Fuzzy Logic Based Sensor Skin for Robotic Applications

E. Meister, I. Zilberman, and P. Levi
Institute of Parallel and Distributed Systems, University of Stuttgart, Germany

Abstract— *Tactile sensors play an important role in many robotic applications providing information about shape, roughness, frictions and acting forces. However, it is challenging cover large robots with tactile sensors. In this paper we introduce a modular tactile sensor skin built on master and slave principle. The structure of the sensor skin was inspired by the biological multi layered skin from humans. Modular design principle allows covering different flat and rough robot geometries. The skin is able to detect tactile and pressure sensor values and is therefore applicable to different applications. Fuzzy logic based data fusion method allows the input values to be fuzzy while receiving numerical values as the output. This concept reduces the number of required sensor to a minimum and consequently also the computational effort and production costs.*

Keywords: Tactile sensing; Artificial Sensor Skin; Fuzzy logic; Modular Master-Slave design.

1. Introduction

Over the past view decades, the attitude towards robots and their acceptance in our environment has changed. Robots are stepwise bridging the gap between being a pure executive machine and becoming fully autonomous systems that are capable to fulfil tasks in our daily life or in structural manufacturing environment without human intervention. To achieve this goal, intelligent sensors play an important role providing the capabilities to sense the environment and the internal states of the robot. Inspired by humans and mammals with visual, auditory, somatosensory, gustatory and with the olfactory sensing capabilities, in robotics these sensory systems are imitating by equipping the robots with a variety of different sensors. Recently, the visual and auditory sensory systems have been experiencing tremendous progress and are already used in many robotic applications. The gustatory and the olfactory senses are difficult to imitate on robots because they are based on complex chemical reactions. However, the field of research related to an artificial somatosensory sensor systems covering the sense of touch, temperature, body position etc. are currently experiencing a rapid growth [4], [5], [16]. In a human body, the 'sense of touch' is provided by millions of skin receptors covering the whole body. In most cased we use hands to grasp and to recognize the objectt's properties such as shape, roughness, softness of the surface, size etc. Therefore, a lot of research in humanoid robotics is focusing on robotic hand applications [2],[13],[1]. However, in an unstructured or hazardous environment, humanoid shape of robot can be impractical or inefficient. Modular self-reconfigurable robots can solve the problem because they are able to reconfigure their shapes and hence are able to adapt to different situations and environments. Self-adaptivity is on the one hand advantageous but on the other hand implicates high complexity for coordination and control. Such systems strongly rely on information provided by different sensors. Therefore, the capability to recognize and sense the forces and pressures acting from each individual module is of great importance, but to sense big parts of the robots shape is still a technological challenge. We speak about artificial sensor skin when more than a few sensors cover a big robot surface. Such a sensor skin needs to fulfil several important requirements for the hardware design such as flexibility, sensitivity or reliability and therefore often requires a cost intensive realization on micro or nano level. Most of the existing artificial skin systems are based on resistive, capacitive, piezoresistive or magnetic transduction methods measuring forces, pressures or proximity. A good overview about the state-of-the-art of tactile sensors and artificial skin systems is given in [14],[9] or in [3].

The paper is organized in the following way. In Section 2 we explain the bio-inspired concept of modular sensor skin. Two different sensing principles, the optical and the capacitive method which are used in this concept are explained in this section. The modular hardware design is introduced in Section 3. In Section 4 we introduce the data processing and data fusion approach based on the Fuzzy logic theory. Implementation strategy as well as software structure are explained in Section 5. In Section 6 we show different experimental results and application scenarios. Sections 7 concludes the work and gives a short outlook.

2. Bio-Inspired Concept

The skin concept was inspired by the human skin, which consists of three layers: the water-repellent *epidermis* layer, protecting the body from infections and poisons, the *dermis* layer responsible for tensile strength, and the basement membrane layer *subcutis* providing protection against external physical influences and also acting as energy storage [6]. All layers are subdivided into more layers providing several types of mechanoreceptors, which react to different stimuli. Human skin combines multiple receptors in order to reach wide operation range. In artificial skin, this means that different kinds of sensor values need to be fused by applying

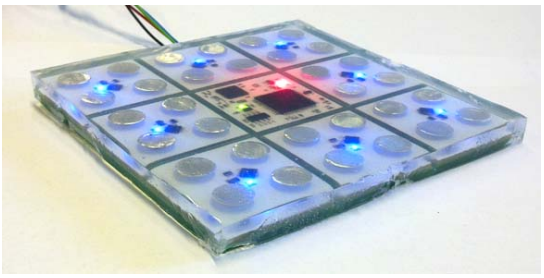

Fig. 1: Artificial sensor skin.

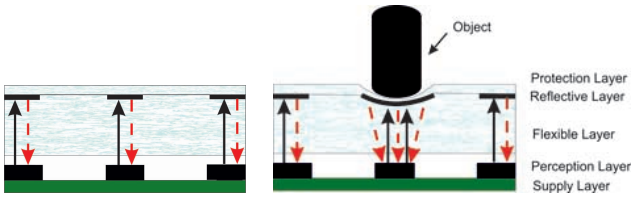
sensor fusion methods. Several sensor fusion techniques such as Fuzzy logic, Dempster-Shafer theory (DST), Kalman filter, Bayesian or Artificial Neural Networks (ANNs) are possible for systems with uncertainties. Fuzzy logic has been chosen as a favourite technique between all these options because it provides an adaptive method that can deal with uncertain data and allows good rule based approximation by absence of exact model of a system. As a result of different input values one numerical output value is calculated that can be directly related to a force or as a pressure value. Additionally, Fuzzy logic based approaches are not computationally and memory intensive and can run as a small stand-alone application on embedded devices. After clarifying the general concept idea for the skin several specifications have been done in order to reduce the complexity for the hardware design and realization:

1) Modularity and Scalability: The skin should be extendable to different structures and shapes.
2) Flexibility and Compliance: The skin hardware should be able to be applied on flat as well as on rough surfaces providing certain degree of bending. Additionally, the used material should provide compliance properties.
3) Master and Slave principle: The sensor pre-processing should be fused to one master unit avoiding to have microprocessors in each skin module, however at the same time keeping wiring as simple as possible.
4) Manufacturability and Maintenance: Should be easy to produce and to maintain without immense effort.
5) Robustness: The skin should resist against strong forces.
6) Adaptivity: Should be adaptive to diverse high and low pressure applications.
7) Attractiveness: The skin should give an attractive look to the robot because it is able to cover big parts of the robot.
8) Power Consumption: The high number of sensors requires that all sensors should consume as little power as possible.

The sensor skin (Figure 1) described in this paper is designed based on the dispersive reflexion principle of the infrared (IR) light in diffuse and flexible materials. The motivation was to utilise the material properties and hence to reduce the number of sensors. The level of reflexion is the quantity that can be related to the distance between the optical sensor and the reflexion layer and correspondingly between the acting load and the distance. The idea to use light as a parameter for measuring forces and loads was also used in [18] and in [12]. Ohmura et al. use visible light reflexions in urethane foam in order to determine the deformation. In [12] infrared sensors embedded into rapid-prototyped elastomer material are used to measure proximity. With the novel skin design concept we are able to detect both, the proximity as well as soft and heavy loads acting on it by using optical as well as capacitive sensors. Reflexion layer allows us to use soft and simultaneously transparent materials. Sensor fusion is based on the Fuzzy logic based approach that reduces the computational complexity and therefore enables the skin to be implemented as a stand-alone embedded sensor.

2.1 Optical method

Light has the property of reflexion and dispersion in transparent or diffuse materials. The level of dispersion depends on the chosen material. Combining these properties together open new possibilities to use light for measuring forces or deformations. When light is dispersed and reflected within the silicone it covers an orbital area surrounding the sensor. Therefore, a low number of IR sensors allows to sense big areas (Figure 2). The maximum distance between sensors that is required to sense the surface without optical gaps is $20mm$. One of the advantages of optical method is



(a) (b)

Fig. 2: IR light reflexion principle of the sensor skin. (a) Without load; (b) With load.

a low degree of complexity for electronic design. Standard reflective sensors such as Sharp $GP2S60$ sensor can be used to build the skin system. In case when no load is acting on the surface, the light produced by the infrared sensor is reflecting by the reflection layer homogeneously through the silicone material settling around one value. The current value in the sensor is changed rapidly when the distance between the reflecting layer and the sensor is decreasing (Figure 2). This dependency between the distance and the collector current is scaled down and is used as force/pressure estimation. This principle depends strongly on the used viscoelastic material. Silicones seems to be a proper material to fulfil the requirements and by choosing from different

mixtures between component A and B different elasticity can be achieved. One important factor that should not be neglected is the nonlinear relaxation of soft materials. The stress relaxation can be obtained by following equations:

$$E = \frac{\sigma}{\epsilon}, where \qquad \sigma(t) = \sigma_0 e^{-\lambda t}, \tag{1}$$

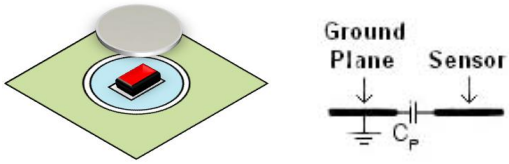
where E is the elastic module, ϵ the constant strain and σ determines the stress depending on time and the relaxation time. The process is reversible as soon the deformation stays in allowed ranges and is not too excessive. In this case the material is able to recover to original stiffness in a short time. This principle allows to measure forces or pressure for a wide range of load, however due to the mentioned nonlinear relaxation not for soft touch applications.

2.2 Capacitive method

Capacitive sensing principle is a common technique used in tactile and touch based technologies. Additional capacitive sensing principle has been included in order to increase the sensitivity range of the skin. A capacitive sensor is simply a pair of adjacent electrodes. The main principle of all non contact capacitive sensors is measuring of the capacitance. The equation for calculation of the capacitance C of a parallel electrically conductive plate is

$$C = \frac{\epsilon * A}{d}, \tag{2}$$

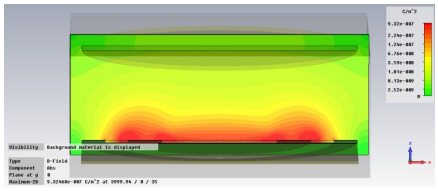
where ϵ is the permittivity of the dielectric between two electrodes, A is the overlap area of the parallel plates and d is the clearance of those plates. It is obvious, that with the same overlap area and dielectric, the capacitance of the sensor depends only on the distance between the plates and is inversely proportional to it. We use integrated capacitive sensors where both electrodes of the capacitor are arranged in the same plane of the PCB. The structure of the capacitor is illustrated in Figure 3(a) and 3(b). To achieve homogeneous field profile a symmetric adjustment of the electrodes has been used. With this design we are able to detect very soft touch on the surface of the skin. A disadvantage of the



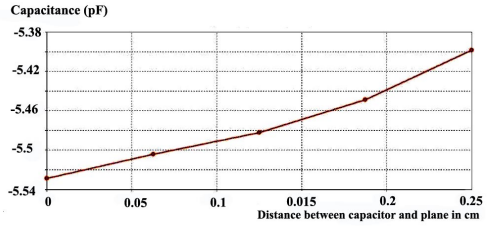
(a) (b)

Fig. 3: (a) Principle of integrated capacitive sensor; (b) Electrodes of the capacitor in the plane.

capacitive sensing technique is that sensors are only able to recognize interaction with a conductive object. To solve this problem a conductive plate is used as a reflective layer. This plate acts as reflector for infrared light and at the same time as a conductive layer changing the electromagnetic field according to the distance between the plate and the planar capacitor. In combination of elastic silicon layer it is possible to achieve a low hysteresis. Silicon acts also as dielectric in this arrangement and increases an electric flux density, which delivers a better sensing property. To achieve appropriate field profile the right size of the capacitive electrode and the gap between the pad and ground layer have been chosen. Before implementing the capacitive method a simulation in COMSOL[1] Multiphysics tool has been done to guarantee that the changes in capacitance will be enough to resolve on a microprocessor. As result an estimated



(a)



(b)

Fig. 4: (a) Electric field profile of capacitive sensors; (b) Capacity analysis dependent on distance.

capacitance of the developed integrated sensor is obtained as a function of distance between PCB plane and conductive plate Figure 4(b) and we also received visualization of the electric field profile shown in Figure 4(a).

3. Hardware

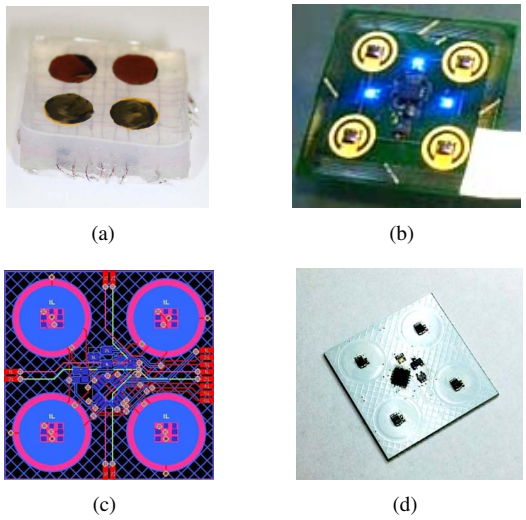
The hardware realization is based on the modular design principle consisting of one master module that carries the embedded microprocessor and a variable number of slave patches equipped with sensors. Both master and slave modules are mounted on the supply layer PCB. Different topologies for the skin can be built by connecting the patches together to one skin pattern. We call the complete system with one master and more than one slave as a Skin Unit (SU) (Figure 1).

3.1 Slave Module

Slave module has a simple structure consisting of four infrared sensors and four integrated planes for capacitive

[1]COMSOL Multiphysics is a finite element analysis solver and simulation software for physics and engineering applications

sensors (Figure 5). For this reason each slave has eight analogue signals connected to the master module. Routing all lines directly to the processor requires for n slave module $n \times 8$ signal lines. Because of limited number of available ADC pins on the microprocessor the lines need to be multiplexed. Multiplexing of signals also simplifies the



(a) (b) (c) (d)

Fig. 5: (a) First slave prototype [11]; (b) Slave module produced on flexible substrate; (c) Layout of slave module; (d) Final prototype produced on stiff PCB.

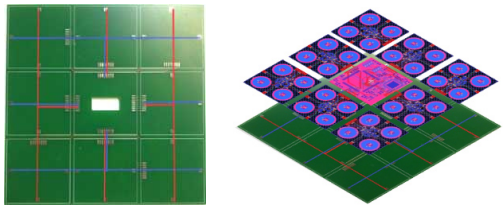
routing problem and allows the extension of slave modules in one skin system. Capacitive sensors are very sensitive to external influences, therefore the top layer of each slave has a grid-like structure ground shape for shielding and a conductive plate on the bottom layer.

3.2 Master Module

The master module controls all slave modules that are connected to it and is responsible for the data processing and for communication control. It contains a $32bit$ Programmable System on Chip (PSoC) main processor from Cypress [8] that enables to use the skin as a stand-alone embedded tool. This novel technology is similar to Field Programmable Gate Array (FPGA) however with much lower power consumption. PSoC is built based on Universal Digital Blocks (UDBs) providing diverse functionalities such as ADC, PWM, I^2C, SPI etc. which can be multiple assigned to general purpose input/output pins (GPIOs) of the processor and therefore makes the layout design very flexible. This PCB includes also a high-speed USB peripheral controller for in-system-programming (ISP) and for live debugging via the USB. The board contains also all required periphery for supplying the slave modules with power. The inter-master communication is possible via I^2C or via Controller Area Network (CAN) multi-master bus systems and allows to connect more than one skin systems.

3.3 Supply Layer

The complete skin is a multi-layer design shown in Figure 6. The lowest layer is the supply and signal layer that connects the master module with the slaves providing channels for communication, pressure signal transfer and power supply. Compared to human skin this layer has similar functionality like the *dermis layer* bundling all nerve cords. Figure 6(a) shows coloured address lines (red and blue) for different rows and columns. These signal lines select and activate the slaves. Because of narrow interface of slave and master modules the structure of the skin unit depends on the hardware structure of the supply layer. The layer can be built



(a) (b)

Fig. 6: (a) Signal routing layer with signal lines for rows and columns; (b) Skin principle.

by using either rigid PCB materials or by flexible substrates for flexible skin applications.

4. Fuzzy Logic Based Sensor Fusion

The skin system proposed in this paper was inspired by the human skin with the goal to sense the whole skin surface without spatial gaps. However equipping the whole skin surface with sensors requires a huge hardware and processing effort. To avoid this effort and complexity, optical method has been chosen with the combination of Fuzzy logic based approach that allows reducing the number of sensors by estimating the values instead. The final skin design end up in a grid-like structure with the sensors placed $20mm$ away from each other. In the case when pressure is applied between two or more sensors without touching the sensor area directly, it becomes difficult to determine the resulting pressure. To estimate this value a cascade of three Fuzzy logic systems is used. The whole procedure is shown in the flowchart, see Figure 7.

The first fuzzy system (FS1) is used for the fuzzification of the digital values from each sensor and maps sensor values to linguistic pressure values. The sensor values are between 0 and 254 while linguistic values are of 'light', 'normal', 'heavy' and 'very heavy' character. Two different membership functions are used to describe different classes of pressure (Figures 8(a)-8(c)). The first function is sigmoidal

$$f(x, a, c) = \frac{1}{1 + e^{-a(x-c)}}, \tag{3}$$

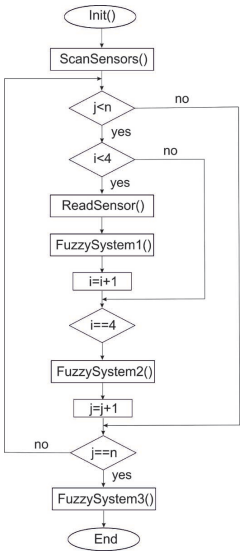


Fig. 7: Program flowchart of the skin system framework.

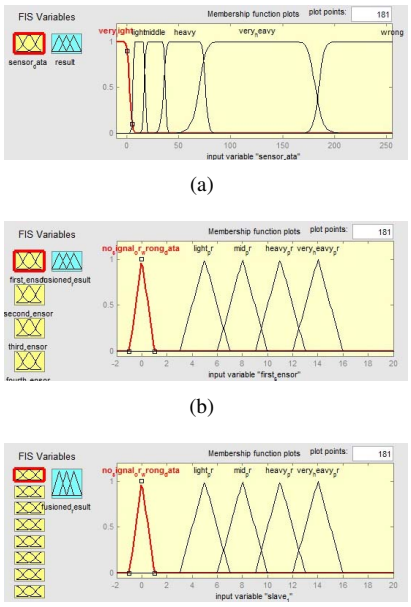

Fig. 8: Three Fuzzy Systems used for sensor fusion. (a) FS1; (b) FS2; (c) FS3.

where parameters a and c allow to shape the functions as required by application. The second function is the bell curve

$$f(x,a,b,c) = \frac{1}{1+\left|\frac{x-c}{a}\right|^{2b}}, \tag{4}$$

where parameter b is usually positive and the parameter c determine the centre of the curve.

The second fuzzy system (FS2) calculates the pressure of a single slave and has four input sets for all four sensors and one output set for the resulting force (Figure 8(b)). The fuzzy system on the highest level is the third fuzzy system (FS3), which collects the data from FS2 and according to these results, calculates the resulting pressure applied to the whole skin system. In a skin which consists of one master and eight slaves modules eight input and one output is required (Figure 8(c)). In case when pressure is applied to the skin on multiple points at the same time for many applications it is necessary to determination the resulting force. The calculation is based on vector analysis and for a single slave can be calculated as follows:

$$\begin{pmatrix} x \\ y \end{pmatrix} = \left(\tfrac{S1}{\Sigma}\right) * \begin{pmatrix} d \\ d \end{pmatrix} + \left(\tfrac{S2}{\Sigma}\right) * \begin{pmatrix} -d \\ d \end{pmatrix} + \left(\tfrac{S3}{\Sigma}\right) * \begin{pmatrix} d \\ -d \end{pmatrix} + \left(\tfrac{S4}{\Sigma}\right) * \begin{pmatrix} -d \\ -d \end{pmatrix}, \tag{5}$$

where S_i are the digital values from the four sensors, $\Sigma = S1+S2+S3+S4$, and d is the distance from the origin of slave sensor to the corresponding sensor. The same principle is used as well for the calculation of the resulting position for the whole skin system.

5. Implementation

The first prototype of the skin has been presented in [11]. At this stage one slave prototype was built in order to proof the idea. The slave was directly connected to a PSoC evaluation kit from cypress that acts as a master module and the sensor data were sent via Universal Asynchronous Receiver Transmitter (UART) interface to the host computer. One Fuzzy System based on MATLAB Fuzzy Toolbox [19] was implemented to represent the data of the four optical sensors as linguistic variables. Simple Graphical User Interface (GUI) visualized the sensor data in a three dimensional mesh. In this paper we present the extended version of the skin and of the evaluation tool. In the current design all three Fuzzy Systems are implemented to fuse the data from the whole skin. The principle is shown in Figure 9. The real

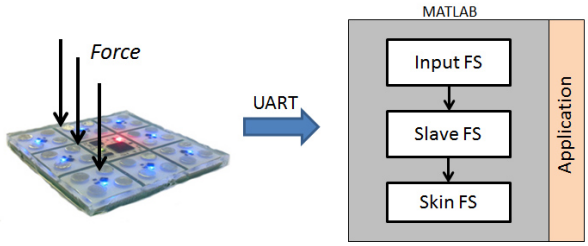

Fig. 9: Working principle of the skin with Fuzzy Systems.

skin deformation can be observed on the screen through the deformation of the two dimensional surface (Figure 10). On the left side of the GUI marked with (1), the axes show visual representation of the skin deformation according to received raw sensor data. Additionally, these values can be observed in the "RAW DATA" matrix (2). On the right side of the

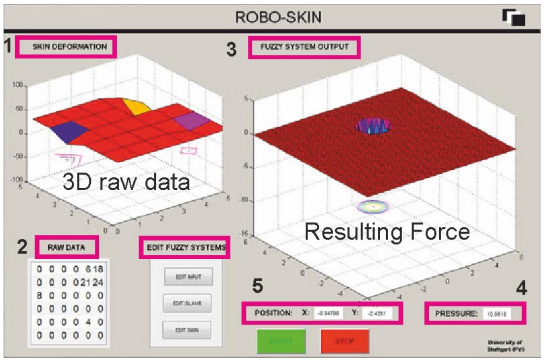

Fig. 10: GUI for monitoring and parameter adaptation.

GUI the axes show graphical representation of the resulting value calculated by all three fuzzy systems (3) as well as the numerical value (4) for it. This value is the result after the calibration process of the skin and its ranges can differ dependent on the used material or different composition of the silicone components. The estimated coordinates for the resulting position of load can also be read (5).

6. Experimental Results

The current skin design is considered to use for modular robot applications with Backbone and Scout robots [7],[10], which are developed in projects Symbrion [17] and Replicator [15]. The goal is to measure the normal forces on the ground and to detect collisions with obstacles or other robots (Figure 13(a)-13(d)). Therefore, for this kind of application we choose a hard silicone composition admitting heavy loads up to $10kg$.

Figures 11(a) and 11(b) show the force responses from one slave element when force is applied in the normal direction at one point and when it is applied sidewise. As can be observed in these figures this difference is clearly detectable. This information can be used to approximate shear forces on the surface of the skin. In this experiment only optical transduction method for pressure measurement was use without activating the capacitive sensors. Force response values are intrinsically nonlinear because of nonlinear relaxation of the silicone. However, Fuzzy logic based approach does not require exact sensor values as an input and therefore even with the sensor values accuracy of about $10-15\%$ it is still enough to determine a good approximation for the resulting force. The evaluation of the approach can be done by using the GUI tool (Figure 10) introduced in the previous section. The sampling rate for the sensors is about $100ms$ therefore forces applied on multiple points can be detected and visualized within GUI. Figures 12(a) and 12(b) show two examples when pressure is applied to one or to multiple points. Another analysis for one slave has been done for the accuracy of the optical based approach. For this experiment slave of size $40 \times 40mm$ has been divided into nine parts

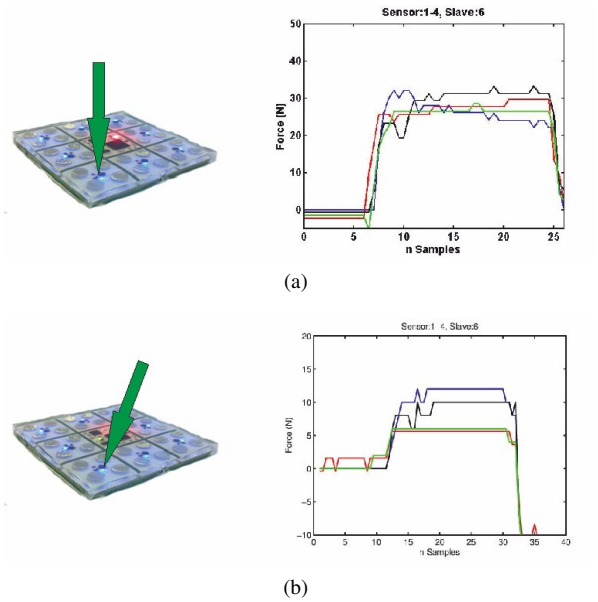

Fig. 11: Different loads applied to one slave of the skin. (a) Force applied in normal direction; (b) Force applied at an oblique angle.

$(3 \times 3$ mesh-like structure). The distance from one sensor to another is $20mm$ and hence only the half to the centre of the skin module. In this experiment we applied repeated constant pressure to different points of the skin collecting statistical values (Table 1). As can be observed from the

Table 1: Accuracy analysis of slave.

Force applied on (X/Y)	Average values	Standard deviation
-1/-1	-0.72/-0.2	0.18/0.31
-1/0*	-0.86/0.8	0.05/0.07
-1/-1	-0.77/0.79	0.09/0.08
0/-1*	0.86/-0.56	0.4/0.15
0/0*	0.6/0.22	0.22/0.29
0/1*	0.48/0.83	0.21/0.09
1/-1	1/-0.93	0/0.15
1/0*	0.88/-0.05	0.29/0.05
1/1	0.78/0.73	0.09/0.14

table, Fuzzy logic based approach is able to detect forces between two sensors (marked with star) where no real sensor is placed. Low standard deviation enables a calculation of the static offset, which can make the sensor more accurate. This analyses show that with given accuracy the skin can be used for diverse robotic platforms such for example the robots Backbone and Scout (Figures 13(a)-13(d). Modular and flexible design allows adapting the shape of the skin and therefore can also find different other applications in areas such as healthcare, eldercare, domestic, entertainment and many others.

7. Conclusion and Future Work

In this paper we present a novel idea for a tactile multi sensor skin based on modular master and slave design principle. General idea of this skin is to measure forces and pressures on the whole skin surface however with a low number of sensors. Two kinds of sensors, optical as well as capacitive sensors are used to range the applied forced from very high to very smooth touching. The hardware structure is inspired from the multi layered human skin providing different functionalities. Compensation of displaced sensors is done by use of Fuzzy logic based sensor fusion method. This concept allows input values to be fuzzy while returning sharp values for the force response. Additionally, the skin is able to determine and to approximate one single point of contact in case when load is acting on multiple points or even on the whole skin surface. This feature is important for model based control algorithms that allow one force response value only. The current prototypes are built on rigid as well as on flexible substrates and allow covering flat and rough robot geometries.

Conceptual Space Filter

Abstract *- This paper presents a filter for "conceptual spaces." The application is image understanding. A conceptual space is a collection of one or more "quality dimensions." In our approach, functionals on various Hough transforms of the input image determine the quality dimensions. For example, how "line-like" and "circle-like" the input image is can be used as quality dimensions. A "natural concept" is a convex region in a conceptual space. A conceptual Space can be partitioned into natural concept using a tessellation and prototypes for each concept. The filter we present takes in an input image and outputs a prototype image which represents the natural concept the input image corresponds to. It serves as an interface between an input image and a human user, aiding comprehension by providing a better match to the human information channel. We use a fuzzy tessellation to account for uncertainties in the mapping to prototypes.*

Keywords: Conceptual spaces, image understanding, fuzzy logic, Hough transforms, tessellation.

1 Quality Dimensions

A conceptual space is a collection of one or more quality dimensions. As an example, sweet, sour, salt, and bitter could be the quality dimensions of the conceptual space representing taste [1, 2]. If the conceptual space is partitioned into convex regions, these regions are *natural concepts* in the conceptual space. For example, an apple could be a natural concept in the space representing taste with quality dimensions sweet, sour, salt, and bitter. A *prototype* is a point in a natural concept in a space which is, in a certain way, the most representative point of the concept. For example, a Red Delicious apple may be a better prototype for the natural concept of apple than a Granny Smith apple would be. Figure 1 shows an example conceptual space with two quality dimensions and partitioned into six convex concepts, with each concept containing a prototype point which is highlighted in a different color. Quality dimensions are sometimes not totally independent entities. For example, the ripeness and color dimensions covary in the space of fruits [1, 2].

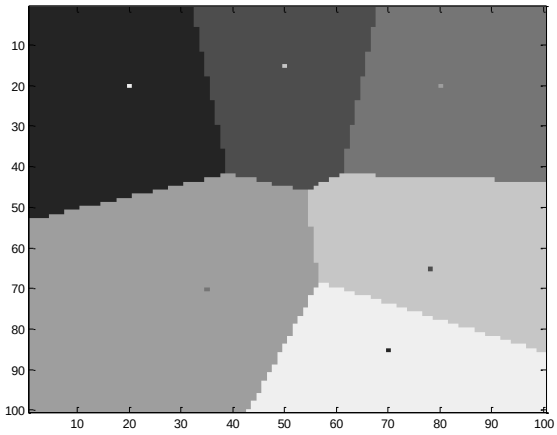

Figure 1: Conceptual Space divided up into six concepts and showing six prototypes indicated by the single pixels.

2 Conceptual Spaces Filter

The problem which the Conceptual Spaces Filter addresses is in the area of image understanding. Often image analysts are overwhelmed by the sheer volume of images they have to inspect in a limited amount of time. This causes incorrect interpretations to be made and important features to be missed. The Conceptual Spaces Filter aides the image analyst by doing part of the comprehension work so that he/she can successfully interpret a large number of images per hour. It presents to the user a prototype image rather than the input image. The prototype, being representative of a concept, is more easily comprehensible to the user than the input image. The degree of membership in a borderline fuzzy concept is also presented at the output of the filter. A high fuzzy membership signals the user that they should assign more resources to that image case, possibly to include direct human inspection of the input image.

So, for the Conceptual Spaces Filter, an input visual image is the input to the filter and a prototype visual image is the output of the filter, along with a fuzzy membership indicator. The Conceptual Spaces Filter sends the input image to a number of different Hough transforms in separate Hough

channels. These Hough transforms help to determine the quality dimensions.

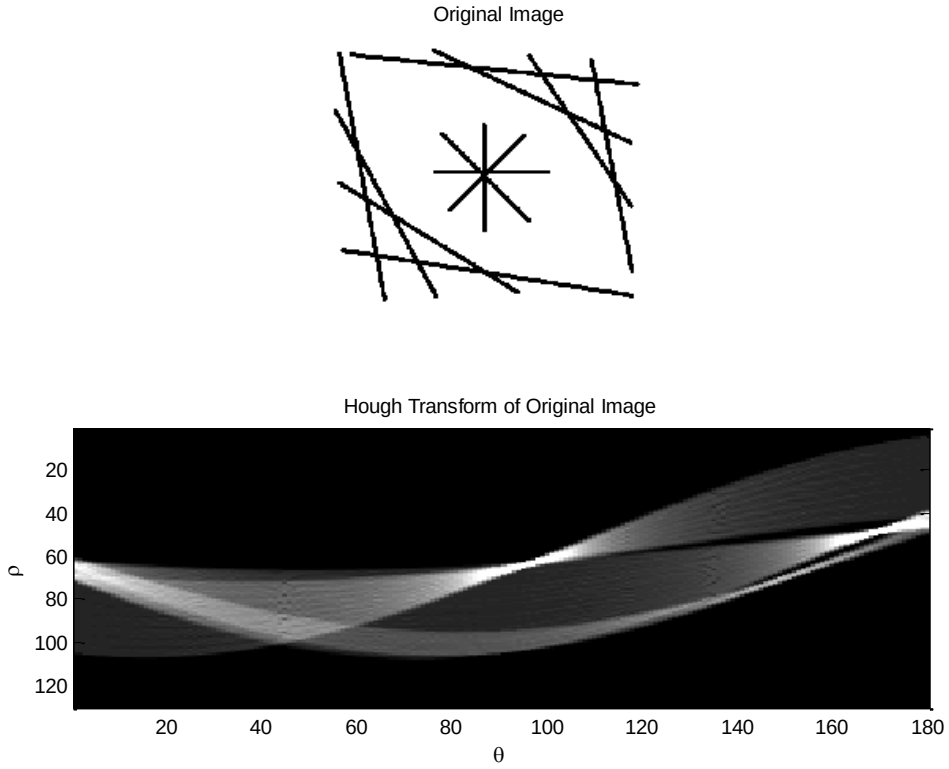

Figure 2: Line Hough detects the presence of lines. In the transform domain, the highest amplitudes are indicated by lighter shades.

Hough Transforms were discovered by Paul Hough [3]. They can be used to detect lines and curves in images [4]. Even arbitrary shapes may be detected using Hough Transforms [5]. Hough Transforms are invariant to rotation, displacement and intensity and so are widely used in image processing. A Line Hough detects the presence of lines. An example is shown in Figure 3. The original input image is shown above the Hough transform accumulator (Hough domain). The high amplitudes in the Hough domain are indicated by light shades. Most of the energy in the Hough transform domain is concentrated in a few small places, indicating that the input image is line-like. The Line Hough transforms the input from the x,y-domain to a θ,ρ-domain. *A* is the accumulator. The algorithm for the Line Hough is as follows:

To filter in the quality dimensions, the Conceptual Spaces Filter sends the input image to a number of different Hough transforms in separate Hough channels. The separate Hough transforms produce separate accumulators. A "peakiness" operator operates separately on each of the accumulators to determine a coordinate along a quality dimension associated with each Hough transform. The coordinates are combined to form an n-tuple in a conceptual space determined by the Hough quality dimensions. The conceptual space is pre-partitioned into convex concepts determined by the application. The n-tuple is a functional of the input image and will fall within one of the space's concepts or on or near a boundary. The output of the Conceptual Spaces Filter is the prototype of the concept which captured the n-tuple.

Fuzzy sets are discussed in the text by Klir and Yuan [6]. On the borders between the natural concepts a fuzzy non-natural concept is pre-determined. The n-tuple's location in the conceptual space determines a discrete membership in a natural concept and a fuzzy membership in the fuzzy non-natural concept. The prototype of the natural concept, determined by the n-tuple, is presented as output to the user along with a display indicating the fuzzy membership in the non-natural concept.

Tessellation is an algorithm for determining convex concepts once the prototypes are known and a distance is defined. In tessellation, a point belongs to a concept if it is closer to the prototype of the concept than to the other prototypes.

By "closer" we mean the distance is smaller. There are many ways to define distance. For example, weighted Euclidean distance is given by:

$$d_E(u,v) = \sqrt{\sum_i w_i (u_i - v_i)^2} \qquad (1)$$

Where the w's are the *attention weights*.

The accumulator, or the array utilized in the Line Hough Transform, detects the existence of a line. A circle Hough detects the presence of circles. Similar Hough transforms can be set up to detect ellipses, squares, and various other shapes.

The Conceptual Spaces Filter has two modes: 1.) Setup Mode and 2.) Run Mode. The diagram of the Setup Mode is presented in Figure 3. The diagram of the Run Mode is presented in Figure 4.

```
function [ x_ness ] = peakiness( B )

[m, n] = size(B)
z_max = max(B);
max_max = max(z_max);
count = 0;
for im = 1:m
   for in = 1:n
      if(B(im,in) > .5*max_max)
         count = count + 1;
end
   end
end
x_ness = m*n/count;
end
```

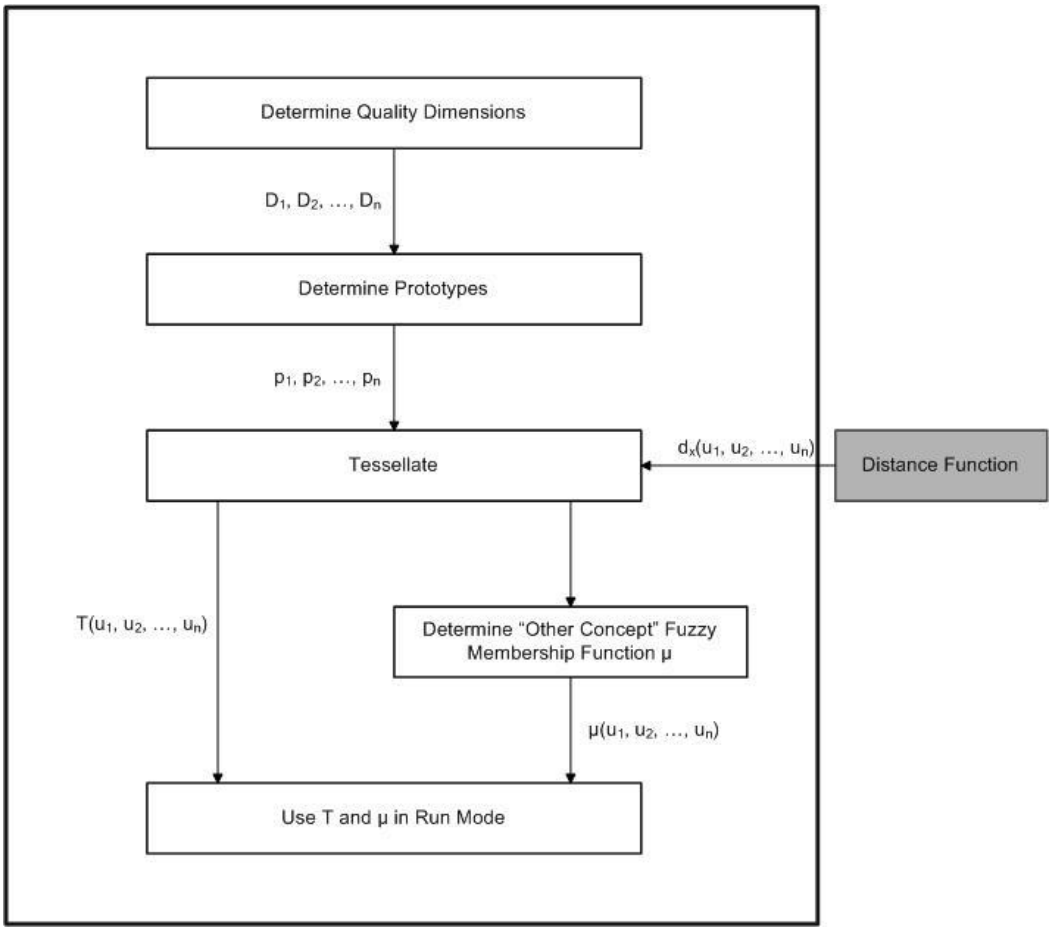

Figure 3: Setup Mode

In Setup Mode, in the first stage, it is determined, for an application, what are the qualities that need to be distinguished. Quality dimensions that have associated Hough transforms are selected. The choices are Circle Hough, Line Hough, Ellipse Hough, Square Hough and other admissible Hough transforms. A subset of these is chosen and associated quality dimensions $D_1, D_2, \ldots, D_n$ are passed to the next stage.

In the second stage in Setup Mode, prototype images are selected. These are fed into the Hough transforms selected in Stage 1. The output Hough accumulators are then fed into the peakiness function to determine the coordinates of the prototypes in the conceptual space. The peakiness is determined as follows:

Here B is the Hough accumulator. The peakiness determines how much of the Hough transform is within 50% of the peak of the Hough transform. The prototypes so determined, p1, p2,…, pn, are then sent to Stage 3.

At Stage 3 the prototypes $p_1, p_2, \ldots, p_n$ and a chosen distance function d_x are used to tessellate in order to determine the convex concepts. The tessellation T is passed to the Final

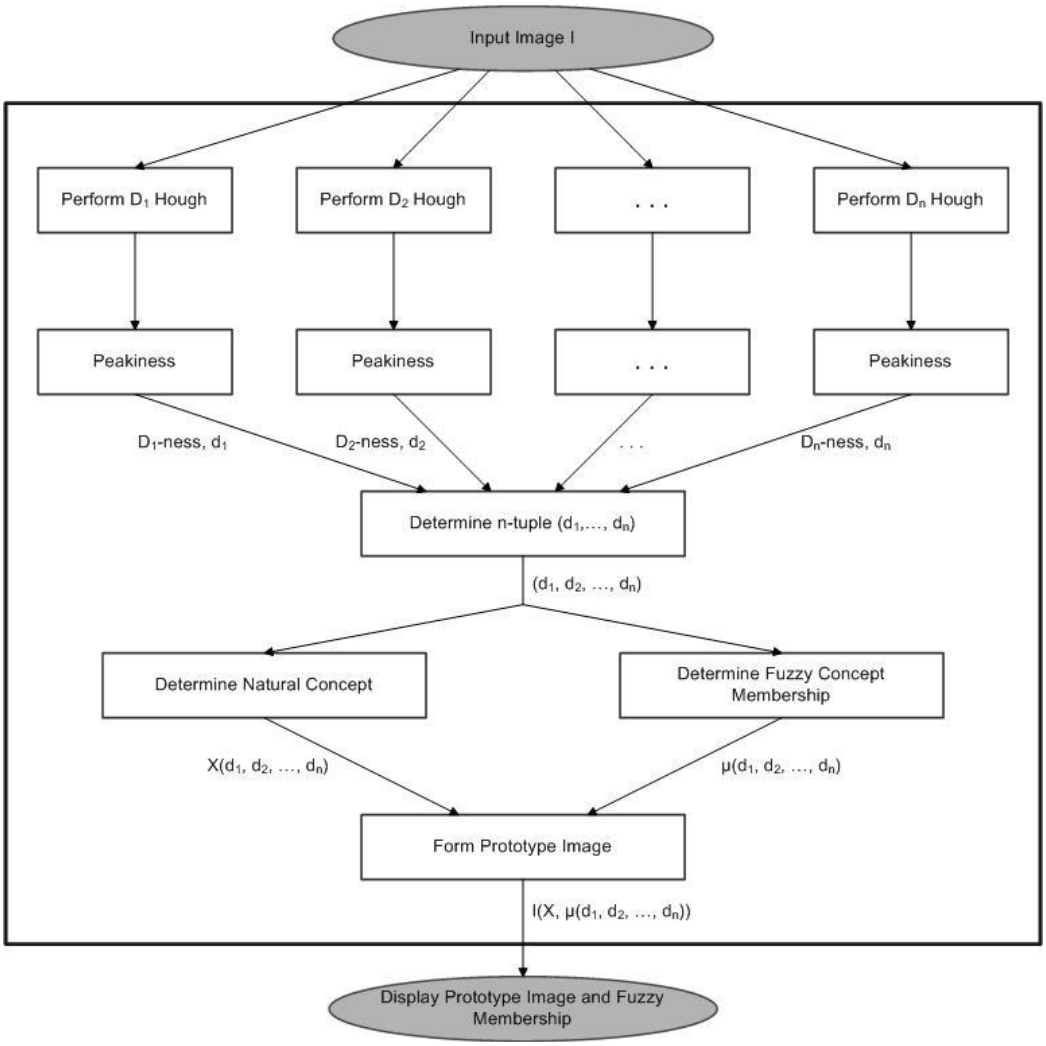

Figure 4: Run Mode

Stage. Example MATLAB code for the tessellation is as follows:

```
for i = 1:100
   for j = 1:100   %  Step through each point in the image.
      for k = 1:6
         x = p(k,1);              % Find the distance between
         y = p(k,2);              % the current point and each of
         d(k) = d_E(i, j, x, y); % the prototypes.
      end
      [y, I] = min(d);            % Find the nearest prototype.
      T(i,j) = I*10;  % Assign color according to prototype.
   end
end
```

The tessellation is also passed to an intermediate stage that determines the fuzzy concept μ. T is stepped through and every 3x3 subarray is tested to determine if it is an edge point. When an edge point is found in T, a non-zero entry is placed in the corresponding location in a buffer array Y. **N**ext, in array Y, the array (image) is smoothed (Gaussian smoothing) by replacing each pixel by the average of its neighbors.

