{nd}	1.00 1^{st}	0.99 2^{nd}	0.0027 2^{nd}	299.00 2^{nd}
faixa etária (age slot)	234 3^{rd}	169.18 3^{rd}	0.98 $13{,}281^{st}$	0.93 4^{th}	0.0012 6^{th}	61.46 15^{th}
presente estudo (current study)	188 4^{th}	167.78 4^{th}	0.73 $13{,}429^{th}$	0.50 42^{nd}	0.0002 57^{th}	3.99 $1{,}276^{th}$
leite materno (mother's milk)	163 5^{th}	143.23 5^{th}	1.00 1^{st}	0.94 3^{rd}	0.0015 3^{rd}	163.00 3^{rd}
idade gestacional (gestacional age)	144 6^{th}	135.60 7^{th}	1.00 1^{st}	0.93 5^{th}	0.0013 4^{th}	144.00 4^{th}
ventilação mecânica (mechanical ventilation)	138 7^{th}	140.85 6^{th}	1.00 1^{st}	0.91 6^{th}	0.0012 5^{th}	138.00 5^{th}
via aérea (airway)	120 8^{th}	132.72 8^{th}	1.00 1^{st}	0.90 7^{th}	0.0011 7^{th}	120.00 6^{th}
pressão arterial (blood pressure)	112 9^{th}	93.27 19^{th}	1.00 1^{st}	0.88 8^{th}	0.0010 8^{th}	112.00 7^{th}
sexo masculino (male sex)	109 10^{th}	125.70 9^{th}	0.88 $13{,}318^{th}$	0.77 14^{th}	0.0003 35^{th}	6.53 543^{th}

similarity. The only significantly change occurs for the term "pressão arterial" ("blood pressure") that drops from the 9^{th} to the 19^{th} position. However, this change does not correspond to a meaningful downgrade, since this term ("blood pressure") seems to be as relevant to Pediatrics as, for instance, "via aérea" ("airway"). In contrast, the quite generic term "presente estudo" ("current study") is not affected at all by *tf-idf*.

Observing the effect brought by the term domain specificity index (*tds* - Eq. 4), we realize the lack of precision, since it assigns an equally important rank to all terms that are not exclusive to the Pediatrics corpus. Consequently, the terms that appears in other corpora are cast out of any list of relevant terms, since, giving the contrasting corpora (SM, DM, PP and GEO), there is more than 13,000 terms appearing only in the Pediatrics corpus. The terms "faixa etária" ("age slot"), "presente estudo" ("current study") and "sexo masculino" ("male sex") are all ranked beyond the $13{,}000^{th}$ position.

The list sorted with the termhood index (*thd* - Eq. 5) shows the downgrade effect on the three terms appearing in the contrasting corpora (grey rows in Tabs. II and III). However, these terms are not sent very low, since even the term "presente estudo" ("current study"), which is very frequent in the contrasting corpora (72 occurrences), is downgraded only to the 42^{th} position.

The list sorted according to term frequency, inverse domain frequency index (*TF-IDF* - Eq. 6) shows a stronger effect than the termhood (*thd* - Eq. 5), since it is based on the number of contrasting corpora the term appear. In consequence, the term "faixa etária" ("age slot") drops to the sixth position because it appears also in the Data Mining corpus, while the term "presente estudo" ("current study") drops to the 57^{th} position because it appears in all corpora, but Geology.

It is important to call the reader attention that our proposed index (*tf-dcf* - Eq. 7) is the only one that takes into account both the number of occurrences in the contrasting corpora (as termhood and term domain specificity), and the number of corpora in which the term appears (as term frequency, inverse corpus frequency). For that reason, the downgrade effect in the list sorted according to our index is the stronger one. Our index casts out the term "presente estudo" ("current study") to the $1{,}276^{th}$ position, while it downgrades significantly the term "sexo masculino" ("male sex") to the 543^{th} position. In opposition, the term "faixa etária" ("age slot") is mildly downgraded from the third to the fifteenth position.

V. CONCLUSION

This paper presented a novel numerical index to estimate the relevance of extracted terms with respect to a specific domain. The inclusion of disjoint corpora frequency (*dcf*) component successfully improved the precision of extracted lists in comparison with the traditional *tf* and *tf-idf*, but also other indices based on comparison with contrasting corpora, namely term domain specificity [11], termhood [12] and term frequency, inverse domain frequency [13].

The proposed *dcf* approach was described here in composition with the absolute frequency (*tf*) and it has the advantage to keep an analogue semantic of the original absolute frequency index. If a given term does not appear in other corpora, its *tf-dcf* index will be equal to the term frequency, *i.e.*, only terms appearing in other corpora will be numerically downgraded. This is not the case of any of the other pre-existent measures.

Our proposal is the follow up to initial studies based on the comparison with contrasting corpora. Such intuitive idea was initially proposed during the last 10 years [10], [22], [29], [11], [12], [13], [15], but, at the authors best knowledge, our proposal is the first one to pay attention to an correct weighting of the influence of occurrences of terms in contrasting corpora.