This step is repeated until the desired fuzziness is achieved. The final smoothed concept is μ. The cross-section of μ is a Gaussian.

In Run Mode, the image is converted from color to grayscale. The image average is first determined. The image is passed to *n* separate "Hough Channels" which work independently. In each Hough channel, a Hough transform associated with each quality dimension D_k is applied to the input. To each Hough transform, a peakiness operator is applied to determine a coordinate d_k in quality dimension D_k.

The Hough channels are combined and a coordinate $(d_1,\ldots,d_n)$ in the conceptual space $S(D_1,\ldots,D_n)$ is produced. The natural concept X that $(d_1,\ldots,d_n)$ corresponds to, is determined. In parallel, the fuzzy membership $\mu(d_1,\ldots,d_n)$ in the non-natural concept μ is determined.

In the final stage, the prototype of natural concept X and the membership in the non-natural concept μ is presented to the user.

An example is shown in Figure 5. Two quality dimensions, "line-ness" L and "circle-ness" C create a conceptual space shown in blue. Using a given set of prototypes, a tessellation has partitioned the space into four natural concepts. Two input images were input to the Conceptual Spaces Filter and their locations in the conceptual space is shown. The Olympic image is well within the Circles concept with fuzzy membership 0. The LinesAndCircles image is well within the LinesAndCircles concept with fuzzy membership 0.

The operation as a filter is illustrated in Figure 6. There are four prototypes that an input image can be mapped to, farm, circles, circles and lines, and lines. The Olympics input image maps to the circles prototype image and has a membership in the fuzzy concept of $\mu = 0$. The lines and

circles input image maps to the lines and circles prototype and also has a membership in the fuzzy concept of $\mu = 0$.

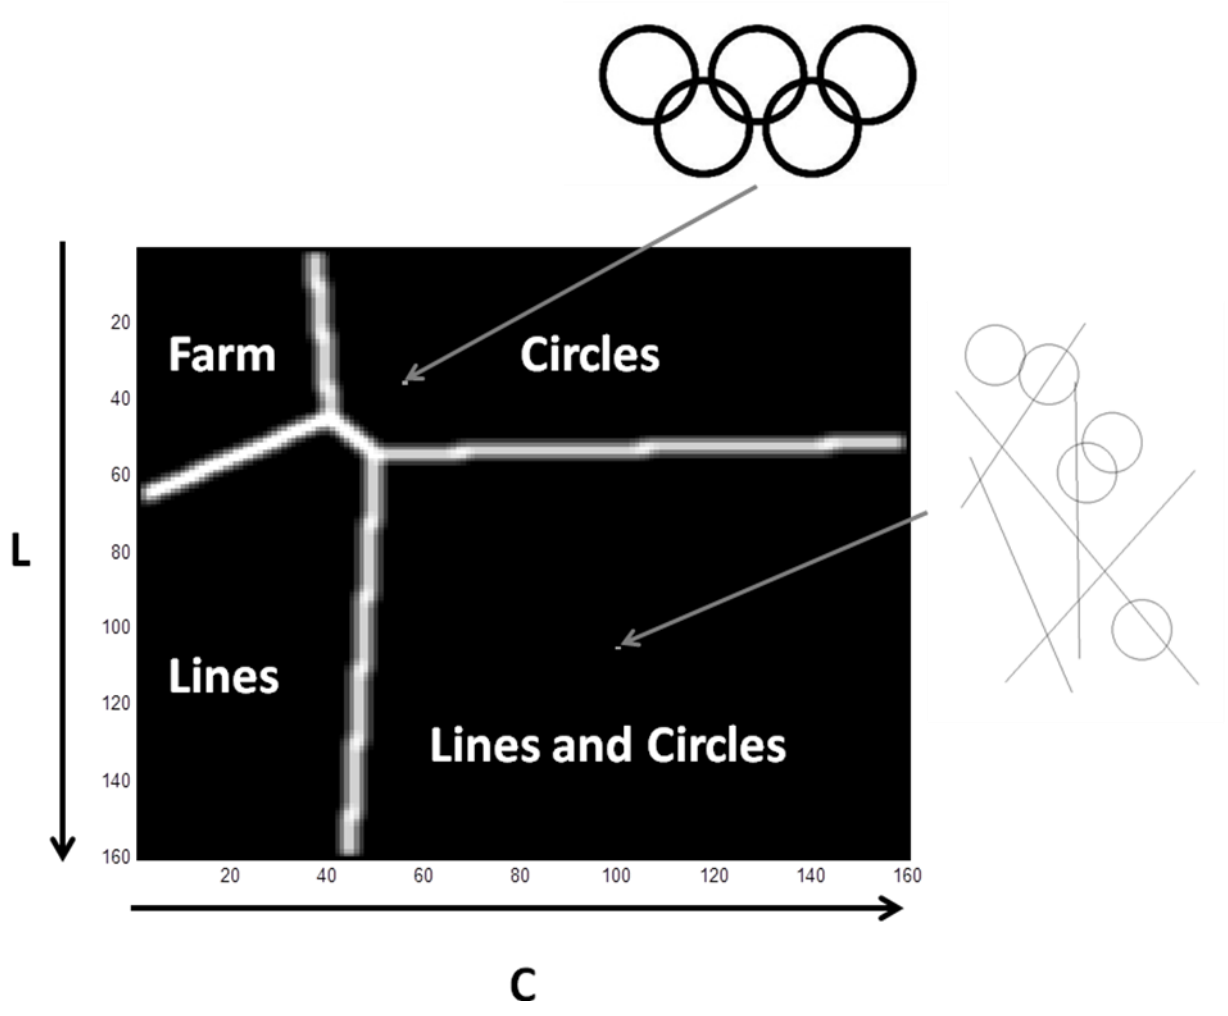

Figure 5: In the final stage, the Olympic image is mapped to the Circles concept and the LinesAndCircles image is mapped to the LinesAndCircles concept.

3 Summary

A Conceptual Spaces Filter was described which may aid image understanding and reduce the workload for image analysts. For the quality dimensions of the conceptual space, we use a peakiness functional on Hough transforms. These Hough transforms are rotationally and affine invariant and pick out special features in the image. We perform a tessellation to partition the conceptual space into convex concepts. We augment the tessellation with a fuzzy non-convex concept which is used to express uncertainties. The filter takes as its input an input image, uses Hough transforms and peakiness to determine coordinates in the conceptual space, and maps from the n-tuple to the prototype which is the output of the filter.

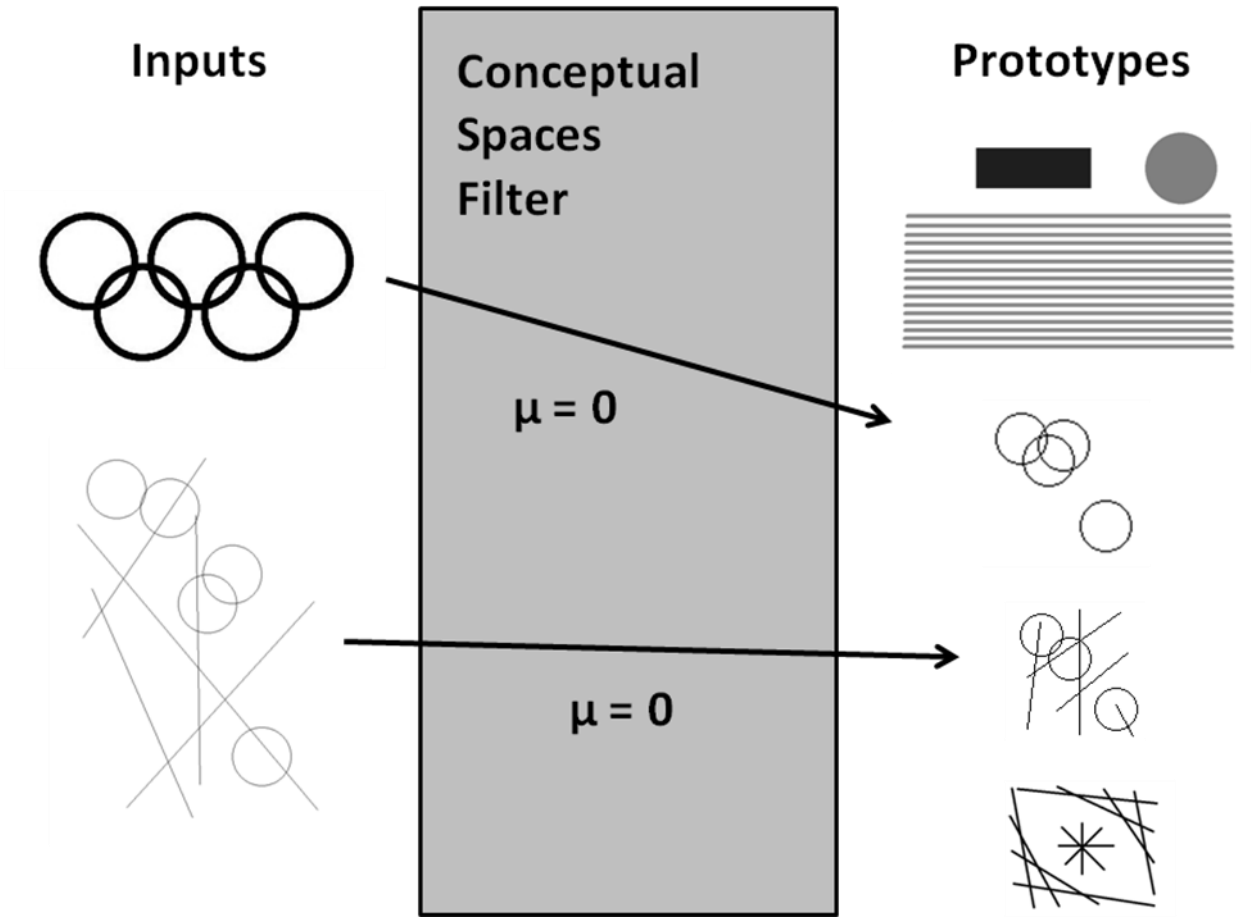

Figure 6 In the final stage, the Olympic image is mapped to the Circles concept and the LinesAndCircles image is mapped to the LinesAndCircles concept.

Abstract *- This paper discusses the design of a controller for low-cost fixed-wing Unmanned Aerial Vehicles (UAV's) using fuzzy rules and fuzzy inference systems. The control flow in the architecture design process consists of four levels: Guidance, Navigation, Control and Stability, Communications. The Fuzzy Logic Control System (FLCS) introduced here, is mainly used to control and stabilize the aircraft while navigating towards different waypoints defined according to the waypoint plan. This idea forms the base for an AI approach to the development of an autopilot unlike the traditional way of using PID (Proportional Integral Derivative) controllers for control and navigation [1].*

Keywords: *Unmanned Aerial Vehicle (UAV), Fuzzy Inference Systems (FIS), Flips, Fuzzy Logic*

1 Introduction

Unmanned Aerial Vehicles (UAV's) have been attracting a lot of attention especially in fields like military, civil and research applications. In addition to these, UAV's are also being used in traffic control, target acquisition, localization and surveillance [2], virtual reality aided control [3], measurement of atmospheric composition [4][5], crop monitoring, telecommunications, reconnaissance, attack roles and many other areas over the last thirty years. Autonomously controlled UAV's are gaining special importance since they do not need a radio link like the remote controlled planes and also, very minimal human support is required for control, stability and navigation.

1.1 Fuzzy Logic and Fuzzy Inference Systems

Fuzzy Logic, introduced by Lofti Zadeh [6] deals with reasoning that is fixed or appropriate rather than fixed and exact. Fuzzy Logic can be used to describe control or describe a system by using "commonsense" rules that refer to inadequate quantities [7] [8]. It incorporates a simple rule-based "if X and Y, then Z" approach to solving a control problem rather than attempting to model a system mathematically [9].

Fuzzy Inference Systems are designed based on the concept of Fuzzy Logic (FL). Fuzzy Inference can be defined as the process of formulating the mapping from a given input to an output. A Fuzzy Logic System or a Fuzzy Inference System (FIS) maps the crisp inputs into crisp outputs. A membership function is such a graph that defines how each point in the input space is mapped to the membership value between 0 and 1. A Fuzzy Inference process comprises of five parts: fuzzification of the input variables, application of the fuzzy operator in the antecedent, implication of the antecedent to the consequent, aggregation of the consequents across the rules and defuzzification.

2 System Architecture

This section introduces a brief overview of the present research article. A rule based system is being developed, where the control flows from the higher levels to the lower levels. The architecture can be described in different operating levels, which are assigned to perform four different kinds of functions. The user specifies his/her goals in a high-level (human-readable) language, which are then converted to tasks with the help of the FLIPS (Flight Instruction Processing System) parser [10]. The autopilot converts these instructions or tasks to fuzzy rules. These fuzzy rules, combined with fuzzy inference systems, send out action commands to the actuators. The actuators then communicate with the hardware (micro-controllers) on-board to execute the mission.

The main focus of this paper is the Fuzzy Logic Controller for Unmanned Aerial Vehicles, which is solely responsible for the Navigation, Control and Stability tasks. Hence, the emphasis of this paper would be the process of conversion of the tasks to actions which is depicted in Figure 1.

Though the practical implementation involves much more than this, the above architecture can be compared to a virtual blackboard. The blackboard idea is such that the values from every level are posted onto the blackboard. Every level gets its instructions or tasks from its corresponding higher level's output values. With the help of the fuzzy inference system (controller) and the values posted on the blackboard, the autopilot sends commands to the actuators for task execution.

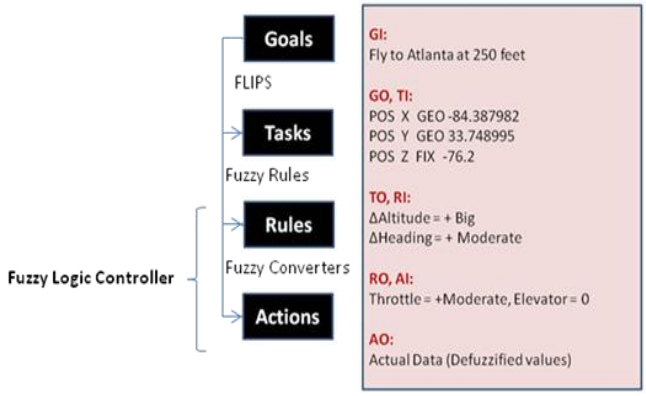

Figure 1: UAV System Overview

Since this is a closed-loop feedback system, the current state of the aircraft is measured and stored. The controller compares these values (current state and the desired state of the aircraft) and executes the tasks accordingly. The present architecture is considered as a black box which is fully autonomous.
The UAV autopilot is said to operate in four levels. They are:

i. Guidance (via FLIPS)
ii. Navigation
iii. Control and Stability
iv. Communications

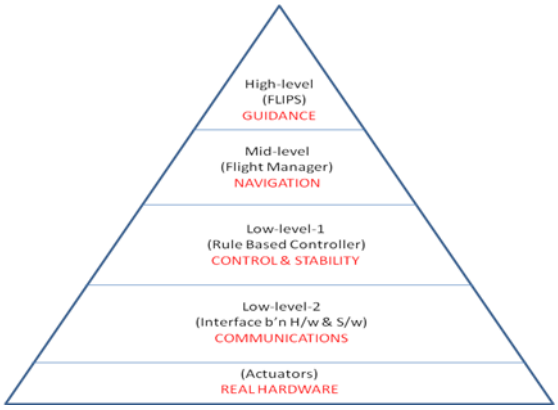

Figure 2: UAV System Architecture

2.1 Guidance (High Level)

This level consists of high-level operations (goals and missions) specified by the user. Any kind of guidance system can be implemented with the present Fuzzy Logic Control System. FLIPS (FLight Instruction Processing System for Unmanned Aerial Vehicles) grammar developed by Robert Eunice has been chosen in order to give instructions / specify waypoints (goals) [11]. FLIPS is a grammar used to define UAV mission commands in a high-level language that can be used as a hardware-independent instruction set architecture (ISA) for implementation of commands. The goal of FLIPS is to provide a better abstraction between the user and the flight hardware. The high-level tasks are specified as FLIPS assembly language instructions. These instructions are presented to MATLAB in a text file. The commands and waypoints used for controller input are specified in the example below to create a better understanding for the user. An example of FLIPS conversion is as follows:
Example1.uav

Commands:	Waypoints – Latitude, Longitude
Normal = 0	Atlanta = 33.748995, -84.387982
Take-off = 1	New York = 40.714269, -74.005973
Inverted = 2	
Hover = 4	
Roll left = 8	
Roll right = 16	

Goals: (High-level instructions) *Example1.uav.asm (FLIPS Assembly)*

a. Take-off = **CMD 1** // Take-off
b. Fly to Atlanta at 50 meters = **POS X GEO -84.387982**
// Atlanta W Longitude
POS Y GEO 33.748995
// Atlanta N Latitude
POS Z FIX -50.0
// 50m Altitude
FLY
c. Fly to New York **POS X GEO -74.005973**
// New York W Longitude
POS Y GEO 40.714269
// New York N Latitude
FLY
d. Fly at 1000 feet **POS Z FIX -304.8**
// 1000 feet = 304.8m
FLY
e. Loiter and Land **CMD 192**
// Loiter and Land

These FLIPS assembly commands are the output commands of the Guidance level.

2.2 Navigation (Mid Level)

The mid-level coordinates the task execution by receiving the task information (FLIPS Assembly) from the high level. The Flight Manager tries to identify the current & desired states of the aircraft and sends commands to the next level. These commands describe the kind of maneuver and the type of maneuver the aircraft needs to perform at that moment. Ex: From the above example, (d.) says: POS Z FIX -304.8 (climb to 1000 feet) and suppose the altitude sensor measures the current altitude as 200 feet. The altitude difference is 800 feet and is very high. The Flight Manager then sends the following instruction:

ΔAltitude = + High => Perform a steep climb

Control is now handed over to the Control and Stability level.

2.3 Control and Stability (Low Level)

The lower level receives the instructions from the mid-level and then tries to match these to the fuzzy rules designed for control and stability of the aircraft. This fires the actual rules that perform the maneuver and type of maneuver action. Examples of the low-level rules for a steep climb are displayed in Table 1:

Table 1: Steep Climb: (ΔAltitude = + High)

If	*Then*
Altitude = +High, Airspeed = High	*Throttle = VeryHigh, Elevator = High*
Altitude = +High, Airspeed = Moderate	*Throttle = VeryHigh, Elevator = High*
Altitude = +High, Airspeed = Low	*Throttle = VeryHigh, Elevator = VeryHigh*

This level is responsible for the defuzzification of the fuzzy output values from the low-level rules fired. These defuzzified values are then converted to electrical signals to be sent to the actuators. This is then sent to Flight Gear for visualization purposes.

The 'Communications' level is not being discussed here since the system has been implemented and tested in a simulation environment only.

3 Implementation

To attain the readability and flexibility of the present control system, the controller has been designed as a rule-based system whose architecture is hierarchically structured with different layers. Each layer consists of a set of rules and is based on the function performed by the autopilot. MATLAB's Fuzzy Logic Toolbox has been used for the development of a rule-base to navigate the aircraft. The rules have been categorized into four categories – Climbs, Descents, Left Turn and Right Turn which are further categorized into subcategories of Steep, Moderate and Shallow.

The climbs and descents rules are designed in such a way that the main factors - altitude and airspeed; contribute equally to the climb and descent paths. Similarly, "Angle of Bank" or "Roll Angle" is another factor which is necessary to be considered during the turns.

A simulation environment has been provided for the UAV in order to provide a platform for testing and tuning algorithms and to foresee the behavior of the UAV prototype in different scenarios. The simulation can also be used as a part of the ground station software to control the UAV.

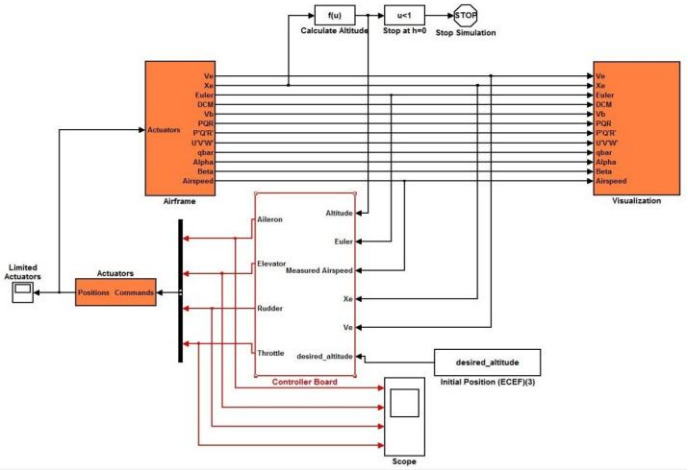

Figure 3: MATLAB Simulink Model

In order to build a base for the development of intelligent systems, the Fuzzy Logic approach has been considered by replacing the traditional PID (Proportional Integral Derivative) controllers with Fuzzy Inference Systems. The simulation environment (current UAV Simulink model in MATLAB) shown in Figure 3 has been developed using Mathwork's Simulink software and FlightGear and has been classified into three key components:

3.1 Aerodynamics and Environmental Model

This contains the 'Airframe' and 'Actuators' blocks. This model is used to characterize the dynamics of a UAV in its environment. The effects of the actuators (throttle, elevator, aileron and rudder) and the environment including gravitational forces, wind forces, aerodynamic forces and moments on the motion of the simulated UAV are taken into account to generate the total force and moment on the Airframe of the UAV.

3.2 Controller Model

This consists of the 'Controller Board', a combination of two fuzzy controllers, one for Turns (lateral controller) and one for Climbs and Descents (longitudinal controller). This model is used for Guidance, Navigation, Control & Stability and Communications. The controller model reads the current state of the aircraft from the airframe through the feedback system and sends output signals to the control actuators to meet its goals. The top-level set points for the fuzzy controllers are the three variables: desired altitude, desired heading and desired

airspeed. The waypoints are defined as parameters (not inputs or outputs) in order to calculate the above three set points. The Fuzzy Inference Systems present in the controller block which made up of rules and fuzzy membership functions pertaining to the inputs and outputs are responsible for all the logic behind the controller.

3.3 Visualization Model

This model communicates with FlightGear and produces useful graphical outputs to analyze and monitor the motion of the aircraft. This block takes in the 12-input values needed to display the state of the aircraft and the output is represented as graphical flight simulation. The whole environment is simply a feedback loop control system with subsystems built into it. This feedback loop control system reports the state of the aircraft every 0.005 sec which is said to be its simulation step time. The accuracy and the length of time of the resulting simulation depend on the size of the step taken by the simulation: the smaller the step size, the more accurate the results. In the fuzzy controllers used, the membership functions are properly chosen and are assigned with membership values with intuition by observing the universes of discourse of the input and output variables. The aircraft would become highly unstable if the values out of the specified ranges are used. The FlightGear simulation environment used in this project is as shown in Figure 4:

Figure 4: FlightGear Flight Simulator

4 Results

The Fuzzy Logic approach appears to be presenting with interesting results in the sense that the autopilot obeys the instructions precisely according to the waypoints defined.

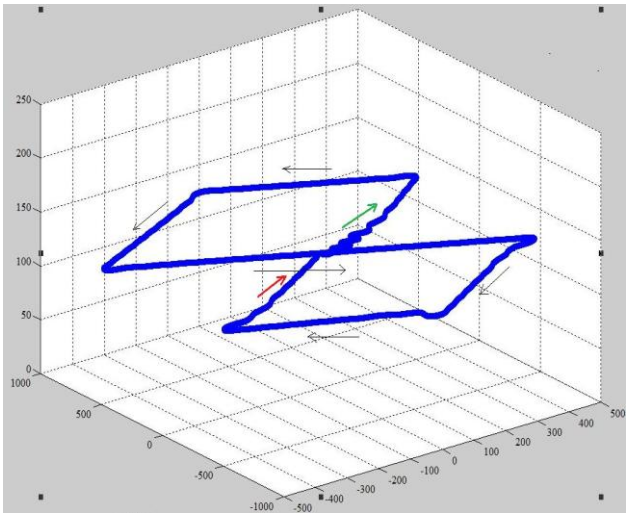

Figure 5: Figure 8 with fixed altitude

Figure Units: X-Axis – Matlab Units, Y-Axis – Matlab Units, Z-Axis – Altitude (m)

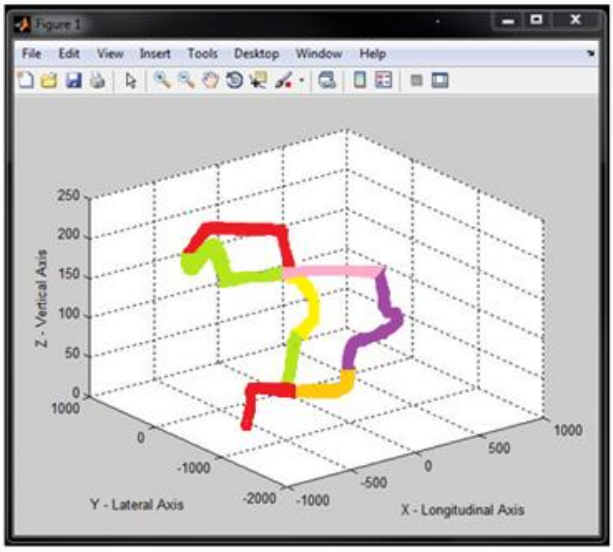

Figure 6: Figure 8 with varying altitude

Figure Units: X-Axis – Matlab Units, Y-Axis – Matlab Units, Z-Axis – Altitude (m)

It also corrects itself from small roll and pitch angle errors during straight and level flight. The autopilot has been tested with various trajectory paths and just not one to test for precision. A comparison of the results with the PID controller model has also been made in order to determine its performance. Figures 5 and 6 depict the 'Figure 8 trajectory' of the aircraft using Fuzzy Logic Control System. As presented in Figure 5, the aircraft starts from waypoint (0, 0); which represent the latitude and longitude and continues to fly according to the waypoints defined in the goal. The axes

in the above Figures depicting the aircraft trajectory define orientation of the aircraft. The 3D plots in Figures 5 and 6 display all the three X (Longitudinal Axis), Y (Lateral Axis) and Z (Vertical Axis) axes respectively. The beginning and end of the trajectory taken by the aircraft in Figure 5 are marked with green and red arrows respectively. In Figure 6, the altitude increases for the first half of 'Figure 8 trajectory' and starts decreasing for the second half. The trajectory of the path in Figure 6 is- Green, Yellow, Red, Green, Pink, Purple, Mustard and Red. The turns, as discussed earlier, seem to appear distorted since controlling the altitude and heading with rules is a challenging task for the controller and better results can be achieved with additional tuning procedures.

5 Conclusion and Future Work

The purpose of this research was to develop navigation and control based fuzzy logic controller for Unmanned Aerial Vehicles. The simulation results depict an adequate overall performance of the autopilot. The results show some deflections during the turns which are due to the adjustment of the controller with the corresponding rules during every time step. Trial and error methods to fine tune them during the turns have been performed but it was disappointing to note that not much tuning was possible to make them smoother. Every method has its own disadvantages and this can be considered as a disadvantage of using fuzzy rules for smoothing the turns. However, this might be improved by employing a very few PID's for just tuning purposes during the turns. The perfect control flow of the architecture at present helps in developing a fuzzy model on the hardware much easier without the PID's. A similar model can be used to develop a controller for elevon controlled aircrafts like Zagi. This research follows waypoint navigation like most of the aircraft control systems. New navigation control methodologies can also be employed like learning the trajectory path while traversing and coming up with a new set of points of interest.

Fuzzy Automaton with Kalman State-Smoothing

Scott Imhoff and Palak Thakkar

Raytheon Intelligence and Information Systems
16800 E. Centretech Parkway
Aurora Colorado 80011

Abstract - *This paper presents a fuzzy automaton/Kalman filter hybrid algorithm (Kalmaton). Automata are of pivotal importance in artificial intelligence (AI), being used in knowledge engines such as Wolfram|Alpha. Also they are applicable to emerging needs for predictive situational awareness involving data mining and data fusion. Kalman filters have many applications which need predictive validity, including GPS. Fuzzy transitions from different learning states associated with fuzzy automata along with estimation of the true state of a system using a Kalman filter creates an algorithm that achieves good stability and reaches a decision boundary early.*

Keywords: Kalman filtering, automaton, fuzzy logic, change detection, state smoothing, machine learning.

1 Introduction

Formal Languages provide an advantageous framework in applications where the essential behavior of a system is language-like. A very approachable treatment of Formal Languages is given by Revesz [1]. An automaton is a kind of language receiver. Automata are not limited to spoken languages but can be used with nearly any sequence of symbols. As an automaton interacts with its environment receiving symbols, it undergoes transitions of its internal state. The internal state of the automaton determines, in part, what the output (response) of the automaton is. Automata learn from the environment what their internal state should be. If you think of an automaton as a machine, you may look inside the machine to see what it is made of. If you 'run' the automaton, and let it interact with the environment, when you open the box again and look you will typically see a different machine.

It is often advantageous to use a fuzzy automaton. When I say "yester," you go partly into a state where you are ready to hear "day." But this is not the whole story. You also go partly (slightly) into a state where you are ready to hear "year" because yesteryear is also a word you might expect to hear occasionally. Fuzzy automata allow you to work with such situations. They allow your state membership to straddle two or more states. In addition to fuzzy states, fuzzy automata also have fuzzy transitions and fuzzy output mappings (responses). Klir and Yuan provide an excellent introduction to fuzzy automata [2].

Fuzzy automata are able to learn from actions A_k produced in the environment by making fuzzy transitions from learning state x_k to learning state x_{k+1} until an admissible response B_k is achieved. This response corresponds to reaching a decision boundary for labelling in active learning. These decisions about what has been detected or acquired (the label) inform the user of what is present in the environment. A pernicious problem with fuzzy automata is the tendency in applications for the internal state to be unstable. The presently discussed new algorithm addresses this problem by integrating components of a Kalman filter to smooth the internal state of the fuzzy automaton.

Sometimes the state of a system cannot be known perfectly. For example, in GPS it is not possible to know the position and velocity perfectly owing to noise and environmental effects. A Kalman filter is used to smooth the state vector (position, velocity, etc.) to provide an optimal approximation to the true state. A Kalman filter is an algorithm for estimating the true state of a system at iteration k by using previous estimates and measured data. State estimates $\hat{x}_k$ are formed using the previous state estimate $\hat{x}_{k-1}$ and measured data z_k as well other variables including Kalman Gain K_k and covariance P_{k-1}. An engineering approach to Kalman Filtering, with a MATLAB disk, is provided by Grewal and Andrews [3] while a mathematical discussion is presented in a Dover book by Stengel [4].

The present paper presents a new algorithm which addresses the stability problem of the fuzzy automaton by smoothing its internal state using a Kalman filter. An example application is change detection. An example of the application of Kalman state-smoothing of a fuzzy automaton is presented in Figure 1. The inputs and outputs of the fuzzy automaton are shown. In Figure 1, in the top of the plot, an input signal A_k over two channels (for example, I and Q) has a hidden, low entropy, signal in one of the channels (the solid line channel). The output (automaton response) B_k is three signals that appear in the lower half of the diagram. (Think of them as three voters.). Here the input actions A_k (the "-." and black curves) produce output B_k ("-", ".", and "+"). A smooth, early arrived at, change detection is demonstrated.

Example decision boundaries could be the horizontal lines at y = .6.

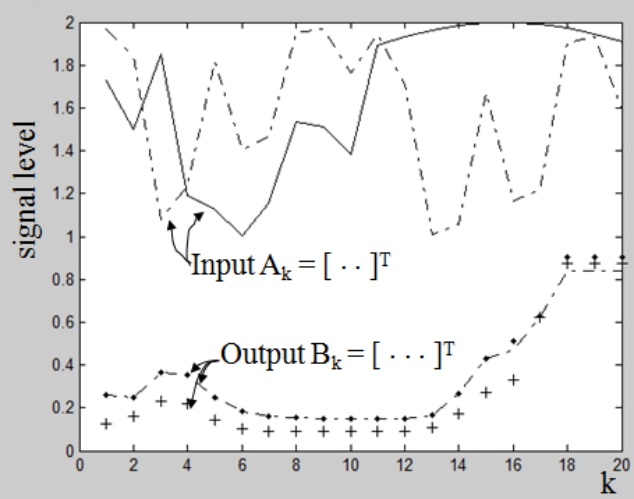

Figure 1: Smooth, early change detection using fuzzy automaton with Kalman state-smoothing. The output signals rise in response to the "hidden" signal in the solid component of the input.

2 Description of the Algorithm

This paper presents a fuzzy automaton/Kalman filter hybrid algorithm ("Kalmaton"). The algorithm is an iterative predictor device which steps through a sequence of steps from $k = 1$ to N, taking input A_k at each step and producing output B_k at each step. The elements that occur together in this algorithm are:

1) An input matrix A_k of actions from the environment external to the device.
2) A matrix B_k of outputs returned from the device and presented to the user.
3) An estimate internal state of the system $\hat{x}_k$ which is updated every iteration, k.
4) A three-dimensional matrix S of fuzzy state transitions.
5) An aggregate matrix SA_k which is derived from the input and the matrix of fuzzy state transitions at each iteration k.
6) A Kalman Gain matrix K_k which is updated each k.
7) A symmetric covariance matrix P_k which is updated each k using a congruence transform.
8) A transition matrix Φ.
9) A fuzzy response matrix R.
10) An observation matrix H.
11) An internal measurement z_k.
12) A white noise covariance matrix ρ.

The sequence of activities of the algorithm at each iteration k are as follows:

1) An input A_k from the environment is aggregated (minmax) with the matrix of fuzzy transitions S to form fuzzy intermediate matrix SA_k.

$$SA_k(\zeta_i, \zeta_j) = \max_{\ell}\left\{\min\left[A_k(\xi_\ell), S(\xi_\ell, \zeta_i, \zeta_j)\right]\right\} \quad (1)$$

2) $\hat{x}_{k-1}$ is aggregated with SA_k and the result of this aggregation is called measurement z_k.

$$z_k = \hat{x}_{k-1} \circ SA_k \quad (2)$$

Where the operator $\circ$ is defined as:

$$A \circ B = \max_{i}\left\{\min[A(i), B(i,j)]\right\} \quad (3)$$

3) The Kalman gain, K_k, is updated using the covariance, P_{k-1}, observation matrix, H, and white noise covariance, ρ.

$$K_k = P_{k-1}H^T(H\ P_{k-1}H^T + \rho)^{-1} \quad (4)$$

4) The covariance is updated to become P_k by using:

$$P_k = (I - K_k H)P_{k-1} \quad (5)$$

5) The state estimate update, $\hat{x}_k$, is then formed by using the Kalman weighted average with z_k serving as the measurement.

$$\hat{x}_k = \hat{x}_{k-1} + K_k(z_k - H\hat{x}_{k-1}) \quad (6)$$

6) Finally, $\hat{x}_k$ is aggregated with response matrix R to form the output B_k.

$$B_k = \hat{x}_k \circ R \quad (7)$$

A point of novelty is that the fuzzy intermediate matrix, SA_k, is aggregated with the state estimate from the Kalman filter, $\hat{x}_{k-1}$. This aggregation amalgamates the state of the automaton with the Kalman filter state so that the state can be smoothed in order to increase the stability. A second point of novelty is that the aggregate, z_k, is used as the input to the Kalman state update operation. This allows an innovation process that smoothes the output, making it easier to place decision boundaries. A third point of novelty is that the output, B_k, to the user is formed by aggregating the state estimate with the fuzzy response matrix R. This allows more flexibility to make the output in a format that is conducive to setting decision boundaries.

The Kalman filter is integrated with the fuzzy automaton as a hybrid algorithm, rather than being a Kalman filter and automaton in series or parallel. The block diagram of the Fuzzy Automaton with Kalman State-Smoothing is presented in Figure 2. The variables are identified in Table 1. Lower-case denotes a vector while upper-case denotes a matrix.

Table 1: List of Variables

Variable	Description
k	Iteration Number
$\hat{x}_k$	Estimate State
A_k	Input from Environment
B_k	Output to User
SA_k	Fuzzy Intermediate Matrix
K_k	Kalman Gain
S	Matrix of Fuzzy Transitions
P_k	State Covariance
R	Response Matrix
z_k	Measurement of State

3 Application of Algorithm

The algorithm described by the diagram in Figure 2 was demonstrated by coding it as a MATLAB script. That script was executed on an HP EliteBook notebook computer, generating the plot appearing in Figure 1. The plot shows a 20x2 matrix input actions, A_k, represented by the ".-" and solid curves, and a 20x3 output matrix, B_k, which is represented by the dot, dash, and plus curves. The meaning of the plot is that there is a smooth response to very noisy input actions while an early change detection capability is demonstrated as the output signals rise at about time k = 14.

For the reduction to practice the authors used the following state transition matrix Φ:

$$\Phi = \begin{bmatrix} 0.320 & 0.188 & 0.567 & 0.145 \\ 0.188 & 0.759 & 0.376 & 0.489 \\ 0.567 & 0.376 & 0.213 & 0.0128 \\ 0.145 & 0.489 & 0.0128 & 0.187 \end{bmatrix} \quad (8)$$

The input actions, A, were given by:

$$A = \begin{bmatrix} 0.0128 & 0.540 \\ 0.377 & 0.705 \\ 0.168 & 0.503 \\ 0.540 & 0.783 \\ 0.102 & 0.927 \\ 0.393 & 0.830 \\ 0.933 & 0.825 \\ 0.972 & 0.767 \\ 0.361 & 0.997 \\ 0.644 & 0.228 \\ 0.891 & 0.292 \\ 0.932 & 0.498 \\ 0.964 & 0.253 \\ 0.985 & 0.612 \\ 0.997 & 0.859 \\ 1.00 & 0.688 \\ 0.992 & 0.680 \\ 0.974 & 0.589 \\ 0.946 & 0.994 \\ 0.909 & 0.0518 \end{bmatrix} \quad (9)$$

The white noise covariance that was used is given by the following:

$$\rho = \begin{bmatrix} 0.485 & 0.691 & 0.112 & 0.499 \\ 0.838 & 0.0345 & 0.743 & 0.568 \\ 0.141 & 0.489 & 0.639 & 0.427 \\ 0.732 & 0.971 & 0.594 & 0.0762 \end{bmatrix} \quad (10)$$

The observation matrix, H, that was used is:

$$H = \begin{bmatrix} 0.291 & 0.978 & 0.474 & 0.960 \\ 0.561 & 0.0936 & 0.356 & 0.891 \\ 0.633 & 0.662 & 0.476 & 0.798 \\ 0.931 & 0.603 & 0.671 & 0.0591 \end{bmatrix} \quad (11)$$

The fuzzy response, R, that was used is:

$$R = \begin{bmatrix} 0.912 & 0.504 & 0.331 \\ 0.101 & 0.768 & 0.453 \\ 0.293 & 0.283 & 0.737 \\ 0.0516 & 0.225 & 0.510 \end{bmatrix} \quad (12)$$

The fuzzy state transition used is a 4x4x2 matrix given by the following:

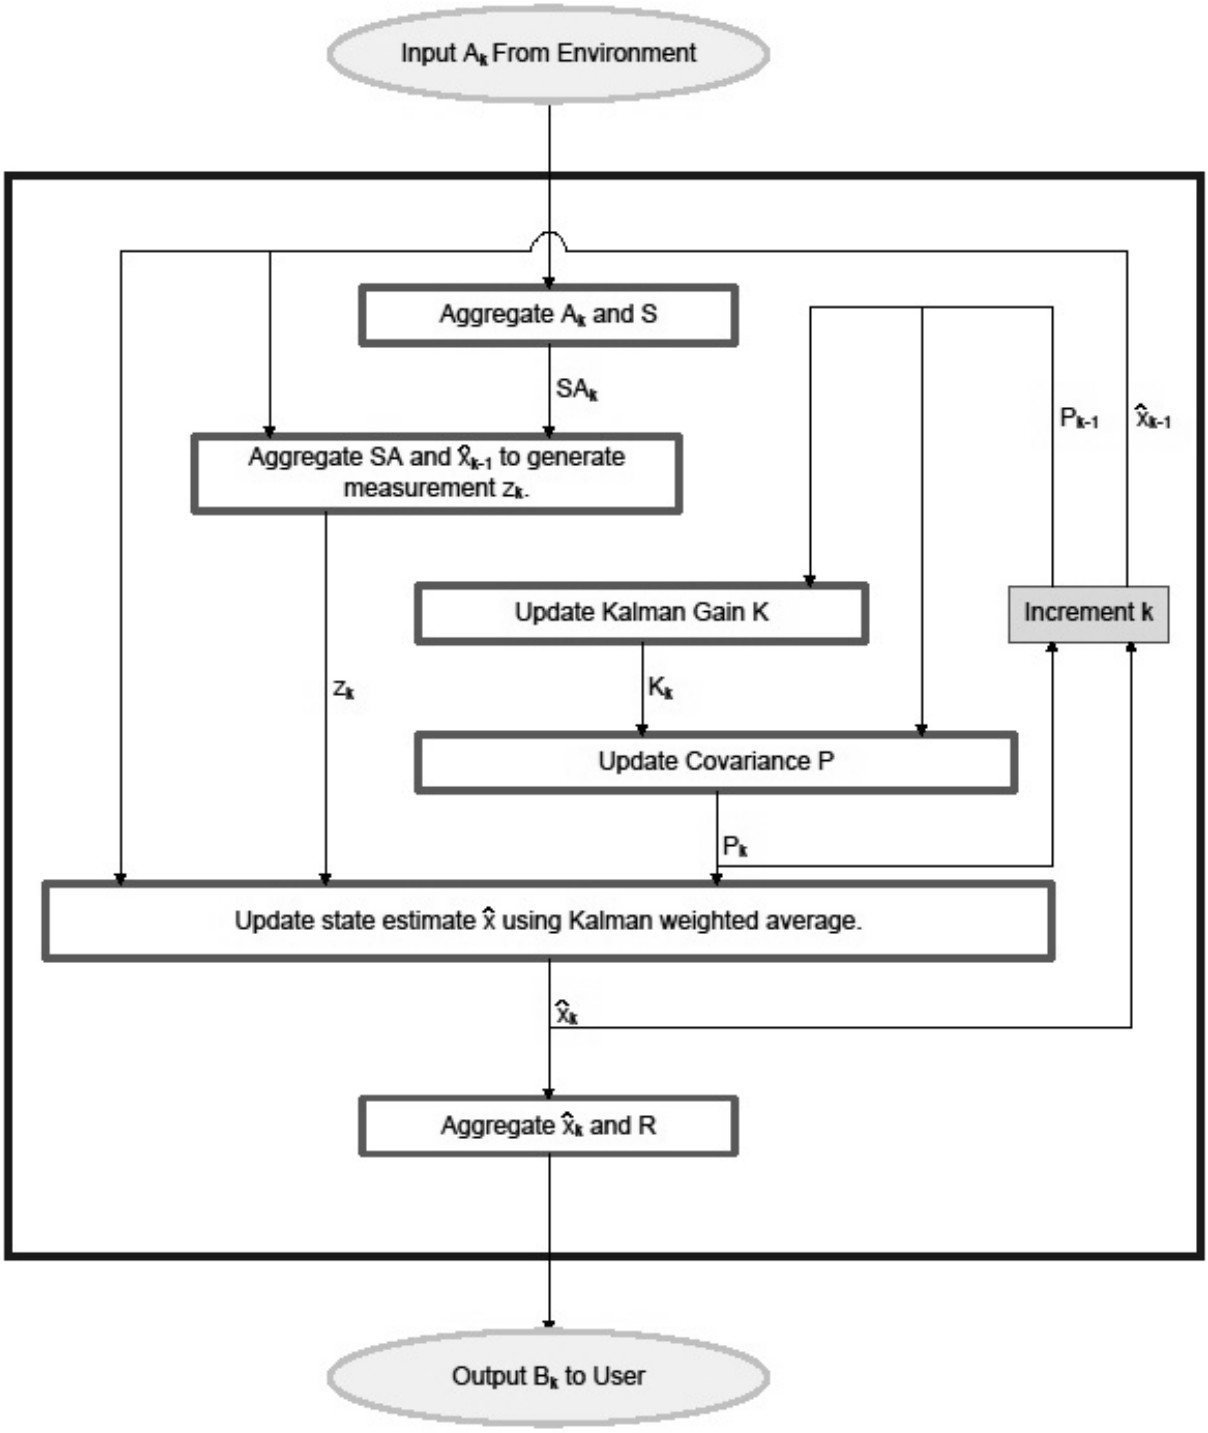

Figure 2: Fuzzy Automaton with Kalman State-Smoothing block diagram.

$$S(:,:,1) = \begin{bmatrix} 0.383 & 0.132 & 0.287 & 0.689 \\ 0.905 & 0.618 & 0.706 & 0.0505 \\ 0.965 & 0.383 & 0.535 & 0.184 \\ 0.628 & 0.991 & 0.193 & 0.0457 \end{bmatrix}$$

$$S(:,:,2) = \begin{bmatrix} 0.885 & 0.120 & 0.990 & 0.973 \\ 0.840 & 0.572 & 0.350 & 0.623 \\ 0.118 & 0.949 & 0.209 & 0.0635 \\ 0.410 & 0.256 & 0.666 & 0.374 \end{bmatrix} \quad (13)$$

The initial state of the system was:

$$x = [0.793 \quad 0.373 \quad 0.832 \quad 0.754]' \quad (14)$$

As a basis of comparison, the Kalman filter was extricated from the algorithm and the same experiment was run. As can be seen in the example in Figure 3, the automaton broke down and failed to respond to the hidden signal.

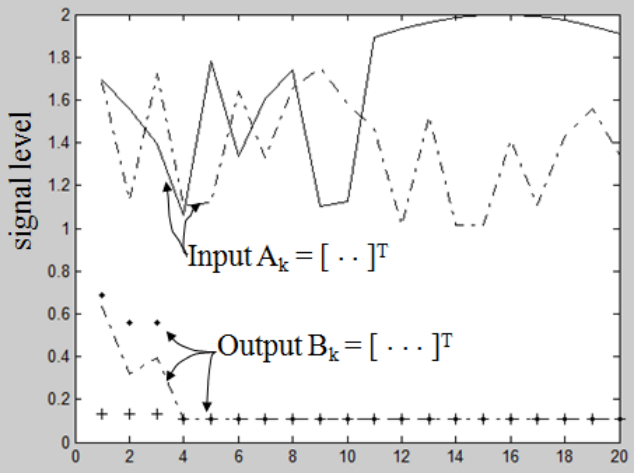

Figure 3. Automaton breaks down and fails to respond to the hidden signal.

The average of 20 Automaton responses shows that the automaton breakdown is typical. See Figure 4. Here, the same input generator was used. The average of output responses of the Kalmaton for the same input signal generator is shown in Figure 5. The response to the "hidden" signal is evident.

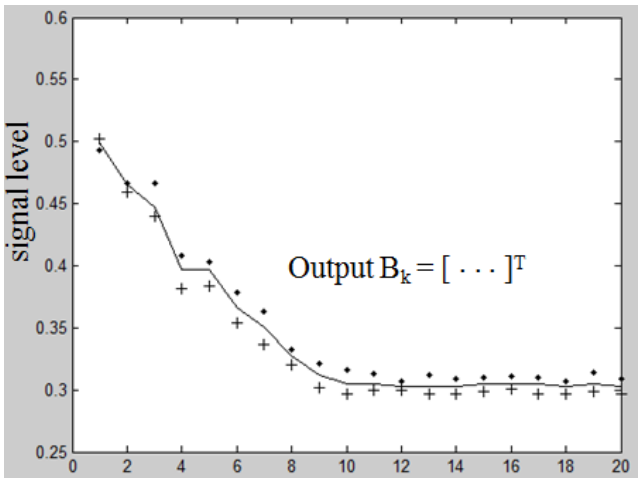

Figure 4. Average of 20 sets of automata show that utomaton breakdown is typical for the input signal of Figure 3.

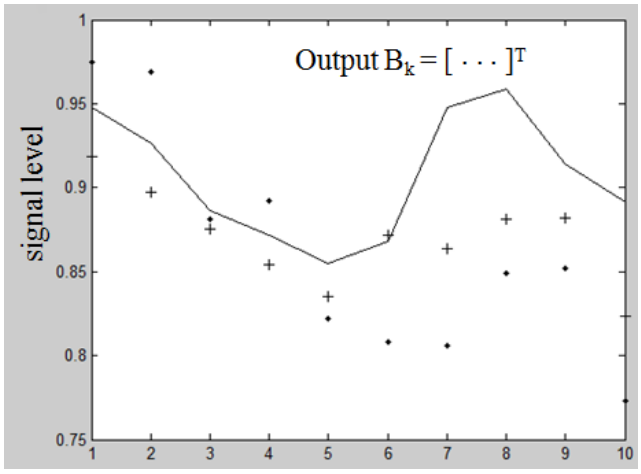

Figure 5. Average Kalmaton output shows response to "hidden" signal is typical.

4 Summary

A Kalman filter can be incorporated into a fuzzy automaton and used to smooth the internal state. The resulting "Kalmaton" can produce a stable automaton response while retaining the ability to perform an effective change detection.

Email: yingkyang@yahoo.com

Abstract - *Some researchers have proposed a self-constructing rule-based fuzzy system based on reinforcement learning, which often results in a 5-layer neural network. The Fuzzy-reasoning Radial Basis Function Neural Network (FRBFN) proposed in this paper has only 3 layers to reduce its forwarding calculation time. The network has no fuzzification and defuzzification in the learning system. The Radial Basis Function Neural Network (RBFN) is employed in FRBFN to offer the generality and smoothness of the network. The conducted experiment shows the proposed network has good performance on well training a rule-based fuzzy system through reinforcement learning.*

Keywords: fuzzy systems, radial basis function neural network, reinforcement learning, supervised learning

1 Motivation

The rule-based fuzzy systems have been successfully used in many real-world control applications [1]. Many researchers have devoted research on constructing rules and membership functions by system itself through learning [2][3][4][5]. Supervised learning requires sample data sufficiently large enough to learn. The use of reinforcement learning is to eliminate this requirement. Reinforcement learning method is based on a trial-and-error method and therefore no precise training pair is required [6][7][8][9][10].

Most researchers have considered a fuzzy system as a five layers neural network. This selection is to map input variables, input membership functions, rule base, output membership functions and output variables to each layer of neural network respectively. The use of five layers has created a complex neural network that requires high computation cost. A less layers of neural network that performs the same function is proposed in this thesis. This idea comes from the similarity between a Radial Basis Function Neural Network (RBFN) and a rule-based fuzzy system [11][12]. The proposed network has only three layers: input layer, hidden layer and output layer. The layer reduction can decrease the computation cost and enhance the learning speed of a network system.

2. The Fuzzy-Reasoning Radial Basis Function Neural Network (FRBFN)

2.1 Network Architecture

The logical network of proposed FRBFN is shown in Figure 1.

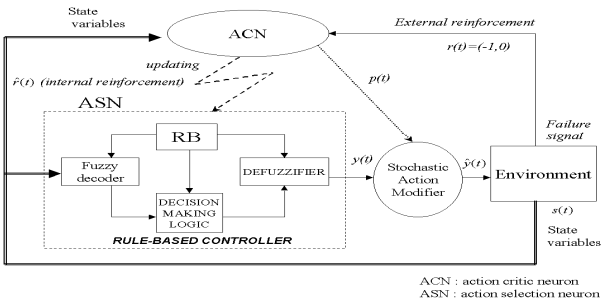

Figure 1. Logical Network Architecture of FRBFN

There are four functional blocks in Figure 1. Action Critic Network (ACN), Action Selection Network (ASN) and Stochastic Action Modifier (SAM) function blocks are the basic components of FRBFN network. The environment function block on the right is the target for control purpose.

2.2 Function of ASN

ASN acts as a rule-based fuzzy logic controller that includes three basic components in a fuzzy system: fuzzification, inference engine and defuzzification [1]. Because of the equivalence between rule-based fuzzy system and RBFN[11][12], a RBFN is introduced to implement an ASN. The RBFN performs the task of what a fuzzy system can do and eliminates the procedures of fuzzification and defuzzification. The network architecture of ASN implemented by RBFN is shown in Figure 2. ASN receives state variables *s(t)* from environment, such as a controlled plant and internal reinforcement signal $\hat{r}(t)$ generated from ACN. The state variables offer the information about plant's current status. For the associated reinforcement learning system, both the state variables and the internal reinforcement signals are used as a criteria to update learning parameters in ASN. The values of these parameters are learned and consequently generated through the signals of state variables *s(t)* and internal reinforcement signal $\hat{r}(t)$.

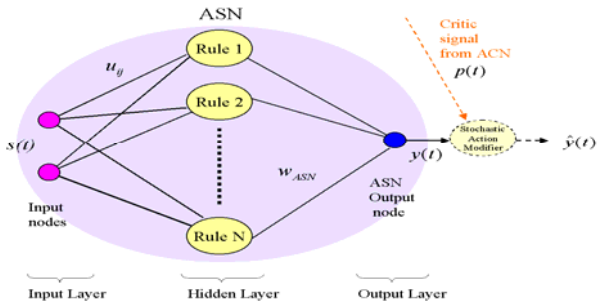

Figure 2. Block diagram of Action Selection Network (ASN)

The output of ASN does not directly apply to the controlled plant. Instead, the output *y(t)* of ASN is first sent to the Stochastic Action Modifier (SAM). The SAM then tries to optimize *y(t)* to generate a modified output $\hat{y}(t)$ based on the predicted reinforcement signal $p(t)$ at that time and its stochastic algorithm.

$$\hat{y}(t) = N(y(t), \sigma(t)) \qquad (1)$$

where N is a normal or Gaussian distribution function with mean $y(t)$ and variance $\sigma(t)$. A small value of $\sigma(t)$ indicates the system is closer to a stable situation. For our learning algorithm, we choose probability function $\sigma_p(t)$ as

$$\sigma_p(t) = \frac{1}{1+e^{2p(t)}} \qquad (2)$$

where $p(t)$ is generated by ACN and is the signal used to predict reinforcement signal $r(t)$.

2.3 Function of ACN

The function of an ACN shown in Figure 1 is to generate signals of $p(t)$ and $\hat{r}(t)$ by receiving state variables and external reinforcement signals. The output signal $p(t)$ is a prediction signal and $\hat{r}(t)$ is an internal reinforcement signal. The purpose of $p(t)$ is to predict the infinite discounted prediction signal $z(t)$ and $\hat{r}(t)$ is the difference between $p(t)$ and $z(t)$. The objective of ACN is to model the environment such that it can perform a multi-step prediction of reinforcement signal for the current action chosen by ASN. Using a Radial Basis Function Network (RBFN) is proposed to implement an ACN, because a RBFN has the ability to approximate the real-valued mapping of continuous or piecewisely continuous function. Another reason to use RBFN is for total network architecture of FRBFN. If both the ASN and ACN use the same neural network architecture, some layers of RBFN can be shared. The network diagram of ACN is shown in Figure 3.

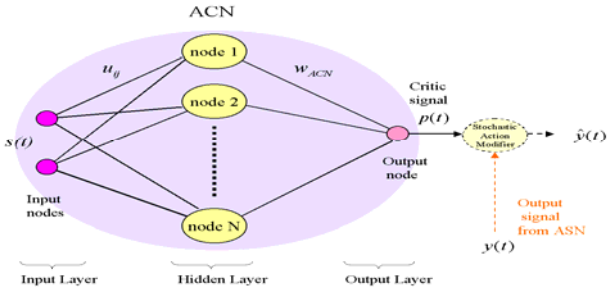

Figure 3. Block diagram of Action Critic Network (ACN)

The input space *s(t)* of ASN and ACN should be identical because they all receive same information of *s(t)* from the same environment. The input and hidden layers of ASN or ACN can be shared each other. The architecture of proposed FRBFN is more compact by sharing the first two layers,. The network architecture shown in Figure 4 is composed of one ASN and one ACN to form the final version of FRBFN.

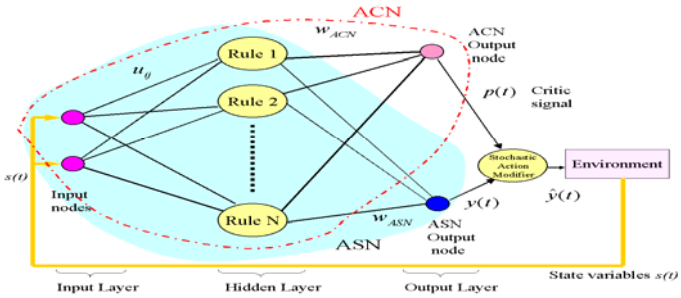

Figure 4. FRBFN implementation diagram

The network diagrams of ASN and ACN shown in Figure 2 and Figure 3 are merged in Figure 4. There are three reasons to combine these two networks: (1) Both ASN and ACN have the same network architecture. (2) The input state space for these two networks is identical. (3) The numbers of hidden nodes in ASN and ACN are identical because of the same input state space. Sharing layer 1 and layer 2 by ACN and ASN will reduce the memory requirement for storage and eliminate the need to recalculate the outputs of hidden nodes. And in learning phase, we do learn widths and centers in hidden nodes once only because ACN and ASN both use the same hidden nodes. These two networks have their own weight parameters between layer 2 and layer3. The network architecture of FRBFN is simpler and the learning parameters are less than others in [3][4][5][6].

2.4 Learning in Action Selection Network

The parameters that need to be adjusted by learning mechanism are centers and widths in nodes of hidden layer and the weights between hidden and output layers. One of the goals of the ASN is to have output that maximizes the

reinforcement signal $r(t)$. The learning relation can be written as:

$$\Delta m_i \propto \frac{\partial r}{\partial m_i} \quad (3)$$

where m_i denotes a parameter to be adjusted and Δm_i is the amount of adjustment applied to the parameter m_i stands for in ASN. The relation indicates that the amount of adjustment to a parameter is proportional to the strength of its associated reinforcement signal. Using chaining rule to expand the right part of equation (3), we have

$$\frac{\partial r}{\partial m_i} = \frac{\partial r}{\partial y} \cdot \frac{\partial y}{\partial m_i} \quad (4)$$

where y is the output of the ASN and $\frac{\partial y}{\partial m_i}$ denotes the amount y is changed when adjustment parameter m_i changes. The equation (4) shows $\frac{\partial r}{\partial y}$ and $\frac{\partial y}{\partial m_i}$ are required in order to determine $\frac{\partial r}{\partial m_i}$. The term $\frac{\partial y}{\partial m_i}$ is the gradient information for output regarding to its operational parameter and can be derived easily. But the reinforcement signal is not generated in every time step. The gradient value of $\frac{\partial r}{\partial y}$ can only be **estimated**. In our learning algorithm, we use stochastic exploration method [13] to estimate gradient information $\frac{\partial r}{\partial y}$. For multi-step prediction, the gradient information $\frac{\partial r}{\partial y}$ is estimated as

$$\frac{\partial r}{\partial y} \approx [z_{t-1} - p_{t-1}] \cdot \left[\frac{\hat{y} - y}{\sigma_p}\right]_{t-1} = \hat{r}(t) \cdot \left[\frac{\hat{y} - y}{\sigma_p}\right]_{t-1} \quad (5)$$

The estimation of $\frac{\partial r}{\partial y}$ is defined in equation (5), where z_{t-1} is infinite discounted cumulated outcome. A general network architecture of ASN based on RBFN is shown in Figure 5.

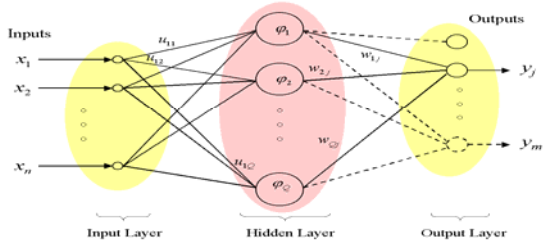

Figure 5. General Network Architecture of ASN

2.5 Learning for weights between hidden and output layers of ASN

Let's discuss weight w_{ij} between *i-th* hidden node and *j-th* output. The kernel function used in ASN is Gaussian function. From Figure 5, the output y_j for *j-th* output node can be expressed as

$$y_j = \sum_{i=1}^{Q} \varphi_i w_{ij} = \sum_{i=1}^{Q} \exp\left(-\frac{(x_{i,1} - v_{i,1})^2}{2\sigma_{i,1}^2} - \frac{(x_{i,2} - v_{i,2})^2}{2\sigma_{i,2}^2} - \cdots - \frac{(x_{i,n} - v_{i,n})^2}{2\sigma_{i,n}^2}\right) \cdot w_{ij} \quad (6)$$

where w_{ij} is the weight between *i-th* hidden node and *j-th* output node. The variable being interested in equation (6) is w. The equation (4) can be re-expressed as (m_i is replaced by w_{ij})

$$\frac{\partial r}{\partial w_{ij}} = \frac{\partial r}{\partial y_j} \cdot \frac{\partial y_j}{\partial w_{ij}} \quad (7)$$

where $y_j = \sum_i \varphi_i w_{ij}$ denotes the output value of the *j-th* output node in ASN.

Because $\frac{\partial y_j}{\partial w_{ij}} = \frac{\partial}{\partial w_{ij}} \sum_i \varphi_i w_{ij} = \varphi_i$, applying equation (5) to equation (7), we have

$$\frac{\partial r}{\partial w_{ij}} = \hat{r}(t) \cdot \left[\frac{\hat{y}_j - y_j}{\sigma_p}\right]_{t-1} \varphi_i(t-1) \quad (8)$$

According to equation (3) and equation (8), the learning rule for weights between *i-th* hidden node and *j-th* output node is

$$\Delta w_{ij} = \alpha_{ASN_w} \cdot \frac{\partial r}{\partial w_{ij}} = \alpha_{ASN_w} \cdot \hat{r}(t) \cdot \left[\frac{\hat{y}_j - y_j}{\sigma_p}\right]_{t-1} \varphi_i(t-1) \quad (9)$$

where α_{ASN_w} is a positive learning rate for weights in ASN. So, the weight $w_{ij}(t+1)$ needs to be adjusted by Δw_{ij}, that is

$$w_{ij}(t+1) = w_{ij}(t) + \Delta w_{ij} = w_{ij}(t) + \alpha_{ASN_w} \cdot \hat{r}(t) \cdot \left[\frac{\hat{y}_j - y_j}{\sigma_p}\right]_{t-1} \varphi_i(t-1) \quad (10)$$

2.6 Learning for centers in ASN hidden layer

The kernel function of hidden nodes in FRBFN is Gaussian function. There are two parameters, width and center, should be adjusted in hidden nodes. The interested variable is center *v* in equation (6). Because a hidden node in FRBFN is a multi-dimensional node, the output of a hidden node is a non-linear transformation based on Euclidean distance. Therefore, only the calculation of the Euclidean norm between input state and its center is required for multi-linguistic variable cases to perform Gaussian transformation.

Since the interested variable is *v*, by equation (4), the center parameters can be adjusted with respect to each individual dimension.

$$\frac{\partial r}{\partial v_{i,j}} = \frac{\partial r}{\partial y} \cdot \frac{\partial y}{\partial v_{i,j}} \quad (11)$$

where *i* stands for the *i-th* rule node and *j* stands for the *j-th* dimension. Referring to equation (5) and (6),

$$y_j = \sum_{i=1}^{Q} \varphi_i w_{ij} = \sum_{i=1}^{Q} \exp\left(-\frac{(x_{i,1}-v_{i,1})^2}{2\sigma_{i,1}^2} - \frac{(x_{i,2}-v_{i,2})^2}{2\sigma_{i,2}^2} - \cdots - \frac{(x_{i,n}-v_{i,n})^2}{2\sigma_{i,n}^2}\right) \cdot w_{ij}$$

the center parameter can be adjusted in every dimension by

$$\frac{\partial r}{\partial v_{i,j}} = \frac{\partial r}{\partial y}\cdot\frac{\partial y}{\partial v_{i,j}} = \frac{\partial r}{\partial y}\cdot\frac{\partial}{\partial v_{i,j}}\sum_i \exp\left(\frac{(x_{i,1}-v_{i,1})^2}{2\sigma_{i,1}^2} - \cdots - \frac{(x_{i,n}-v_{i,n})^2}{2\sigma_{i,n}^2}\right)\cdot w_{ij}$$

$$= \frac{\partial r}{\partial y}\cdot\left(\sum_i \exp\left(\frac{(x_{i,1}-v_{i,1})^2}{2\sigma_{i,1}^2} - \cdots - \frac{(x_{i,n}-v_{i,n})^2}{2\sigma_{i,n}^2}\right)\cdot w_{ij}\right)\cdot\frac{\partial}{\partial v_{i,j}}\left(\frac{(x_{i,1}-v_{i,1})^2}{2\sigma_{i,1}^2} - \cdots - \frac{(x_{i,j}-v_{i,j})^2}{2\sigma_{i,j}^2} - \cdots - \frac{(x_{i,n}-v_{i,n})^2}{2\sigma_{i,n}^2}\right)$$

$$= \frac{\partial r}{\partial y}\cdot\left(\sum_i \exp\left(\frac{(x_{i,1}-v_{i,1})^2}{2\sigma_{i,1}^2} - \cdots - \frac{(x_{i,n}-v_{i,n})^2}{2\sigma_{i,n}^2}\right)\cdot w_{ij}\right)\cdot\left(0 - \cdots + \frac{(x_{i,j}-v_{i,j})_{t-1}}{\sigma_{i,j}^2(t-1)} - \cdots - 0\right)$$

$$= \underbrace{\hat{r}(t)\cdot\left[\frac{\hat{y}-y}{\sigma_p}\right]_{t-1}}_{a}\cdot\underbrace{\varphi_i(t-1)}_{b}\cdot\underbrace{\frac{(x_{i,j}-v_{i,j})_{t-1}}{\sigma_{i,j}^2(t-1)}}_{c} \qquad (12)$$

a: estimated gradient
b: to decide effectiveness
c: to decide direction & amount

Part a is an estimated gradient information, as discussed in equation (5). Part b is one of the factors affects the adjustment amount. In part c, the nominator decides the direction and amount of adjustment. According to equation (3) and equation (12), the learning rule for center in *j-th* dimension of *i-th* output node is

$$\Delta v_{i,j} = \alpha_{ASN_v}\cdot\frac{\partial r}{\partial v_{i,j}} = \alpha_{ASN_v}\cdot\hat{r}(t)\cdot\left[\frac{\hat{y}-y}{\sigma_p}\right]_{t-1}\cdot\frac{(x_{i,j}-v_{i,j})_{t-1}}{\sigma_{i,j}^2(t-1)}\cdot\varphi_i(t-1) \quad (13)$$

where α_{ASN_w} is a positive learning rate for weight in ASN. So, the center $v_{ij}(t+1)$ needs to be adjusted by Δv_{ij}, that is

$$v_{i,j}(t+1) = v_{i,j}(t) + \alpha_{ASN_v}\cdot\hat{r}(t)\cdot\left[\frac{\hat{y}-y}{\sigma_p}\right]_{t-1}\cdot\frac{(x_{i,j}-v_{i,j})_{t-1}}{\sigma_{i,j}^2(t-1)}\cdot\varphi_i(t-1) \quad (14)$$

2.6 Learning for widths in ASN hidden layer

The interested variable is center σ in equation (6). The width in dimensions can be either equal to or different from each other.

2.6.1 Equal width in each dimension

A Gaussian kernel function is described in equation (3) a hidden node as:

$$y = \sum_i \varphi_i w_i = \sum_i \exp\left(-\frac{\|\vec{x}_i - \vec{v}_i\|^2}{2\sigma_i^2}\right)\cdot w_i \qquad (15)$$

Since the interested variable is σ, by equation (4) and (5) the width parameters can be adjusted by.

$$\frac{\partial r}{\partial \sigma_i} = \frac{\partial r}{\partial y}\cdot\frac{\partial y}{\partial \sigma_i} = \frac{\partial r}{\partial y}\cdot\frac{\partial}{\partial \sigma_i}\left(\exp\left(-\frac{\|\vec{x}_i - \vec{v}_i\|^2}{2\sigma_i^2}\right)\right)\cdot w_i$$

$$= \frac{\partial r}{\partial y}\cdot\left(\exp\left(-\frac{\|\vec{x}_i - \vec{v}_i\|^2}{2\sigma_i^2}\right)\right)\cdot w_i\cdot\frac{\partial}{\partial \sigma_i}\left(-\frac{\|\vec{x}_i - \vec{v}_i\|^2}{2\sigma_i^2}\right)$$

$$= \frac{\partial r}{\partial y}\cdot\varphi_i\cdot w_i\cdot\|\vec{x}_i - \vec{v}_i\|^2\cdot\sigma_i^{-3}$$

$$= \hat{r}(t)\cdot\left[\frac{\hat{y}-y}{\sigma_p}\right]_{t-1}\cdot\left(\varphi_i\cdot w_i\cdot\|\vec{x}_i - \vec{v}_i\|^2\cdot\sigma_i^{-3}\right)_{t-1} \qquad (16)$$

According to equation (3) and equation (16), the learning rule for width at *i-th* hidden node is

$$\Delta\sigma_i = \alpha_{ASN_\sigma}\cdot\frac{\partial r}{\partial \sigma_i} = \alpha_{ASN_\sigma}\cdot\hat{r}(t)\cdot\left[\frac{\hat{y}-y}{\sigma_p}\right]_{t-1}\cdot\left(\varphi_i\cdot w_i\cdot\|\vec{x}_i - \vec{v}_i\|^2\cdot\sigma_i^{-3}\right)_{t-1} \quad (17)$$

where α_{ASN_σ} is a positive learning rate for a width in ASN. The width $\sigma_i(t+1)$ needs to be adjusted by $\Delta\sigma_i$, that is

$$\sigma_i(t+1) = \sigma_i(t) + \Delta\sigma_i = \sigma_i(t) + \alpha_{ASN_\sigma}\cdot\hat{r}(t)\cdot\left[\frac{\hat{y}-y}{\sigma_p}\right]_{t-1}\cdot\left(\varphi_i\cdot w_i\cdot\|\vec{x}_i - \vec{v}_i\|^2\cdot\sigma_i^{-3}\right)_{t-1} \quad (18)$$

Here all width parameters in each dimension are assumed to have equal width to simplify the learning algorithm. This scaling factor u_{ij} is shown in Figure 5. This assumption does not violate the correctness of our proposed network.

2.6.2 Different width in each dimension

Since the interested variable is $\sigma_{i,j}$, by equation (4)(5) and (15) the width parameters can be adjusted by.

$$\frac{\partial r}{\partial \sigma_{i,j}} = \frac{\partial r}{\partial y}\cdot\frac{\partial y}{\partial \sigma_{i,j}} = \frac{\partial r}{\partial y}\cdot\frac{\partial}{\partial \sigma_{i,j}}\sum_i \exp\left(\frac{(x_{i,1}-v_{i,1})^2}{2\sigma_{i,1}^2} - \cdots - \frac{(x_{i,n}-v_{i,n})^2}{2\sigma_{i,n}^2}\right)\cdot w_{ij}$$

$$= \frac{\partial r}{\partial y}\cdot\sum_i \exp\left(\frac{(x_{i,1}-v_{i,1})^2}{2\sigma_{i,1}^2} - \cdots - \frac{(x_{i,n}-v_{i,n})^2}{2\sigma_{i,n}^2}\right)\cdot w_{ij}\cdot\frac{\partial}{\partial \sigma_{i,j}}\left(\frac{(x_{i,1}-v_{i,1})^2}{2\sigma_{i,1}^2} - \cdots - \frac{(x_{i,j}-v_{i,j})^2}{2\sigma_{i,j}^2} - \cdots - \frac{(x_{i,n}-v_{i,n})^2}{2\sigma_{i,n}^2}\right)$$

$$= \frac{\partial r}{\partial y}\cdot\sum_i \exp\left(\frac{(x_{i,1}-v_{i,1})^2}{2\sigma_{i,1}^2} - \cdots - \frac{(x_{i,n}-v_{i,n})^2}{2\sigma_{i,n}^2}\right)\cdot w_{ij}\cdot\left(-0 - \cdots + \|\vec{x}_i - \vec{v}_i\|^2\cdot\sigma_{i,j}^{-3} - \cdots - 0\right)$$

$$= \frac{\partial r}{\partial y}\cdot\varphi_i\cdot w_{ij}\cdot\|\vec{x}_i - \vec{v}_i\|^2\cdot\sigma_{i,j}^{-3}$$

$$= \hat{r}(t)\cdot\left[\frac{\hat{y}-y}{\sigma_p}\right]_{t-1}\cdot\left(\varphi_i\cdot w_i\cdot\|\vec{x}_i - \vec{v}_i\|^2\cdot\sigma_{i,j}^{-3}\right)_{t-1} \qquad (19)$$

This is the amount need to be adjusted for the *i-th* node in dimension *j*. According to equation (3) and equation (19), the learning rule for width at *i-th* hidden node is

$$\Delta\sigma_{i,j} = \alpha_{ASN_\sigma}\cdot\frac{\partial r}{\partial \sigma_{i,j}} = \alpha_{ASN_\sigma}\cdot\hat{r}(t)\cdot\left[\frac{\hat{y}-y}{\sigma_p}\right]_{t-1}\cdot\left(\varphi_i\cdot w_i\cdot\|\vec{x}_i - \vec{v}_i\|^2\cdot\sigma_{i,j}^{-3}\right)_{t-1} \quad (20)$$

where α_{ASN_σ} is a positive learning rate for a width in ASN. The width in each dimension $\sigma_{i,j}(t+1)$ needs to be adjusted by $\Delta\sigma_{i,j}$, that is

$$\sigma_{i,j}(t+1)=\sigma_{i,j}(t)+\Delta\sigma_{i,j}=\sigma_{i,j}(t)+\alpha_{ASN_\sigma}\cdot\hat{r}(t)\cdot\left[\frac{\hat{y}-y}{\sigma_p}\right]_{t-1}\cdot\left(\varphi_i\cdot w_i\cdot\left\|\vec{x}_i-\vec{v}_i\right\|^2\cdot\sigma_{i,j}^{-3}\right)_{t-1} \quad (21)$$

3. Conclusion

The proposed Fuzzy-reasoning Radial Basis Function Neural Network has been applied to control a cart-pole balancing system and the result has shown our proposed system works better. The experiment is not discussed detailed here due to space limit.

The contribution of this paper can be summarized as:

1. The Fuzzy-Reasoning Radial Basis Function Neural Network (FRBFN) is proposed to incorporate the reinforcement learning method with a neural network.
2. Because of the corresponding equivalence between a fuzzy system and a radial basis function neural network, the proposed FRBFN has only three layers due to the elimination of fuzzification and defuzzification functions. This feature significantly reduces the computation cost.
3. The suggestion of combining together the input and hidden layers of ASN and ACN, which simplifies the proposed FRBFN architecture.

The formula of adjusting parameters in ASN and ACN are derived for the proposed architecture.

Fuzzy Coincidence Analyzing Automaton

Joel Shaklee, Scott Imhoff, John Mallinger, and Palak Thakkar
Intelligence and Information Systems, Raytheon Company, Aurora, Colorado, USA

Abstract - *This paper describes a Fuzzy Coincidence Analyzing Automaton. In network applications, when a number of channels are being monitored, it often happens that signals on different channels coincide in time. Usually, different combinations of coinciding signals in different combinations of channels give rise to different semantics. The present algorithm is an automaton, which monitors a set of L signal channels and, when pre-selected coincidences occur, outputs signals in alarm channels. Other sets of coinciding signals do not activate the alarm. Alarms may persist until reset by a pre-selected set of reset signals on the same L channels. The automaton is fuzzy so that it can operate in conditions of varying signal strength and in the presence of drop-outs.*

Keywords: Fuzzy logic, coincidence detection, automaton, change detection, machine learning

1 Introduction

We present an algorithm for monitoring a set of signal channels appearing at a number of separate points at fixed locations within the same system. We use a fuzzy automaton to monitor the signals so that an alarm can be issued if certain known sets of coinciding signals occur. Several of the antecedents of our approach are as follows: Hildebrand [1] applied fuzzy logic to monitoring resource status of enterprise systems so that alerts to personnel are sent when triggering events occur. Zaitsev discusses monitoring system resource utilization using fuzzy logic rules [2]. Our algorithm works for similar applications but uses fuzzy automata to transition a fuzzy internal state vector until conditions warrant the issuance of an alarm. Fuzzy automata are discussed in Klir and Yuan [3]. The training of fuzzy automata using genetic algorithms is discussed in Nguyen, Imhoff, and Kent [4].

Aggregation is a way of combining matrices that replaces the binary multiplication operation with binary min and replaces the sum with the max operation. If $\circ$ denotes the aggregation operation then we have the following:

$$[1 \quad 0.8 \quad 0.6] \circ \begin{bmatrix} 0 & 0.4 & 0.4 \\ 0.3 & 1 & 0 \\ 0.5 & 0 & 0 \end{bmatrix} =$$
$$\{max[min(1,0), min(0.8,0.3), min(0.6,5)], \ldots$$
$$max[min(1,0.4), min(0.8,1), min(0.6,0)], \ldots$$
$$max[min(1,0.4), min(0.8,0), min(0.6,0)]\} = [0.5 \quad 0.8 \quad 0.4]$$

(1)

An example of the aggregation of a 1-D matrix with a 3-D matrix is as follows:

$$[1 \quad 0.4] \circ \left[\begin{bmatrix} 0 & 0.4 & 0.2 \\ 0.3 & 1 & 0 \\ 0.5 & 0 & 0 \end{bmatrix} \begin{bmatrix} 0 & 0 & 1 \\ 0.2 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}\right] =$$
$$\begin{bmatrix} max\{min(1,0), min(0.4,0)\} & max\{min(1,0.4), min(0.4,0)\} & max\{min(1,0.2), min(0.4,1)\} \\ max\{min(1,0.3), min(0.4,0.2)\} & max\{min(1,1), min(0.4,0)\} & max\{min(1,0), min(0.4,0)\} \\ max\{min(1,0.5), min(0.4,0)\} & max\{min(1,0), min(0.4,0)\} & max\{min(1,0), min(0.4,0)\} \end{bmatrix} =$$
$$\begin{bmatrix} 0 & 0.4 & 0.4 \\ 0.3 & 1 & 0 \\ 0.5 & 0 & 0 \end{bmatrix}$$

(2)

An automaton is a kind of state machine. There is typically more than one state that the automaton can be in. As symbols (inputs) from the environment arrive, the automaton may or may not transition from one state to the next, depending on the allowable transitions S. For example, suppose an automaton which detects English language receives the symbol "th" and transitions to a state i. If the next symbol arriving from the environment is "q", the automaton will not transition to state $i + 1$ because "thq" is not a word in the English language. If, however, the environment inputs the symbol "e", the automaton will transition to state $i + 1$ because "the" is an English word. When "q" arrives, the automaton's response is "this is not English." When "e" arrives, the automaton's response is "this is English."

A fuzzy automaton consists of a 3-D matrix of fuzzy state transition, S, of size $N \times N \times L$, a fuzzy input from the environment, which is a vector, A, of length L, a 2-D fuzzy response matrix, R, of size $N \times P$, a vector initial internal state vector, c, of length N, a vector current internal state E, of length N, and an output 2-D matrix, B, of size $N \times P$.

The algorithm appears in block diagram in Figure 1. It consists of a Learning Algorithm, by which the automaton learns its fuzzy transitions S and a Run Algorithm by which S is applied to an arriving stream of several channels of data represented by A. It is in operation of the Run Algorithm that the system responds to certain combinations of coinciding signals and raises the alarm.

The algorithm uses a novel technique of distributing the anti-diagonal to initialize the 3-D matrix S of fuzzy transitions. Other points of novelty include equipping S with a diagonal in $S(:,:,1)$ to propagate the internal state E and the anti-diagonal in $S(:,:,L)$ to reset the automaton after an alarm has occurred.

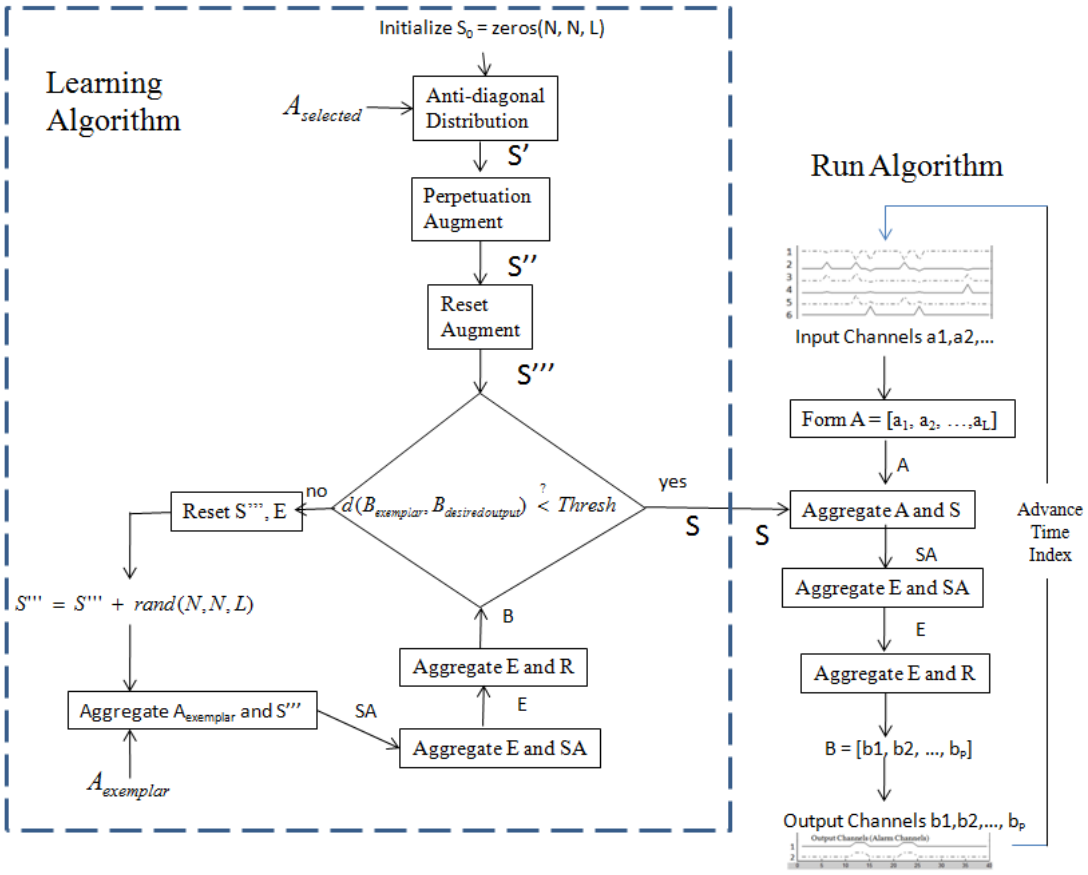

Figure 1: Fuzzy Coincidence Analyzing Automaton

2 Description of Algorithm

In the Learning Algorithm, the matrix of fuzzy transitions S''' is formed by advancing S through a series of procedures which equip S with the properties it needs to function properly in the run environment. As we equip S with the properties it needs, S becomes S', S' becomes S'', and S'' becomes S'''.

It becomes easy to detect a set of coinciding signals that flip the internal state of an automaton. The internal state of an automaton is said to *flip* when $[e_1\ e_2\ e_3\ \ldots\ e_j]^T$ becomes $[e_j\ e_{j-1}\ \ldots\ e_1]^T$. A selected coincidence of signals $A_{selected}$ is used to equip S with the ability to flip the internal state of the automaton when the selected signal coincidence occurs. A technique of *anti-diagonal distribution* is used to determine a matrix of fuzzy transitions S'. An example is shown in Figure 2. The algorithm provides that each non-zero element of A activates a portion of an anti-diagonal during an $A \circ S$ aggregation so that the aggregated *intermediate* matrix SA is the anti-diagonal. Then SA reverses the internal state E during its aggregation with E. The algorithm for the anti-diagonal distribution is as follows:

$$
\begin{array}{l}
Initialize\ S = zeros(N,N,L) \\
Initialize\ c = 0 \\
for\ k = 1{:}L \\
\quad if\ a_k == 1 \\
\quad\quad c = c + 1 \\
\quad\quad for\ i = 1{:}N \\
\quad\quad\quad S_{(i)(N+1-k)(k)} = \begin{cases} 1, & \eta(c-1)+1 \le \eta c + 1 \\ 0, & otherwise \end{cases} \\
\quad\quad end\ for \\
\quad end\ if \\
end\ for
\end{array}
$$

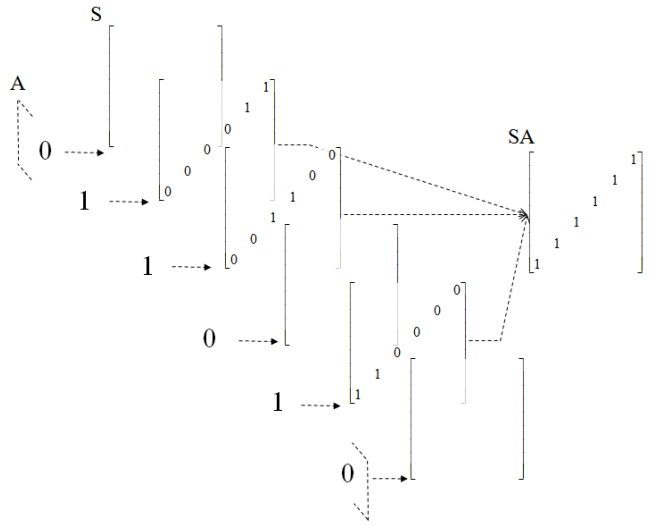

Figure 2: 'Distributing the Antidiagonal' – Preparing a transition matrix so that, when select coincidence occurs, the internal state of the automaton flips over.