Specifically, our *tf-dcf* index formulation consider the product of the log of the number of occurrences in other corpora as reductive factor for the domain corpus absolute term frequency. This choice is justified by the fact that term occurrences are likely to be distributed by a Zipf law [23]. In Park *et al.* [11] this fact was ignored. In Kit and Liu [12] this fact was approached by the rank difference. In Kim *et al.* [13] this fact was approached by term relative frequency and the logarithm in the *IDF* part. Therefore, our formulation seems to be mathematically more robust.

The main limitation of the current study is the lack of thorough experiments with other corpora. We had choose to limit our experiments to the studied corpora because there were no sign of availability of data sets previously employed by other authors. Nevertheless, since the objective of this paper is to propose the *tf-dcf* index, it remains as a natural future work the experimentation of our proposal to a statistically significant set of corpora. Such future work will demand the analysis of the proposed *tf-dcf* index, in comparison with other indices, in terms of numerical measures, as precision, and the gathering of corpora and corresponding lists of references.

Another valid future work is the study of heuristics to choose a good cut-off point to apply in the extracted term lists. With the use of a simple index of relevance, like the absolute term frequency, the cut-off point choice seems simple, since it is enough to define a minimum number of term occurrences. However, with a more sophisticated one, as the *tf-dcf* index proposed here, it is a little less obvious to define a meaningful and effective cut-off point [30].

Temporal Term Frequency Analysis of Technology

Aviv Segev
Department of Knowledge Service Engineering
KAIST
Daejeon, Korea
aviv@kaist.edu

***Abstract* — The paper suggests a method for analyzing cause and effect of technology. The process can be identified as a flowchart of technologies over time. The method analyzes term frequency of technological terms in patents to identify the prior technologies that lead to a new technology and the identified technology outcome. The analysis was performed on 4,354,054 patents from the US Patent Office from 1975 until today.**

I. INTRODUCTION

The problem of identifying new technologies has implementations in the area of stock prediction, technology venture funds, and government research investment planning. The current work presents a method for analyzing technology trends and identifying the cause and effect of a given technology. The method is based on temporal term frequency analysis and identification of similar technologies that present exponential growth. These technologies are compared to the analyzed technology to identify cause and effect according to the prediction ability of each technology based on their coefficient of determination value over a delta time difference from the original technology.

II. RELEATED WORK

Previous work in Information Retrieval (IR) has targeted patent documents. During the NTCIR Workshops [1], [2] a patent retrieval task was organized in which a test collection of patent documents was produced and used to evaluate a number of participating IR systems. In the NTCIR-3 Patent Retrieval Task, participant groups were required to submit a list of relevant patent documents in response to a search topic consisting of a newspaper article and a supplementary description. Search topics were in four languages. All topics were initially written in Japanese and were manually translated into English, Korean, and traditional or simplified Chinese. In NTCIR-4 the search topic files were Japanese patent applications that were rejected by the Japanese Patent Office. The English patent abstracts were human translations of the Japanese patent abstracts. Currently, the NTCIR tasks aim at machine translation of sentences and claims from Japanese to English. Other work analyzed Japanese-English cross-language patent retrieval using Kernel Canonical Correlation Analysis (KCCA), a method of correlating linear relationships between two variables in the kernel defined by feature spaces [3].

The Workshop of Cross-Language Evaluation Forum (CLEF 2009) [4] gave separate topic sets for the language tasks, when the document language of the topics was English, German, and French. CLEF-IP included Prior Art Candidate Search task (PAC) and Classification task (CLS). Participants in the PAC task were asked to return documents in the corpus that could constitute prior art for a given topic patent. Participants in the CLS task were given patent documents that had to be classified using the International Patent Classification codes. In addition, evaluations were performed on chemical datasets in chemical IR in general and chemical patent IR in particular. A chemical IR track in TREC (TREC-CHEM) [5] addressed the challenges in chemical and patent IR.

Previous work analyzes automatic patent retrieval, while this work describes a method that involves a manual decision process assisted by an automatic suggestion of relevant concepts related to patent technology evolution over time.

III. TECHNOLOGY TEMPORAL ANALAYSIS METHOD

The technology temporal analysis method is based on analyzing a large data set of technology-based documents such as patents. The data set is assumed to be organized sequentially by date of issue. The method includes identifying the main terms related to a given, the next step involves extracting the sequential graph describing the frequency of the terms, followed by an elimination of graphs with different behavior, and finally identification of graphs with closest delta distance that represent the cause and effect of the analyzed technology.

A. Extracting Related Terms

The first step identifies all the terms related to the technology being analyzed. A method to extract the relevant terms can include extracting all of the linked terms that appear in the technology term description in Wikipedia. The extracted term list can be filtered and additional terms can be added manually.

B. Extracting All Graphs

The second step involves extracting values that represent term frequency in a large data set of documents that can represent the different technologies. An example of such data sets can be patents or research publications. The term frequency uses simple keyword search in either the subject, abstract, full description of the document, or all of these options. The time slot being analyzed usually involves a year since smaller time slots can entail high incidents seasonal noise. The term frequency has to be weighted since the

extraction searches for an increase in term frequency rather than just elevated values. The weight method analyzed used $max_j\ (tf_j)$ value on all technology term frequencies. Other terms such as $(tf_i - tf_{i-1})/max_j\ (tf_j)$ were also evaluated. An example of the results of term frequency of related terms to *email* technology is presented in Figure 1 (top).