The next step in the Learning Algorithm is to equip the $S(:,:,1)$ matrix with the diagonal. This maintains automaton health, meaning that the automaton won't get stuck in a state where its responses become insensitive to the inputs. Thus S'' is formed. The next step is to equip the $S(:,:,L)$ matrix with the anti-diagonal. This is used to reset the automaton after an alarm has been sent. This is S'''.

The remainder of the Learning Algorithm serves to make the automaton fuzzy and able to respond to exemplar signals in a desired way. For each exemplar, the Euclidean distance between the desired output and the actual exemplar output, $d(B_{exemplar}, B_{desired\ output})$, is monitored while S''' is perturbed by the addition of random numbers. Each $d(B_{exemplar}, B_{desired\ output})$ that does not meet a selected threshold causes the automaton to reset to S'''. After a reset, $A_{exemplar}$ is aggregated with S''', E is aggregated with SA, and then E is aggregated with R to produce the next output $B_{exemplar}$ to be used in the comparison. This is repeated until a fuzzy state matrix S having the desired exemplar responses, is obtained.

The Run Mode algorithm provides for the automaton to monitor a channel of L signals. For each time sample, an input vector $A = [a_1, a_2, \ldots, a_L]$ is formed from the L channels. This is aggregated with the automaton S in order to form the intermediate matrix SA. The internal state E is aggregated with SA to form the updated state E. E is aggregated with the response matrix R to form the output vector B. The elements of B represent one time instance of the output channels. As the time index advances, the L channels of the input are sampled, processed by the automaton, and the output channels (e.g. alarms) are generated.

3 Application of Algorithm

The algorithm was successfully demonstrated. A program Fuzzy_Coincidence_Analyzing_Automaton.m was written to illustrate a simple demonstration instantiation of the algorithm. The demonstration input channels and output alarm channels are plotted in Figure 3. In this example, there are 6 input channels and two output alarm channels. The demonstration shows how a pre-selected fuzzy coincidence sets off alarms while dissimilar fuzzy signals and coinciding signals do not set off the alarms. The algorithm analyzes coinciding signals to determine if the coincidence is important to the overall system and merits the tripping of the alarms. In this demonstration, signals close to $[0.1 \quad 0.9 \quad 0.9 \quad 0.1 \quad 0.9 \quad 0.1]$ cause the alarms to go off while other signals, such as $[0.8 \quad 0.9 \quad 0.8 \quad 0.2 \quad 0.1 \quad 0.1]$ and $[0.9 \quad 0.2 \quad 0.8 \quad 0.9 \quad 0.1 \quad 0.1]$ do not cause the alarms to go off. A signal close to $[0.1 \quad 0.1 \quad 0.1 \quad 0.2 \quad 0.3 \quad 0.9]$ is used to reset the alarms. In this example, the inputs A, the output of the alarms B, the response R, the state transitions S, and the internal states E and C are all fuzzy. The fuzzy state transitions S were initialized using the anti-diagonal algorithm.

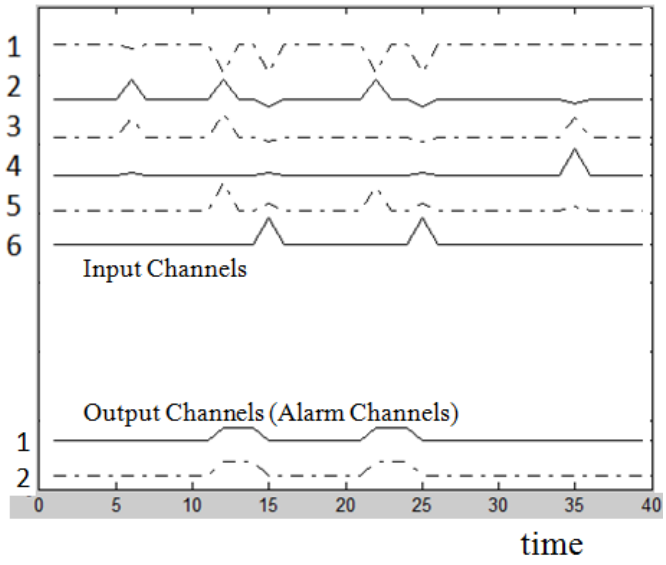

Figure 3: Fuzzy Coincidence Analyzing Algorithm. This example has six input channels and two output channels. An alarm occurs when a pre-selected combination of signals is present.

4 Conclusion

Certain sets of events falling together in time may signal a system condition that warrants the issuance of an alarm. An algorithm for detecting and alarming on certain special coincidences was described as well as an algorithm for training it. In the Learning Algorithm, a fuzzy automaton is prepared so that an arriving signal A_{alarm}, that should cause an alarm, causes the fuzzy transitions S to form an antidiagonal

during the aggregation which forms the intermediate matrix *SA*.

Fuzzy Artificial Fish Ensemble Extreme Learning Machine

João Fausto Lorenzato de Oliveira and Teresa B. Ludermir
Center of Informatics, Federal University of Pernambuco, Recife, Pernambuco, Brazil

Abstract— *Neural networks have been largely applied into many real world pattern classification problems, and the combination of neural networks to overcome the natural limitations of single classifiers is one strategy to achieve better accuracy. Due to the need of having accurate classifiers with different knowledge for the same problem, ensembles need to measure their diversity. In this work we employ a Fuzzy Adaptive Modified Artificial Fish Swarm Algorithm for evolving Extreme Learning Machine Ensembles. The ensemble selection is performed by the use of a hierarchical clustering algorithm, and two diversity measures. Experimental results show that the proposed method achieved promising results.*

Keywords: Neural Networks, Optimization, Ensembles, Fuzzy Logic

1. Introduction

In the field of pattern recognition the ensemble techniques based on the combination of different classifiers were proposed in order to improve the accuracy of a system. The classifiers in an ensemble should be as accurate as possible and should make different errors [1], hence the classifiers should present diversity among themselves.

Techniques such as *Adaboost* [2] and cross validation can be applied in order to introduce diversity among the base classifiers. Studies on composing ensembles with artificial neural networks (ANNs) show that networks with different topologies can produce promising results [3], and many optimization algorithms may be used to optimize a population of neural networks and make use of the population intelligence to compose an ensemble [4].

This work is focused on combining ANNs trained by the Extreme Learning Machine (ELM) [5] algorithm. Fast training speed, good generalization performance, small set of configurable parameters are characteristics of the ELM. The usual learning methods for single layered or multilayered neural networks are the gradient descent algorithms such as the backpropagation (BP) [6], which iteratively adjust the weights until the algorithm stop condition is reached. The ELM algorithm is not based on iterative adjustments on the weights, it uses fixed random initial weights and bias for training and the output weights are analytically determined.

Classifiers in an ensemble will contribute with its knowledge over a classification region which may vary for each classifier, thus promoting the diversity among them. To combine the opinions of different classifiers, the outputs of each classifier for a given instance are combined through a fusion rule

Ensembles of extreme learning machines can be found in [7], which a trimming coefficient is introduced into the adaboost algorithm in order to use a fraction of the training set in the initial stages of execution. In [8] cross validation technique is used as a method for divide the search space to crate new classifiers. Another implementation of the ELM algorithm called online sequential ELM (OS-ELM) [9] algorithm was used in an ensemble strategy in [10].

In this work we use the fuzzy strategy presented in [11] in order to regulate the local and global search of the Modified Artificial Fish Swarm Algorithm (MAFSA) and to select the classifiers with the hierarchical clustering algorithm, and also we perform experiments with other ensemble techniques with the ELM algorithm as base classifier.

This paper is organized as follows. On Section 2 a brief overview of the ELM algorithm and the ensemble methods based on ELM are given. On section 3 the proposed algorithm is explained. On section 4 the experiments are showed along with the results of the simulations. The conclusion is presented on section 5.

2. Extreme Learning Machine

The ELM [5] is a simple algorithm for the training of single layer feedforward neural networks (SFLNs), whose learning speed can be faster then traditional gradient descent methods such as back-propagation (BP) [6] and better generalization capacity may also be obtained.

In this algorithm, the input weights and hidden layer biases are randomly set, and through matrix operations the output weights are calculated without tuning. The absence of a tuning phase, enables the training to be performed faster.

Given n distinct training samples (x_i, t_i), where $x_i = [x_{i1}, x_{i2}, ..., x_{in}]^T \in \Re^n$ and $t_i = [t_{i1}, t_{i2}, ..., t_{im}]^T \in \Re^m$ $(i \in [1, ..., n])$, the SLFN with s hidden nodes needs to learn all the training samples. Since the input weights $w_j = [w_{j1}, w_{j2}, ..., w_{jn}]^T$ and hidden biases $b = [b_1, b_2, .., b_j]$ $(j = [1, ..., s])$ are randomly generated, the task performed in the training phase is to find the appropriate output weights for the given input weights and biases through the calculation of the linear system $H\beta = T$.

The matrix $H = \{h_{ij}\}$ is the hidden-layer output matrix and $h_{ij} = g(w_j * x_i + b_j)$ corresponds to the result from the j_{th} hidden neuron to x_i, $T = [t_1, t_2, ..., t_i]$ represents the target (desired output) matrix, and $\beta_j =$

$[\beta_{j1}, \beta_{j2}, ..., \beta_{jm}]^T (j \in [1, ..., s])$ is the output weight matrix. In order to compute the output weights, an inverse matrix operation is needed. The output weight matrix will be calculated as the minimum least-square (LS) solution of a linear system, through a pseudo-inverse matrix operation [12]. The next step for the calculation of the output weight matrix is to compute the pseudo-inverse matrix of H which results in $\hat{\beta} = H^+T$.

Through these calculations the ELM algorithm achieves good generalization performance and the learning speed is reduced due to the absence of continuous weight adjustments.

3. Fuzzy Artificial Fish Ensemble Extreme Learning Machine

The hybrid algorithm named *Modified Artificial Fish Swarm for the optimization of Extreme Learning Machines* (MAFSA-ELM) aggregates characteristics from AFSA and DE, and has the primary objective to optimize weights of ELM.

In order to further explore the search capacity of the MAFSA-ELM algorithm, we employ fuzzy strategies in oder to adapt the search process, regulating a global search or a more refined local search. Yazdani *et al.* [11] proposed a fuzzy adaptive strategy to improve the AFSA algorithm using two approaches: the Fuzzy Uniform Fish and Fuzzy Autonomous Fish.

Th improve the performance of the MAFSA-ELM algorithm these two strategies are adopted, and after its execution, an ensemble selection strategy is applied using the population of ELMs.

3.1 Modified Artificial Fish Swarm Algorithm

The AFSA algorithm [13] is based on the social behavior of the fishes. Each fish will represent a potential solution, in the case of ELM optimization, each fish will represent the input weights and hidden biases. The movements of the population will be based on the actual position of each fish and the nearby fishes inside its visual field ($visual$). Two important variables are the $visual$ and $step$ which regulates how the search will be conducted. The $step$ variable will control how far a fish can move. Higher values of $visual$ and $step$ the fishes will move faster towards the best solution, passing through local minimums without getting stuck, this configuration is desired in the initial stages of execution. Lower values will produce an exploitation characteristic, desired on the last stages of the algorithm. Each fish will be represented by an input matrix W_{ij} and a bias vector b_i, and these informations are used to calculate the distance.

In order to calculate whether a certain fish is within the visual field of another fish, the distance between them is calculated using a euclidean distance. The output weights on the ELM algorithm are unknown *a priori*, hence the distance d is calculated as showed on equation 1, where p and q represent the indexes of two different fishes.

$$d_{pq} = \sum_{i=1}^{s} \sum_{j=1}^{h} (W_{ij}(p) - W_{ij}(q))^2 + \sum_{i=1}^{h} (b_i(p) - b_i(q))^2 \quad (1)$$

The number of input parameters on a given instance is represented by s and the number of hidden neurons is represented by h. The original AFSA algorithm has some basic behaviors (Follow, swarm and leap) executed by each fish, the behavior that produces the highest result will be the one used for updating the fish position. The Follow behavior as shown in equation 2 influences the fish by the best fish inside its visual range W_{max} (not necessarily the best fish in the swarm).

$$Follow(W_i) = W_i + rand() step \frac{W_{max} - W_i}{\|W_{max} - W_i\|}, \quad (2)$$

The swarm behavior influences the fish based on the central position (represented by W_c) of the fishes inside its visual field. The swarm behavior strengthens the idea of group search, and is presented in equation 3.

$$Swarm(W_i) = W_i + rand() step \frac{W_c - W_i}{\|W_c - W_i\|} \quad (3)$$

And the leap behavior, presented on equation 4, represents the capacity of the fish to move on its own, independent of any other fish.

$$Leap(W_i) = W_i + rand() step \quad (4)$$

Since the traditional Artificial Fish Swarm Algorithm does not perform well, a new behavior is introduced, using the genetic operators of *Crossover/Mutation* [14] from the Differential Evolution algorithm. The Crossover/Mutation behavior will produce new individuals based on informations of the population independently of their position in the search space. This behavior chooses randomly three fishes from the swarm, and then a new fish is created based on their positions and a mutation factor. The next step is to mix the informations of the created fish, with the original fish based on a given probability. If the new individual performs better on the validation set, then the position is updated.

In the modified AFSA algorithm (MAFSA), the additional behavior was inspired by the capacity of fishes to evolve and be selected by nature. For that purpose we use the Differential Evolution (DE) algorithm proposed by Storn and Price [14] which is known as one of the most efficient evolutionary algorithms. In order to create the next generation of individuals, the algorithm uses mutation and

crossover operators. The new behavior is executed in three steps: Mutation, Crossover and Selection [14]. The first step is the mutation:

$$W_i = W_{r_1} + F * (W_{r_2} - W_{r_3}), \quad (5)$$

where r_1,r_2 e r_3 are distinct indexes randomly chosen and F is an amplitude factor with values within the range $(0, 2)$. In the crossover phase, a new vector V is created with the same dimensionality of the individuals.

$$V_{ij} = \begin{cases} W_{ij} & \text{if } rand() < CR \quad \text{and } j = rdInd(i) \\ W_{ij} & \text{if } rand() > CR \quad \text{or } j \neq rdInd(i) \end{cases} \quad (6)$$

If the new vector has better fitness than its predecessor, the new vector will be selected, otherwise the predecessor will be selected.

By adding the crossover mutation behavior, the probability of finding better solutions increases due to the total amount of possible results (4 results) instead of the original 3 (from the three original behaviors), so the algorithm incrementally has more chances to find better solutions. And the reason why this new behavior is not affected by the $visual$ and $step$ parameters is simply to produce more diversity in the results and occasionally escaping from local minimums. Since $rdInd(i)$ is a randomly chosen index from the entire swarm, informations from the best (or worst) fishes could be gathered to produce a new individual (new solution), so this new behavior adds a stochastic strategy to the algorithm.

The first step is to initialize the population (weights and biases) along with the parameters, including the distance matrix of each fish for initialization of the visual parameter. Then each fish will execute all the behaviors, however the position adjustments will be accomplished by the behavior that yields the highest accuracy on a validation set.

Once the weights and bias are adjusted with the best values, this information is used to calculate the input variables for the fuzzy engine. There are to main approaches to this fuzzy strategy called Fuzzy Uniform Fish (FUF) and Fuzzy Autonomous Fish (FAF) [11].

3.2 Self-Adaptation with Fuzzy Autonomous Fish and Fuzzy Uniform Fish

The fuzzy strategies adopted will adjust the values of the *visual* and *step* parameters, based on the FUF and FAF approaches. In order to control the balance between global search and local search, another parameter, *constriction weight* (CW), will be introduced for the adjustments of the parameters in both approaches. The adjustment procedures are presented as follows:

$$visual_{l+1} = CW * visual_l \quad (7)$$

$$step_{l+1} = CW * step_l \quad (8)$$

In the Fuzzy Uniform Fish Ensemble ELM (FUFE-ELM) approach every fish in the swarm shares the same values for the *visual* and step parameters. Thus, the population will start searching locally or globally at the same time. The fuzzy engine based on FUF consists of two inputs and one output. The input parameters are the ratio of improved fish, and the iteration number. The output parameter is the constriction weight. The iteration number, is the proportion between the current iteration and the total number of iterations. The algorithm needs to perform a global search in the initial stages of the algorithm, so the reduction of the *visual* and step parameters in these stage must be minimal. Near the end of the execution the algorithm has already approached the global optimum region, and needs to perform a local search, thats when higher values of the *iteration Number* parameter will influence significantly on the reduction of the *visual* and step parameters.

Table 1: Fuzzy Associative memory for the FUF Engine [11]

Iteration Number	Ratio of Improved Fish	Constriction Weight
L	H	VH
L	M	H
L	L	M
M	H	H
M	M	M
M	L	L
H	H	M
H	M	L
H	L	VL

The *ratio of improved fish* is the proportion of fishes that find better solutions (weights and biases) to the total number of fishes. When most of the artificial fishes find better solutions the value will be close to 1, then there is no need to reduce the *visual* and step parameters. However, when the proportion is close to 0, there is no improvement on finding better solutions , the two parameters are reduced in order to perform a local search, raising the probability of finding better solutions.

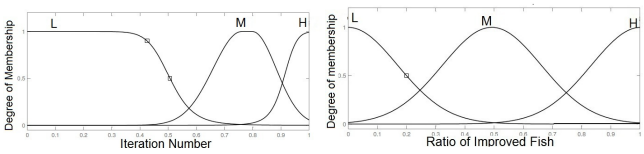
In the Fuzzy Autonomous Fish Ensemble ELM (FAFE-ELM) approach, each fish will have its own *visual* and *step* variables with individual adjustments, producing more diverse results and allowing that a given fish start to perform more refined local search earlier than other fishes. This strategy could led to more diverse ensembles since each fish is capable of start a local search before the others, and consequently it could find a better solution.

In the initial stages of the algorithm these variables have the same value, and will be individually adjusted through the execution based on the output of the fuzzy engine which is calculated using three input parameters namely *Distance from best*, *Fitness Ranking* and *Iteration Number*.

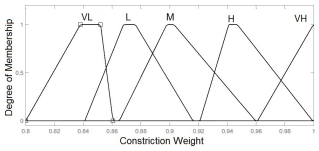
The *Distance from best* rank-based parameter which is based in the distance between the fishes and the best fish (with highest validation accuracy), the distance is calculated in the same way is shown on equation 1. After the distance is computed, all distances are sorted, and then the proportion

Fig. 1: Fuzzy Uniform Fish Membership Functions. 1a Iteration Number. 1b Ratio of improved fish. 1c Constriction Weight.

(a) Iteration Number (b) Ratio of Improved Fish



(c) Constriction Weight



of the current rank to the total of fishes is presented to the fuzzy engine. When the distance to the best fish is low, then the *visual* and *step* parameters will be less reduced, however when a fish is close to the best fish then those values are decreased considerably, in order to perform a more refined search.

The *Fitness Ranking* is based on the fitness of each fish with respect to the validation accuracies obtained with the ELM algorithm. All fitnesses from each fish will be sorted and then the proportion to the total amount of fishes will be presented. Lower rankings on this variable will produce less reductions on the *visual* and *step* parameters. The *Distance from Best* will have the same definitions as in the FUF-ELM approach.

On figure 2 the membership functions are presented for each variable.

The swarm will loop through the algorithm until a stop condition (number of iterations) is met. The steps for ensemble selection will be explained on Section 3.3.

3.3 Ensemble selection

The ensemble selection phase is executed after the FAFE-ELM algorithm is finished. Our criteria for selection are the performance and the diversity of each classifier. In the literature there are many diverse measures such as interrater agreement, double-fault, Q-statistic [1]. In this work we will use a two-stage selection. The first stage will use a pairwise measure of diversity namely Double-fault, and this measure yields the probability of two given classifiers be both wrong, and the application of the hierarchical clustering algorithm to reduce the number of possible ensembles. The second stage uses the Entropy diversity measure which will measure the diversity of an ensemble.

In [15], this measure was used for the construction of a distance matrix for distinct classifiers, and group them with a hierarchical cluster algorithm. In this work we will use the same approach as was used in [15], however with the ELM classifiers optimized differently by the MAFSA algorithm. This measure will be used to compute a distance measure to build a distance matrix that will be used for the selection of the classifiers of the ensemble.

$$D_{i,m} = 1 - \frac{u(-1,-1)}{u(-1,-1) + u(1,-1) + u(-1,1) + u(1,1)} \quad (9)$$

The diversity measure is given above, where $u(-1,-1)$ indicates the number of cases where both classifiers are wrong, $u(-1,1)$ is the number of cases where only the first classifier is wrong, $u(1,-1)$ is the number of cases where $u(1,1)$ number of cases that neither of them are wrong.

With the distance matrix we apply the hierarchical cluster algorithm [16] to group the classifiers based on their diversity. Lower values of the distance mean that there are more coincident errors between the classifiers, thus they present lower diversity. The classifiers with lower distances are put in the same cluster. Classifiers that present higher distance will be grouped in a different cluster, as they will make fewer coincident errors.

In the first step, all classifiers are considered to be in individual clusters, and they are iteratively grouped based on the smallest distance between them. The distance between two different clusters will be the highest distance between two classifiers that belong to each of them.

Algorithm 1 Fuzzy Artificial Fish Ensemble Extreme Learning Machine

$c \leftarrow 0$
Initialize population $P, \forall p_i \in P$
while $c < C$ **do**
  while $i < N$ **do**
    Determine Output Weights of fish i β_i and assess the classification accuracy CA_i
    Execute the behaviors ($follow(p_i)$, $swarm(p_i)$, $leap(p_i)$, $crossover - mutation(p_i)$)
    Update with the best result :
    $p_i \leftarrow max$[follow(p_i), $swarm(p_i)$, $leap(p_i)$, $crossover - mutation(p_i)$]
    $i \leftarrow i + 1$
  end while
  Calculate parameters for the fuzzy engine (Uniform Fish, or Autonomous Fish) $CW_i^{c+1} \leftarrow$fuzzy_Engine(Distance from best, Fitness Ranking,Iteration Number) $\times CW_i^c$
  $c \leftarrow c + 1$
end while
Build distance matrix with the Double-Fault diversity measure
Group the Ensembles with the Hierarchical Cluster
Use the Entropy diversity measure to select the final ensemble

The hierarchical clustering was used because the number of possible ensembles in a set of classifiers $V = v_1, v_2, ..., v_T$ is equal to $\sum_{r=1}^{T} \binom{T}{r}$, thus the brute force approach is unfeasible. So the number of possible ensembles is reduced through the hierarchical clustering approach. By the end of the clustering process, all the possible ensembles clustered by the hierarchical algorithm are tested using the outputs of each classifier on the validation set, combined by the majority vote rule. During the simulations we verified that more than one ensemble may yield the same highest value. In order to select the best ensemble among the ones with highest accuracy, we use an entropy [1] diversity measure. The entropy is a non-pairwise diversity measure, that verifies how diverse is an ensemble of classifiers. The ensemble with highest entropy value, is selected as the final ensemble.

This approach does not exclude the possibility of using all the classifiers in the population, the criteria for comparing the ensembles is the entropy diversity measure. In the algorithm 3, the pseudocode for the FAFE-ELM algorithm is presented.

4. Experiments

On the experiments we used the ELM, Dynamic Adaboost Ensemble ELM (DAEELM), EN-ELM, FAFE-ELM, FUFE-ELM, and a standard Artificial Fish Ensemble-ELM with no self-adaptation (AFE-ELM). They were applied on five (Sonar, Ionosphere, Horse, Glass and Vehicle) datasets from UCI machine learning repository [17].

The data from each dataset were split into training set (50%), validation set (25%) and test set (25%) randomly generated for 30 iterations. Except for the EN-ELM algorithm that uses 75% for training and 25% for testing. All algorithms receive the same testing set.

Table 3: Results for all data sets

Data set	Method	Mean	SD	h
Sonar	ELM	72.97	4.58	20
	AFE-ELM	78.65	7.03	20
	FAFE-ELM	78.97	8.11	20

	AFE-ELM	68.60	4.14	20
	FAFE-ELM	69.05	4.39	20
	FUFE-ELM	68.77	3.95	20
	EN-ELM	62.86	3.30	20
	DAEELM	65.51	3.58	20
Glass	ELM	63.76	5.58	20
	AFE-ELM	66.05	4.83	20
	FAFE-ELM	66.12	4.43	20
	FUFE-ELM	65.81	4.49	20
	EN-ELM	66.36	5.28	20
	DAEELM	62.33	5.67	15
Diabetes	ELM	76.92	1.19	20
	AFE-ELM	78.13	3.44	20
	FAFE-ELM	78.00	3.03	20
	FUFE-ELM	78.29	3.06	20
	EN-ELM	76.98	3.17	20
	DAEELM	75.97	1.58	15

For each iteration all the classifiers receive the exact

training, validation and test sets. All the attributes from the datasets were normalized into the interval $[0..1]$. The simulations were performed with 10, 15 and 20 hidden neurons, and the configuration that produced the best result was selected. The optimization algorithms are executed for 50 iterations. The initialization of the MAFSA-ELM parameters in this work is described as follows: The $visual$ parameter was set as the mean of all the initial distances between the fishes. The number of fishes $N = 30$, $step = 0.6$, crowd factor $\delta = 0.8$, in this work we set the visual parameter as the mean for all the initial distances between the fishes. Amplitude factor for the mutation $F = 1$ and crossover rate $CR = 0.5$. The same parameters for the MAFSA-ELM algorithm are also used on the AFE-ELM, FUFE-ELM and FAFE-ELM. The EN-ELM algorithm only has the number of folds=10 and the number of hidden neurons as an input parameter. The configuration for the DAEELM algorithm is the trimming factor γ=0.1.

The experiments were measured with respect to the mean accuracy on the test set. The analysis of the results was performed through the use of the Wilcoxon Sign-rank test with 95% of confidence interval.

On Table 2 the results for all the data sets are presented. Under an empirical analysis the proposed methods performed better on the Diabetes (FUFE-ELM) ,Horse (FAFE-ELM), Vehicle (FUFE-ELM), Sonar (FAFE-ELM) datasets. Using the Wilcoxon sign-rank test the FUFE-ELM, FAFE-ELM and AFE-ELM performed similarly in all data sets, and they were superior to all other algorithms (ELM, DAEELM, EN-ELM) except for the Glass data set where the EN-ELM algorithm also achieved a similar result with higher standard deviation. The DAEELM and the EN-ELM algorithms performed worse than the single ELM classifier in some data sets because there is no guarantee that the classifiers in these ensembles will be accurate and diverse enough. Since some data sets are unbalanced, in the EN-ELM algorithm some folds might not have all the classes and this can contribute negatively for the training of the base classifiers.

The DAEELM algorithm draws samples with reposition, according to the current probability distribution, hence the accuracy of the weak classifier on the drawn sample may not be the best. The algorithm can easily stop on early iterations if the size of the sample set is equal to the size of the training set ant the error is above 0.5. This leads to ensembles with few classifiers and without the possibility to raise the accuracy of the system. The number of hidden neurons was the same for almost all techniques except for the DAEELM which, in some datasets, achieved its best values with 15 hidden neurons.

5. Conclusions

In this paper, we applied two fuzzy strategies in order to adjust the parameters of the Modified Artificial Fish Swarm Algorithm on the optimization of Extreme Learning Machines, and combined the individuals through a hierarchical clustering algorithm.

The hierarchical clustering algorithm uses a distance matrix based on the double-fault diversity measure. After the ensembles are formed, the entropy diversity measure is used to select the final ensemble. The performance of the tested algorithms was evaluated with well known benchmark classification datasets (Ionosphere, Diabetes, glass, sonar, vehicle and horse-colic), obtained from UCI Machine Learning Repository [17].

Experimental results show that our hybrid obtained promising results, in some datasets achieved better accuracy on the test sets.

As future works, we plan to evaluate the influence of using other fusion rules as well as other clustering algorithms for the composition of ensembles. Other optimization algorithms used for evolving an ELM population such as Particle swarm optimization (PSO) [18] could be explored for evolving ELM ensembles.

A New Neural Fuzzy System Using Fuzzy Linguistic Input-output Training Samples

Jing Lu , Blayne Mayfield , and Jia Liu

Computer Science Department, Oklahoma State University , Stillwater, OK, USA

Abstract - *This paper proposes a new fuzzy neural system that deals with fuzzy training samples. That is, the proposed learning system includes training of a neural network using fuzzy training samples, and it outputs fuzzy value according to a set of given rules. The learning algorithm used in the system is composed of two phases. The first phase transforms crisp samples into fuzzy ones; the second phase trains the network according to the fuzzy samples through a new neural network structure proposed in this paper. Finally, two error evaluation methods and comparison between them are given.*

Keywords: Fuzzy logic, neural network, mean solution, gragh solution.

1 Introduction

Fuzzy logic [1] and neural networks [2] play an important role in the modeling of intelligent control in complex systems. Their combination is widely used in solving problems such as classification, identification, pattern recognition and so on.

There are three common ways to combine these techniques. The first one is a fuzzy neural network [3] (FNN), which increases the efficiency of the neural network and its velocity of convergence; the second one is a neural-fuzzy system[4], the activation function of which is related to fuzzy relations or fuzzy operators; the third one is a fuzzy neural hybrid system[5], where fuzzy logic and neural networks perform separately to attain a common goal.

In our previous studies, the first and second types used crisp input-output samples to train the neural network and to output crisp values. Using these approaches, FNNs embed fuzzy logic into a neural network and use that fuzzy logic in order to reach some goal; however, the input and output values of these networks are crisp values. In this paper, by contrast, the neural network uses crisp logic, but the input and output values are fuzzy values. In other words, the previous approaches and the new approach operate in opposite ways.

The new neural fuzzy system can deal with fuzzy input-output training samples, but also with crisp training samples. And, it can output fuzzy values according to fuzzy rules given in advance. The new approach adds two extra layers in front of the network to generate fuzzy training samples. These additional layers generate crisp training samples and then fuzzify them for use as input to the network.

The organization of this paper is as follows. In section 2, we briefly introduce the preliminaries of the paper: fuzzy logic theory and neural network theory. Section 3 presents the main structure of the system and algorithm used in the new network. Section 4 is an example of the system. Finally, the experiment of the example is shown and the conclusion is summarized.

2 Preliminaries

2.1 Fuzzy Logic Theory

Fuzzy logic is a form of many-valued logic; it deals with reasoning that is approximate rather than fixed and exact. In contrast with traditional logic theory, where binary sets have two-valued logic, fuzzy logic variables may have a true value that ranges in degree between 0-1. Fuzzy logic is used to handle the concept of partial truth, in which the value may range between completely true and completely false. Furthermore, when linguistic variables[6] are used, these degrees may be managed by specific functions called membership function, which is a function from a universal set U to the interval [0,1]. A fuzzy set A is defined by its membership function μ_A over U.

2.2 Neural Network Theory

Artificial neural networks refer to computer algorithms and structures that mimic the function of the biological neutrons. Similarly, it is composed of artificial neurons. The connections of the biological neuron are modeled as weights. A negative weight reflects an inhibitory connection, while positive values mean excitatory connections. The following components of the model represent the actual activity of the neuron cell. All inputs are modified by a weight and summed altogether. This activity is referred as a linear combination. Finally, an activation function controls the amplitude of the output. For example, an acceptable range of output is usually between 0 and 1, or it could be -1 and 1.

Mathematically, this process is described in Figure 1.

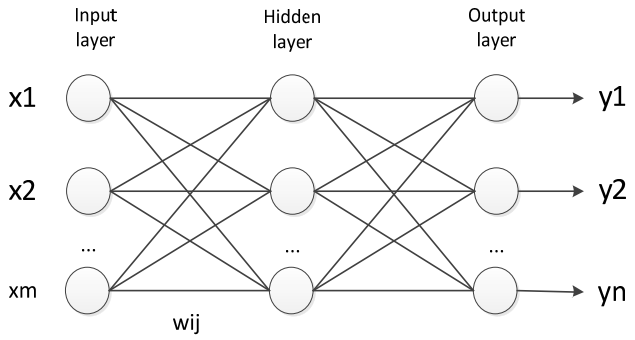

Figure 1. Neural network structure.

This network has an input layer (on the left) with m neurons, a hidden layer (in the middle) and an output layer (on the right) with n neurons.

There is one neuron in the input layer for each predictor variable. In the case of categorical variables, *N*- 1 neurons are used to represent the *N* categories of the variable.

Input Layer : A vector of predictor variable values from x1 to xm is presented to the input layer. The input layer distributes the values to each of the neurons in the hidden layer. In addition to the predictor variables, there is a constant input of 1.0, called the bias that is fed to each of the hidden layers; the bias is multiplied by a weight wij and added to the sum going into the neuron.

Hidden Layer : Arriving at a neuron in the hidden layer, the value from each input neuron is multiplied by a weight, and the resulting weighted values are added together producing a combined value, which is fed into a transfer function, which outputs a value. The outputs from the hidden layer are distributed to the output layer.

Output Layer : The y values are the outputs of the network. If a regression analysis[7] is being performed with a continuous target variable, then there is a single neuron in the output layer, and it generates a single y value. For classification problems with categorical target variables, there are *N* neurons in the output layer producing *N* values, one for each of the *N* categories of the target variable.

3 Neural fuzzy system with crisp input and fuzzy output

Herein, we consider a neural fuzzy system with a rule base of R rules, e.g., n-input m-output. The jth control rule is described as following form:

Rj: IF x1 is A1 AND x2 is A2 AND …AND xn is An, THEN y1 is B1 AND y2 is B2 AND … AND ym is Bm. Where j is a rule number, n is the total number of input variables and m is the total number of output variables, A1-An denotes the fuzzy set over the universe of x(X) and maybe not identical to each other, B1-Bm denotes the fuzzy set over the universe of y(Y) and maybe not identical to each other.

However, we cannot use fuzzy words to train the neural network and the conception of fuzzy logic can be introduced to solve such problem. In fact, it is necessary to use fuzzy values which depict the degree to which a crisp value belongs to a fuzzy set (fuzzy words) to train the neural network. By transferring the crisp samples into fuzzy ones, we could train the neural network using the fuzzy samples and output fuzzy values.

The whole structure of the neural fuzzy system with fuzzy output is show as Figure 2.

We can see from the picture that the whole neural network has several parts: Input layer, Fuzzification layer, Neural training layer and Output layer.

There may be many dashed parts. The dashed area is similar to the solid part but differ from each other corresponding to different rules. That is, the number of the solid parts and dashed parts depend on the number of the rules. We will give the reason why there is dashed part later.

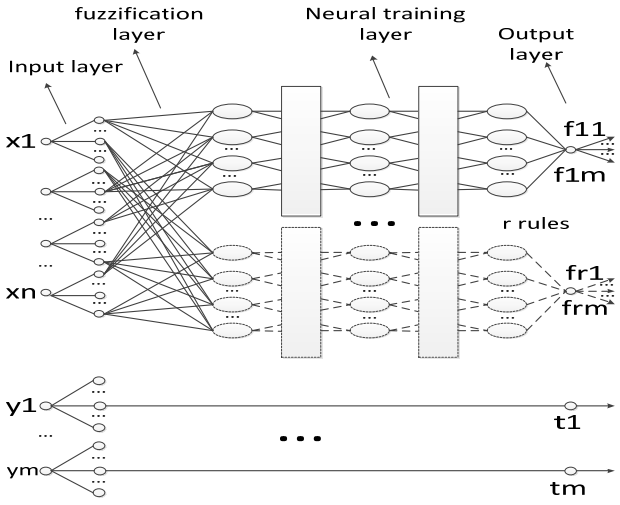

Figure 2. Fuzzy neural system.

Take a simple rule as an example:

(R1) IF x1 is Small AND x2 is Small, THEN y is Small; (R2) IF x1 is Small AND x2 is Large, THEN y is Middle; (R3) IF x1 is Large AND x2 is Small, THEN y is Middle; (R4) IF x1 is Large AND x2 is Large, THEN y is large.

There are 4 rules in the example, where n is 2 and m is 1, A1 (Small) and A2 (Small) denotes the fuzzy set (fuzzy words) over the universe of x, which are not identical to each

other in rule 1 but identical in rule 2, since A1 is Small and A2 is Large, B1denotes the fuzzy set (fuzzy words) "Small" over the universe of y, B2 denotes the fuzzy set (fuzzy words) "Middle" over the universe of y, B3 denotes the fuzzy set "Large" over the universe of y.

The network structure of this example is show as Figure 3.

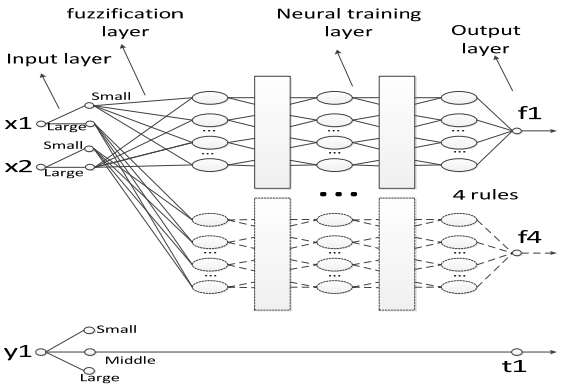

Figure 3. Fuzzy neural system with two inputs and one output.

Specification:

Input layer: If the neural fuzzy system is given suitable fuzzy training samples containing fuzzy values, this layer isn't a necessary part. But, what is the suitable fuzzy training sample? Just as the name implies, a suitable fuzzy training sample is a training sample whose members are fuzzy values corresponding to some fuzzy set (word). Besides, "suitable" means that the training sample must obey the rules we set in advance.

The main goal of this layer is to generate some crisp training samples randomly, each of which contains independent variable values and expected values of induced variable.

Using the example above, obviously, there are 2 independent variable values (x1, x2) and 1 expected value y1. Specifically, we should generate members of a training sample in the same universe of discourse for x and do the same for y.

Fuzzification layer: This layer is also redundant if the neural fuzzy system is given suitable fuzzy training samples containing fuzzy values.

If necessary, it transfers the training samples into fuzzy ones according to fuzzy logic theory. For each value in a sample, firstly, the system gets several membership function values corresponding to the current value being checked within its universal; secondly, compare membership function values and get the biggest one as a member of the fuzzy sample, at the same time, records the fuzzy word with the biggest membership function value. That is the maximum membership degree principle[8].

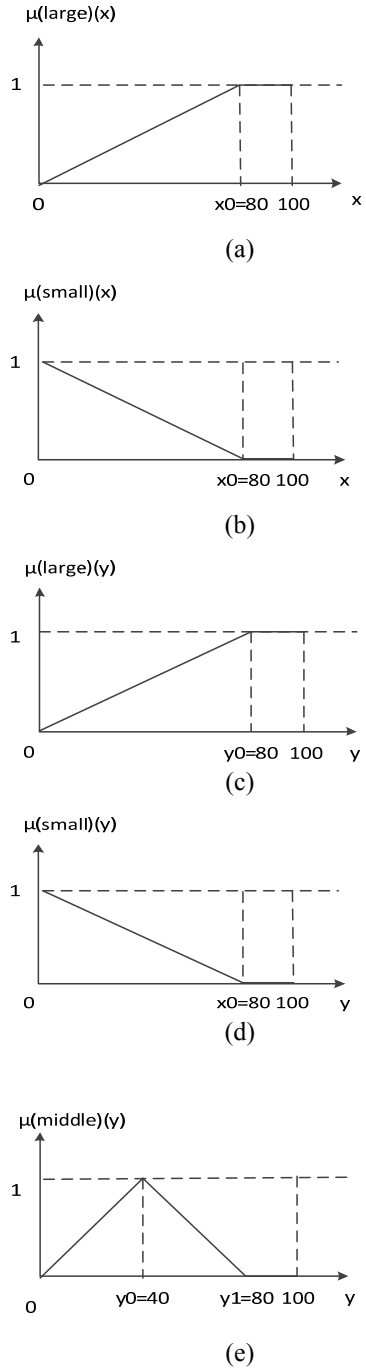

Figure 4. Membership fuction curve of fuzzy set (a) "large" with universal x, (b) "small" with universal x, (c) "large" with universal y, (d) "small" with universal y, (e) "middle" with universal x.

Assuming there is a training sample <24, 42, 90>.Firstly, the system gets 2 values for "24" according to the curve in graph(a) and graph(b); Secondly, compare them, get the biggest one --- max(μ_{large}(24), μ_{small}(24)) and the fuzzy words "small" since max(μ_{large} (24), μ_{small} (24)) is μ_{small}(24).

Sometimes, we generate some samples which are not accordance with the fuzzy rules we care, at this time, we discard these useless samples.

In the given example, we should notice (from the membership function graph of x and y) that the fuzzy sets (fuzzy words) over x and over y we have defined are not always the same but it could be.

Neural training layer: The function of this layer is similar to existing neural network, but the difference between them is that the system proposed in this paper use different structure related to the different rule to train the neural network in order to output expected value in keeping with the rule. In addition, we may make use of the same neural training layer working area, instead of open up a new working area. That is why there is dashed part in Figure 2 and 3.

Output layer: This layer outputs fuzzy values labeled by output fuzzy words. It is easy to see that one output has two meanings. One is the fuzzy set (word), the other is the fuzzy value corresponding to this fuzzy set. The point is how to decide for a fuzzy output which fuzzy set it belongs to. Deciding the fuzzy set of the output according to the given rules and the record of the fuzzy words of the inputs is a direct method.

4 Evaluation methodology

4.1 Graph solution

Here, we introduce a new evaluation methodology called "graph solution" to evaluate the performance of the neural network. This method can only be applied when the membership functions are given.

Step1: Draw the membership function of different fuzzy sets given the same universal in one graph.

For example, Figure 5 denotes the graph solution for y within the universal 0-100.

Step2: Find the biggest values for each interval. For example, [0-27]: μ_{small} (y) has the biggest values;[27-53]: μ_{middle}(y) has the biggest values;[53-100]:(y) has the biggest values.

Step3: Within each interval, find out the difference of the biggest membership function value and the smallest membership function value for the fuzzy word with the biggest values. Obviously, the example above has the same differences, which are "μ_{small}(0) - μ_{small}(27)", "μ_{middle}(40) - μ_{middle}(27)" and "μ_{large}(80) - μ_{large}(53)".

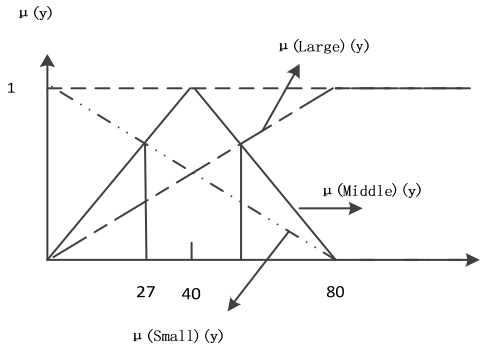

Figure 5. Graph solution.

If the error is between "0" to "0.47", the training of the neural network is reasonable.

We should notice that this method is useless if we do not know the membership function.

4.2 Mean solution

If there is a one-many relationship between the inputs and targets in the training data, then it is not possible for any mapping of the form to perform perfectly. It is straightforward to show that if a probability density P(Y|X) describes the data, then the minimum of error measure is attained by the map taking **X** to the average target

$$\int d\boldsymbol{Y}\, P(\mathbf{Y}|\mathbf{X})\mathbf{Y}$$

Any given network might or not be able to approximate this mapping well, but when trained as well as possible it will form its best possible approximation to this mean.

For the fuzzy linguistic inputs and outputs, one input set may match along with many outputs. We calculate the average target based on P(**Y**|**X**) for each rule.

5 Experiment

Rule specification:

(R1) IF x1is Small AND x2 is Small, THEN y is Small;
(R2) IF x1 is Small AND x2 is Large, THEN y is Middle;
(R3) IF x1 is Large AND x2 is Small, THEN y is Middle;
(R4) IF x1 is Large AND x2 is Large, THEN y is large.

Original training sample:

Universal of x (X) and Universal of y (Y) are [0,100]. We just generate randomly these samples such as (x1, x2, y), each of which ranges from 0 to 100, inclusively.

Algorithm to train the neural network:

BP Algorithm.

Neural network structure:

4 layers having 3, 3, 3 and 1 neutrons respectively.

Experiment environment:

Matlab.

5.1 Experiment using graph solution

The system generates 100000 samples randomly, where 28793 samples are satisfied with the 4 rules in the example. Using these training samples to train the neural network, we get error values below (Figure 6) and the error is reasonable since it fall within the interval [0-0.47] according to the "graph solution" mentioned above.

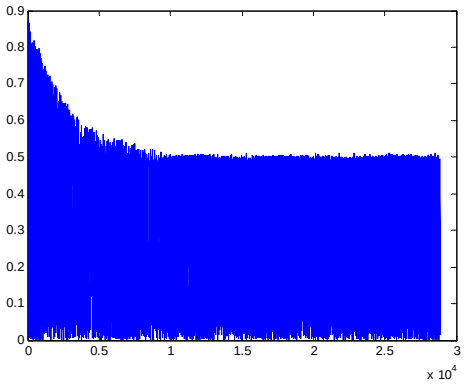

Figure 6. Training error using graph solution.

Using 14428 testing samples on this network, we get error values shown as Figure 7. The result is approximately between 0-0.47 and reasonable.

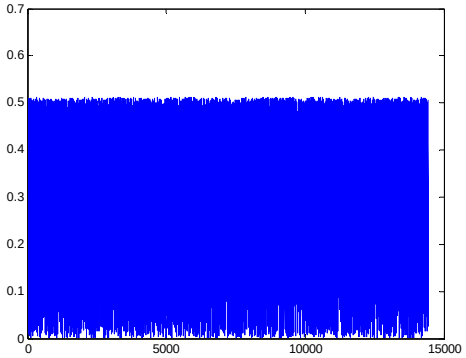

Figure 7. Testing error using graph solution.

5.2 Experiment using mean solution

Assuming P(**Y**|**X**) of each rule is an average distribution, we easily calculate the average target for four rules and they are 0.8313, 0.8375,0.8375,0.8313 separately. We get error values below (Figure 8).

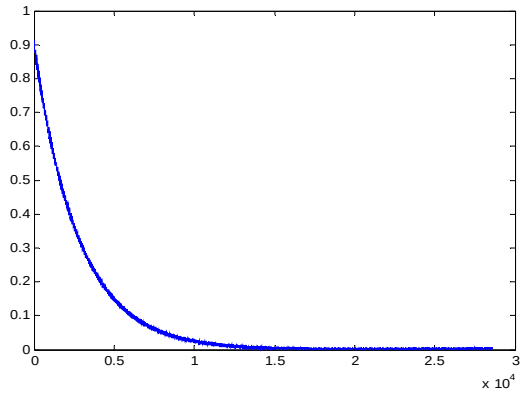

Figure 8. Training error using mean solution.

Using 14455 testing data samples on this network, we get error values shown as Figure 9. The result is between 0.015-0.04 and reasonable.

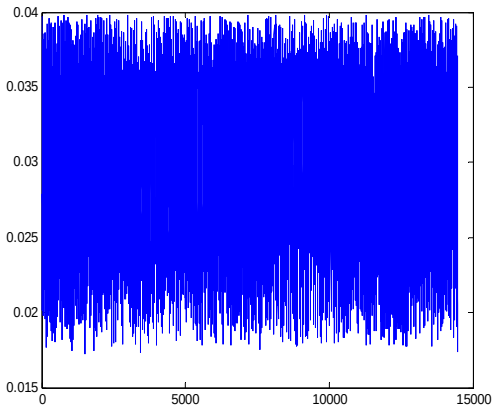

Figure 9. Testing error using mean solution.

Experiments show that the graph solution goes a litter faster than the mean solution to get to a stable state. However, mean solution could deal problems which have background knowledge P(**Y**|**X**). They are determined by properties of probability mathematics and the practical needs. So, we could realize that mean solution make use of known conditions more sufficiently. On the other hand, graph solution would be chosen if we do not want to fix fuzzy output and there is no background knowledge at all.

6 Conclusions

This neural fuzzy system could deal with problem of fuzzy rules.

Obviously, this system can input crisp values and output fuzzy values, which is more convenient compare to previous fuzzy neural networks with crisp inputs and outputs.

In addition, this system is also suitable for fuzzy reference problems. That is, if we are given the membership function value of X, what the membership function value of Y should be? It is already known that there are different fuzzy reasoning rules defined by human-beings in the fuzzy logic area, such as Mamdanian Larsen fuzzy reference[9], Zadeh fuzzy reference[1], and so on. We may choose different methods doing fuzzy reference. But which method is better? It depends on needs. For complex reference problem, fuzzy neural network system could be used to get the relationship between fuzzy variable X and Y---R(X, Y), which is a good method to get a suitable rule according to our needs.

Adaptive Two-stage Fuzzy Logic Controllers for Urban Traffic Signals at Isolated Intersections

Yang Wenchen[1], Zhang Lun[1,*], He Zhaocheng[2] and Yang Yuchen[1]
[1] School of Transportation Engineering, Tongji University, Shanghai 201804, P.R. China
[2] Intelligent Transportation Research Centre, Sun Yat-sen University, Guangzhou 510275, P.R. China

Abstract - *This paper presents two optimal approaches of two-stage fuzzy controller for traffic signals at isolated intersections. Firstly, in the light that traffic status variables in two-stage controller leads to the inefficiency of traffic status weakening under low traffic flow, a two-stage combination fuzzy controller is designed from the perspective of structural optimization; this controller introduces 0-1 combination and determines the variables of fuzzy controller's inputs according to real-time traffic status identification. Secondly, aiming at the problems of fuzzy controller parameter empirical settings and functional disability of learning, a two-stage fuzzy logic traffic signal controller with online optimization is proposed; this controller introduces the rolling horizon framework and optimizes parameters of membership functions and controller rules by an improved hybrid genetic algorithm. The performance of the two proposed models is validated via online Paramics-based simulation platform, and extensive relative simulation tests have demonstrated the potential of the proposed controllers for adaptive traffic signal control.*

Keywords: Traffic signal; fuzzy logic; combination fuzzy; hybrid genetic algorithm; isolated intersection

1 Introduction

Single fuzzy controller considers all of status variables which lead to the increasing number of control rules and interference among status variables, or the only selection of queue length as status variable could not respond to traffic status[1,2]. Multi-stage fuzzy controller takes traffic status variables such as queue length, phase time, and saturation etc., into account, and processes these status variables dispersedly, optimizes phase sequences, and improves the performance of fuzzy controllers[3,4]. However, the adoption of standard four phase structures ignores the noncritical traffic flow and right turn flow, leading to insufficient response to fluctuation of complex traffic flow and weekending of traffic status under the low or medium saturation at intersections, and due to empirical parameters assured by experts, multi-stage fuzzy controller is still without learning ability[5]. From previous optimization work on the selection of traffic status variables and structure of fuzzy controller to current optimization of controller parameters with intelligent algorithms. Optimization of fuzzy logic-based control for traffic signals at isolated intersection have attracted the attention of scholars at home and aboard.

Ballester[6], Henry[7], and Bingham[8]etc., introduces artificial intelligent algorithms, such as genetic algorithm, neural networks, reinforcement learning, to learn fuzzy controller's parameters in the course of traffic signal control's interaction with traffic environment, and the simulation results indicate effectiveness of multi-stage fuzzy optimizing control, but many of which are off-line optimizing methods, and performance of these controllers mainly depend on the efficiency of optimizing algorithm, the valid sample sets, and the design of the feedback function. Genetic algorithm(GA) has the ability of global search and does not depend on gradient information and experiential knowledge[9]. In the light of this, Lekova[10], Kim[11] and Yang[12]etc., widely employs GA in researches of parameter optimization of fuzzy controllers, which could be divided into there categories: optimizing fuzzy membership parameter under experimental fuzzy rules, optimizing of fuzzy rules under experimental membership parameters, and optimizing membership parameters and fuzzy rules at the same time. Moreover, the majority of existing methods applies Matlab and computer program to simulate operation of traffic flow at intersections which does not represent the actual traffic flow in the road network, and thus lacks simulation evaluation method to evaluate implementation of fuzzy optimal controller[13].

Along the line of previous studies and in response to the above critical issues of traffic intensity-based two stage fuzzy controller, this paper presents adaptive two-stage fuzzy controllers for traffic signals at isolated intersections: architecture, algorithms, and online Paramics simulation. The remainder of this paper is organized as follows. Section II will detail the research scope and illustrate traffic intensity-based two-stage fuzzy control model for traffic signals. Section III illustrates two-stage combination fuzzy control model for traffic signals, including modeling theory analysis and conceptual models. Section IV details HGA-based two-stage fuzzy controller, which includes rolling horizon framework, online optimization design of two-stage fuzzy controller, objective function based on traffic status identification, and solution algorithm. Section V evaluates the proposed fuzzy controller with extensive experimental tests via Paramics-based simulation platform of online two-stage fuzzy optimal

control, which still includes development of Paramics-based simulation platform via Matlab and VC++ hybrid programming, and Paramics simulation experiment design. Section VI analyzes simulation results in detail. Section VII concludes the work.

2 Research scope and two-stage fuzzy model for traffic signals

2.1 Experimental test intersection

A typical cross intersection is shown in the left of Fig.1. The intersection has four approaches, and each approach has three types of traffic flow named straight flow, left flow and right flow. When right traffic volume is heavy, to avoid that vehicles interweave with each other and affect the passing efficiency by disrupting the straight flow in the opposite direction and the left flow in the same direction, the right-turn vehicles are under the signal control to simulate a real-world control environment, and the revised standard four-phase is shown in the right of Fig.1.

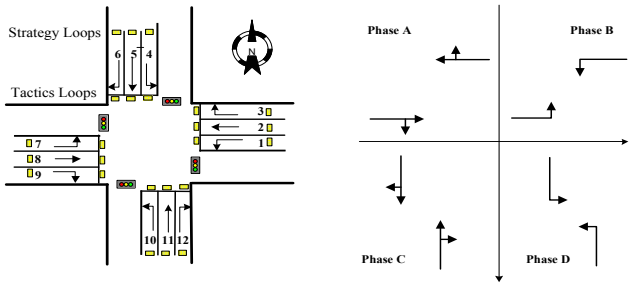

Figure 1. Experimental test intersection

To detect real-time traffic flow arrival and departure of each lane at intersection, the strategic and tactical loops are respectively deployed in each lane of each approach. As shown in left part of Fig.1, the tactical loops are deployed before the stop line to detect the throughput of each lane, including the number of leaving vehicles and their departure time, while the strategic loops are deployed at a distance of 150m away from tactical loops upstream of each approach to detect the arrival traffic demand of each lane, including the number of arrival vehicles and their arrival time.

2.2 Two-stage fuzzy control algorithm

Following basic principles of traffic signal control such as the maximum and minimum cycle and the maximum and minimum green time, the two-stage fuzzy control algorithm is as follows: (1) give minimum green time to the current green phase until the remainder of green time is 2s; (2) traffic intensity module determine red-urgency or green-urgency of each phase according to real-time detected traffic flow data, and select the red phase with maximum red-urgency as the next target green phase; (3) decision module determines extension time of current green phase (g_e) based on green-urgency and maximum red-urgency; (4) whether to switch current phase is determined by control logic that phase switch to next target green phase if g_e is less than 6s.

2.3 Structure of two-stage fuzzy controller

The Control rules of traffic signal fuzzy controller increase by exponent with the increase of the number of status variables, and each status variable interferes with each other. In order to make traffic signal fuzzy controller to respond to traffic flow change swiftly, this paper introduces traffic intensity to apply the two-stage fuzzy control model for isolated traffic signals, and denominates traffic intensity of red light phase and traffic intensity of green light phase as red urgency and green urgency respectively depending on their control features. Following this, the number of control rules decreases through multi stage and the interference between status variables of green light phase and those of red light phases is avoided. The structure of traffic signal two-stage fuzzy controller is shown in Fig.2.

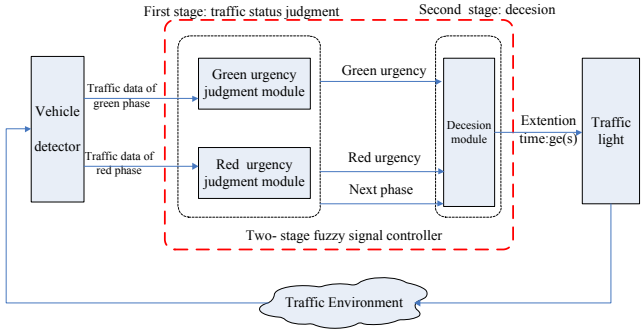

Figure 2. The structure of traffic signal two-stage fuzzy controller

The first stage is to determine the level of the traffic statues, which includes determining the urgent degree of red phase, the urgent degree of green phase and the optimal choice of next target phase. Among the three items, analyzing the traffic flow data collected at intersections, the urgent degree of red phase and the urgent degree of green phase are determined by green urgency module and red urgency module to evaluate the traffic intensity of signal phases. As to adapt to the dynamic features of traffic flow at intersections and the non-uniformity of traffic flow distribution, the function of the optimal choice of next target phase is aimed at selecting the highest phase among the urgent degree of red phases as the next target phase of green light, so as to achieve the optimization of phase sequence.

The second stage is to determine the extension time of the phase of green light. Based on the urgent degree of the current green phase and the urgent degree of the current red phase, the values of the current extension time of current green phase is determined by decision module.

The details on the above three fuzzy modules that determine red urgency, green urgency and decision time

respectively could see Yang's models[12]. Because of the uncertainty of traffic flow arrival for different phases, to consider non-critical flows, the average value of traffic flow parameters is selected as the input of controllers. And to formulate the reasonable control scheme representing traffic reality, vehicle flows of right turn are taken into account.

3 Two-stage combination fuzzy model

3.1 Theory analysis of modeling

The urban traffic signal two-stage fuzzy controller is influenced by the choice of traffic status variables and the reasonable setting of control parameters. When saturation of traffic flow is high, a certain number of queuing vehicles appears in each red light phase, thus it is hard to accurately represent the traffic status at intersections only considering the number of queuing vehicles, and two-stage fuzzy control based on traffic intensity, considering the phase time traffic status variables, meets control demands. However, the traffic flow is free under the condition of low vehicle flow and the number of queuing vehicles is less[3-5]. Under this situation, traffic status at intersections is weakened due to consideration of phase time and two-stage fuzzy control under low traffic flow approximately equals to the minimum-cycle based control. The reasons of the worse performance in low traffic flow condition is illustrated as follows: (1) Because of the short extension time of green phase, the phases switches frequently, and most of new coming vehicles have to queue before going through intersections; (2) Because of the consideration of time of red light phase, the waste of green time under no queuing vehicles is severe as the queuing vehicle of the new green light phase is less.

Thus, the status variables' choice of two-stage fuzzy controller's inputs should be directly relevant to traffic status at intersections. The choice of status variables is determined by features of traffic status. Based on respective traffic status variables of different traffic status at intersections, the structure of fuzzy controller under different traffic status should be adaptive.

3.2 Conceptual model of comination fuzzy

In the light that the standard fuzzy controller has achieved better control performance under low traffic flow and two-stage fuzzy control based on traffic intensity has achieved effective performance under high or middle traffic flow, the two-stage combination fuzzy control for urban traffic signals introduces "0-1" combination[14], in which choose the number of queuing vehicles as the traffic status variable under the condition of low traffic flow and thus apply the standard traffic signal single-stage fuzzy control (SFTSC)[2], while choose the phase traffic intensity as the traffic status variable under the condition of high traffic flow, and thus apply the traffic signal two-stage fuzzy control (TFTSC)[12]. The conceptual model of traffic signal two-stage combination fuzzy control is shown in (1).

$$\begin{cases} SFTSC & if \ \ Y \le Y_0 \\ TFTSC & if \ \ Y > Y_0 \end{cases} \tag{1}$$

In (1), Y_0 denotes total flow rate of intersections. And the identification of high or low traffic flow at intersections applies the method of two-dimension traffic status identification in reference [15]. According to the features of high or low traffic flow, the standards of identification of high and low traffic flow uses the threshold of free status that is Y_0 is 0.42 while occupancy of intersections is lower than 0.33.

Based the real-time ability of traffic signal control schemes and demand of the balanced transition of control schemes, T_c is selected as roll optimization cycle of two-stage combination fuzzy controller, that is at every T_c, by judging the traffic status of the intersection, the model of fuzzy controller for the following control interval is selected based the traffic status at isolated intersections.

4 Online optimization design for two stage fuzzy control

4.1 The rolling horizon framework

This paper optimizes parameters of membership functions and parameters of fuzzy rules at the same time[9]. To set the parameters of two-stage fuzzy controller response to real-time traffic conditions at intersections, this study introduces the rolling horizon[16]. With detecting traffic data, at each control interval, the controller parameters can be updated to adapt to real-time traffic flow characteristics accordingly. The framework of rolling horizon is shown in Fig.3. And the illustration of rolling horizon are as follows.

(1) Detect real-time traffic data during entire control time horizon H, such as arrival and leaving vehicles, etc.; (2) Setting length of projection stage T, decide each roll period length or each control interval(the accumulated time under latest controller with optimal parameters is just over T_o), and optimize parameters of fuzzy controller by hybrid genetic algorithm(HGA) according to quasi real-time historical traffic data; (3) Update parameters of fuzzy controller in time after optimization; (4) Repeat the above optimization process when it comes to the next control interval.

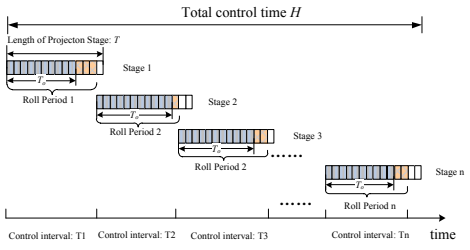

Figure 3. Illustration of the rolling horizon

And the structure of two-stage fuzzy controller based hybrid genetic algorithm for traffic signals is shown in Fig.4.

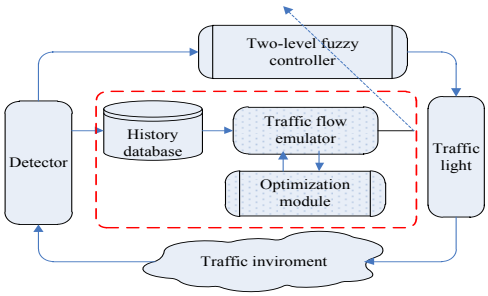

Figure 4. Structure of optimal two-stage fuzzy control system

In Fig.4, the designed HGA-based optimal fuzzy control system includes four following sub-modules: the two-stage fuzzy control in implementation, the reappearance of quasi real-time historical traffic flow, HGA-based optimization of parameters of fuzzy controllers and history database for managing traffic data.

4.2 Objective function based on traffic status identification

This study adopts average delay at an intersection as evaluation index of each controller with specific controller parameters. There are two methods to calculate delay: Mesoscopic numerical simulation[17] and Microsimulation [18]. Limited to the support of secondary development kits of most simulation software, this study employs mesoscopic numerical simulation to model the average delay.

To model the discrete process of vehicle arrival at intersections, the assumption that one vehicle is queuing when it just arrives strategic loops is mostly used. Though delay models based this assumption fit better relatively under high saturation that traffic volume at intersection is heavy and there are certain queuing vehicles at most approaches, the delay error is larger under low saturation due to vehicle's discrete process between strategic and tactics loops. Therefore, this study models average delay at intersections based traffic status identification[15]. Under low saturation, the newly arrived vehicles enter the queuing with the possibility of 50%[12], while the newly arrived vehicles enter the queuing with the possibility of 100% under high saturation[17].

4.3 Solution algorithm

(1) Decoding for controller parameters

The traffic intensity-based two-stage fuzzy controller employed in this study has two input variables and one output variable, and all of which are divided into five fuzzy sets. Decoding for this controller includes parameters of membership function and fuzzy rules. To improve control algorithm's accuracy and solution algorithm's convergence speed, real number encoding is designed to decrease the length of the chromosome. As shown in the left part of Fig.5, this study adopts triangle membership function to reduce the number of controller parameters, and let the base vertices of each membership function separately superpose centers of two adjacent membership function, consequently, with the center of membership functions, its position and shape could be effectively given.

For the chromosome of control rules,, to decrease the complexity and enhance the real-time ability of controller, utmostly 25 controller rules could be selected. considering following integer matrix R: $R=[r_{ij}]_{5\times5},\ i\in[1,5], j\in[1,5]$, while r_{ij} is a integer within [1,5], denoting the index value of output of fuzzy sets. Then R can be converted into a row vector R' that can denote the chromosome of fuzzy rule, i.e. replacing the first element of the next row just behind the last element of the former row. Individual coded schema of two-stage fuzzy controller is shown in the right part of Fig.5.

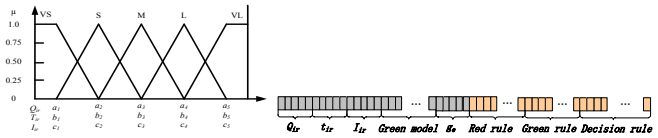

Figure 5. Decoding for parameters of fuzzy controller

(2) Hybrid genetic algorithm

A GA-based heuristic(HGA) extended form the method by Yang has been developed to yield approximate solutions for each control interval during the entire optimization period[15]. The proposed heuristic features its capability to identify the solution closest to the best solution by introducing simulated annealing algorithm to enhance the local optimal capability of genetic algorithm. The process of improved hybrid genetic algorithm is as follows:

i) Initialization: generate initial population, and initialize GA and SA parameters. According to generation and fitness value, crossrate and mutationrate is adaptive.

ii) Fitness evaluation: Evaluating performance of each controller with specific controller parameters is to calculate average delay at intersection (d) based traffic status identification, then the fitness value is computed in (2).

$$f(d)=\frac{1}{1+d} \tag{2}$$

iii) Selection: roulette wheel selection.

iv) Crossing: non-uniform arithmetic crossover operator.

v) Mutation: non-uniform mutation operator, by which the degree of mutation is adaptively adjusted with generation and fitness value.

vi) Elitist strategy: replace the worst individual by the best.

vii) Local optimization by Simulated Annealing: introduced the best individual of cur-generation as initial vector, enhancing the local optimization via SA.

a) Generate new individuals by status function of SA;

b) Select the individual by metropolis principle in SA;

c) Judge the stability of SA, if non-steady, go to a); Otherwise, execute annealing operation and go to step viii);

viii) Judgment of termination principle: if $n<Gen$, go to Step2. Otherwise, output the best solution.

5 Case study

5.1 Quasi-online Paramics-based simulation platform

Traffic simulation, which could simulates the operation of traffic flow under different control strategies, is an effective evaluation approach for urban traffic signal controls. The microscopic simulator Paramics was employed as an unbiased evaluator for model performance, and a Paramics-based simulation platform of quasi-online two-stage fuzzy optimization control is developed. The Paramics-based simulation platform of two-stage fuzzy optimization control consists of implementation module for actual control and optimizing module for learning parameters. Taking the efficiency of optimizing module into account, in the process of optimizing, the implement module is still operating. The novel optimizing codes come into operation just at the end of previous optimizing request. The following are the features of the developed simulation platform:

(1) To shorten the development cycle and improve the accuracy of fuzzy decision, three types of fuzzy controller are developed via Matlab;

(2) To make Paramics simulation platform of fuzzy control interact with above three fuzzy controller, the hybrid programming of Matlab and VC++ is introduced by which interface between VC++ and Matlab is defined and control strategies such as actuated control, two-stage fuzzy control, and HGA-based two-stage fuzzy control are secondarily developed into Paramics via Paramics API[18], and to establish the communication between implementation module and optimal module, database-based command queuing technology is used;

(3) Physical simulation network for a typical urban isolated intersection is developed via Paramics's Modeler module, and by loading control strategies' Plug-in into Paramics, the performance of those traffic signal controllers could be validated under different traffic scenarios designed in Paramics.

5.2 Paramics simulation

(1) Simulation algorithm

Following the basic algorithm of two-stage fuzzy control, in the two-stage combination fuzzy controller, T_c is 5*min*, that is when the accumulated time is just over 5*min*, two-stage combination fuzzy optimization module selects the most appropriate fuzzy controller based real-time traffic status at intersections; For HGA-based fuzzy controller, T is 10*min* and T_o is 8*min*, that is when the accumulated time under latest controller with optimal parameters is just over 8*min*, HGA-based two-stage fuzzy optimization module learns parameters of three fuzzy controllers, and updates the parameters of fuzzy controllers of implementation module at the end of parameter optimization.

(2) Simulation scenarios

In order to examine the proposed control method under different traffic flow conditions and different traffic flow fluctuation, this paper designs a variety of simulation scenarios, including uniform arrival for each approach, a sudden change in one of direction flows, and unbalanced arrival for each approach. The specification of simulation scenario is as follows:

i) Simulation length is 13*h*, approach arrival flow ranges from 400 to 1600 per hour. And every per hour is a simulation time period, and the turning ratio of left-straight-right 0.25-0.60-0.15;

ii) To simulate traffic fluctuation in short-term, vehicle's departure rate in 10*min* intervals per hour, set in the Profiles of Paramics, is as follows: 15-11-17-22-16-19;

iii) According to the design standard of urban roads in china that the capacity of straight, left and right are 1650*pcu/h*, 1550*pcu/h* and 1550*pcu/h*, the key simulation parameters of mean driver reaction time(*MDT*) and mean headway time (*MHT*) are respectively calibrated to1.8*s* and 1.5*s*;

iv) To overcome the stochastic nature of simulation results, an average of 20 simulation runs has been used.

(3) Simulation experiments

Experiment I is designed to verify two- stage combination fuzzy control (CTFIFuzzy), compared to fixed-timing, actuated, and traffic intensity-based two-stage fuzzy control. Here, fixed-timing scheme (Fixed) is Webster signal timing under average traffic flow at intersections (05:0-06:000)[19], while in actuated control (Actuated), detector loop is 30m away from the stop line, and the extension unit time is 3*s*[15]; and traffic intensity-based two-stage fuzzy control (TFIFuzzy) adopt Yang's method[12]. And compered to fixed-timing, actuated and two-stage fuzzy control based

traffic intensity, experiments II are designed to validate two-stage fuzzy control based HGA (GAFuzzy).

Considering traffic flow characteristics and safety demands at signalized intersections, simulation parameter settings are as follows：maximum green time for phase1 and phase 3 is 80*s*, while 50*s* for phase 2 and phase 4, and minimum green time for four phases is 12*s*.

6 Results

Performance indices in this study are average delay (*Delay*), average queuing number (*Queue*) and average speed (*Speed*), and approach throughput (*Count*). Among them, speed and throughput are benefit indicators, while delay and queue are efficiency indicators.

(1) Two-stage combination fuzzy controller

Simulation results of the two-stage combination fuzzy control's performance are shown in Fig.6. The performance of two-stage fuzzy controller is poor in the low traffic flow due to the weakening of traffic status, which result in the frequent shifts of phases and the waste of phase green time when less vehicles passing. Throughout the whole simulation process, combination fuzzy control is stable, and compared to the fixed, actuated or two-stage fuzzy control, the performance of combination fuzzy controller are improved greatly. For example, the delay decreases by 30% to 10%. And simulation results indicate that this controller improves the performance of two-stage fuzzy control in low traffic flow conditions.

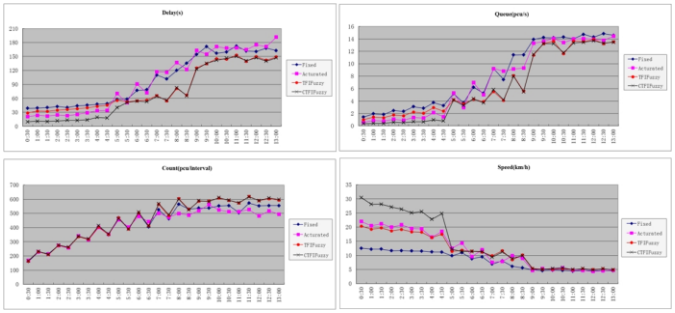

Figure 6. Simulation results of two-stage combination fuzzy controller

(2) HGA-based two-stage fuzzy controller

Simulation results of HGA-based two-stage fuzzy controller's performance indices are shown in Fig.7. Throughout the simulation process, HGA-based two-stage fuzzy control is stable. Performance of delay, queue length etc., are better than those of fixed-timing, actuated control and two-stage fuzzy control. Furthermore, performance of this controller is still getting better as traffic arrival volume of each approach is increasing. Taking delay as an example, compared to the actuated control, fixed control, and two-stage fuzzy control, GA-based fuzzy control decreases delay by 27%, 30% and by 13% respectively.

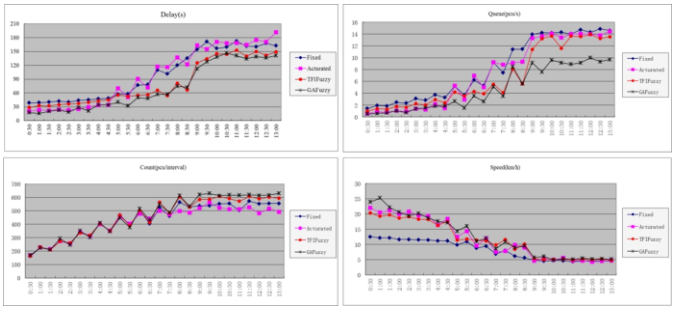

Figure 7. Simulation results of HGA-based two-stage fuzzy controller

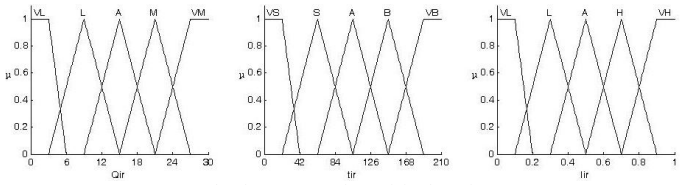
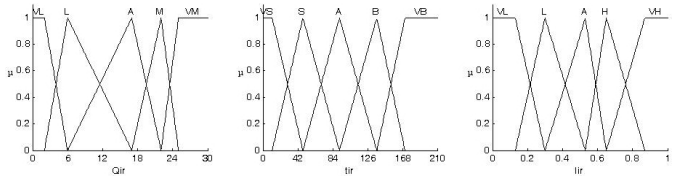
At a certain control interval, taking the red urgency module as an example, the differences between membership functions with empirical parameters and membership functions with optimized parameters are shown in Fig.8.



(a) The fuzzy sets of empirical settings



(b) The fuzzy sets aft optimization

Figure 8. Parameters of Membership functions of Red urgency judgment

7 Conclusions

This paper presents two adaptive two-stage fuzzy controllers for unban traffic signals at isolated intersections. From the perspective of structural optimization, the two-stage combination fuzzy controller introduces 0-1 combination, in which the single-stage controller will be applied under low traffic flow, while the traffic intensity-based two-stage fuzzy controller will be used under medium or high traffic flow. This combination controller determines traffic status variables of fuzzy controller's inputs depending on the traffic status at intersections, and adapts to the influence of traffic flow change on the performance of different fuzzy controllers. Then, aiming at the problems of fuzzy controller parameter empirical settings and functional disability of learning, the HGA-based two-stage fuzzy control introducing rolling horizon framework develops an adaptive optimization framework of fuzzy controller to adjust fuzzy membership functions and controller rules with on-line learning. At regular time intervals, HGA-based controller employs a hybrid genetic algorithm to efficiently yield the reliable solution through reappearance of statistical traffic flow. Experiments are carried on typical urban isolated intersection and the performance of proposed model and algorithm is validated via Paramics-based simulation platform of on-line two-stage fuzzy optimization control.

Extensive Paramics simulation results indicate that different traffic signal controller has its application boundaries. It is reasonable that combination fuzzy control selects traffic state variables of fuzzy controller according to traffic status at intersection, which improves the performance of two-stage fuzzy control in low flow conditions; and HGA-based fuzzy controller learns parameters with quasi-online optimization, which is stable and get better performance. Compare to fixed-time, actuated, and two-stage fuzzy controller for different traffic conditions, the two proposed controller offer a better performance as the traffic flow increases, and control effects are consistent with traffic manager's control object.

Abstract— **A Firefly Algorithm (FA) based on Fuzzy PID controller is proposed in this paper to solve the Load Frequency Control (LFC) problem in a deregulated environment. In multi area electric power systems, if a large load is suddenly connected (or disconnected) to the system, or if a generating unit is suddenly disconnected by the protection equipment, there will be a long-term distortion in the power balance between that delivered by the turbines and that consumed by the loads. This imbalance is initially covered from the kinetic energy of rotating rotors of turbines, generators and motors and, as a result, the frequency in the system will change. This paper applied a fuzzy controller to solve this problem. The results of the proposed controller are compared with the classical fuzzy PID type controller and classical PID controller through ITAE and FD performance indices.**

Keywords; FA, Load Frequency Control, Two-Area Power System, Deregulated Environment.

I. INTRODUCTION

For large scale electric power systems with interconnected areas, Load Frequency Control (LFC) is important to keep the system frequency and the inter-area tie power as near to the scheduled values as possible. The input mechanical power to the generators is used to control the frequency of output electrical power and to maintain the power exchange between the areas as scheduled. A well designed and operated electric power system must cope with changes in the load and with system disturbances, and it should provide acceptable high level of power quality while maintaining both voltage and frequency within tolerable limits. Many control strategies for Load Frequency Control (LFC) in electric power systems have been proposed by researchers over the past decades[1] .

The foremost task of LFC is to keep the frequency constant against the randomly varying active power loads, which are also referred to as unknown external disturbance[2] . Another task of the LFC is to regulate the tie-line power exchange error. A typical large-scale power system is composed of several areas of generating units. In order to enhance the fault tolerance of the entire power system, these generating units are connected via tie-lines. The usage of tie-line power imports a new error into the control problem, i.e., tie-line power exchange error. When a sudden active power load change occurs to an area, the area will obtain energy via tie-lines from other areas. But eventually, the area that is subject to the load change should balance it without external support. Otherwise there would be economic conflicts between the areas. Hence each area requires a separate load frequency controller to regulate the tie-line power exchange error so that all the areas in an interconnected power system can set their set points differently[3] .

There are lots of techniques to solve the LFC problem in power system [4]. The Proportional Integral (PI) controllers have been broadly used for the load frequency controllers [5]. The LFC design based on an entire power system model is considered as centralized method. In [6] and [7], this centralized method is introduced with a simplified multiple-area power plant in order to implement such optimization techniques on the entire model. However, the simplification is based on the assumption that all the subsystems of the entire power system are identical while they are not.

In this paper, to overcome these problems, Firefly technique (FA) is proposed for the solution of tuning the fuzzy controller parameters. The FA is a meta-heuristic, nature-inspired, optimization algorithm which is based on the social (flashing) behavior of fireflies, or lighting

bugs, in the summer sky in the tropical temperature regions [8]. Its main advantage is the fact that it uses mainly real random numbers, and it is based on the global communication among the swarming particles, and as a result, it seems appropriate technique to use LFC problem solution. The effectiveness of the proposed method is tested on a three-area deregulated power system. Also the result of the proposed technique is compared with classical fuzzy PID type controller and classical PID controller [9] through Integral of the Time multiplied Absolute value of the Error (ITAE) and the Figure of Demerit (FD) performance indices.

II. POWER SYSTEM DESCRIPTION

Power systems have variable and complicated characteristics and comprise different control parts and also many of the parts are nonlinear [1]. These parts are connected to each other by tie lines and need controllability of frequency and power flow [4]. Deregulated power system consists of GENCOs, TRANSCOs and DISCOs with an open access policy. This is obvious that all transactions have to be cleared via Independent System Operator (ISO) or other responsible infrastructure. In this latter environment, it is appropriate that a new model for LFC scheme is improved to account for the effects of possible load following contracts on the system's dynamics [10].

In the restructured power system, Generation Companies (GENCOs) may or may not participate in the LFC task. On the other hand, distribution Companies (DISCOs) have the liberty to contract with any available GENCOs in their own or other areas. Thus, there can be various combinations of the possible contracted scenarios between DISCOs and GENCOs [1-3]. The concept of an Augmented Generation Participation Matrix (AGPM) is introduced to express these possible contracts in the generalized model. The dimension of the AGPM matrix in terms of rows and column is equal the total number of GENCOs and DISCOs in the overall power system, respectively. Consider the number of GENCOs and DISCOs in area i be ni and mi in a large scale power system with N control areas. The structure of the AGPM is given by:

$$AGPM = \begin{bmatrix} AGPM_{11} & \cdots & AGPM_{1N} \\ \vdots & \ddots & \vdots \\ AGPM_{N1} & \cdots & AGPM_{NN} \end{bmatrix} \quad (1)$$

$$AGPM_{ij} = \begin{bmatrix} gpf_{(s_i+1)(z_j+1)} & \cdots & gpf_{(s_i+1)(z_j+m_j)} \\ \vdots & \ddots & \vdots \\ gpf_{(s_i+n_i)(z_j+1)} & \cdots & gpf_{(s_i+n_i)(z_j+m_j)} \end{bmatrix}$$

$$s_i = \sum_{k=1}^{i-1} n_i, z_j = \sum_{k=1}^{j-1} m_j, i, j = 2,...,N \;\&\; s_1 = z_1 = 0$$

Where, n_i and m_i define the number of GENCOs and DISCOs in area i and gpf_{ij} refers to the 'generation participation factor' and displays the participation factor of GENCO i in total load following requirement of DISCO j based on the possible contracts. The sum of all inputs in each column of AGPM is univalent. The block diagram of a generalized LFC model with AVR loop in a deregulated power system to control area *i*, is presented in Fig.1. These new information signals are considered as disturbance channels for the decentralized LFC design [4]. As there are many GENCOs in each area, ACE signal has to be distributed among them due to their ACE participation factor in the LFC task and $\sum_{j=1}^{ni} apf_{ij} = 1$. It can be written that [5]:

$$d_i = \Delta P_{Loc,j} + \Delta P_{di} \quad , \quad \Delta P_{Loc,j} = \sum_{j=1}^{m_i} (\Delta P_{Lj-i} + \Delta P_{ULj-i}) \quad (2)$$

$$\eta_i = \sum_{j=1\,\&\, j\neq i}^{N} T_{ij} \Delta f_j \,, \quad \zeta_i = \sum_{k=1\,\&\, k\neq i}^{N} \Delta P_{tie,ik,sch}$$

$$\Delta P_{tie,ik,sch} = \sum_{j=1}^{n_i} \sum_{t=1}^{m_k} apf_{(s_i+j)(z_k+t)} \Delta P_{L(z_k+t)-k} - \sum_{t=1}^{n_k} \sum_{j=1}^{m_i} apf_{(s_k+t)(z_i+j)} \Delta P_{L(z_i+j)-i}$$

$$\Delta P_{tie,i-error} = \Delta P_{tie,i-actual} - \zeta_i$$

$$\rho_i = [\rho_{1i} \;\cdots\; \rho_{ki} \;\cdots\; \rho_{n_i i}] \quad , \quad \rho_{ki} = \Delta P_{m,k-i}$$

$$\Delta P_{m,k-i} = \sum_{j=1}^{z_{N+1}} gpf_{(s_i+k)j} \Delta P_{Lj-i} + apf_{ki} \sum_{j=1}^{m_i} \Delta P_{ULj-i}, k = 1,2,...,n_i$$

Where, $\Delta P_{m,ki}$ is the desired total power generation of a GENCO k in area i and must track the demand of the DISCOs in contract with it in the steady state. Two GENCOs and DISCOs are assumed to each control an area for which the system parameters are given in [3].

To make the visualization of contracts easier, the concept of a "DISCO Participation Matrix" (DPM) will be used. Essentially, DPM gives the participation of a DISCO in contract with a GENCO. In DPM, the number of rows has to be equal to the number of GENCOs and the number of columns has to the number of DISCOs in the system. Any entry of this matrix is a function of the total load power contracted by a DISCO toward a GENCO.

A. Firefly Algorithm

The Firefly Algorithm (FA) is a meta-heuristic, nature-inspired, optimization algorithm which is based on the social (flashing) behavior of fireflies, or lighting bugs, in the summer sky in the tropical temperature regions and introduced by Xin-She Yang [11]. Although FA has many similarities with other algorithms which are based on the so-called swarm intelligence; it is indeed much simpler both in concept and implementation [12].

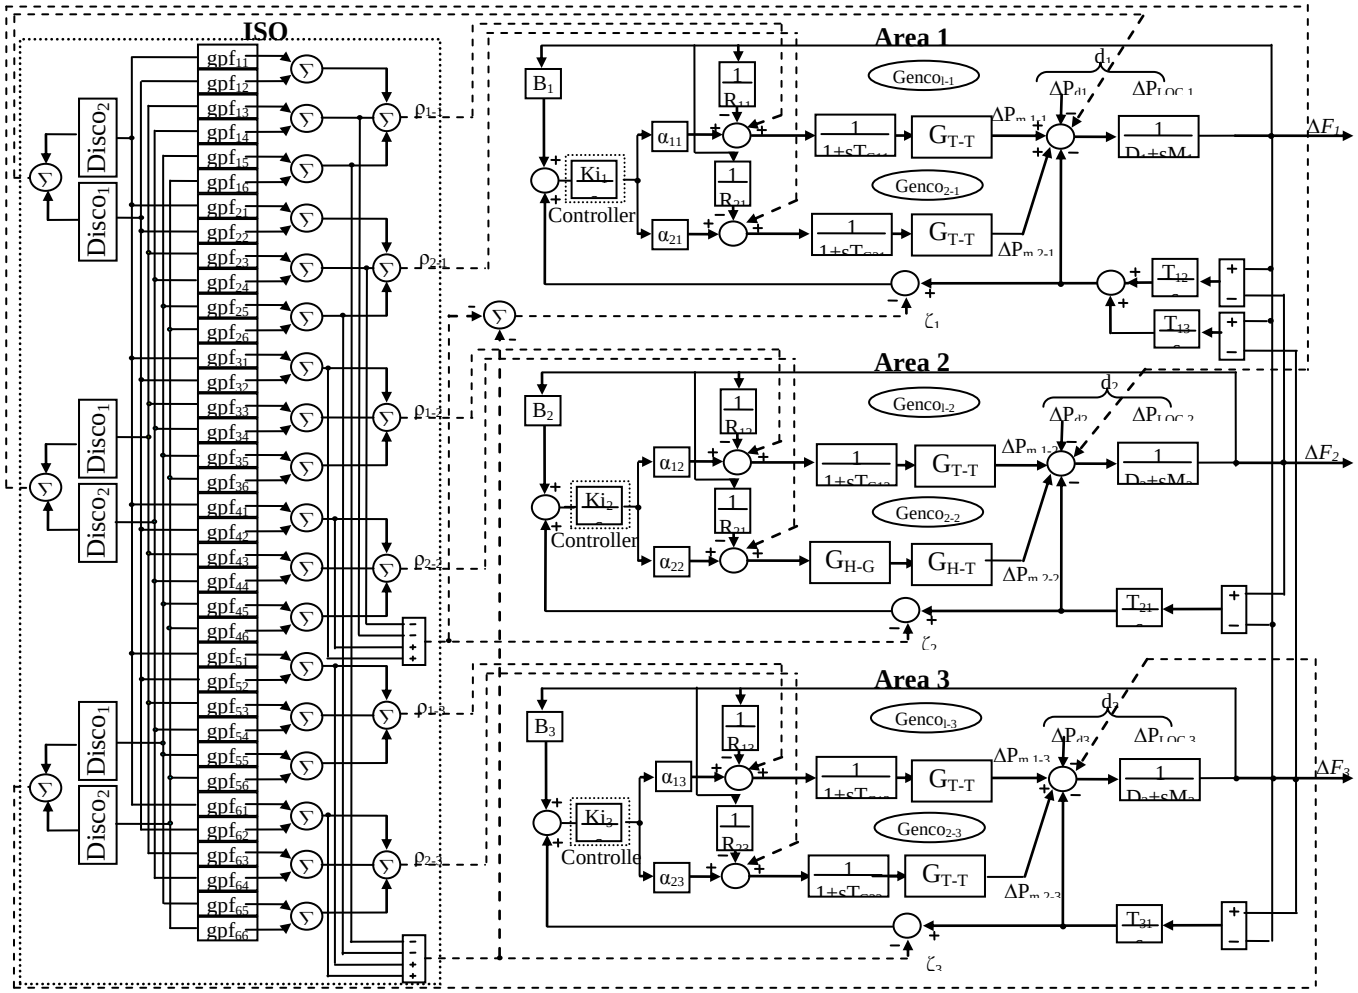

Figure 1. Generalized LFC model in the restructured system

Furthermore, this proposed technique is very efficient and can outperform other conventional algorithms, for solving many optimization problems; where the statistical performance of the firefly algorithm was measured against other well-known optimization algorithms using various standard stochastic test functions [13]. For simplicity, summarize of these flashing characteristics as the following three rules [11-13]:

- All fireflies are unisex, so that one firefly is attracted to other fireflies regardless of their sex.
- Attractiveness is proportional to their brightness, thus for any two flashing fireflies, the less bright one will move towards the brighter one. The attractiveness is proportional to the brightness and they both decrease as their distance increases. If no one is brighter than a particular firefly, it moves randomly.
- The brightness of a firefly is affected or determined by the landscape of the objective function to be optimized.