C. Elimination Process

The elimination process includes identifying all the graphs that do not represent exponential growth of a new technology. The following types of regression functions were analyzed to identify the best fitting function for technology growth including linear, quadric, cubic, quadratic, exponential, and mixed. The best matching function based on a predefined set of sample of existing technologies was an exponential regression and the values selected as coefficients were based on the average values of the sample technology functions:

$$y= 0.055558046* 1.160450815^x -0.084088217$$

For all technologies, the coefficient of determination R^2 was calculated as the square of the sample correlation coefficient between the outcomes and their predicted values in the matching function y. If the value of $R^2<0.94$, then the technology was discarded as not representing new technology exponential growth.

D. Graph Distance

Once all of the exponential growth technologies have been identified, the next step includes classifying technologies that are cause, effect, or non-related to the technology being analyzed. The coefficient of determination is used again to identify the distance between the technology being analyzed and all other technologies. A similar process is used based on predefined Δt time difference. The Δt represents the possible prediction time of one technology affected by the other. The last step identifies the number of data samples that appear before and after the analyzed technology. If the majority of the data samples are before, then the current technology is a predictive cause of the current technology (Figure 1 - middle). If the majority of samples are after the technology, then the current technology is a cause of the new technology, or an effect of the analyzed technology (Figure 1 - bottom).

IV. Technology Temporal Analysis Experiences

The analysis was performed on 4,354,054 patents from the US Patent Office from 1975 until today. An example of *email* technology is displayed in Figure 1. The method allows an identification of contributing technologies which led to the fast growth of the *email* technology. In addition, the method enables the elimination of possible irrelevant technologies that existed at the time but did not directly contribute directly to the analyzed technology. Additional work is currently being performed to create an ongoing flow chart of all technologies that presented exponential growth and their contribution to other new technologies.

Enhancing Syntactic Models in the Set-Phrase Machine Translation

A. Khoroshilov, E. Kozerenko
Institute of Informatics Problems of the Russian Academy of Sciences, Moscow, Russia

Abstract - *The paper focuses on the issues of introducing syntactic expertise into the example-based machine translation framework largely based on automatically compiled set-phrase dictionaries and translation memory. The functionally motivated syntactic semantic rules are incorporated into the heuristic language processing tools. Machine learning techniques are used for expansion of seed rules and templates.*

Keywords: Machine Translation, Syntax, Semantics, Set-phrase Dictionaries, Machine Learning, Translation Memory

1 Introduction

The paper deals with the problem of enhancing the example-based (set-phrase) machine translation by linguistic expertise representing the syntactic rules of parse and transfer of the whole sentence structures. The main thesis of the set-phrase translation is the statement that the concept names in texts are determined by word combinations rather than single words, the meaning of units of higher level cannot be fully reduced to the sum of meanings of the lower level units comprising them [1-6]. Usual approaches to machine translation concentrate on the study of words and modes of their combinations, being unaware of the two-level structure of languages and its crucial implications both for linguistic theory and for the construction of the models for machine translation. A greater part of the expertise of our system resides outside the lexicon, in a body of knowledge about how meanings and operations on meanings are distributed with reference to the symbolic expressions of language.

The basic method of the set-phrase machine translation is single-step compiling of bilingual frequency dictionaries of words and set-phrase word combinations (Fig. 1).

The systems of machine translation of texts simulate operation of a human translator. Their efficiency depends on how the nature of language operation and mentation are taken into account, and this nature has not yet been adequately studied. Therefore, developers, dealing with the problem of machine translation, must take into account the experience in international communication and translation that has been accumulated by human and machine translators. That experience testifies that in the process of text translation the phraseological word combinations expressing the concepts rather than single words are the basic units of sense. The concepts are the elementary intellectual images, by the use of which it is possible to create more complex intellectual image corresponding to translated text.

In this case, the single words were considered to be basic units of sense expressing the concepts, and the sense of larger speech units (word combinations, phrases and utterance-length units) was supposed to be determined on the base of the sense of words comprising them. In dictionaries the use of word combinations along with single words was also admitted. But these combinations were mainly the idiomatic expressions, and their amount in dictionaries of machine translation systems was negligible in comparison with the amount of single words. Statistical machine translation allows to select the variant for the word combination translation based on matching frequency of the language pair elements.

A weak point of statistical systems is partial or total absence of a mechanism of grammatical rules analysis for the source and target languages. A system which does not analyze the text from the point of view of grammar is unable to release the correct translation of semantically complex texts.