B. Attractiveness

The form of attractiveness function of a firefly is the following monotonically decreasing function [24]:

$$(\beta_r) = \beta_0^{*} \exp(-\gamma r^m), with m \geq 1, \tag{3}$$

Where, r is the distance between any two fireflies, β_0 is the initial attractiveness at $r = 0$.

γ, is an absorption coefficient which controls the decrease of the light intensity.

C. Distance

The distance between any two fireflies i and j, at positions x_i and x_j , respectively, can be defined as [12]:

$$r_{ij} = \left\| x_i - x_j \right\| = \sqrt{\sum_{k=1}^{d} (x_{i,k} - x_{j,k})^2} \tag{4}$$

Where $x_{i,k}$ is the k_{th} component of the spatial coordinate x_i of the i_{th} firefly and d is the number of

dimensions.

However, the calculation of distance *r* can also be defined using other distance metrics, based on the nature of the problem, such as Manhattan distance or Mahalanobis distance [12].

D. Movement

The movement of a firefly *i* which is attracted by a more attractive firefly *j* is given by the following equation:

$$x_i = x_j + \beta_0 * \exp(-\gamma r_{ij}^2) * (x_j - x_i) + \alpha * (rand - \frac{1}{2}) \quad (5)$$

Where, the first term is the current position of a firefly, the second term is used for considering a firefly's attractiveness to light intensity seen by adjacent fireflies, and the third term is used for the random movement of a firefly in case there are not any brighter ones. Actually α is a randomization parameter determined by the problem of interest between [0, 1].

E. FA-based PID type controller

This paper applied the PID controller for the solution of LFC problem [7]. Actually, the PID controller in wide range of operating conditions which provides robust performance. It is clear that, transient performance of the power system with respect to the control of the frequency and tie-line power flows obviously depends on the optimal tuning of the PID controller's parameters. In order to overcome the backwashes of conventional method and supply optimal control performance, FA technique is proposed to optimal tune of PID controllers parameters under different operating conditions. The block diagram of proposed technique for PID controller is presented in Fig. 2. Also the equation of load frequency control for PID in each control area is:

$$PID = k_P + \frac{k_I}{S} + k_D \quad (6)$$

Actually, in industrial PID controller is applied for low pass filter which is necessary to omit high frequency noise in entry of differentiator. Therefore in this paper for PID controller, conversion function of differentiator is:

$$k_D\, S/(1+T_dS),\ T_d=100,\ k_D \langle\langle T_d \quad (7)$$

By taking Area Control Error (ACE_i) as the input of PID controller in two case studies, the control vector for PID controller in each control area is given by:

$$u_i = k_{Pi} ACE_i + k_{Li} \int ACE_i dt + k_{Di} ACE_i \quad (8)$$

According to equation 8, in this paper the K_{Pi}, K_{Ii} and K_{Di} gains are tuned by proposed FA technique. The design problem can be formulated as the following constrained optimization problem, where the constraints are the PID controller parameter bounds:

$$\begin{aligned} &K_{Pi}^{\min} \le K_{Pi} \le K_{Pi}^{\max} \\ \textit{Minimize } u \textit{ subject to}: \quad &K_{Ii}^{\min} \le K_{Ii} \le K_{Ii}^{\max} \\ &K_{Di}^{\min} \le K_{Di} \le K_{Di}^{\max} \end{aligned}$$

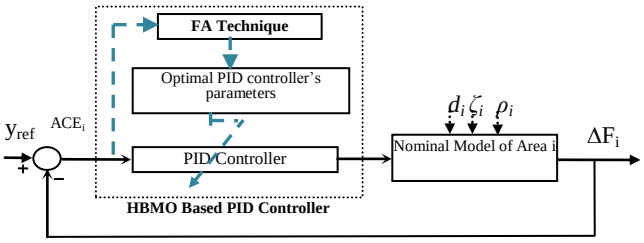

Figure 2. The introduced FA based PID controller structure.

Accordingly, the PID controller generates the control signal that applies to the governor set point in each area where the FA module works offline. For testing the robustness of the proposed technique, the power system is analyzed through some performance indices as ITAE and FD which are based on ACE_i and system responses characteristic, respectively [14]. The formulation of ITAE and FD are described as:

$$ITAE = \int_0^{10} t\left(|ACE_1(t)| + |ACE_2(t)| + |ACE_3(t)|\right)dt \quad (9)$$

$$FD = (OS \times 10)^2 + (US \times 4)^2 + (TS \times 0.3)^2$$

In other words, the concept of appropriate situation for LFC problem is based on overshoot (OS), undershoot (US) and settling time of frequency deviation in comparison of other techniques. It is clear that, the lower value of this objective functions is the best situation for system. The result of PID parameters are shown in Table 1. Also, the numerical results of these indices are presented in Table. 2.

To improve the overall system dynamic performance in a robust way and optimization synthesis, FA technique is employed to solve the above mentioned optimization problem and search for optimal or near optimal set of off-nominal PID controller parameters (K_{Pi}, K_{Ii} and K_{Di} for i=1, 2 ,…, N) where, N introduce the number of control areas [4]. Hence, the proposed method finds appropriate PID parameters with considering objective functions optimization. The convergence trend of proposed technique is presented in Fig. 3.

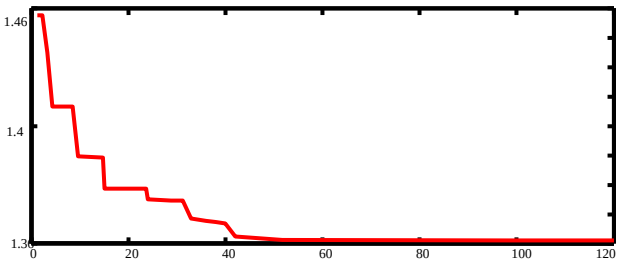

Figure 3. Variations of fitness function.

TABLE I. OPTIMUM PID CONTROLLER GAINS

FAPID	Area 1	Area 2	Area 3
K_p	2.597	1.784	1.684

K_d	1.245	1.013	1.003

In this paper, a nonlinear model with ±0.1 replaces the linear model of turbine ΔPVki/ΔPTki is considered which is shown in "Fig. 4". The proposed controller reduces the Frequency Deviance (ΔF) in dynamic status Per Load variations (ΔPL). This is to take Generation Rate Constraints (GRC) in to account, i.e. the practical limit on the rate of the change in the generating power of each GENCO.

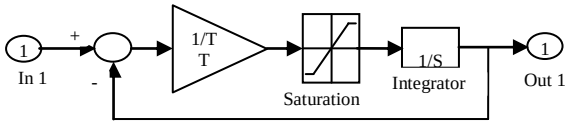

Figure 4. Nonlinear turbine model with GRC

I. SIMULATION RESULTS

In this paper for each DISCO demands 0.1 pu MW is considered. Also, it is possible that a DISCO violates a contract by demanding more power than that of specified in the contract. This excess power must be reflected as a local load of the area but not as the contract demand and taken up by the GENCOs in the same area [14].

Also for test the robustness of proposed controller the case study is tested against uncertainties and large load disturbances in the presence of GRC [14]. For this purpose two scenarios are applied as:

- *Scenario 1*

The GENCOs participate only in load following control of their areas. It is assumed that a large step load of 0.1 p.u. is demanded by each DISCO in areas 1 and 2. Assume that a case of *Poolco* based contracts between DISCOs and available GENCOs are simulated based on the following AGPM. Also the GENCOs of area 3 do not participate in the AGC task [9]. Essentially, DPM gives the participation of a DISCO in contract with a GENCO. The deviation of frequency and tie lines power flows for +25% changes is presented in Fig. 5. The element of DPM matrix and desired values for this scenario are:

$$\Delta P_{M,1\text{-}1}=0.11 \text{ pu MW}, \Delta P_{M,2\text{-}1}=0.09 \text{ pu MW}$$
$$\Delta P_{M,1\text{-}2}=0.1 \text{ pu MW}, \Delta P_{M,2\text{-}2}=0.1 \text{ pu MW}$$

$$DPM = \begin{bmatrix} 0.6 & 0.5 & 0 & 0 & 0 & 0 \\ 0.4 & 0.5 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0.5 & 0.5 & 0 & 0 \\ 0 & 0 & 0.5 & 0.5 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

- *Scenario 2*

In this Scenario, it is assumed that in addition to the specified contracted load demands and 25% increase in parameters, DISCO 1 in area 1, DISCO 1 in area 2 and DISCO 2 in area 3 demand 0.05, 0.04 and 0.03 pu MW as large un-contracted loads, respectively [9]. Using Eq. (2), the total local load in all areas is obtained as:

$$P_{Loc,1}=0.25, P_{Loc,2}=0.24, P_{Loc,3}=0.23 \text{ MW} \quad (10)$$

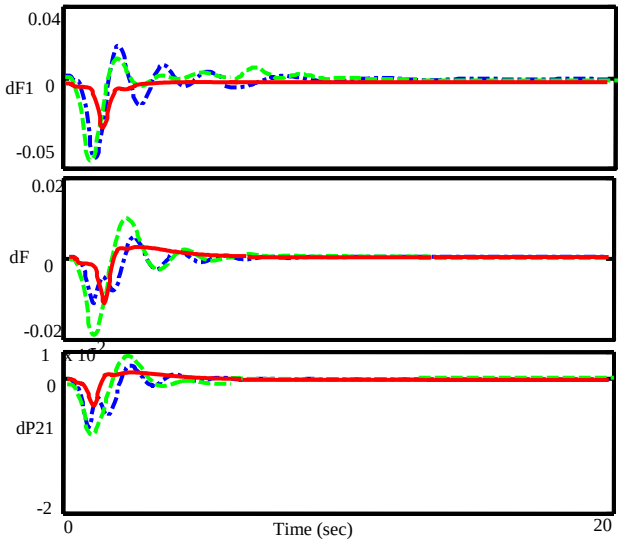

Figure 5. Frequency deviation and tie line power flows; solid (FAPID), dashed (CFPID) and dotted (PID)

The simulation results of scenario 2 are presented in Fig. 6.

II. CONCLUSION

This paper presents a Firefly Algorithm to solve the LFC problem in power system. It is well known that the conventional method to tune gains of the PID controller with numerical analysis may be tedious and time consuming. This control strategy was chosen because of the increasing complexity and changing structure of the power systems. Also, it is easy to implement without additional computational complexity. The Firefly Algorithm is a meta-heuristic, nature-inspired, optimization algorithm which is based on the social (flashing) behavior of fireflies, or lighting bugs, in the summer sky in the tropical temperature regions. Its main advantage is the fact that it uses mainly real random numbers, and it is based on the global communication among the swarming particles, and as a result. The effectiveness of the proposed method is tested on a three-area restructured power system for a wide range of load demands and disturbances under different operating conditions in comparison with CPID and PID through ITAE and FD. Simulation results demonstrate its superiority and robustness.

D. degree in Electrical Engineering from Michigan State University, U.S.A., in 1981. Currently, he is a Full Professor in Electrical Engineering Department of Iran University of Science and Technology, Tehran, Iran. His research interests are in the Application of Artificial Intelligence to Power System Control Design, Dynamic Load Modeling, Power System Observability Studies, Voltage Collapse, Congestion Management in a Restructured Power System, Reliability Improvement in Distribution Systems and Reactive Pricing in Deregulated Power Systems. He has published more than 405 technical papers in the International Journals and Conferences proceedings. He is a member of Iranian Association of Electrical and Electronic Engineers and IEEE.

An Evolutionary Extreme Learning Machine based on Fuzzy Fish Swarms

João Fausto Lorenzato de Oliveira and Teresa B. Ludermir
Center of Informatics, Federal University of Pernambuco, Recife, Pernambuco, Brazil

Abstract— *Neural networks have been largely applied into many real world pattern classification problems. During the training phase, every neural network can suffer from generalization loss caused by overfitting, thereby the process of learning is highly biased. In this work we propose an Adaptive Modified Artificial Fish Swarm Algorithm applied to the optimization of Extreme Learning Machines. The algorithm presents the basic* Artificial Fish Swarm Algorithm *(AFSA) with some features from* Differential Evolution *(Crossover and Mutation) and fuzzy rules to improve the quality of the solutions during the search process. The results of the simulations demonstrated good generalization capacity from the best individuals obtained in the training phase.*

Keywords: Neural Networks; Optimization; Fuzzy Logic

1. Introduction

When a mathematical model is applied in classification problems, the main task is to find a hypothesis that represents best the training set, in order to correctly classify unseen instances. The representation of a hypothesis in a neural network is based on the networks architecture, thus finding better weights and bias will improve the performance of the system. One way to improve the performance of the system is to use swarm based algorithms to search for better configurations of the networks. The search process is not an easy task due to the dimensionality of the search space, which will depend basically on the number of attributes of the problem, the number of hidden neurons and the number of layers of the network.

This work is focused on finding the best set of weights and bias for the Extreme Learning Machine (ELM) [1] through the use of swarm based search algorithms. The ELM is a technique applied to the training of Single Layered Feedforward Neural Networks (SLFNs) and its main advantage over the traditional gradient descent methods is the reduced number of parameters of the network and the learning speed. Although the ELM algorithm can only be employed in SLFNs, this is not a major constraint because with just one layer it is possible to model any continuous function [2]. With just one layer, the dimensionality of the search space will only depend on the problems attributes and the number of hidden neurons of the network. In the ELM algorithm the initial weights and bias are randomly set, and the output weights are analytically determined through matrix operations, thus the optimization of ELMs will focus on searching optimal initial weights.

In the literature the Particle Swarm Optimization (PSO) algorithm [3] has been successfully applied on the ELM algorithm [4]. In [4] the PSO algorithm is used to optimize the weights and bias of the ELM, and the best solution is applied on regression problems. The Artificial Fish Swarm Algorithm (AFSA) was applied on the optimization of ELMs (AFSA-ELM) in this work, however the results were not satisfying due to some limitations of the algorithm, conducting to modifications on the traditional algorithm in order to obtain better results. The modified AFSA called MAFSA obtained faster convergence and better results on the optimization of ELMs (MAFSA-ELM).

The PSO and the AFSA techniques differ significantly on their search methodologies. The PSO conducts the search based on their past movements of the particles and their previous experiences. The movements done in the AFSA algorithm are based on the actual position of the fishes and the situations of the neighbor fishes.

In the AFSA and MAFSA algorithms there are two important parameters used to control the way the search will be performed, namely the *visual* and *step* parameters. These two parameters are used to balance exploration and exploitation characteristics during the search. On the first stages of the algorithm the particles will move faster towards a global optimum passing through local minima, thus an exploration configuration is desired. However on the last stages of execution, the search needs to be more specific in some area in the search space, hence an exploitation characteristic is needed. Higher values of *visual* and *step* will produce an exploration characteristic while lower values will produce and exploitation characteristic. In the traditional AFSA and MAFSA algorithms these parameters are manually set and remain unchanged for the rest of the execution, thus the search process may not be performed appropriately.

In [5] simulated annealing is used along with the AFSA algorithm in order to improve the local search. The AFSA algorithm was also used on the optimization of neural networks in [6], which also modified the algorithm by introducing an aleatory *step* parameter to achieve better global search capacity. In [7] two fuzzy strategies are employed

in the AFSA algorithm, and were applied on benchmark functions. One is the Fuzzy Uniform Fish (FUF) and the other is the Fuzzy Autonomous Fish (FAF) which will be described in details.

In this work we use the fuzzy strategies presented in [7] in the MAFSA-ELM algorithm, and real world benchmark problems from the UCI repository [8] are used to validate the effectiveness of these methods. The proposed method presented better convergence than the AFSA and MAFSA, and competitive results in comparison to existing techniques.

This paper is organized as follows. On Section 2 the Evolutionary Extreme learning Machine based on Particle Swarm optimization (PSO-ELM) is presented along with the Modified Artificial Fish Swarm Algorithm for the optimization of Extreme Learning Machines (MAFSA-ELM). On section 3 the proposed method is explained in details and the experimental results are given on Section 4. On Section 5 the conclusions are presented.

2. Preliminaries

2.1 Extreme Learning Machine

The ELM [1] is a simple algorithm for the training of SLFNs, whose learning speed can be faster then traditional gradient descent methods such as back-propagation (BP) [9] and better generalization capacity may also be obtained. In this algorithm, the input weights and hidden layer biases are randomly set, and through matrix operations the output weights are calculated without tuning. The absence of a tuning phase, enables the training to be performed faster.

Given n distinct training samples (x_i, t_i), where $x_i = [x_{i1}, x_{i2}, ..., x_{in}]^T \in \Re^n$ and $t_i = [t_{i1}, t_{i2}, ..., t_{im}]^T \in \Re^m$ $(i \in [1, ..., n])$, the SLFN with s hidden nodes needs to learn all the training samples. Since the input weights $w_j = [w_{j1}, w_{j2}, ..., w_{jn}]^T$ and hidden biases $b = [b_1, b_2, .., b_j]$ $(j = [1, ..., s])$ are randomly generated, the task performed in the training phase is to find the appropriate output weights for the given input weights and biases through the calculation of the linear system $H\beta = T$.

The matrix $H = \{h_{ij}\}$ is the hidden-layer output matrix and $h_{ij} = g(w_j * x_i + b_j)$ corresponds to the result from the j_{th} hidden neuron to x_i, $T = [t_1, t_2, ..., t_i]$ represents the target (desired output) matrix, and $\beta_j = [\beta_{j1}, \beta_{j2}, ..., \beta_{jm}]^T (j \in [1, ..., s])$ is the output weight matrix. In order to compute the output weights, an inverse matrix operation is needed. The output weight matrix will be calculated as the minimum least-square (LS) solution of a linear system, through a pseudo-inverse matrix operation [10]. The next step for the calculation of the output weight matrix is presented $\hat{\beta} = H^+T$:

Through these calculations the ELM algorithm achieves good generalization performance and the learning speed is reduced due to the absence of continuous weight adjustments.

2.2 Evolving ELMs using a Modified Artificial Fish Swarm Algorithm

The AFSA algorithm is based on the social behavior of the fishes. Each fish will represent a potential solution, in the case of ELM optimization, each fish will represent the input weights and hidden biases. The movements of the population will be based on the actual position of each fish and the nearby fishes inside its visual field ($visual$). Two important variables are the $visual$ and $step$ which regulates how the search will be conducted. The $step$ variable will control how far a fish can move. Higher values of $visual$ and $step$ the fishes will move faster towards the best solution, passing through local minimums without getting stuck, this configuration is desired in the initial stages of execution. Lower values will produce an exploitation characteristic, desired on the last stages of the algorithm. Each fish will be represented by an input matrix W_{ij} and a bias vector b_i, and these informations are used to calculate the distance.

In order to calculate whether a certain fish is within the visual field of another fish, the distance between them is calculated using a euclidean distance. The output weights on the ELM algorithm are unknown *a priori*, hence the distance d is calculated as showed on equation 1, where p and q represent the indexes of two different fishes.

$$d_{pq} = \sum_{i=1}^{s}\sum_{j=1}^{h}(W_{ij}(p) - W_{ij}(q))^2 + \sum_{i=1}^{h}(b_i(p) - b_i(q))^2 \quad (1)$$

The number of input parameters on a given instance is represented by s and the number of hidden neurons is represented by h. The original AFSA algorithm has some basic behaviors (Follow, swarm and leap) executed by each fish, the behavior that produces the highest result will be the one used for updating the fish position. The Follow behavior as shown in equation 2 influences the fish by the best fish inside its visual range W_{max} (not necessarily the best fish in the swarm).

$$Follow(W_i) = W_i + rand()step\frac{W_{max} - W_i}{\|W_{max} - W_i\|} \quad (2)$$

The swarm behavior influences the fish based on the central position (represented by W_c) of the fishes inside its visual field. The swarm behavior strengthens the idea of group search, and is presented in equation 3.

$$Swarm(W_i) = W_i + rand()step\frac{W_c - W_i}{\|W_c - W_i\|} \quad (3)$$

And the leap behavior represents the capacity of the fish to move on its own, independent of any other fish.

$$Leap(W_i) = W_i + rand()step \quad (4)$$

In the modified AFSA algorithm (MAFSA), the additional behavior was inspired by the capacity of fishes to evolve and be selected by nature. For that purpose we use the Differential Evolution (DE) algorithm proposed by Storn and Price [11] which is known as one of the most efficient evolutionary algorithms. In order to create the next generation of individuals, the algorithm uses mutation and crossover operators. The new behavior is executed in three steps: Mutation, Crossover and Selection [11]. The first step is the mutation:

$$W_i = W_{r_1} + F * (W_{r_2} - W_{r_3}), \quad (5)$$

where r_1,r_2 e r_3 are distinct indexes randomly chosen and F is an amplitude factor with values within the range $(0, 2)$. In the crossover phase, a new vector V is created with the same dimensionality of the individuals.

$$V_{ij} = \begin{cases} W_{ij} & \text{if } rand() < CR \quad \text{and } j = rdInd(i) \\ W_{ij} & \text{if } rand() > CR \quad \text{or } j \neq rdInd(i) \end{cases} \quad (6)$$

If the new vector has better fitness than its predecessor, the new vector will be selected, otherwise the predecessor will be selected. By adding the crossover mutation behavior, the probability of finding better solutions increases due to the total amount of possible results (4 results) instead of the original 3 (from the three original behaviors), so the algorithm incrementally has more chances to find better solutions. And the reason why this new behavior is not affected by the $visual$ and $step$ parameters is simply to produce more diversity in the results and occasionally escaping from local minimums.

3. Proposed Method

In the AFSA-ELM and MAFSA-ELM algorithms, both values of the *visual* and *step* parameters remain unchanged for the whole execution of the algorithms. In the initial stages of execution, higher values of *visual* and *step* are desired in order to explore the search space towards the global best solution. In the last stages, lower values are desired in order to perform a more refined local search. In this work we use fuzzy strategies to adjust the values of these two parameters, based on the *Fuzzy Uniform Fish* (FUF) and *Fuzzy Autonomous Fish* (FAF) approaches presented in [7]. In order to control the balance between global search and local search, another parameter, *constriction weight* (CW), will be introduced for the adjustments of the parameters in both approaches. The adjustment procedures are presented as follows:

$$visual_{l+1} = CW * visual_l \quad (7)$$

$$step_{l+1} = CW * step_l \quad (8)$$

The *CW* is generated as an output for the fuzzy engines described in [7]. Since the traditional AFSA algorithm acts better at global searching, higher values will be assigned to the parameters on the initial stages, and they will be reduced adaptively. In this work we use the same engine presented in [7], which is a Mamdani fuzzy inference system with centroid of area defuzzyfication strategy, and the rules are shown in tables 1 and 2 for the Uniform Fish and Autonomous Fish respectively. The values of the input and output values can be represented by the following linguistic variables: Very low (VL), low (L), medium (M), high (H) and very high (VH).

3.1 Evolving ELMs with Fuzzy Uniform Fish

In the FUF approach every fish in the swarm shares the same values for the *visual* and step parameters. The fuzzy engine based on FUF consists of two inputs and one output. The input parameters are the ratio of improved fish, and the iteration number. The output parameter is the constriction weight. The iteration number, is the proportion between the current iteration and the total number of iterations. The algorithm needs to perform a global search in the initial stages of the algorithm, so the reduction of the *visual* and step parameters in these stage must be minimal. Near the end of the execution the algorithm has already approached the global optimum region, and needs to perform a local search, thats when higher values of the *iteration Number* parameter will influence significantly on the reduction of the *visual* and step parameters.

Table 1: Fuzzy Associative memory for the FUF Engine [7]

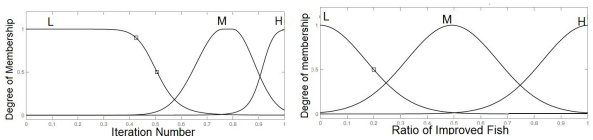
Iteration Number	Ratio of Improved Fish	Constriction Weight
L	H	VH
L	M	H
L	L	M
M	H	H
M	M	M
M	L	L
H	H	M
H	M	L
H	L	VL

The *ratio of improved fish* is the proportion of fishes that find better solutions (weights and biases) to the total number of fishes. When most of the artificial fishes find better solutions the value will be close to 1, then there is no need to reduce the *visual* and step parameters. However, when the proportion is close to 0, there is no improvement on finding better solutions , the two parameters are reduced in order to perform a local search, raising the probability of finding better solutions.

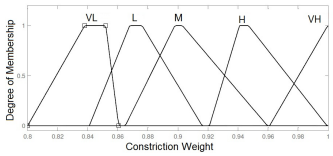
On figure 1 the membership functions for the FUF engine are presented. The membership functions for the *iteration number* and *ratio of improved fish* are shown on figures 1(a) and 1(b) respectively. The output of this fuzzy system is given by a set of fuzzy rules (same as [7]) in order to compute the value of the constriction weight parameter. The

Fig. 1: Fuzzy Uniform Fish Membership Functions. 1(a) Iteration Number. 1(b) Ratio of improved fish. 1(c) Constriction Weight.

(a) Iteration Number (b) Ratio of Improved Fish



(c) Constriction Weight



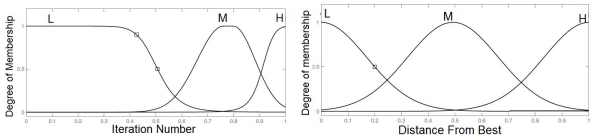
membership function for the variables is presented on figure 1(c).

3.2 Evolving ELMs with Fuzzy Autonomous Fish

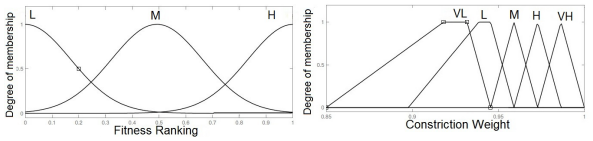
In the FAF approach, each fish will have its own *visual* and *step* variables with individual adjustments, producing more diverse results and allowing that a given fish start to perform more refined local search earlier than other fishes. In the initial stages of the algorithm these variables have the same value, and will be individually adjusted through the execution based on the output of the fuzzy engine which is calculated using three input parameters namely *Distance from best*, *Fitness Ranking* and *Iteration Number*.

Fig. 2: Fuzzy Autonomous Fish Membership Functions. 2(a) Iteration Number. 2(b) Distance from best. 2(c) Fitness Ranking. 2(d) Constriction Weight.

(a) Iteration Number (b) Distance from Best



(c) Fitness Ranking (d) Constriction Weight



The *Distance from best* rank-based parameter which is based in the distance between the fishes and the best fish (with highest validation accuracy), the distance is calculated in the same way is shown on equation 1. After the distance is computed, all distances are sorted, and then the proportion of the current rank to the total of fishes is presented to the fuzzy engine. When the distance to the best fish is low, then the *visual* and *step* parameters will be less reduced, however when a fish is close to the best fish then those values are decreased considerably, in order to perform a more refined search.

Table 2: Fuzzy Associative memory for the FAF Engine [7]

Distance from Best	Fitness Ranking	Iteration	Weight
L	L	H	VL
L	L	L	VL
L	L	L	L
L	M	H	L
L	M	M	M
L	M	H	VL
L	M	L	H
L	H	H	L
L	H	M	M
L	H	L	VL
M	L	H	VL
M	L	M	L
M	L	L	M
M	M	H	L
M	M	M	M
M	M	L	H
M	H	H	M
M	H	M	H
M	H	L	VH
H	L	H	L
H	L	M	M
H	L	L	H
H	M	H	M
H	M	M	H
H	M	L	VH
H	H	H	M
H	H	M	H
H	H	L	VL

The *Fitness Ranking* is based on the fitness of each fish with respect to the validation accuracies obtained with the ELM algorithm. All fitnesses from each fish will be sorted and then the proportion to the total amount of fishes will be presented. Lower rankings on this variable will produce less reductions on the *visual* and *step* parameters. The *Distance from Best* will have the same definitions as presented on section 3.1.

On table 2 the associative memory is showed and on figure 2 the membership functions are presented for each variable.

4. Experiments

On the experiments we used the ELM, AFSA-ELM, PSO-ELM, MAFSA-ELM and Levenberg Marquardt (LM) algorithms [9] to compare with the proposed methods (FAF-ELM and FUF-ELM) and they were applied on five (Sonar, Ionosphere, Ecoli, Horse, and Vehicle) datasets from UCI machine learning repository [8].

Table 3: Experimental results for all datasets.

The data from each dataset were split into training set (50%), validation set (25%) and test set (25%) randomly generated for 30 iterations. For each iteration all the classifiers receive the exact training, validation and test sets. All the attributes from the datasets were normalized into the interval $[0..1]$. The simulations were perfomed with 10, 15 and 20 hidden neurons, and the configuration that produced the best result was selected. The optimization algorithms executed for 50 iterations. The initialization of the AFSA-ELM and MAFSA-ELM parameters in this work is described as follows: The $visual$ parameter was set as the mean of all the initial distances between the fishes. The number of fishes $N = 30$, $step = 0.6$, lotation factor $\delta = 0.8$, in this work we set the visual parameter as the mean for all the initial distances between the fishes. Amplitude factor for the mutation $F = 1$ and crossover rate $CR = 0.5$. The same parameters for the MAFSA-ELM algorithm are also used on the FUF-ELM and FAF-ELM. For the experiments using the PSO-ELM method, we used the same configuration presented in [4] with some modifications. The constants $C1$ and $C2$ were initialized as $C1 = 2$ e $C2 = 2$, the inertia factor was set to $w = 0.9$, number of particles is 30, and the number of iterations is 50.

The experiments were measured with respect to the mean accuracy error over the 30 simulations on the validation set of the optimization techniques and the mean accuracy on the test set. The analysis of the results was performed through the use of the Wilcoxon Sign-rank test with 95% of confidence interval. Figures 3 to 10 present the mean accuracy over the iterations of the algorithms on the validation set.

For the Ionosphere dataset (figure 3), the proposed methods achieved better validation errors than the PSO-ELM and the AFSA-ELM. The FUF-ELM algorithm obtained the smallest validation error, while the the FAF-ELM and MAFSA-ELM obtained similar results. The FAF-ELM technique achieved higher mean accuracy on the test set than the other techniques according to table IV(b). The FUF-ELM and FAF-ELM algorithms outperform the ELM and PSO-ELM algorithms.

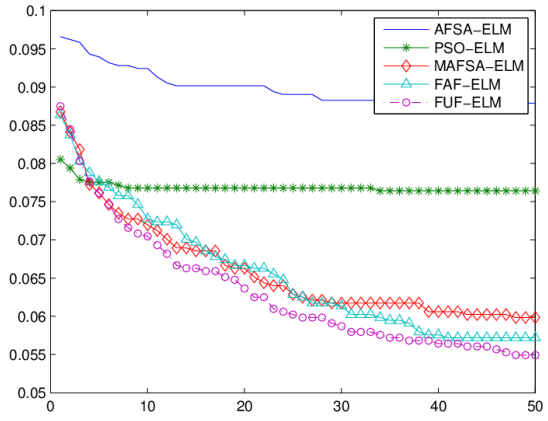

Fig. 3: Ionosphere

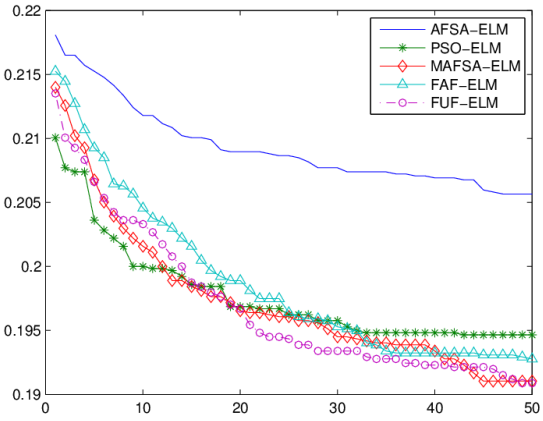

Fig. 4: Vehicle

In the Vehicle dataset (figure 4) the the FUF-ELM and the MAFSA-ELM obtained similar results, but the FUF-ELM achieved lower errors with fewer iterations. The AFSA-ELM algorithm achieved the worse results in this dataset. On table IV(c) the PSO-ELM and the FUF-ELM obtained the highest mean accuracy on the test set. The FUF-ELM and the PSO-ELM were superior to the ELM algorithm. The other algorithms obtained similar results under this level of significance (95%).

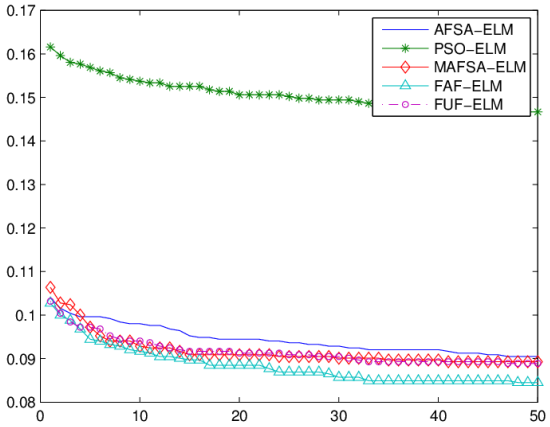

Fig. 5: Ecoli

The results concerning the Ecoli dataset (figure 5) show that the FAF-ELM method achieved lowest errors on the validation set, and the MAFSA-ELM and the FUF-ELM obtained similar results. The mean accuracy on table IV(d) shows that the FAF-ELM obtained highest accuracy with fewer hidden neurons than the other techniques. There was no significant difference on the results among the techniques.

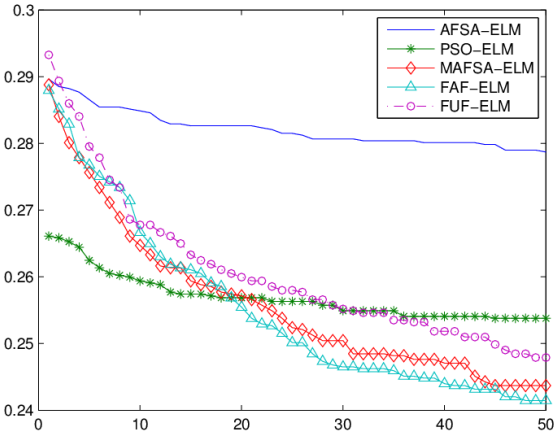

Fig. 6: Horse

With respect to the Horse dataset (figure 6) the FAF-ELM technique achieved lower errors than the MAFSA-ELM technique, the AFSA-ELM did not perform well in comparison with the other techniques. According to table IV(e) the mean accuracy of the FAF-ELM method was superior to the ELM, AFSA-ELM, FUF-ELM, MAFSA-ELM and PSO-ELM. The FAF-ELM technique was superior to the ELM, AFSA-ELM, FUF-ELM and PSO-ELM.

In the Sonar dataset (figure 7) the FUF-ELM approach

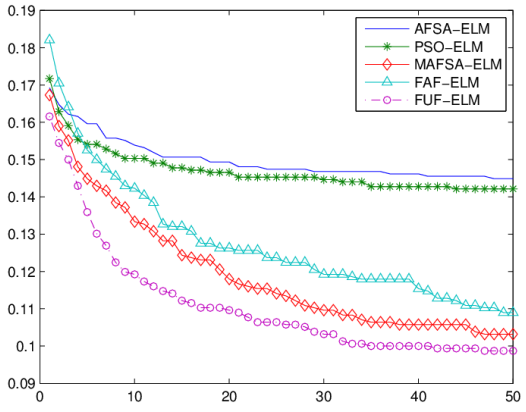

Fig. 7: Sonar

obtained smaller validation errors with fewer iterations. According to table IV(f) the FAF-ELM approach obtained acceptable results with the slowest standard deviation and fewer hidden neurons while the FUF-approach obtained the highest mean accuracy, with more hidden neurons and higher standard deviation. The results for all the techniques were similar.

5. Conclusion

In this paper, we applied two fuzzy strategies in order to adjust the parameters of the Modified Artificial Fish Swarm Algorithm on the optimization of Extreme Learning Machines, namely FAF-ELM and FUF-ELM. These algorithms optimize the random initial weights and bias from the ELM algorithm through the adjustments of global and local search using the $visual$ and $step$ parameters. The output weights are analytically determined through the pseudo-inverse matrix operation.

The performance of the tested algorithms was evaluated with well known benchmark classification datasets (Ionosphere, ecoli, sonar, vehicle and horse-colic), obtained from UCI Machine Learning Repository [8].

Experimental results show that our hybrid approaches achieve better validation errors, and in some datasets achieved better accuracy on the test sets.

As future works, we plan to evaluate the influence of using the Autonomous Fish (FAF-ELM) and Uniform Fish (FUF-ELM) for the composition of homogeneous ensembles.

Abstract— **In this paper a new Modified Invasive Weed Optimization is proposed to find a parameters of fuzzy PID controller as a stabilizer in multi-machine power system. Actually, IWO is a bio-inspired numerical algorithm which is inspired from weed colonization and motivated by a common phenomenon in agriculture that is colonization of invasive weeds. Also, finding the parameters of PID controller in power system has direct effect for damping oscillation. Thus, to reduce the design effort and find a better fuzzy system control, the parameters of proposed controller is obtained by MIWO that leads to design controller with simple structure that is easy to implement. The effectiveness of the proposed technique is applied to Single machine connected to Infinite Bus (SMIB) and IEEE 3-9 bus power system. The proposed technique is compared with some intelligent algorithms through ITAE and FD.**

Keywords: MIWO, Multi-machine System, FPID, Oscillation.

I. INTRODUCTION

In the last few decades, considerable attention has been given to the excitation system and its role in improving power system stability. Because of the small effective time constants in the excitation control loop, it was assumed that a large control effort could be expanded through excitation control with a relatively small input of control energy. By the use of a voltage regulator in the excitation control system, the output of the exciter can be adjusted so that the generated voltage and reactive power change in a desired way [1]. In early systems, the voltage regulator was entirely manual. In modern control systems the voltage regulator is an automatic controller that senses the generator output voltage as a feedback signal then adjusts the generator excitation level in the desired direction. This kind of voltage regulator has been known as an Automatic Voltage Regulator (AVR) [2].

The application of a power system stabilizer (PSS) is to generate a supplementary stabilizing signal, which is applied to the excitation control loop of a generating unit, to introduce a positive damping torque. By using the supplementary stabilizing signal, the negative damping effect of the AVR regulation can be cancelled, at the same time, the positive damping effect of the system can also be increased so that the system can operate even beyond the steady-state stability limit [3].

Several techniques have been proposed for tuning of the PSSs in power system [4]. In recent decades intelligent techniques are proposed to tune the PSS parameters. However, these controllers don't have appropriate reaction in different load conditions.

Genetic Algorithm (GA) is one of the powerful optimization techniques which is independent on the complexity of problems and no prior knowledge is available. This technique is applied to tune the PSS parameters [5]. However, GA is very sufficient in finding global or near global optimal solution of the problem, it requires a very long run time that may be several minutes or even several hours depending on the size of the system under study [6].

Recently, Fuzzy based PSS (FPSS) schemes have been proposed [7]. The first application of a traditional Fuzzy Logic Controller (FLC) as a PSS was reported in 1990 [8Hsu, 1990]. The FLC has been applied to a multi-machine power system. The performance of the FLC has been compared with the classic PSS through digital simulation and found to be better [9].

Accordingly, to overcome to the mentioned problems, this paper proposed the new meta-heuristic of MIWO based on fuzzy PID to damp low frequency oscillation in

* Correspanding Author. E-Mail Address: hashayanfar@yahoo.com (H. A. Shayanfar)

multi-machine power system. This method is inspired from weed colonization and motivated by a common phenomenon in agriculture that is colonization of invasive weeds. Weeds have shown very robust and adaptive nature which turns them to undesirable plants in agriculture. Recently, this technique is used in different application domains [10], which demonstrate the advantages of this method to other compared techniques.

This proposed technique is applies on two power system case studies as Single-machine Infinite Bus System (SMIB) and 3 machine 9 bus IEEE standard power system in comparison of GA-PSS [10] and CPSS [11] in first case study and PSOPSS and CPSS [12] in 3-9 bus test system. The mentioned technique is compared in different load condition through some performance indices as Time multiplied Absolute value of the Error (ITAE) and Figure of Demerit (FD). The results of the simulation demonstrate that MIWO-fuzzy controller is robust than other compared techniques.

II. POWER SYSTEM EXPLANATION

The complex nonlinear model related to multi-machine interconnected power system, can be described by a set of differential-algebraic equations by assembling the models for each generator, load, and other devices such as controls in the system, and connecting them appropriately via the network algebraic equations. Fig. 1 shows the main model of power system with location of controller [7].

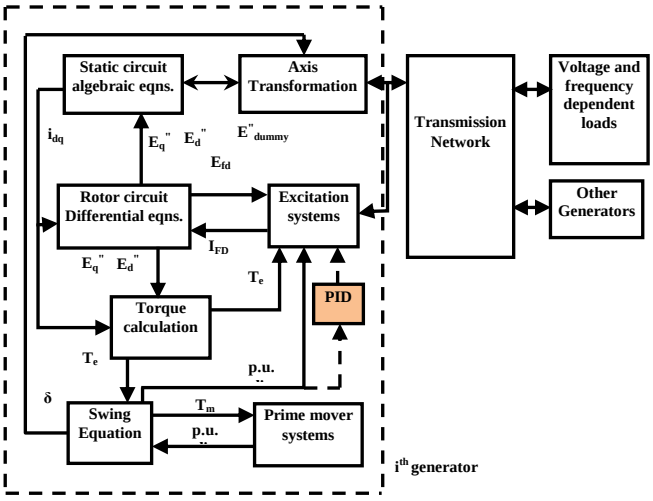

Figure 1. Structure of PSS in power systems

A. Single-machine Infinite Bus System

The Single-machine Infinite Bus system considered for small-signal performance study which is shown in Fig. 2.