2 Method and implementation of the set phrase machine translation

The starting point of our semantic operators establishment is the phrase structure level. The structures are segmented on the semantic principle of functional transferability, i.e. these structures should be "translatable" which is not always the case if the existing phrase structure grammars are employed. The orientation at the semantic-syntactic and mainly word-by-word translation alone could not lead to the solution of the basic problems of machine translation, because within language and speech the sense of units of higher level, as a rule, cannot be reduced or fully reduced to the sense of the lower level units comprising them. Almost all known systems related to traditional machine translation systems, developed in that direction. Later the developers of traditional systems began to include more terminological word combinations into their dictionaries.

The concept of translation memory (sentence memory) appeared as an alternative to traditional machine translation. That concept can be regarded as an attempt to realize the

idea of Japanese computer scientist Makoto Nagao, that in the process of machine translation it is necessary to use the large corpora of parallel texts, earlier translated by humans [7-10]. A more adequate approach is based on the concept of statistical machine translation (statistics-based machine translation), which is defined by some authors as a "sort of machine translation of texts, based on comparing of large corpora of language pairs". In contrast to traditional machine translation, statistical approach is based on statistical computation of matching probability and does not use the linguistic algorithms. Large corpora of parallel texts are necessary for operation of this system. A statistical mechanism of text analysis is used in the process of translation. This mechanism allows to select the variant for the word combination translation based on matching frequency of the language pair elements. A weak point of statistical systems is partial or total absence of a mechanism of grammatical rules analysis for source and target languages.

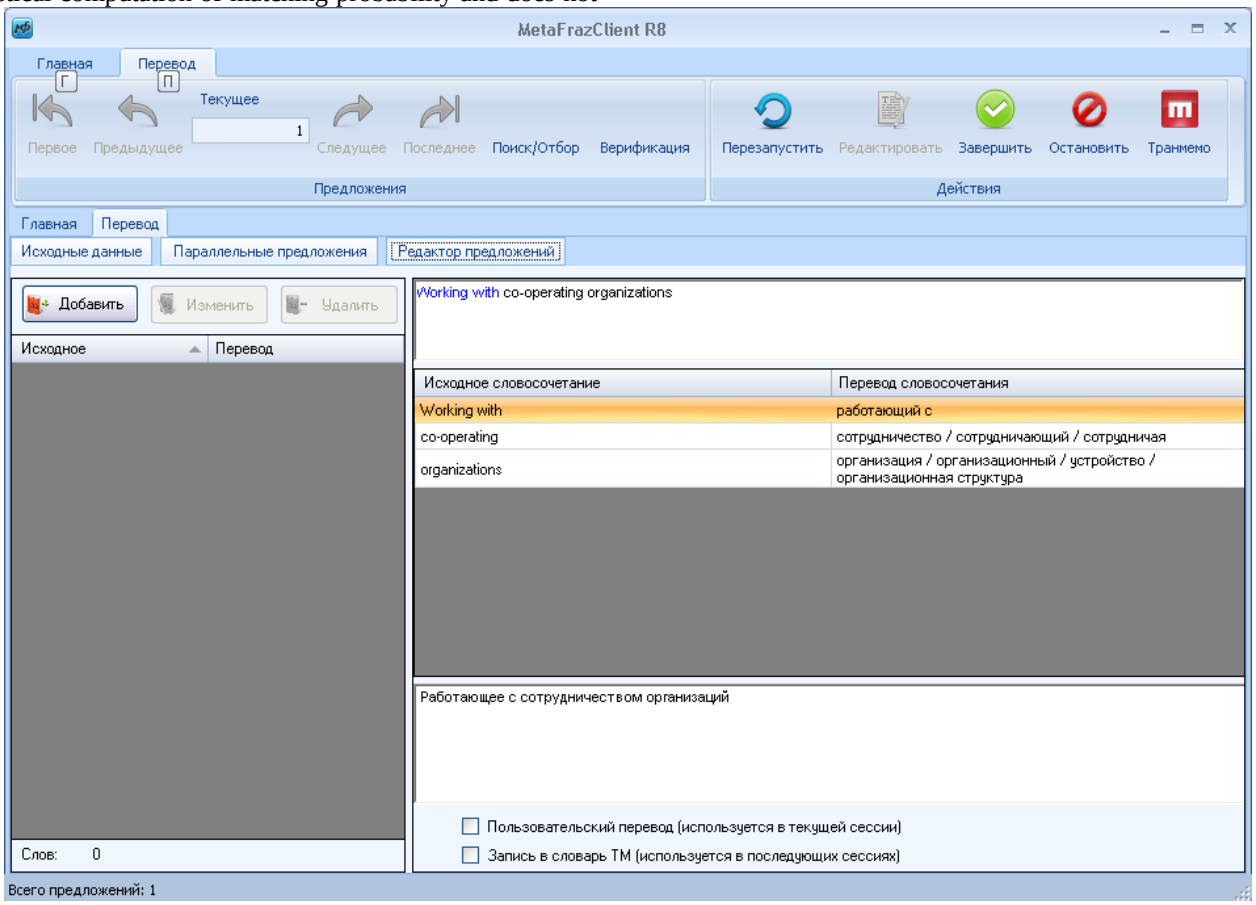

Fig. 1. The MetaPhrase translation system environment: set phrases with translations from parallel texts.

3 Translation memory and example-based translation

A translation memory, or TM, is a database that stores so-called "segments", which can be sentences, paragraphs or sentence-like units (headings, titles or elements in a list) that have previously been translated, in order to aid human translators. The translation memory stores the source text and its corresponding translation in language pairs called “translation units”. The idea to create machine translation systems on the base of previously translated texts presented in the form of "large corpora of language pairs" is not objectionable. It can be realized in different ways. The first way provides text translation with the use of statistic analysis of large corpora of bilingual texts in the process of translation. This way is "statistical machine translation". The second way is connected with a single-step compiling of bilingual frequency dictionaries of words and phraseological word combinations. The creators of the systems of the set-phrase machine translations follow the second way. This way excludes the fatal dependence of the translation process on availability of large volumes of parallel texts and quality of their translation.

The systems of phraseological machine translation are based on the theoretical concept, the main thesis of which is a statement that the concept names in texts are determined by word combinations rather than single words. Therefore, in the process of text translation from one language to another, it is necessary to use the phraseological combinations expressing the concepts, relationships between concepts and the typical situations rather than single words

as basic units of sense. The single words may also be used if the translation with the help of the phraseological word combinations fails.

In compliance with that thesis, the system of phraseological machine translation must comprise the knowledge base of translation equivalents for most frequent phrases, phraseological combinations and single words. In the process of text translation the system should use the translation equivalents stored in its knowledge base in the following order: at first, an attempt to translate the successive sentence of the source text as the integral phraseological unit is made; then, if this attempt fails, words combinations being a part of the sentence should be translated; and, finally, if both above-mentioned attempts fail, word-by-word translation of the text fragments is performed. The fragments of the target text translated with the use of all three approaches, must grammatically agree with one another with the help of procedures of morphological and syntactic synthesis). Let's give consideration to this conception in detail. It is necessary to apply the following principles in the process of development of phraseological machine translation systems:

1. The phraseological units (word combinations and phrases).are basic language and speech units, which should be primarily included in the computerized dictionary.

2. Along with the phraseological units composed of continual word sequences, so called "speech models", phraseological units with slots that may be filled with different words and word combinations, generating meaningful segments of speech, may be used in machine translation systems.

3. Real texts, without regard to their subject area, tend to be polythematic, if they have sufficiently large size. These texts differ from each other not so much by word stock as by probability distribution of occurrence of different words and word combinations from national word stock in them. Therefore, the computerized dictionary designed for translation of the text belonging to a single subject area must be polithematic, not to speak of translation of texts belonging to different subject areas.

4. Systems of phraseological translation need high-volume computerized dictionaries. Such dictionaries should be created on the base of computer-aided processing of parallel texts - bilingual texts, which are translations of each other, and in the process of translation system operation.

5. Along with the main high-volume polithematic dictionary, it is also reasonable to use a set of additional small-volume highly specialized dictionaries in systems of phraseological machine translation. The additional dictionaries should only contain information missing from the main dictionary (for example, data on priority translation equivalents of word combinations and words for different subject areas, if these equivalents are not equal to priority translation equivalents of the main dictionary).

6. The main means for solution of the problem of words polysemy in phraseological translation systems is their use in phraseological word combinations. The additional means is a set of additional specialized dictionaries, where the priority translation equivalent specific for subject area in question is identified for each multiple-meaning word or word combination.

7. The procedures of morphological and syntactic analysis and synthesis of texts that are built on the base of linguistic analogy may play a major role in the systems of phraseological machine translation of texts. These procedures allow us to give up storing large amounts of grammatical information in dictionaries and generate it automatically in the process of translation when the need arises. They make the translation system open - able to process texts with "new" words.

8. Along with text translation in automatic mode, it is reasonable to provide for an interactive mode of operation for the systems of phraseological machine translation. In that mode the user should have potentiality to intervene in the translation process and adapt the additional computerized dictionaries for the subject area of the translated text.

4 Adult learning memory metaphor

Human cognitive systems are likely to be conditioned by principles of efficiency. It is best to concentrate on frequency in search for repeating patterns. There is a clear theoretical justification in associationist psychology for regarding frequency as an important variable in learning. The importance of frequency was recognized in [11, 12, 13].

Actually, our approach takes into account the following principal conclusions:

- human language mechanisms employ a number of complementary techniques, the core being the demand for generalization which is presented in the system of grammar rules;
- the disambiguation process, as well as picking out the particular sense of a given language unit in a given context, is to a great extent similar to the way parallel texts in different languages are aligned, the “statistical mechanisms” incorporated into human brain being at work;
- operation by ready patterns which have been successfully learned at previous stages of a human language activity, and which are stored in the human memory without being subjected to further analysis. This mechanism is simulated in a number of modern machine translation systems, and is known as “translation memory”.

Hence, the computational simulation of language processing mechanisms should employ procedures for all these activities to be more adequate to the complicity of the task. The “adult learning memory” (ALM) means that the system will be supplied with the “adult rule kit” – a starter set of about 300 rules stating the structural semantic correspondences between source and target languages.