The generator is represented by the third-order model comprising of the electromechanical swing equation and the generator internal voltage equation [2]. The swing equations of this system are:

$$\dot{\delta} = \omega_b(\omega - 1) \quad (1)$$

$$\dot{\omega} = \frac{1}{M}(P_m - P_e - D(\omega - 1)) \quad (2)$$

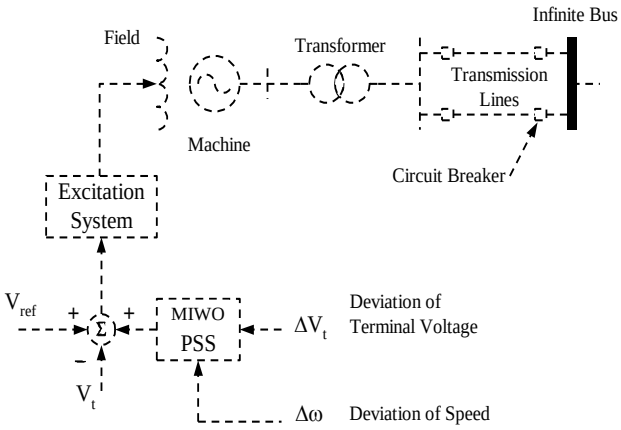

Figure 2. Schematic diagram of single machine infinite bus system

B. 3-9 bus IEEE Power System

The proposed approach is extended to a multi-machine power system as a second case study. The widely used Western Systems Coordinating Council (WSCC) 3-machine, 9-bus system shown in Fig. 3 is considered. The simplified IEEE type-ST1A static excitation system has been considered for all three generators. Also, the proposed controller is connected to all of the generators. The system data are given in [3].

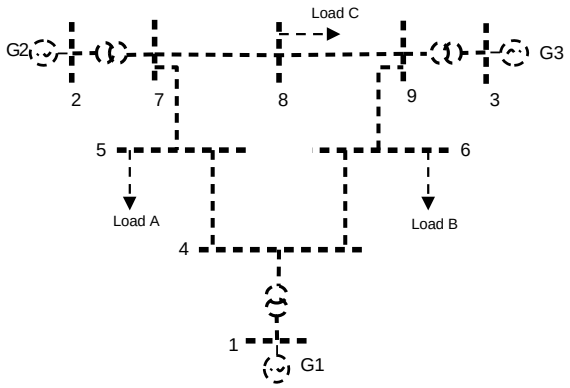

Figure 3. Three-machine nine-bus power system.

C. Design of Fuzzy PID Controller

The classical Proportional-Integral-Derivative (PID) controller and its variants remain the controllers of choice in many industrial applications [7, 9]. PID controller structure remains an engineer's preferred choice because of its structural simplicity, reliability, and the favorable

ratio between performance and cost. Beyond these benefits, it also offers simplified dynamic modeling, lower user-skill requirements, and minimal development effort, which are issues of substantial importance to engineering practice. The performance of the PID controller depends on its setting of parameters.

Basically, all the approaches to fuzzy controller design can be classified as follows:

1. Expert systems approach,
2. Control engineering approach,
3. Intermediate approaches,
4. Combined approaches and synthetic approaches.

In this paper, the gains of the Fuzzy PID controller are tuned on-line in terms of the knowledge based and fuzzy inference, and then, the conventional PID controller generates the control signal. Fig. 4 shows the block diagram of the classical fuzzy type controller to PSS design for each generator [13].

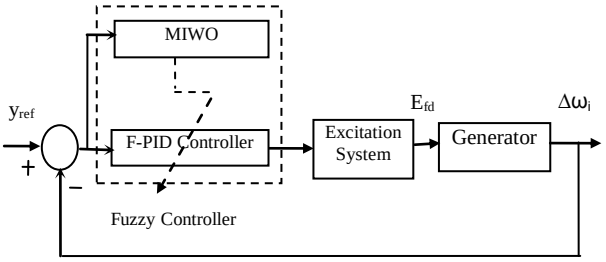

Figure 4. The FPID controller design

In the design of fuzzy logic controller, there are five parts of the fuzzy inference process:

- Fuzzification of the input variables.
- Application of the fuzzy operator (AND or OR) in the anteceden.
- Implication from the antecedent to the consequent.
- Aggregation of the consequents across the rules.
- Defuzzification.

The controller block of fuzzy is formed by fuzzification of ($\Delta\omega_i$), the interface mechanism and defuzzification. Therefore, u_i is a control signal that applies to the excitation system in each generator. By taking $\Delta\omega_i$ as the system output, control vector for the conventional PID controller is given by:

$$u_i = K_{Pi\,i}\Delta\omega_i(t) + K_{Ii}\int_0^t \Delta\omega_i(t)dt + K_{di}\Delta\dot{\omega}_i(t) \quad (3)$$

The parameters, K_{Ii}, K_{di} and K_{pi} are determined by a set of fuzzy rules of the form:

If $\Delta\omega_i$ is A_i and $\Delta(\Delta\omega_i)$ is B_i then, K_{di} is C_i and K_{pi} is D_i and K_{Ii} is E_i, $i=1,2,\cdots,n$.

Where, A_i, B_i, C_i, D_i and E_i are fuzzy sets on the corresponding supporting sets.

For the PSS optimization the ITAE and ***FD*** are considered which are described as:

$$ITAE_i = 100\int_0^{10} t(|\Delta\omega_i|)dt \quad (4)$$

$$FD = (OS\times10^{-4})^2 + (US\times10^{-4})^2 + T_s^{\,2} \quad (5)$$

Where, the constraints of the PID controller parameter bounds are considered as:

$$Minimize\, u \;\; subject\; to:$$

$$K_{Pi}^{\min} \le K_{Pi} \le K_{Pi}^{\max}$$

$$K_{Ii}^{\min} \le K_{Ii} \le K_{Ii}^{\max}$$

$$K_{Di}^{\min} \le K_{Di} \le K_{Di}^{\max}$$

III. MODIFIED INVASIVE WEED OPTIMIZATION

Invasive Weed Optimization (IWO) is inspired from weed colonization and motivated by a common phenomenon in agriculture that is colonization of invasive weeds. Weeds have shown very robust and adaptive nature which turns them to undesirable plants in agriculture. Since its advent IWO has found several successful engineering applications like tuning of Robot Controller [14], Optimal Positioning of Piezoelectric actuators [15], development of recommender system [16], antenna configuration optimization [17], computing Nash equilibria in strategic games [18], DNA computing [19], and etc.

IWO is a meta-heuristic algorithm which mimics the colonizing behavior of weeds. In Invasive Weed Optimization algorithm, the process begins with initializing a population. It means that a population of initial solutions is randomly generated over the problem space. Then members of the population produce seeds depending on their relative fitness in the population. In other words, the number of seeds for each member is beginning with the value of S_{min} for the worst member and increases linearly to S_{max} for the best member [18]. This technique can be summarized as:

A. Initialization

In this step, a finite number of weeds are initialized at the same element position of the conventional array which has a uniform spacing of "$\gamma/2$" between neighboring elements.

B. Reproduction

The individuals, after growing, are allowed to reproduce new seeds linearly depending on their own, the lowest, and the highest fitness of the colony (all of plants). The maximum (S_{max}) and minimum (S_{min}) number of seeds are predefined parameters of the algorithm and adjusted according to structure of problem. The schematic seed production in a colony of weeds is presented in Fig. 2. In this figure, the best fitness function is the lower one [14].

C. Spatial distribution

The generated seeds are being randomly distributed over the d-dimensional search space by normally distributed random numbers with mean equal to zero; but varying variance. This step ensures that the produced seeds will be generated around the parent weed, leading to a local search around each plant. However, the standard deviation (*SD*) of the random function is made to decrease over the iterations, which is defined as:

$$SD_{ITER} = \left(\frac{iter_{\max} - iter}{iter_{\max}}\right)^{pow}(SD_{\max} - SD_{\min}) + SD_{\min}$$

SD_{max} and SD_{min} are the maximum and minimum standard deviation, respectively. And *pow* is the real no. This step ensures that the probability of dropping a seed in a distant area decreases nonlinearly with iterations, which result in grouping fitter plants and elimination of inappropriate plants.

D. Competitive Exclusion

When the maximum number of population in a colony is reached (P_{max}), each weed can to produce seeds and spread them according to the mechanism mentioned in step 3.2 and step 3.3, respectively. Then, new seeds with their parents are ranked together with respect to their fitness. This method is known as competitive exclusion and is also a selection procedure of IWO. Next, weeds with lower fitness are eliminated to reach the maximum allowable population size in a colony. This mechanism by using the "survival of the fittest" idea [14] gives a chance to plants with lower fitness to reproduce, and if their offspring have good fitness, they can survive in their offspring's existence.

E. Termination Condition

The whole process continues until the maximum number of iterations has been reached, and we hope that the plant with the best fitness is the closest one to the optimal solution.

F. Modifications

For modified IWD, if we add the $|cos(iter)|$ which is a variation in *SD*, it can helps in exploring the better solutions quickly and prevents the new solutions to be spread out of the search space when the SD is relatively large which is described as:

$$SD_{ITER} = \left(\frac{iter_{\max} - iter}{iter_{\max}}\right)^{pow}|\cos(iter)|(SD_{\max} - SD_{\min}) + SD_{\min}$$

In classical IWO, the seeds are generated from a plant with a certain standard deviation, which is decreased as number of iteration increases. Thus, the plants slowly undergo a behavioral transformation from an explorative nature to an exploitative one.

Actually the routine of decreasing SD is modified, such that if the weeds are near a suspected optimal solution then it can exploit it quickly rather than wait for the standard deviation to decrease to a reasonable value, which might occur near the end of the run. In this strategy the SD varies within an envelope, so lesser values of SD are obtained much before the end of the run.

IV. Simulation Results

A. SMIB

For this case study the fitness function trend of proposed technique is presented in Fig. 5. This case is compared with GAPSS [10] and Classic PSS (CPSS) [11]. Accordingly, Fig. 6-7, shows the response of system against 6-cycle three-phase fault in different load condition. Also, the optimized parameters of the PID are presented in Table. 1.

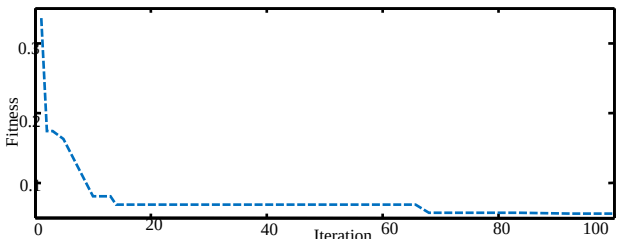

Figure 5. Optimal trend of fitness function evaluation

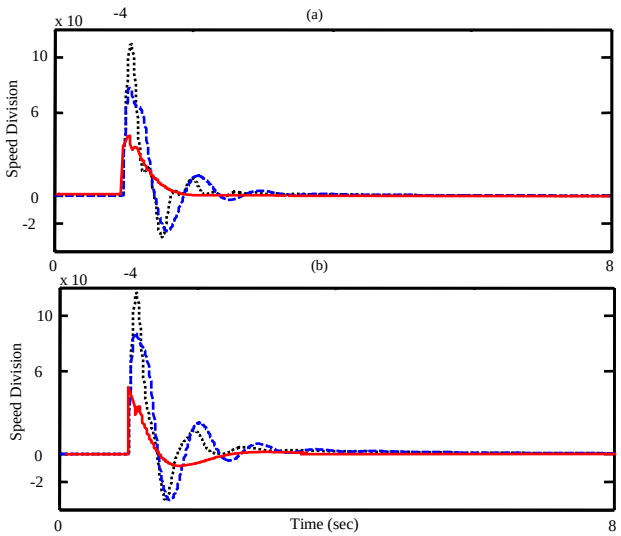

Figure 6. Fig.6: System response by applying a 6-cycle three-phase fault at t=1: Solid (MIWO-F), Dashed (GA-PSS) Doted (CPSS). a :P=0.8,Q=0.4,Xe=0.3 b: P=0.5,Q=0.1,Xe=0.3

TABLE I. OPTIMUM PID CONTROLLER PARAMETERS BY MIWO

Gain \ Gen.		G_1	G_2	G_3
Case One	K_{p1}	11.34	-	-
	K_{i1}	2.24	-	-
	K_{d1}	2.13	-	-
Case Two	K_{p1}	1.452	1.946	2.465
	K_{i1}	1.647	2.056	2.134
	K_{d1}	1.684	2.135	2.254

B. 3-9 bus IEEE Power System

The convergence of the proposed technique over second case study is shown in Fig. 7. Actually, the performance of the proposed controller under transient conditions is verified by applying a 6-cycle three-phase fault at t=1 sec, on bus 7 at the end of the line 5-7. The fault is cleared by permanent tripping the faulted line. The speed deviation of machines under the nominal loading conditions is shown in Fig. 8.

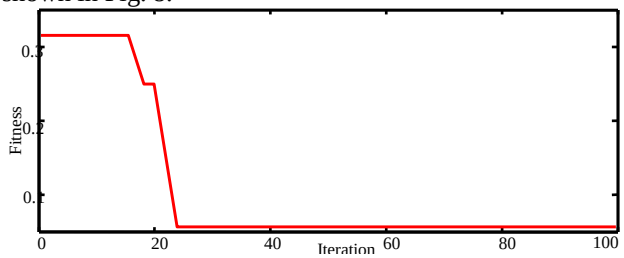

Figure 7. Optimal trend of fitness function evaluation

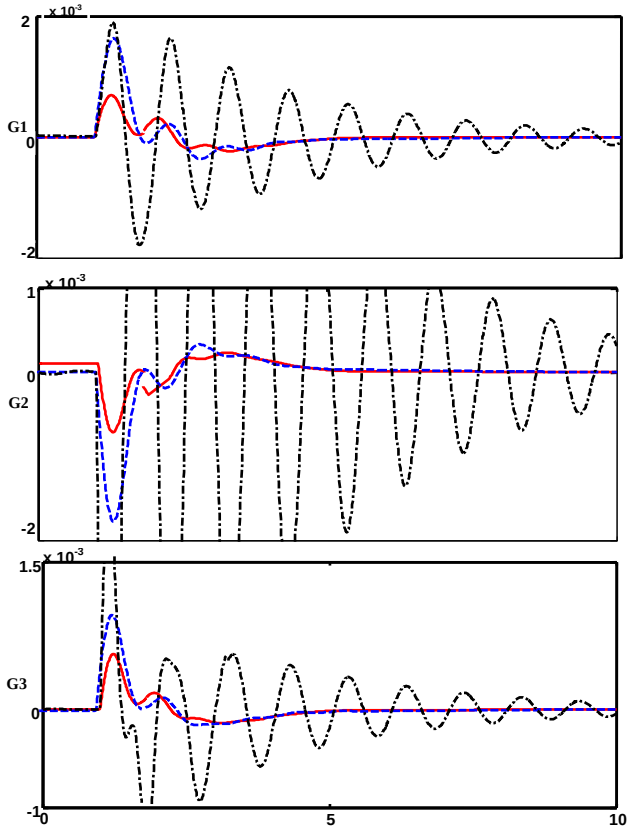

Figure 8. System response under scenario 1 with heavy loading condition: Solid (MIWOFPSS) Dashed (PSOPSS) Doted (CPSS).

For more testing, a 0.2 p.u. step increase in mechanical torque was applied at t=1.0. The results of system response are presented in Fig. 9.

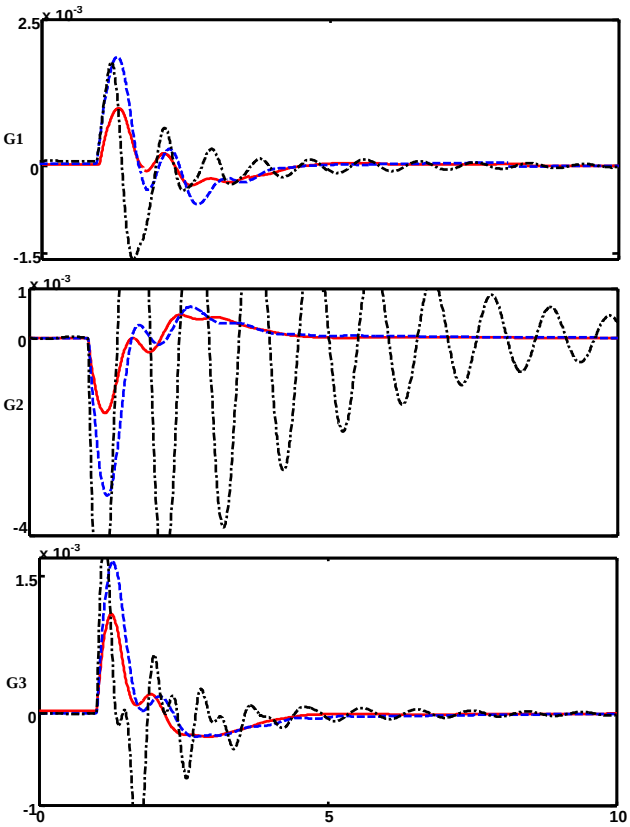

Figure 9. System response under scenario 2 with nominal loading condition: Solid (MIWOFPSS) Dashed (PSOPSS) Doted (CPSS).

According to the numerical results, it can be seen that the values of these system performance characteristics with the proposed controller are much smaller to other compared techniques. This demonstrates that the overshoot, undershoot settling time and speed deviations of all machines are greatly reduced by applying the proposed algorithm based fuzzy PSSs. The numerical results of ITAE and FD are listed in Table 2-3.

TABLE II. VALUE OF ITAE IN DIFFERENT TECHNIQUES

Method	Scenario 1			Scenario 2		
	Nominal	Light	Heavy	Nominal	Light	Heavy
MIWOFPSS	0.60	0.64	0.65	0.62	0.64	0.68
GA-FPSS	0.76	0.73	0.84	0.73	0.70	0.79
GAPSS	37.1	36.7	38.5	36.03	36	37.4

TABLE III. VALUE OF FD IN DIFFERENT TECHNIQUES

Method	Scenario 1			Scenario 2		
	Nominal	Light	Heavy	Nominal	Light	Heavy
MIWOFPSS	2.06	2.46	2.67	2.12	2.44	2.58
GA-FPSS	2.45	2.86	3.04	2.36	2.64	2.71
GAPSS	55.4	58.6	60.4	54.1	55.4	57.7

V. CONCLUSIONS

In this paper a new MIWO based fuzzy controller is proposed to provide the stability of the power system in low frequency oscillation problem in multi machine. IWO is a bio-inspired numerical algorithm which is used herein as the optimization method of players to solve optimization and control problems. This method is inspired from weed colonization and motivated by a common phenomenon in agriculture that is colonization of invasive weeds. Weeds have shown very robust and adaptive nature which turns them to undesirable plants in agriculture. The proposed technique convergence rate is really less than in comparison other methods in solving complex mathematical problems. The effectiveness of the proposed technique is tested over two case studies as SMIB and 3-9 bus IEEE power systems. The results are compared with other intelligent algorithms through ITAE and FD. Simulation results show the effectiveness of the proposed MIWO fuzzy controller which can work effectively over a wide range of the loading conditions and is superior to other compared methods.

BIOGRAPHIES

Oveis Abedinia received the B.S. and M.Sc. degrees in Electrical Engineering from Azad University, Ardabil and Science and Technology Research Branch, Tehran, Iran in 2005 and 2009, respectively. Currently, he is PhD student in Semnan University. His areas of interest in research are Application of Artificial Intelligence to Power System and Control Design, Load and Price Forecasting, Distribution Generation, Restructuring in Power Systems, Congestion Management, Optimization.

Asghar Akbari Foroud was born in Hamadan, Iran, in 1971. He received B.Sc. degree from Tehran University and M.Sc. and PhD degrees from Tarbiat-modares University, Tehran, Iran. He is now with Semnan University. His research interests include power system dynamics & operation and restructuring.

Nima Amjady (SM'10) was born in Tehran, Iran, on February 24, 1971. He received the B.Sc., M.Sc., and Ph.D. degrees in electrical engineering from Sharif University of Technology, Tehran, Iran, in 1992, 1994, and 1997, respectively. At present, he is a Professor with the Electrical Engineering Department, Semnan University, Semnan, Iran. He is also a Consultant with the National Dispatching Department of Iran. His research interests include security assessment of power systems, reliability of power networks, load and price forecasting, and artificial intelligence and its applications to the problems of power systems.

Heidarali Shayanfar received the B.S. and M.S.E. degrees in Electrical Engineering in 1973 and 1979, respectively. He received his Ph. D. degree in Electrical Engineering from Michigan State University, U.S.A., in 1981. Currently, he is a Full Professor in Electrical Engineering Department of Iran University of Science and Technology, Tehran, Iran. His research interests are in the Application of Artificial Intelligence to Power System Control Design, Dynamic Load Modeling, Power System Observability Studies, Voltage Collapse, Congestion Management in a Restructured Power System, Reliability Improvement in Distribution Systems and Reactive Pricing in Deregulated Power Systems. He has published more than 405 technical papers in the International Journals and Conferences proceedings. He is a member of Iranian Association of Electrical and Electronic Engineers and IEEE.

APPLICATION OF TRAPEZOIDAL FUZZIFICATION APPROACH (TFA) AND PARTICLE SWARM OPTIMIZATION (PSO) IN FUZZY TIME SERIES (FTS) FORECASTING

by

Abstract

The trapezoidal fuzzification approach (TFA) model implemented in this paper utilizes aggregation and particle swarm optimization (PSO) to reduce the mismatch between the forecasted data and the actual data using maximum temperature data of Zaria for the period 1990-2003, obtained from Nigerian Meteorological Agency (NIMET) Zaria. The defuzzification module (including the developed PSO algorithm using C-#) of this model is then implemented on the hitherto fuzzified maximum temperature data so as to obtain forecasts. Statistical measures of MSE and MAPE are used to test the reliability of the model.

Keywords: TFA, PSO, Fuzzy Time Series, Forecasting, Temperature

1. INTRODUCTION

Cheng et al [1] introduced an approach where the crisp intervals, generally defined by the user at the initial step of FTS, are replaced with trapezoid fuzzy sets with overlapping boundaries. This overlap implies that a value may belong to more than one set. If a value belongs to more than one set, it is associated to the set where its degree of membership is highest. Poulsen's [2] approach, however, differed from this approach by performing automatically the calculations of the fuzzy intervals. Another area of difference is the notion of non-static universe of discourse. Whenever values are encountered which fall outside the boundaries of the current universe of discourse, it has to augment accordingly. The basic idea here is to repeat the fuzzification procedure when the dataset is updated.

The TFA technique is divided into two main components, fuzzification and defuzzification. These components are decoupled which implies that they can be integrated independently with other alternatives [1][2][3][4]. This will be applied to the monthly maximum temperature data to demonstrate the role of the TFA as an optimization technique to aid the fuzzy time series (FTS) forecasting. Actual maximum temperature data of Zaria for the period 1990-2003, as obtained from Nigerian Meteorological Agency (NIMET), Zaria are as shown in Table 1.

Table 1: Maximum Monthly Temperatures of Zaria

	1990	1991	1992	1993	1994	1995	1996	1997	1998	1999	2000	2001	2002	2003

1.1 METHODOLOGY

The TFA-based FTS technique has two main components: fuzzification and defuzzification. The fuzzification module can be decomposed into a six-step process [2][3][4]:

i) Sorting of the values in the current dataset in ascending order.
ii) Computation of the average distance between any two consecutive values in the sorted dataset and the corresponding standard deviation.
iii) Elimination of outliers from the sorted dataset.
iv) Computation of the revised average distance between any two remaining consecutive values in the sorted dataset.

v) Definition of the universe of discourse.
vi) Fuzzification of the dataset using the trapezoid fuzzification approach.

The defuzzification module can be decomposed into a four-step process [2][3][4]:
i) Establishment of the fuzzy set groups (FSGs).
ii) Conversion of the FSGs into corresponding If-Then statements.
iii) Training of the If-Then rules.
iv) Derivation of the forecasts

The process will be concluded with the statistical and qualitative evaluation of the forecasts.

FUZZIFICATION MODULE

The forecasting process will be carried out on the data of Table 1 on a monthly basis. The data of January (1990 – 2003) will be used for demonstration. The data is sorted in ascending order as in Table 2:

Table 2: Temperature Data Sorted in Ascending Order (January 1990-2003).

Year	Temperature (^{0}C)
2002	26.8
1992	27.1
1993	27.4
1995	28.3
1991	29.5
1998	29.5
2001	29.9
1994	30.1
1999	30.9
1990	31.3
2000	31.3
1997	31.4
2003	31.4
1996	32.2

The next step is computing the average distance (AD) between any two consecutive values in the sorted dataset and the corresponding standard deviation (σ_{AD}) using equations (1) and (2) respectively.

$$AD\ (x_i \ldots x_n) = \frac{1}{n-1}\sum_{i=1}^{n-1} \left| x_{p(i)} - x_{p(i+1)} \right| \quad (1)$$

$$AD \approx 0.415$$

$$\sigma_{AD} = \sqrt{\frac{1}{n}\sum_{i=1}^{n} (x_i - AD)^2} \quad (2)$$

$$\sigma_{AD} \approx 0.376$$

The next step is eliminating outliers from the sorted dataset. Outliers are values which are either abnormally high or abnormally low and are eliminated from the sorted dataset, because the intention here is to obtain an average distance value free of distortions. It is obtained as a value less than or larger than one standard deviation from average [2][3][4]

$$0.415 - 0.376 \le x \le 0.415 + 0.376$$

$$0.039 \le x \le 0.791$$

After the elimination process is completed, a revised average distance value is computed for the remaining values in the sorted dataset,

$$AD_R = \frac{0.3 + 0.3 + 0.4 + 0.2 + 0.4 + 0.1}{6}$$

$$AD_R \approx 0.283$$

The value of AD_R is now taken as the segment length, S which is used in the next two steps to partition the universe of discourse into a series of trapezoidal fuzzy sets. This is to create a series of trapezoidal approximations which capture the generic nature of data as closely as possible, in the sense that the spread of individual functions will neither be too narrow or too wide.

The lower and upper bound of the universe of discourse is determined by locating the largest and lowest values in the dataset and augment these by:
i) subtracting the revised average distance from the lowest value and
ii) adding the revised average distance to the highest value.

If D_{max} and D_{min} are the highest and lowest values in the dataset, respectively, and AD_R is the revised average distance, then the universe of discourse, U can be defined as:

$$U = [D_{min} - AD_R,\ D_{max} + AD_R] \quad (3)$$

$$U = [26.517, 32.483]$$

When U has been determined, fuzzy subsets can be defined on U. Since the subsets are represented by trapezoidal functions, the membership degree, for a given function, μ_A and a given value, x is obtained by:

$$\mu_A = \begin{cases} \dfrac{x - a_1}{a_2 - a_1}, a_1 \le x \le a_2 \\ 1, a_2 \le x \le a_3 \\ \dfrac{a_4 - x}{a_4 - a_3}, a_3 \le x \le a_4 \\ 0, otherwise \end{cases} \quad (4)$$

Prior to the fuzzification of data, the number of subsets to be defined on U needs to be known. The number of subsets, n is determined by:

$$n = \frac{R - S}{2S} \quad (5)$$

R denotes the range of the universe of discourse and S denotes the segment length.

$$R = UB - LB \quad (6)$$

$$R = 5.966$$

$$n = \frac{5.966 - 0.283}{2 * 0.283}$$

$$n \approx 10$$

As can be seen in Table 3, the segment length is selected, such that the lowest value in the dataset always appears as the left bound in the first crisp interval, and the highest value in the dataset always appears as the right bound in the last crisp interval. It can also be seen that the lowest of the values (26.80), appears as the lower bound of the first crisp interval, A_1, and the highest value (32.20), appears as the upper bound in the last crisp interval, A_{10}. The average temperatures are then fuzzified according to membership functions A_1 to A_{10} as in Table 3.

Table 3: Generated Fuzzy Sets (January 1990 – 2003)

Fuzzy set	Fuzzy number
A_1	(26.52, 26.80, 27.08, 27.37)
A_2	(27.08, 27.37, 27.65, 27.94)
A_3	(27.65, 27.94, 28.22, 28.50)
A_4	(28.22, 28.50, 28.79, 29.07)
A_5	(28.79, 29.07, 29.36, 29.64)
A_6	(29.36, 29.64, 29.92, 30.21)
A_7	(29.92, 30.21, 30.49, 30.78)
A_8	(30.49, 30.78, 31.06, 31.34)
A_9	(31.06, 31.34, 31.63, 31.91)
A_{10}	(31.63, 31.91, 32.20, 32.48)

In situations where intervals overlap, the value is assigned to the interval with the higher membership degree. A special case occurs when the membership degree is 0.5, as this implies that a value has the same membership status in two different sets. In such cases, the respective value is associated to both sets, as in the case of 1991 and 1998 in Table 4.

Generally it is assumed that the fuzzy sets, A_1, A_2, ... , A_n, individually represent some linguistic value. Adopting the same procedure used for generating the fuzzy sets and fuzzified average temperatures for January 1990-2003, the values of average distance (AD), standard deviation (σ_{AD}), revised average distance (AD_R), universe of discourse (U) and number of sets (n) are shown in Table 5 for January (1990-2003) to December (1990-2003).

Table 4: Fuzzified Maximum Temperatures (January 1990-2003).

Year	Temperature (^{0}C)	Fuzzy set
1990	31.3	A_9
1991	29.5	A_5, A_6
1992	27.1	A_1
1993	27.4	A_2
1994	30.1	A_7
1995	28.3	A_3
1996	32.2	A_{10}
1997	31.4	A_9
1998	29.5	A_5, A_6
1999	30.9	A_8
2000	31.3	A_9
2001	29.9	A_6
2002	26.8	A_1
2003	31.4	A_9

Table 5: AD, σ_{AD}, AD_R, U and n for the entire Maximum Temperatures

	Average distance (AD)	Standard deviation (σ_{AD})	Revised average distance (AD_R)	Universe of discourse (U)	Number of sets (n)
JAN	0.415	0.376	0.283	[26.517, 32.483]	10
FEB	0.562	0.438	0.533	[28.167, 36.533]	7
MAR	0.462	0.465	0.342	[33.258, 39.942]	9

3 DEFUZZIFICATION

3.1 PARTICLE SWARM OPTIMIZATION

Particle Swarm Optimization (PSO), first introduced by Kennedy and Eberhart, is an algorithm that simulates the social behaviours shown by various kinds of organisms such as bird flocking or fish schooling. PSO is initiated with a set of randomly generated particles which in fact are candidate solutions [5].

A set of n particles is created, where n is chosen as 5 in this case. The randomly generated velocities are all initialized to v1 and v2. The positions w1 and w2 (depending on R) are then assigned to all the particles. Each particle's local best value is then initialized to the set w1 and w2, as well the global best value. The initial randomly generated velocities are stored in an array A4, designated in the program as the array *initialVelocities*. The squared errors are then calculated for the initial values specified, and stored in another array designated as A1, represented in the program as the array *oldSquaredErrors*.

An iteration loop is instantiated, whose limit is the maximum number of iterations specified. Per iteration, each particle's velocity is calculated and normalized if necessary, and then the position is then updated based on the new velocity. The squared errors after the first iteration are then stored in an array designated as A2, which is represented in the program as the array *intermediateSE*.

Per iteration, the squared errors per particle are calculated and stored in an array designated as A3, represented in the program as the array *currentSquaredErrors*. A3 is then compared with the existing values in the array A1. If the squared error for any given particle (in A3) is less than the corresponding value in the array A1, then the value in A1 is updated with this new value from A3. At the same time, if the given particle's squared error in this current iteration is better than the current local best value, then the particle's local best value is updated accordingly. If previously, any of the local best values was updated, then the global best value is then reassigned to be the smallest value in the array A3. The index of the particle whose squared error is the least in A3 is then taken. Each particle updates its velocity and position with the equations (6) and (7) [2][3][4]:

$$v_i = wv_i + c_1 r_1(\hat{x}_i - x_j) + c_2 r_2(\hat{g} - x_j) \quad (9)$$

$$x_j = x_j + v_i \quad (10)$$

where, v_i is the velocity of particle p_i and is limited to $[-V_{max}, V_{max}]$ where V_{max} is user-defined constant, w is an inertial weight coefficient, $\hat{x}_i$ is the current personal best position, x_j is the present position, $\hat{g}$ is the global best position, c_1 and c_2 are user defined constants that say how much the particle is directed towards good positions. They affect how much the particle's local best and global best influence its movement. Generally c_1 and c_2 are set to 2 and r_1 and r_2 are randomly generated numbers between 0 and 1.

At this point, if the minimum squared error obtained in this iteration is less than or equal to the user-specified target squared error value, then all further iterations are terminated, and the result object shows that the criterion was reached. All squared error values, all particle indices, initial velocities (in array A4), the best particle index and the number of iterations are all stored in the result object. However, if the iteration loop reaches the specified maximum number of iterations which the user specified, then the result object shows that the criterion was not reached. All the other values (initial velocities, etc) are all stored in the result object. The Squared Error (SE), defined by:

$$SE = (forecast_t - actual_t)^2 \quad (11)$$

3.2 AGGREGATION

This process is meant to aggregate pieces of data in a desirable way in order to reach final decision. Typically this data is represented by numerical values which make some kind of sense with regards to the application. Hence the aggregation problem is generally regarded as the problem of reducing a series of numerical values into a single representative value. Formally an aggregation operator can be defined as function h which assigns a real number y to any n-tuple $(x_1, x_2, \ldots\ldots, x_n)$ of real numbers [6]

$$y = h(x_1, x_2, \ldots\ldots, x_n)$$

Basically the idea is to evaluate the aggregated result, Y(t), against the actual outcome at time t, and adjust the weights in the defuzzification operator such that the squared error is minimized. By minimizing *SE* for t, *MSE* is minimized as well.

3.3 DEFUZZIFICATION MODULE

The data of February 1990 to 2003 (Table 6) is used to demonstrate the module

Table 6: Fuzzified maximum temperatures (February 1990-2003)

Year	Temperature (^{0}C)	Fuzzy set
1990	30.4	A_2
1991	36.0	A_7
1992	30.3	A_2
1993	33.0	A_5
1994	32.3	A_4
1995	31.1	A_3
1996	34.8	A_6
1997	28.8	A_1
1998	33.7	A_5
1999	34.4	A_6
2000	28.7	A_1
2001	30.7	A_3
2002	32.2	A_4
2003	34.9	A_6

Fuzzy Set Groups (FSGs) are established (as against the conventional Fuzzy Logic Relationship Groups (FLRG) in order to partition the historical data into unique sets of sub-patterns which subsequently are converted into corresponding If-statements. During the first pass of the algorithm, consecutive sets are grouped pair-wise. Table 7 shows the fuzzified data of Table 6 grouped in this manner. Every FSG appears in chronological order.

Table 7: Establishment of Fuzzy Set Groups (February 1990-2003)

Label	FSG
1	$\{A_2, A_7\}$
2	$\{A_7, A_2\}$
3	$\{A_2, A_5\}$
4	$\{A_5, A_4\}$
5	$\{A_4, A_3\}$
6	$\{A_3, A_6\}$
7	$\{A_6, A_1\}$
8	$\{A_1, A_5\}$
9	$\{A_5, A_6\}$
10	$\{A_6, A_1\}$
11	$\{A_1, A_3\}$
12	$\{A_3, A_4\}$
13	$\{A_4, A_6\}$

The essence of grouping sets in this manner is to obtain a series of FSGs free of ambiguities. An ambiguity occurs, if two or more FSGs contain the same combination of elements. It can be seen from Table 7 that FSGs labelled as 7 and 10 are identical. In order to obtain a series of disambiguated Fuzzy Set Groups (Table 8), the ambiguous FSGs are extended to third order FSGs, by including the previous set in the corresponding time series. The extension process is continued until a unique combination of elements is obtained for each FSG.

Table 8: Disambiguated Fuzzy Set Groups (February 1990-2003)

Label	FSG
1	$\{A_2, A_7\}$
2	$\{A_7, A_2\}$
3	$\{A_2, A_5\}$
4	$\{A_5, A_4\}$
5	$\{A_4, A_3\}$
6	$\{A_3, A_6\}$
7	$\{A_3, A_6, A_1\}$
8	$\{A_1, A_5\}$
9	$\{A_5, A_6\}$
10	$\{A_5, A_6, A_1\}$
11	$\{A_1, A_3\}$
12	$\{A_3, A_4\}$
13	$\{A_4, A_6\}$

The If-statements are generated on the basis of the content of the FSGs. This task is fairly simple as the sequence of elements of each FSGs is the same as they appear in time. Each FSG can therefore easily be transformed into If-Then rules of the form:

$$\begin{aligned} &\textit{if } (F(t-1) = A_{i,t-1} \wedge F(t-2) \\ &= A_{i,t-2} \wedge \ldots \wedge F(t-n+1) \\ &= A_{i,t-n+1} \wedge F(t-n) = A_{i,t-n}); \qquad (12) \\ &\textit{then } w_{1,t-1} = ? \wedge w_{2,t-2} \\ &= ? \wedge \ldots \wedge w_{n-1,t-n+1} \\ &= ? \wedge w_{n,t-n} = ? \end{aligned}$$

For practical reasons, the sequence of conditions in the If-statement appears in the reverse order compared to their equivalent FSGs. When a rule is matched, the resultant weights are returned and the forecasted value, Y(t), is computed according to:

$$Y(t) = \sum_{i=1}^{n} a_{t-i}.w \qquad (13)$$

$$\textit{where} \quad w_i \in [0,1]$$

By processing all the data in Table 8, a series of incomplete If-statements are generated as shown in Table 9. In order to determine the weights, PSO is utilized to train the rules individually to match the data they represent.

Table 9: Generated If-rules in Chronological Order (February 1990-2003)

Rule	Matching part
1	$if\,(F(t-1)=A_7 \wedge F(t-2)=A_2)$
2	$if\,(F(t-1)=A_2 \wedge F(t-2)=A_7)$
3	$if\,(F(t-1)=A_5 \wedge F(t-2)=A_2)$
4	$if\,(F(t-1)=A_4 \wedge F(t-2)=A_5)$
5	$if\,(F(t-1)=A_3 \wedge F(t-2)=A_4)$
6	$if\,(F(t-1)=A_6 \wedge F(t-2)=A_3)$
7	$if\,(F(t-1)=A_1 \wedge F(t-2)=A_6 \wedge F(t-3)=A_3)$
8	$if\,(F(t-1)=A_5 \wedge F(t-2)=A_1)$
9	$if\,(F(t-1)=A_6 \wedge F(t-2)=A_5)$
10	$if\,(F(t-1)=A_1 \wedge F(t-2)=A_6 \wedge F(t-3)=A_5)$
11	$if\,(F(t-1)=A_3 \wedge F(t-2)=A_1)$
12	$if\,(F(t-1)=A_4 \wedge F(t-2)=A_3)$
13	$if\,(F(t-1)=A_6 \wedge F(t-2)=A_4)$

PSO is then utilized to tune the weights in the defuzzification operator in equation (6). The following parameters are user defined:

- The inertial coefficient, w, equals 1.4.
- The self confidence and social confidence coefficients, c_1 and c_2, respectively, both equals 2.
- The minimum and maximum velocity is limited to [-0.01, 0.01].
- The minimum and maximum position is limited to [0, 1].
- The number of particles equals five.
- The stopping criteria are defined by setting the minimum *SE* to 1 and the maximum number of iterations to 500.

The PSO algorithm is coded using C-#.

Table 10: Initial Positions of all Particles

Particle	**Position 1 (w_1)**	**Position 2 (w_2)**	**SE**
1	0.75	0.5	141.61
2	0.75	0.5	141.61
3	0.75	0.5	141.61
4	0.75	0.5	141.61
5	0.75	0.5	141.61

To demonstrate the algorithm, rule 1 in Table 9 is trained. As can be seen from Table 10, the personal best positions are the same for all particles during initialization. Hence the personal best positions equal the global best position for all particles.

Table 11: Randomized Initial Velocities of all Particles

Particle	v_1	v_2
1	0.0026	0.0012
2	0.0036	0.0017
3	0.0038	0.0022
4	0.0098	0.0047
5	0.0025	0.0071

When all particles and velocities have been initialized (Table 11), the velocities are updated before positions are incremented. Velocities are updated according to equation (9). The computation yields:

$$v_{1,1} = (1.4 * 0.0026) + 2 * r_1(0.75 - 0.75) + 2 * r_2(0.75 - 0.75) = 0.0036$$
$$v_{1,2} = (1.4 * 0.0012) + 2 * r_1(0.5 - 0.5) + 2 * r_2(0.5 - 0.5) = 0.0017$$
$$v_{2,1} = (1.4 * 0.0036) + 2 * r_1(0.75 - 0.75) + 2 * r_2(0.75 - 0.75) = 0.0050$$
$$v_{2,2} = (1.4 * 0.0017) + 2 * r_1(0.5 - 0.5) + 2 * r_2(0.5 - 0.5) = 0.0024$$
$$v_{3,1} = (1.4 * 0.0038) + 2 * r_1(0.75 - 0.75) + 2 * r_2(0.75 - 0.75) = 0.0053$$
$$v_{3,2} = (1.4 * 0.0022) + 2 * r_1(0.5 - 0.5) + 2 * r_2(0.5 - 0.5) = 0.0031$$
$$v_{4,1} = (1.4 * 0.0098) + 2 * r_1(0.75 - 0.75) + 2 * r_2(0.75 - 0.75) = 0.0137$$
$$v_{4,2} = (1.4 * 0.0047) + 2 * r_1(0.5 - 0.5) + 2 * r_2(0.5 - 0.5) = 0.0066$$
$$v_{5,1} = (1.4 * 0.0025) + 2 * r_1(0.75 - 0.75) + 2 * r_2(0.75 - 0.75) = 0.0035$$
$$v_{5,2} = (1.4 * 0.0071) + 2 * r_1(0.5 - 0.5) + 2 * r_2(0.5 - 0.5) = 0.0099$$

Positions are incremented according to equation (2). Incremented positions after the first iteration are shown in Table 12.

Table 12: The Positions of all Particles after the First Iteration

Particle	w_1	w_2	SE
1	0.7526	0.5012	145
2	0.7536	0.5017	147
3	0.7538	0.5022	148
4	0.7598	0.5047	155
5	0.7525	0.5071	151

After the first iteration, none of the computed *SE* values in Table 12 is less than 141.61. Thus no personal best positions or global best positions are reached at this point. The iteration continues until either or both of the stopping criteria are met. The personal best positions of all particles after termination are listed in Table 13.

Table 13: The Personal Best Positions of all Particles after Termination

Particle	w_1	w_2	SE
1	0.5963	0.3531	3
2	0.5932	0.3502	2
3	0.5928	0.3482	2
4	0.5921	0.3414	1
5	0.5971	0.3421	2

According to Table 13, particle 4 has the global best position. Hence the weights associated to rule 1 equals 0.5921 and 0.3414.