The machine translation technique will comprise analysis, transfer and generation across the functional –

categorial values of language units. The core set of language structures designed for the transfer will be upgraded taking into account the cases of categorial shifts and structural polysemy in accordance with the Generalized Nucleus Law [14].

The process of structural patterns recognition will be performed basing on the multiple transfer rule set and the probabilistic functional tree substitution grammar (PFTSG) [15]. New language patterns will be acquired with the employment of machine learning methods.

The rule system design is a sophisticated task, and will employ the following techniques:

"Didactic Expertise" (DE) which includes didactical competence and sufficient language structures coverage: singling out and stating first the most important (highly relevant) rules covering the systems of the source and target languages on the basis of functional similarity.

"Interpreter Expertise" (IE) consists in bridging the gap and establishment of correspondences between the source and target language structures. A very important interpretation technique employing the segmentation of structures will be carried out on the basis of the functional transfer principle. Segmentation and unification of utterances in the course of translation is a major task for human professional interpreters. The selectivity of languages as to the choice of specific characteristics of description of one and the same situation results in numerous distinctions, and one of the most crucial of them is the degree of particularity in conveying a referential situation. Therefore, a situation which in one language is described by means of one specific feature, in another language may require two or more characteristics.

5 Syntactic rules in digital dictionaries

Syntactic rules in the set-phrase machine translation are part of the dictionary enties representing the syntactic information as the sequeces of the categorial tags for the phrasal segments acquired by the system from parallel texts. At first glance, the machine translation concept offered by professor Makoto Nagao in 1984 [7-10] fundamentally differs from the concept, formulated by professor G.G. Belonogov [1-6] nine years earlier. But this is not true. Indeed, in the process of practical realization of Makoto Nagao's concept, it is difficult to imagine that the text written in any language is completely the same as another text written earlier and translated into foreign language. It is not to be expected that this text contains long fragments (chapters, paragraphs and etc.), that are the same as the fragments of the text written and translated earlier but, as our investigations showed, the continuous texts fragments including over ten words repeat on rare occasions - their total frequency doesn't exceed 1%. It is necessary to use only short sentences, single words and text fragments (word combinations) including less than 10-12 words. This is the semantic-syntactic phraseological translation (see Fig. 2).

Of course, along with the translation equivalents of the relatively short fragments of texts, it is possible to include the translation equivalents of longer fragments in the computerized dictionaries. But in this case one should keep in mind, that the computerized dictionaries will be filled with "dead" ballast, i.e. with the dictionary entries, which will be used on rare occasions or will not be used at all in the process of text translation.

When developing the systems of phraseological machine translation, most difficult and time-consuming problem is a problem of compiling sufficiently high-volume computerized dictionaries. The quality of translation depends on the volume of these dictionaries and on the quantity of the phraseological word combinations in them. And those volumes need to be sufficiently large to provide the good covering of texts.

It is known, that in modern languages of the world (for example, in Russian or English) the amount of different words exceeds one million, and the amount of concept names determined by word combinations exceeds hundreds of millions. The authors of this article came to this conclusion on the basis of many years' experience of the statistical study of texts. Confirmation of such viewpoint is the report of All-European terminological centre "Infoterm" (Vienna, Austria, 1998), in which it was found that in modern languages of the world, such as English and German, a total amount of different terms exceeds 50 million, and nomenclature of goods exceeds 100 million. It is well known, that the connected texts consist of not only terms and names of goods.

The computerized dictionaries of such volume cannot be created quickly, but as experience shows, it is possible to achieve satisfactory quality of translation at the first stage in the presence of only several millions of entries in dictionaries, at least 80% of which should be word combinations. In this case the polithematic texts have the coverage of about 99, 7%.

Thereafter, the volume of dictionaries must be constantly increased and with the growth in amount of phraseological combinations, the quality of machine translation should improve. This problem cannot be solved by manual methods. For its solution, a system of computerized compiling and maintenance of the computerized dictionaries was created.

The systems of phraseological machine translation should be orientated at translation of texts on business, science, technologies, politics and economy. Translation of literary texts is a more complex task. But success can be also achieved in this area in future, if modern technological means are used to compile huge phraseological dictionaries for these texts.

6 Well-formed nonterminals and dynamic rules

Conventional machine translation systems use rules as the knowledge. This framework is called Rule-Based Machine Translation (RBMT). The translation mechanism which retrieves similar examples from the database, adapting the examples to the new source text is called Example-Based Machine Translation (EBMT). Enhancment of the set-phrase translation with the syntactic parse and transfer rules consists in the process of grammar formalism design over the set of cognitive transfer structures. In our case a generative unification grammar will be employed incorporating the feature-value structures into the hybrid system of context-free (and partly context-sensitive) productions. The parse and generation will be performed on the basis of these rule systems. We assume a computationally practical approach of feature-valued head-driven phrase structure rules for all the languages included.

The further development of the rules set will be carried out on the basis of Semiotic Universal Grammar (SUG) principles: the ordering of the tree structures and the head features inheritance will be determined by the Nucleus Law (stating that the nucleus of a configuration takes on the function of this configuration on top of its own function of the nucleus of this configuration), and the multiple transfers will be supported by the typing strategy proposed in the SUG approach [14].

The rule systems for functional transfer [15] will comprise about 350 well-formed nonterminals : grammar rules capturing the paradigmatic syntactic structures of the Russian and English languges, and the dynamic rules represented in the SUG categorial grammar formalism will be automatically generated by the system in the course of operation and reflect the dynamic character of the actual speech (discourse).

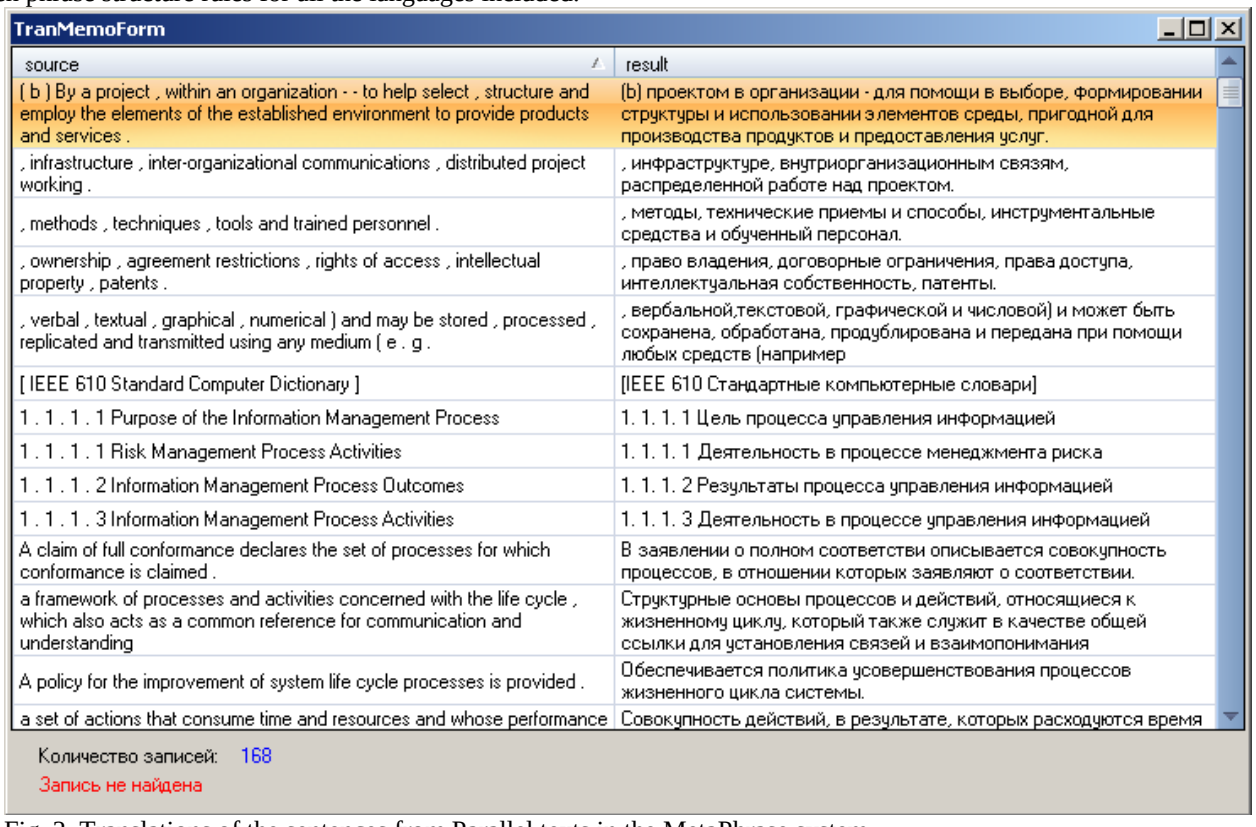

Fig. 2. Translations of the sentences from Parallel texts in the MetaPhrase system.

7 System performance

The implementation of the computerized phraseological text translation from one language into another must have three stages. At first stage, the semantic-syntactic analysis of the source text is carried out. During that analysis the text is split into sentences and then their conceptual and syntactic structure is determined. At the second stage (at the transfer stage) the concept names of the source text are substituted by the concept names in target language and the information on the syntactic structure of the source text is transformed into information required for the target text synthesis. At the final stage (the stage of semantic-syntactic synthesis of the target text) the text in the target language is formed.

The stages listed above are present in the process of translation of texts from any language to any other language, but their specific content for different pairs of languages has

a specific character. This specific character can be seen in procedures of semantic-syntactic analysis and synthesis of texts, which include the procedures of morphological, syntactic and conceptual analysis and synthesis [1-6].

The set-phrase machine translation based on the multilingual dictionaries will operate in the same way, but these systems should be complemented with the procedures of semantic-syntactic and conceptual analysis and synthesis of all languages, which will be included in the system. The authors developed the effective technology based on the use of principles of linguistic analogy for creation of these procedures.

The computerized dictionaries are the most important part of the systems of phraseological machine translation. They should have sufficiently large volume, in order to cover texts, and should contain mainly word combinations. The authors developed the original methods, algorithms and programs for automated compiling and maintaining dictionaries for the system of phraseological machine translation. In cooperation with other specialists, the large-volume Russian-English and English-Russian phraseological computerized dictionaries containing 2, 6 million dictionary entries each were compiled. These dictionaries cover 99, 7% of the lexical content of modern texts and they represent the powerful bilingual conceptual model for a wide range of fields of human activity .

8 Generation of dictionaries

The experience in creation of the large-volume Russian-English and English-Russian computerized dictionaries convinced authors, that Russian and English texts, which are translations to each other (for example, bilingual titles of the documents), can serve as the most reliable source for dictionaries compiling.

The compiling of the computerized dictionaries with the use of bilingual texts was carried out both manually and with the assistance of computers. The manual dictionary making requires huge expenditures of human labour. Therefore the authors of the article developed the procedure for automated dictionary making [3].This procedure is based on the hypothesis, that in numerous bilingual pairs of sentences, which are translations to each other and which contain the same word or word combination of one of the languages, the word or word combination of another language, which is the translation of this word or word combination has maximal occurence frequency.

The procedure was used for processing bilingual (Russian and English) titles of the documents from the databases of VINITI (All-Union Scientific and Technical Information Institute). In this case more than one million pairs of the document titles were processed. The computerized dictionaries of MetaPhrase system can be corrected and completed in the process of text translation in the interactive mode. In that mode there is an opportunity to identify the words and word combinations, which have no translation equivalents in the dictionary or these equivalents do not comply with the context or several equivalents are given, but the first equivalent does not comply with the context. These equivalents can be replaced by the equivalents complying with the textual context.

In compliance with the method described above, the large-scale experiment on compiling English-Russian frequency dictionaries on the base of the automated concept analysis of English and Russian titles of the documents, which are translations to each other, was carried out. For this purpose, the corpus of English titles of the polithematical documents and their Russian translations having the volume of about 2 million pairs of sentences from the VINITI's databases (1994-1999) were processed. The total volume of the corpus of texts is 390 Mb.

In the process of research three English-Russian frequency dictionaries were created:

1. The dictionary, items of which are the combinations of fragments of English and Russian titles of documents, between which the translation equivalents were determined with the assistance of MetaPhrase system;

2. The dictionary, items of which are fragments of titles of documents, between which the translation equivalents were not determined, but they are surrounded by the other fragments, between which such equivalents were determined , or by signs of beginning or end-of-the title;

3. The dictionary, items of which are fragments of English and Russian titles of documents, between which translation equivalents were determined on the initial stage of titles processing.

The first frequency dictionary includes bilingual phraseological word combinations containing 2 to 16 words. It had 3.127.363 dictionary entries.

The value of the dictionary in question is that it contains translation equivalents between English and Russian fragments of titles of documents, which are longer than their fragments selected at the first stage of conceptual analysis of titles. Each of the newly formed dictionary entries practically has just one translation version of English word combination (the percentage of dictionary entries having more than one version of translation is less than 0.1).

The second frequency dictionary includes translation equivalents between fragments of titles of documents that were not found at the initial stage of conceptual analysis of these titles. This dictionary contains 1.825.612 dictionary entries. The most frequent dictionary entries have the frequency of 1.008, and infrequent dictionary entries have the frequency equal to one. 87% of dictionary entries have the frequency equal to one. A spot-check of the dictionary showed that about 50 % of translation equivalents were incorrect. The quantity of such translation equivalents can be reduced at the final stage of dictionary making, if the procedure of semantic-syntactic checking is applied. After that, the dictionary must be edited by humans.

The third frequency dictionary contains translation equivalents between fragments of English and Russian titles

of documents that were found at the initial stage of processing of these titles. It contains 387.025 dictionary entries. The most frequent dictionary entries have the frequency of 4.985, and most infrequent dictionary entries have the frequency equal to one. 56% of dictionary entries had the frequency equal to one.

This dictionary contains only translation equivalents of English concept names, which are found in Russian titles of documents. Therefore, it proved to be tuned to the subject field of translated titles. It allows to consider the compiling procedure of such a dictionary as a means for automated creation of thematically oriented dictionaries.

9 Conclusion

The modern multilingual machine translation systems should be based on set-phrase translation enhanced by functionally motivated grammar. The extensive application of the means for automation allowed the authors to essentially reduce expenditures of human labour in the process of creation of the MetaPhrase system, and therefore, to reduce the creation cost of such systems. The main method for syntactic model enhancement in the set-phrase machine translation is including well-formed non-terminals in the general system of sentence analysis. The non-terminals constitute the complete parse tree of a sentence comprising set-phrase models. The dynamic formation of syntactic structures is supported by alternative categorial grammar parse on the basis of the rules dynamically extracted from parallel corpora.

Further research and development is connected with the expansion and semantic structuring of dictionaries and syntactic transformations introduction. The synergistic approach built on the joint employment of the rule-based and example-based approaches will provide new insights into the language processing theory and practice. This will also be important in developing more efficient educational programs for computer science and computational linguistics courses.