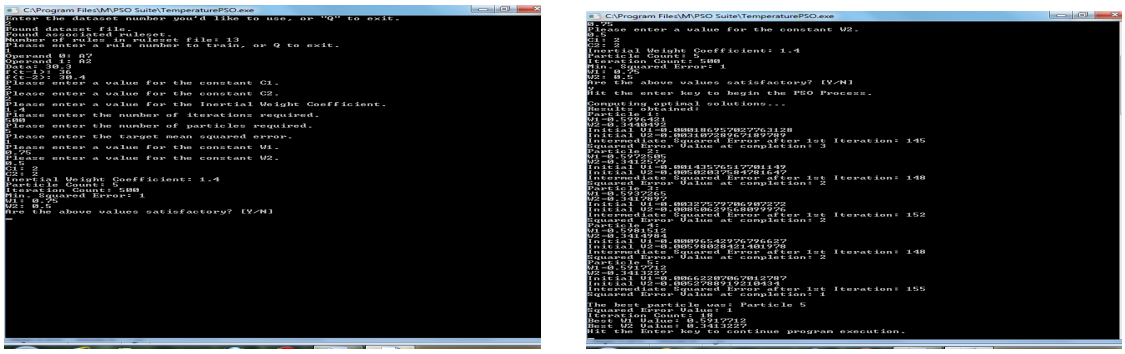

Figure 2: Screenshot Showing Inputted Parameters and Results

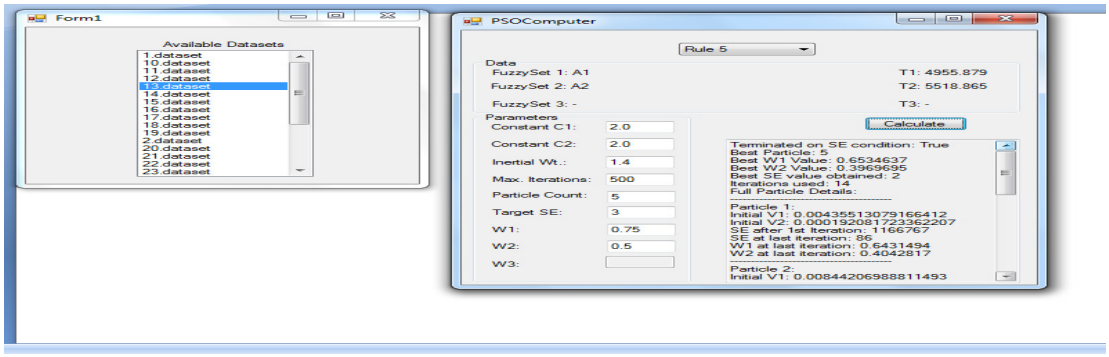

Figure 3: Graphical User Interface Showing Results

After the weights have been optimized via PSO (as shown in Figures 2 and 3), the 'blanks' in the 'Then' part can be filled. The partially completed If-rules from Table 9 are shown in fully completed form in Table 14.

Table 14: Generated if-then Rules in Chronological Order (February 1990-2003)

Rule	Matching Part	Weights
1	$if\ (F(t-1)=A_7 \wedge F(t-2)=A_2)$	$then\ w_1=0.5900\ and\ w_2=0.3400$
2	$if\ (F(t-1)=A_2 \wedge F(t-2)=A_7)$	$then\ w_1=0.6497\ and\ w_2=0.4037$
3	$if\ (F(t-1)=A_5 \wedge F(t-2)=A_2)$	$then\ w_1=0.6500\ and\ w_2=0.4000$
4	$if\ (F(t-1)=A_4 \wedge F(t-2)=A_5)$	$then\ w_1=0.6247\ and\ w_2=0.3700$
5	$if\ (F(t-1)=A_3 \wedge F(t-2)=A_4)$	$then\ w_1=0.6915\ and\ w_2=0.4480$
6	$if\ (F(t-1)=A_6 \wedge F(t-2)=A_3)$	$then\ w_1=0.5687\ and\ w_2=0.3200$
7	$if\ (F(t-1)=A_1 \wedge F(t-2)=A_6 \wedge F(t-3)=A_3)$	$then\ w_1=0.4466, w_2=0.3500\ \&\ w_3=0.2500$
8	$if\ (F(t-1)=A_5 \wedge F(t-2)=A_1)$	$then\ w_1=0.6797\ and\ w_2=0.4334$
9	$if\ (F(t-1)=A_6 \wedge F(t-2)=A_5)$	$then\ w_1=0.5584\ and\ w_2=0.3100$
10	$if\ (F(t-1)=A_1 \wedge F(t-2)=A_6 \wedge F(t-3)=A_5)$	$then\ w_1=0.4100, w_2=0.3100\ \&\ w_3=0.2066$
11	$if\ (F(t-1)=A_3 \wedge F(t-2)=A_1)$	$then\ w_1=0.6899\ and\ w_2=0.4325$
12	$if\ (F(t-1)=A_4 \wedge F(t-2)=A_3)$	$then\ w_1=0.6907\ and\ w_2=0.4400$
13	$if\ (F(t-1)=A_6 \wedge F(t-2)=A_4)$	$then\ w_1=?\ and\ w_2=?$

4: DERIVATION OF FORECASTS

Adopting the same procedure, the If-Then rules are generated for the months of January to December (1990 – 2003). Based on the rules of Table 14, the forecast for February (1990-2003) is obtained as in Table 15. Using similar tables for all the months, forecast values for January to December 2004 are

obtained as in Table 16. Adopting the same procedure, the If-Then rules are generated for the months of January to December (1990 – 2003). Based on the rules of Table 14, the forecast for February (1990-2003) is obtained as in Table 15. Using similar tables for all the months, forecast values for January to December 2004 are obtained as in Table 16. The performance of the developed model is evaluated by the Mean square Error (MSE) and the Mean Average Percentage Error (MAPE). The plot of the actual and forecasted temperatures is as shown in Figure 5

The Mean Squared Error (MSE) and Mean Absolute Percentage Error (MAPE) are defined thus:

$$MAPE = \frac{1}{n}\sum_{t=1}^{n}\frac{|forecast_t - actual_t|}{actual_t} \times 100 \quad (14)$$

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(forecast_i - actual_i)^2 \quad (15)$$

Table 15: Forecast Results (February 1990-2003)

5. CONCLUSION

The Fuzzy Time Series (FTS) model employed in this work uses a fuzzification algorithm, based on the trapezoid fuzzification approach (TFA), which objectively partitions the universe of discourse into intervals without requiring any user defined parameters. PSO and aggregation are utilized to reduce the mismatch between the forecasted and actual data, to individually tune forecast rules and to ensure consistency between defuzzified outputs and actual outputs, regardless of selected interval partitions. As a consequence, data utilisation is improved by minimising the loss of forecast rules and minimising the number of pattern combinations to be matched with future time series data.

The FTA-based FTS technique is employed on maximum temperature data of Zaria for the period 1990-2003, as obtained from Nigerian Meteorological Agency (NIMET), Zaria and these are used to obtain the forecast for January to December 2004. A performance measure of MAPE of 3.64% is obtained, which indicates that the technique can result in the improvement of the forecasting accuracy.

Abstract- *This paper presents a Novel Fuzzified Multi Objective (MO) version of Honey Bee Mating Optimization (MOHBMO) approach for optimal tuning of linear parameters (such as the gain and time constant) and nonsmooth nonlinear parameters (such as saturation limits) of Power System Stabilizer (PSS). The problem of robustly tuning of PSS based SMIB design is formulated as an optimization problem according to the time domain-based and eigenvalue based objective functions which are solved by the MOHBMO technique that has a strong ability to find the most optimistic results. The effectiveness of the proposed Fuzzy based MOHBMO based PSS is demonstrated on a Single-Machine Infinite-Bus (SMIB) power system through the nonlinear time domain simulation and some performance indices under different operating conditions in comparison with the SPEA algorithm based tuned stabilizer and conventional PSS.*

Keywords: PSS Design, HBMO, MOHBMO, Low Frequency Oscillations, SMIB.

1. Introduction

Low frequency oscillations are detrimental to the goals of maximum power transfer and optimal power system security [1]. A contemporary solution to this problem is the addition of power system stabilizers to the automatic voltage regulators on the generators in the power system. The damping provided by this additional stabilizer provides the means to reduce the inhibiting effects of the oscillations [2]. The application of Power System Stabilizer (PSS) can help in damping out these oscillations and improve the system stability. The traditional and till date the most popular solution to this problem is application of the Conventional Power System Stabilizer (CPSS). However, continual changes in the operating condition and network parameters result in corresponding change in system dynamics. This constantly changing nature of power system makes the design of CPSS a difficult task [3].

A more reasonable design of the PSS is based on the gain scheduling and adaptive control theory as it takes into consideration the nonlinear and stochastic characteristics of the power systems [4-5]. This type of stabilizer can adjust its parameters on-line according to the operating condition. Many years of intensive studies have shown that the adaptive stabilizer can not only provide good damping over a wide operating range but more importantly, it can also solve the coordination problem among the stabilizers. Many random heuristic methods, such as like Improved honey bee mating optimization algorithm, chaotic optimization algorithm, artificial bee colony algorithm, Particle Swarm Optimization (PSO), Improved version of PSO algorithm have recently received much interest for achieving high efficiency and search global optimal solution in the problem space and they have been applied to the problem of PSS design [6-11]. These evolutionary based methods are heuristic population-based search procedures that incorporate random variation and selection operators. In addition, the PSS design problem was formulated as a single objective for optimization in all of the above methods.

It should be noted that the PSS design problem is a multiobjective optimization problem due to system characteristics and nonlinear behavior of the power systems. Thus, a fuzzy based Multi Objective Honey Bee Mating Optimization (MOHBMO) technique is proposed for optimal tune of PSS parameters to improve power system low frequency oscillations damping in this paper. The HBMO algorithm is a typical swarm-based approach to optimization, in which the search algorithm is inspired by the honey-bee mating process [12-13] and has emerged as a useful tool for engineering optimization. There is no absolute global best in MOHBMO, but rather a set of nondominated solutions. Also, there may be no single local best queen for each individual of the colony. Selecting the global best and local best to guide the colony bees becomes nontrivial task in multi-objective domain. Thus, for non-

*Corresponding Author (hashayanfar@gmail.com)

dominance solutions sorting the Pareto archive maintenance approach and to ensure proper diversity amongst the solutions of the non-dominated solutions in Pareto archive maintenance the crowding distance measure concept is used [14].

In this study, the problem of robust PSS design is formulated as a multi objective optimization problem and MOHBMO technique is used to solve it. Two performance indices based on time and frequency domains characteristics are defined and used to form the objective function of the design problem. The proposed MOHBMO based designed PSS has been applied and tested on a weakly connected power system under wide range of operating conditions to illustrate their ability to provide efficient damping of low frequency oscillations. To show the superiority of the proposed design approach, the simulations results are compared with the SPEA based designed [15] and classical PSS under different operating conditions through some performance indices. The results evaluation shows that the proposed method achieves good robust performance for wide range of load changes in the presence of very highly disturbance and is superior to the other stabilizers.

2. Power system model

For stability analysis of power system adequate mathematical models describing the system are needed. The models must be computationally efficient and be able to represent the essential dynamics of the power system. The stability analysis of the system is generally attempted using mathematical models involving a set of nonlinear differential equations. A schematic diagram for the test system is shown in Fig. 1. The generator is equipped with excitation system and a power system stabilizer. System data are given in Appendix.

The synchronous generator is represented by model 1.1, i.e. with field circuit and one equivalent damper winding on q axis. The nonlinear dynamic equations of the SMIB system considered can be summarized as [2, 11].

$$\begin{aligned}
\dot{\delta} &= \omega_B S_m \\
\frac{dS_m}{dt} &= \frac{1}{2H}(-DS_m + T_m - T_e) \\
\dot{E}'_q &= \frac{1}{T'_{do}}(E_{fd} + (x_d - x'_d)i_d - E'_q) \\
\dot{E}_{fd} &= \frac{1}{T_A}(k_A(v_{ref} - v_t + V_s)) - E_{fd})
\end{aligned} \tag{1}$$

$$T_e = E'_q i_q + (x'_d - x'_q) i_d i_q \tag{2}$$

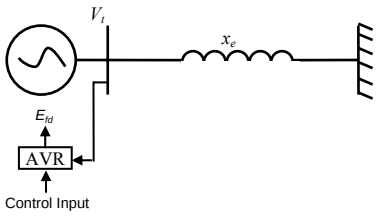

Fig. 1. SMIB power system

2.1. PSS model

The structure of PSS, to modulate the excitation voltage is shown in Fig .2. The structure consists a gain block with gain K, a signal washout block and two-stage phase compensation blocks. The input signal of the proposed method is the speed deviation ($\Delta\omega$) and the output is the stabilizing signal V_S which is added to the reference excitation system voltage. The signal washout block serves as a high-pass filter, with the time constant T_W, high enough to allow signals associated with oscillations in input signal to pass unchanged. From the viewpoint of the washout function, the value of T_W is not critical and may be in the range of 1 to 20 seconds [11]. The phase compensation block (time constants T_1, T_2 and T_3, T_4) provides the appropriate phase-lead characteristics to compensate for the phase lag between input and the output signals.

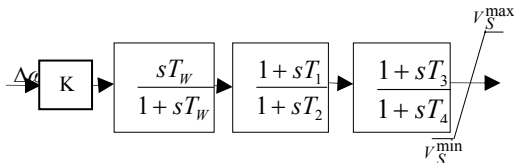

Fig .2. Structure of power system stabilizer

3. Multi Objective HBMO

A. Brief HBMO Review

A honey-bee colony typically consists of a single egg laying long-lived queen, several thousand drones (depending on the season), workers and a large family of bees living in one bee-hive [12]. Each bee undertakes sequences of actions which unfold according to genetic, ecological and social condition of the colony.

A mating flight starts with a dance performed by the queen who then starts a mating flight during which the drones follow the queen and mate with her in the air. After the mating process, the drones die. In each mating, sperm reaches the spermatheca and accumulates there to form the genetic pool of the colony. Each time a queen lays fertilized eggs, she randomly retrieves a mixture of the sperm accumulated in the spermatheca to fertilize the egg and this task can only be done by the queen [16-17].

The HBMO algorithm combines different phases of the marriage process of the honey bee. It starts with random generation of a set of initial solutions. Based on their fitness, randomly generated solutions are then

ranked. The fittest solution is named queen, whereas the remaining solutions are categorized as drones (i.e., trial solutions). In order to form the hive and start mating process, the queen, drones and workers (predefined heuristic functions) should be defined. Each queen is characterized with a genotype, speed, energy and a spermatheca with defined capacity. In the next step, drones must be nominated to mate with the queen probabilistically during the mating flight. At the start of the flight, the queen is initialized with some energy content and returns to her nest when the energy is within some threshold of either near zero or when the spermatheca is full. The mating flight may be considered as a set of transitions in a state-space (the environment). An annealing function is used to describe the probability of a drone (D) that successfully mates with the queen (Q) as follows [12]:

$$prob(Q,D) = e^{\frac{-\Delta(f)}{S(t)}} \quad (3)$$

Where, $\Delta(f)$ is the absolute difference of the fitness of D and the fitness of Q and the $s(t)$ is the speed of queen at time t. The fitness of the resulting chromosomes of drone, queen or brood is determined by evaluating the value of the objective function. After each transition in space, the queen's speed and energy decays is given by:

$$S(t+1) = \alpha \times S(t) \quad (4)$$

$$E(t+1) = E(t) - \gamma \quad (5)$$

Where, $\alpha(t)$ is speed reduction factor and γ is the amount of energy reduction after each transition (α , $\gamma \in [0,1]$).

B. MOHBMO

In most of practical cases, multi-objective optimization problems require simultaneous optimization of several incommensurable and often competitive/conflicting objectives. Because of presence of the multiple conflicting objectives, there is not exist one solution, which is the optimum of all objectives simultaneously. Instead, the solutions exist in the form of alternative trade-offs, also known as the Pareto optimal solutions. In other word, a multi-objective optimization problems always has a set of optimal solutions, for which there is no way to improve one objective value without deterioration of at least one of the other objective values. Pareto dominance concept classifies solutions as dominated or non-dominated solutions and the "best solutions" are selected from the non-dominated solutions. To sort non-dominated solutions, the first front of the non-dominated solution is assigned the highest rank and the last one is assigned the lowest rank. When comparing solutions that belong to a same front, another parameter called crowding distance is calculated for each solution. The crowding distance is a measure of how close an individual is to its neighbors. Large average crowding distance will result in better diversity in the population [14]. In order to investigate multi-objective problems, some modifications in the HBMO algorithm were made.

Here, fuzzy set theory has been implemented to derive efficiently a candidate Pareto optimal solution for the decision makers [16]. The fuzzy set theory has been implemented to derive efficiently a solution from the set of non-dominated solutions. The fuzzy decision making function is represented by the membership function to replace each variable as a precise value. Fig. 3. depicts the membership function μ_c for the fuzzy variable signifying total fuel cost $f_i(.)$. The decision maker is fully satisfied with the cost if, μ_c is one, and not satisfied at all if μ_c is zero. Therefore, the value of membership function indicates the adaptability of the economy index. Due to the imprecise nature of decision maker's judgment, the ith objective function of a solution in the non-dominated set f_i is represented by a membership function $\mu_i(.)$ defined as [17]:

$$\mu_i = \frac{f_i^{\max} - f_i}{f_i^{\max} - f_i^{\min}} \quad (6)$$

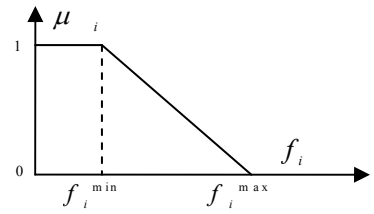

Fig. 3. Membership function of fuzzy cost.

Where f_i^{max} and f_i^{min} are the maximum and minimum values of i^{th} objective, respectively. We can have:

$$FDM_i = \begin{cases} 0 & \mu_i \le 0 \\ \mu_i & 0 < \mu_i < 1 \\ 1 & \mu_i \ge 1 \end{cases} \quad (7)$$

For each non-dominated solution k, the normalized membership function FDM^k can be defined as follows:

$$FDM^k = \left[\frac{\sum_{i=1}^{2} FDM_i^k}{\sum_{j=1}^{M} \sum_{i=1}^{2} FDM_i^j} \right] \quad (8)$$

The best compromise solution of PSS problem is the one having the maximum value of FDM^k as fuzzy decision making function. Where M is the total number of non-dominated solutions. Then all the solutions are arranged in descending order according to their membership function values which will guide the decision makers with a priority list of non-dominated solutions in view of the current operating conditions. Flowchart of MOHBMO algorithm is summarized in Fig. 4.

4. Problem formulation

In the present study, washout time constant T_W =10 sec is used for the given lead-lag structure in Fig. 2. For the optimal tuning of the PSS parameters in Fig. 4, both linear parameters (K, T_1, T_2, T_3 and T_4) and nonlinear parameters (V_{smax} and V_{smin}) are to be determined. It is worth mentioning that the PSS is designed to minimize the power system oscillations after a large disturbance so as to improve the power system stability. To increase the system damping to the electromechanical modes and find appropriate location of PSSs the objective functions for optimization is defined as follow:

$$J_1 = \sum_{j=1}^{NP} \int_0^{t_{sim}} t.\omega dt + 0.07 \times OS^2 \quad (9)$$

$$J_2 = \sum_{j=1}^{NP} \sum_{\sigma_i \geq \sigma_0} (\sigma_0 - \sigma_i)^2 + 5 \times \sum_{j=1}^{Np} \sum_{\zeta_i \leq \zeta_0} (\zeta_0 - \zeta_i)^2 \quad (10)$$

Where $\sigma_{i,j}$ and $\zeta_{i,j}$ are the real part and the damping ratio of the i^{th} eigenvalue of the j^{th} operating point. The t_{sim} is the time range of simulation and NP is the total number of operating points for which the optimization is carried out.

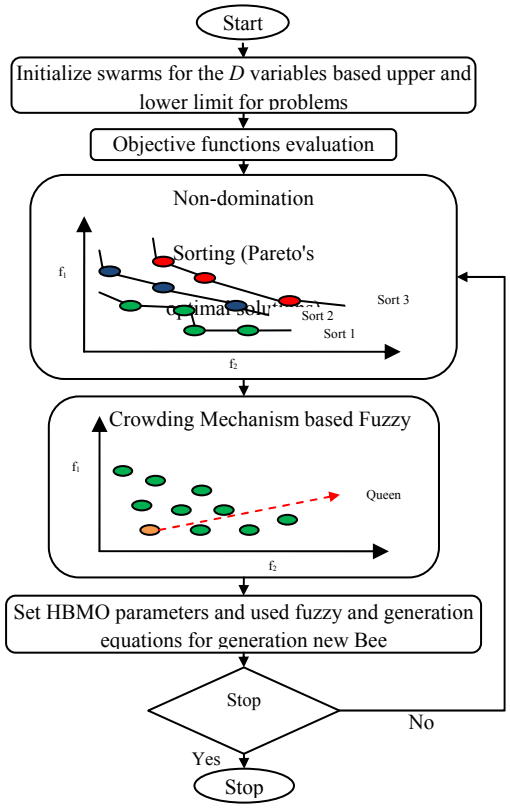

Fig. 3. Algorithm and computational flowchart of Fuzzified MOHBMO

Typical ranges of the optimized parameters are [0.1-100] for K and [0.01-5] for T_1, T_2, T_3 and T_4 and [0.05-0.5] for V_{smax} and $-V_{smin}$. The optimization of the PSS parameters is carried out by evaluating the objective cost function as given in Eqs. (9) and (10), which considers a multiple of operating conditions are given in Table 1. The operating conditions are considered for wide range of output power at different power factors. Results of the PSS parameter set values based on the objective function J_1 (by applying a three phase-to-ground fault for 100 ms at generator terminal at t=1 sec) and J_2, using the proposed MOHBMO and SPEA [15] and CPSS [2] algorithms are given in Table 2. Fig. 5 shows the minimum fitness functions evaluating process.

5. Simulation results

The behavior of the proposed MOHBMO based designed PSS (MOHBMOPSS) under transient conditions is verified by applying disturbance and fault clearing sequence under different operating conditions. In comparison with the SPEA based tuned PSS (SPEAPSS) and classical PSS. The disturbances are given at t = 1 sec. System responses in the form of slip

(S_m) are plotted. The following types of disturbances have been considered.

Scenario 1: A step change of 0.1 pu in input mechanical torque.

Scenario 2: A three phase-to-ground fault for 100 ms at generator terminal.

Figure 6 shows the system response at the lagging power factor operating conditions with weak transmission system for scenario 1. It can be seen that the system with CPSS is highly oscillatory. MOHBMO and SPEA based tuned stabilizers are able to damp the oscillations reasonably well and stabilize the system at all of the operating conditions. Figure 7 depicts the responses of same operating conditions but with strong transmission system. System is more stable in this case, following any disturbance. Both PSSs improve its dynamic stability considerably and MOHBMOPSS shows its superiority over SPEAPSS and CPSS. Figure 8 refers to a three-phase to ground fault at generator terminal. Figure 9 depicts the system response in scenario 1 with inertia $H'= H/4$. It can be seen that the proposed MOHBMO based PSS has good performance in damping low frequency oscillations and stabilizes the system quickly. Moreover, it is superior to the SPEA and classical based methods tuned stabilizer.

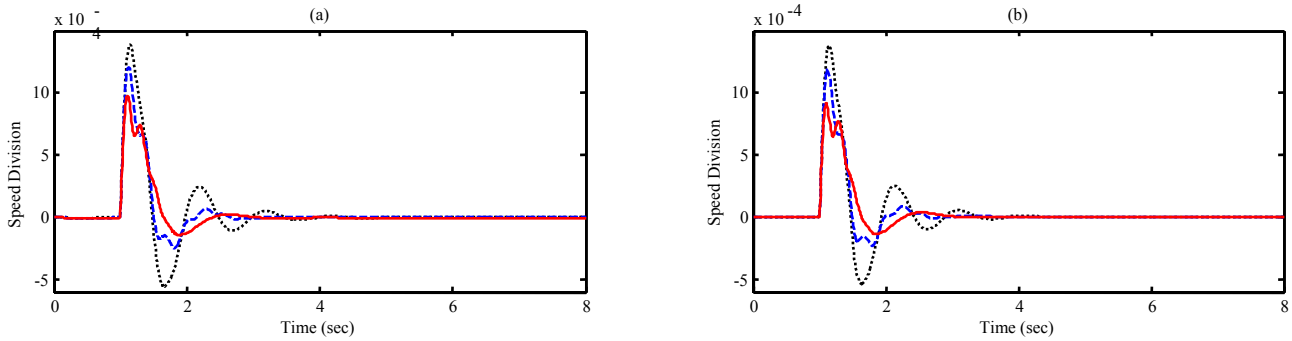

Fig. 9. ΔT_m=0.1 (p.u.) under Xe=0.6 and H'=H/4, CPSS (Dotted), SPEAPSS (Dashed) and MOHBMOPSS (Solid)
a) P=1.0, Q=0.5 b) P=0.6, Q=0.0

To demonstrate performance robustness of the proposed method, two performance indices: the Integral of the Time multiplied Absolute value of the Error (ITAE) and Figure of Demerit (FD) based on the system performance characteristics are defined as [17]:

$$FD = 10 \times [(500 \times OS)^2 + (8000 \times US)^2 + 0.01 \times T_s^2] \quad (10)$$

$$ITAE = 1000 \times \int_0^8 t \,|\Delta\omega|dt \quad (11)$$

Where, Overshoot (OS), Undershoot (US) and settling time of rotor angle deviation of machine is considered for evaluation of the FD. It is worth mentioning that the lower the value of these indices is, the better the system response in terms of time-domain characteristics. Numerical results of performance robustness for all cases as given in Table 1 for scenario 1 are listed in Table 3, respectively.

Table 3. Performance indices for scenario 1

Case No	MOHBMO		SPEA		Classic	
	ITAE	FD	ITAE	FD	ITAE	FD
1	0.5022	0.4757	0.6775	0.9942	0.5632	1.4729
2	0.8381	0.5644	1.0422	1.4799	0.9042	1.7696
3	0.3780	0.4722	0.5544	0.9281	0.4465	1.4774
4	0.7822	1.1298	1.4842	3.7696	1.1311	3.4747
5	1.1247	1.4463	1.8102	4.5268	1.4959	4.2209
6	0.7777	1.2171	1.5885	4.0670	1.1631	3.6312
7	0.7822	1.1298	1.4842	3.7696	1.1310	3.4747
8	0.3780	0.4722	0.5544	0.9281	0.4465	1.4774
9	1.1247	1.4463	1.8102	4.5268	1.4959	4.2209
10	0.3780	0.4722	0.5544	0.9281	0.4465	1.4774

It can be seen that the values of these system performance characteristics with the proposed MOHBMO based tuned PSSs are much smaller compared to that SPEA and classical based designed PSS. This demonstrates that the overshoot, undershoot settling time and speed deviations of machine is greatly reduced by applying the proposed MOHBMO based tuned PSS.

6. Conclusions

An attempt has been made in this paper to develop a simple but robust PSS with particular emphasis on achieving a minimum closed loop performance over a wide range of operating and system conditions. For dealing with different solutions in multi-objective optimization problem, Pareto dominance concept is used to generate and sort the dominated and non-dominated solutions. The minimum performance requirements of the stabilizer have been decided and this performance has been obtained using Fuzzified multi objective honey bee mating optimization. The nonlinear simulation results under wide range of operating conditions show the superiority and robustness of the Fuzzified multi objective HBMO method for the PSS design and their ability to provide efficient damping of low frequency oscillations in comparison with SPEA and classical methods. The effectiveness of the proposed method is tested on SMIB power system for a wide range of load demands and disturbances under different operating conditions. The nonlinear time simulation results confirm that the proposed MOHBMO based tuned PSS can work effectively over a wide range of loading conditions and is superior to the SPEA based tuned PSS and CPSS.

Abstract - *We propose TSK (Takagi-Sugeno-Kang)-type Adaptive Neuro-Fuzzy Classifier (ANFC) for physical activity classification based on triaxial accelerometer and biomedical signal information. For this purpose, we design intelligent classifier with the ability to incorporate human knowledge and to adapt the knowledge base with the use of Gustafson-Kessel (GK) fuzzy clustering. We also obtain movement information and heart rate from the developed patch-type sensor module. This small sensor is patched onto the user's chest to obtain physiological data. The experiments consist of normal walking, brisk walking, slowest running, and jogging as physical activity classification in outdoor environments. The experimental results revealed that the presented intelligent classifier showed good performance in comparison to the previous studies.*

Keywords: Physical activity classification, neuro-fuzzy classifier, GK fuzzy clustering, patch-type sensor module

1 Introduction

Conventional approaches of pattern classification involve clustering training data and organizing clusters to given categories. The complexity and limitations of previous scheme are largely due to the lacking of an effective way of defining the boundaries among clusters. This problem becomes more intractable when the number of features used for classification increases. In contrast to conventional clustering method, neuro-fuzzy classification assumes the boundary between two neighboring classes as a continuous, overlapping area within an object has partial membership degree in each class [1]. Furthermore, clustering techniques are used in conjunction with radial basis function classifier, fuzzy classifier, and neuro-fuzzy classifier primary to determine initial locations for radial basis function of receptive field or fuzzy if-then rules [2-4]. On the other hand, the accurate measurement of energy expenditure from physical activity is a challenging problem that is important to exercise scientists and clinicians. For this, we recently developed a patch-type sensor module to solve these problems [5]. The main characteristics of this sensor module are small size, wireless operation, low cost, light weight, and comfort for long-term wear, as well as integrating all required measurement parameters into a single sensor. We shall obtain movement information and biomedical signals from this sensor patched onto the user's chest and only perform activity classification.

Therefore, this paper is concerned with the intelligent Adaptive Neuro-Fuzzy Classifier (ANFC) with the use of the developed patch-type sensor module from a given input-output data pairs such as movement information and heart rate. The Takagi-Sugeno-Kang (TSK)-type ANFC is designed by Gustafson-Kessel (GK) fuzzy clustering with fuzzy covariance matrix. This clustering technique is based on Mahalanobis distance to consider the distribution of input variables by incorporating the covariance of data points [6]. Furthermore, TSK type is by far the most popular candidate for fuzzy classifier and effective to develop a systematic approach [7]. Thus, the TSK-ANFC can possess the intensive classification capability together with meaningful fuzzy if-then rules. The experiments are performed on normal walking, brisk walking, slowest running, and jogging in outdoor environments. The experiments results revealed that the proposed intelligent classifier outperformed in the previous methods. The material of this paper is organized in following fashion. In section 2, we describe the proposed neuro-fuzzy classifier based on GK fuzzy clustering. In section 3, we perform the experimental setup and performance comparison. Finally the conclusions and comments are given in section 4.

2 Architecture of TSK-ANFC

In this section, we describe the architecture and learning rules of the TSK-ANFC. Let us now consider the TSK-ANFC with first-order TSK fuzzy rules. It also involves two phases including structure identification and parameter identification. The former is related to determining the number of fuzzy if-then rules and a proper partition of the input space. The latter is concerned with the learning of model parameters such as membership functions, linear coefficients, and so on. Fig. 1 shows the architecture of the proposed TSK-ANFC. As shown in Fig. 1, this network is composed of five layers similar to the well-known ANFIS (Adaptive Neuro-Fuzzy Inference System) introduced by Jang [1]. While ANFIS often raises the "curse of dimensionality" problem that the number of fuzzy rules exponentially increases due to the grid partitioning of the input space, the TSK-ANFC can effectively solve such a problem due to the flexible scatter partitioning of the GK fuzzy clustering approach.

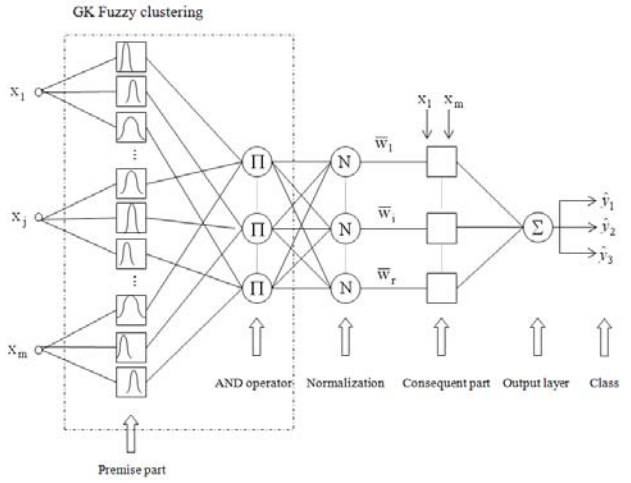

Fig. 1 Architecture of a TSK-ANFC

For simplicity, we suppose that the TSK-ANFC under consideration has m input variables $x_j, j = 1,2,\ldots,m$. For a first-order TSK fuzzy type, a typical fuzzy if-then rule has the following form [7]

$$R^i : If\ x_1\ is\ A_1^i\ and\ x_2\ is\ A_2^i, \cdots, x_m\ is\ A_m^i,$$
$$then\ y^i = a_o^i + a_1^i x_1 + a_2^i x_2 + \cdots + a_m^i x_m \quad (1)$$

where R^i, i=1,2,…,r, denotes the ith fuzzy rule. A_j^i is a linguistic label associated with the jth input variable in the premise of the ith rule and $\{a_o^i, a_1^i, \ldots, a_m^i\}$ are consequent parameters. Every node of the first layer consists of linguistic labels build by a parameterized membership function. Here, we use a Gaussian membership function specified by two parameters. A Gaussian membership function is determined completely the center and width of the membership function, respectively. Each of the cluster centers obtained by the GK fuzzy clustering method represents a prototype that exhibits significant characteristics of the target system under consideration. For further details on GK fuzzy clustering refer to [6]. Here, the membership's width, representing the initial standard deviation for each cluster center in the jth input variable, is computed by statistical method. Every node in the second layer represents the firing strength of a rule by using the product of all of the incoming signals as follows

$$w_i = \prod_{j=1}^{m} A_j^i(x_j)\ ,\ i = 1,2,\ldots,r,\ j = 1,2,\ldots,m \quad (2)$$

Every node in the third layer calculates the ratio of the ith rule's firing strength to the sum of all rule's firing strengths. Every node in the fourth layer computes the product between the normalized firing strength and the constant of the consequent part. The single node in the final layer computes the overall inference class as the summation of all incoming signals as follows

$$\hat{y} = \sum_{i=1}^{r} \overline{w}_i y^i = \frac{\sum_{i=1}^{r} w_i (a_0^i + a_1^i x_1 + \cdots + a_m^i x_m)}{\sum_{i=1}^{r} w_i} \quad (3)$$

where $\overline{w}_i$ is a normalized firing strength of the ith rule and $\hat{y}$ is the classified output of the model. $\hat{y}$ is represented as class number by class bound value. Here, the learning scheme of the proposed TSK-ANFC is performed by the hybrid learning scheme using Back-Propagation (BP) and Least Square Estimator (LSE).

3 Experimental results

The patch-type sensor module is a wireless, small size and light weight sensor that can be patched on the chest of participants to obtain physiological data. The sensor board shown in Fig. 2 consists of a 3-axis accelerometer and three ECG electrodes to detect movement information (MI) and heart rate (HR), respectively [5].

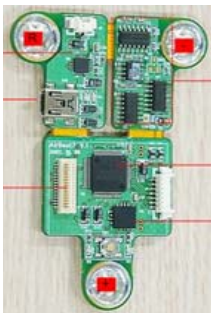

Fig. 2 Patch-type sensor module

The experiments are performed under outdoor environments. In order to obtain heart rate, we used three electrodes for ECG measurement on the chest. These electrodes without gel are mounted on a conductive adhesive patch. The ECG analog circuitry was specifically designed for effective motion artifact rejection during exercise. On the other hand, we used three-axis accelerometer (MMA7260Q) was used to detect acceleration changes during exercise. This device is a cheap capacitive micro-machined accelerometer featuring good sensitivity, low power consumption, and very small size. We used 206 samples with 4 classes. The input consists of two variables. The variables were the movement information (MI) and heart rate (HR). The output variable to be classified is physical activities. In order to evaluate the resultant model, we divided the data sets into training (odd number) and test data (even number) sets. Here, we selected 103 training sets for model construction, while the other checking data set was used for model validation. We performed the experiments as the number of cluster increases from 3 to 6. Fig. 3 shows data distribution of movement information obtained from triaxial

accelerometer sensor regarding each physical activity. As shown in Fig. 3, the movement information of brisk walking is similar to that of slowest running. Fig. 4 shows the classification performance (70.37%, 5 rules) of the proposed TSK-ANFC regarding only movement information. Fig. 5 shows data distribution of heart rate obtained from ECG sensor regarding each physical activity. As shown in Fig. 5, the heart rate has good characteristics in discrimination of each physical activity. Fig. 5 shows the classification performance (98.06%, 5 rules) of the proposed TSK-ANFC regarding only heart rate. Fig. 7 visualizes the distribution of two input variables obtained from normal walking, brisk walking, slowest running, and jogging in outdoor environments. Fig. 8 shows the classification performance representing 99.03% when the number of rule is 5. The clusters estimated by GK fuzzy clustering are shown in Fig. 9. Table 1 lists the comparison of classification performance. As listed in Table 1, the proposed TSK-ANFC showed good performance in comparison with the previous work.

Table 1 Comparison of classification performance for checking data

	No. rule	Classification rate (%)
NFC [1]	6	79.61
The proposed TSK-ANFC	3	98.06
	4	98.06
	5	99.03
	6	99.03

4 Conclusions

We developed the ANFC with a TSK fuzzy type based on by GK fuzzy clustering technique for physical activity classification based on triaxial accelerometer and biomedical signal information. The experiments are performed on normal walking, brisk walking, slowest running, and jogging in outdoor environments. The experiments results revealed that the proposed intelligent classifier showed good performance in comparison with the previous work. In the future, we shall use three-axis based action data well as Vicon physical action data for activity recognition.

Intelligent Agents for Mobile Network Coverage Analysis

Robert M. McGraw, Richard A. MacDonald
RAM Laboratories, Inc., San Diego, CA, USA

Abstract - *Techniques and tools are needed that allow Commanders and Analysts to intelligently plan and re-assess mobile networks that are supporting missions and courses of action in the battlespace and emergency response settings. Many techniques, simulations, and tools are available to model, represent, and analyze the RF environment, however they are typically used for a priori planning or after action analysis. Unplanned changes to the RF environment such as environmental variations, position, jamming, and terrain effects may result in coverage shortfalls that hinder mission performance. As such, there exists a need to provide visual analysis of network coverage to Warfighters executing the mission in real-time.*

This paper details an ongoing research effort that seeks through provide real-time visualization of mobile network coverage through the orchestration of a variety of data sources, simulations, network analysis techniques and cognitive models. This variety of applications is assembled into a workflow through an intelligent agent framework and used to assess and display the expected coverage for the mission under way on a GoogleEarth map, resulting in mission participants being able to "see" where the coverage begins and ends for their device.

Keywords: intelligent agents, MANETs, Signal Planning, Coverage Analysis, Bayesian Analysis

1 Introduction

This paper discusses an effort to provide the visualization of network coverage through the use of an intelligent agent framework known as the Course of Action (COA) Analysis with Radio-time Effects Toolbox (CARET). The CARET Agent Framework makes use of distributed agents that gather, process, and inject real-time data into embedded simulations for use in evaluating COAs amidst real-time RF effects. This framework provides capabilities that assist signal planners and Warfighters / mission participants in visualizing changing mobile coverage presented by uncertainties associated with forces-on-the-move. While this paper provides a discussion on the Agent Framework design, this has been provided for completeness, as much of that work has been presented elsewhere [1][2][3][4][5]. This particular paper focuses on the techniques employed for our coverage analysis that is subsequently relayed for viewing via the GoogleEarth overlay.

2 Problem Being Solved

This research addresses the issue of mobile network coverage shortfalls that can result from some type of deviation from an initial signal plan. This deviation may be a result of participants being out of position, environmental or terrain effects, adversary jamming, equipment damage or health issues, and other criteria. An example illustrating this problem is shown in Figures 1 and 2. In Figure 1, a signal planner has laid out his/her plan for the mission that supports blue force movement in accomplishing their mission. The blue arrows indicate participant movement, while the circles indicate the coverage areas for those radios. Figure 1 also indicates adversary or target positions built into the map overlays and adversary jamming or interference sources. This analysis and planning is typically performed a priori. Figure 2 details some of the unplanned activities that may affect the network support for the mission, participants may stray from their coverage areas or jamming or interference sources may move. Additionally, weather or terrain may also affect the coverage.

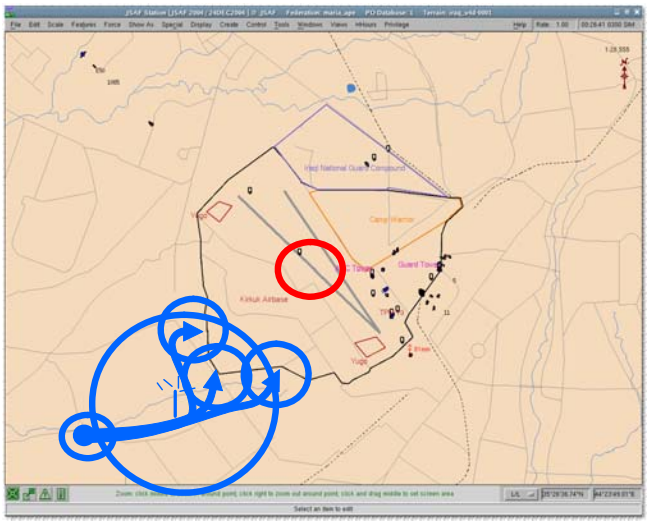

Figure 1: Network Propagation and Connectivity for a Given Mission Plan

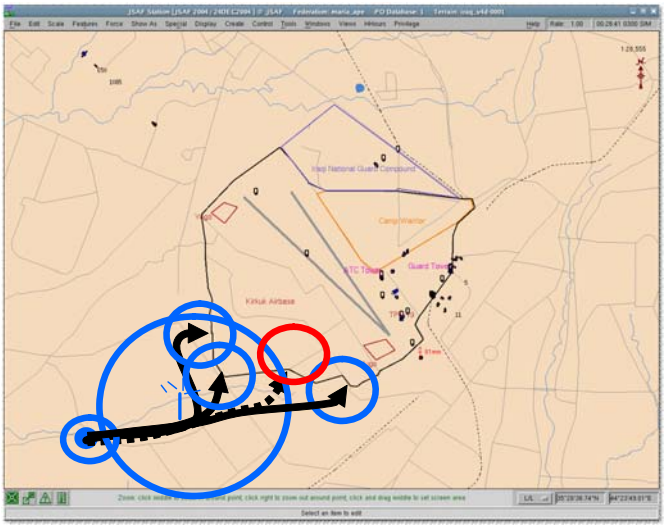

Figure 2: Plan Deviation Result in Coverage Shortfalls

3 CARET Agent Framework

The CARET Agent Framework design serves three main purposes: (1) enable the development of highly capable applications that are able to meet the demands of current and future requirements, (2) provide a development platform that is highly flexible and easily extensible, and (3) ensure that applications developed from the framework are highly interoperable with other applications, systems, and platforms, particularly legacy software and systems.

3.1 Basic Components

The first principle was the need to build applications from composable components, such as web services and/or intelligent agents. To implement our selection of software agents as a base component type, we have selected the Java Agent Development Environment (JADE) [6]. JADE is a software framework to develop agent-based applications in compliance with the FIPA specifications for interoperable intelligent multi-agent systems [7].

3.2 Handling Data

The second core principle was the use of abstract data interfaces wherever possible in order to simplify the burden on application developers. Due to this principle, our approach adopted use of Service Data Objects (SDOs), whose specification [8] prescribes a way for all compliant data exchanges to take place using a common representation for all data types. Figure 3 shows a UML diagram of the basic SDO representation for data.

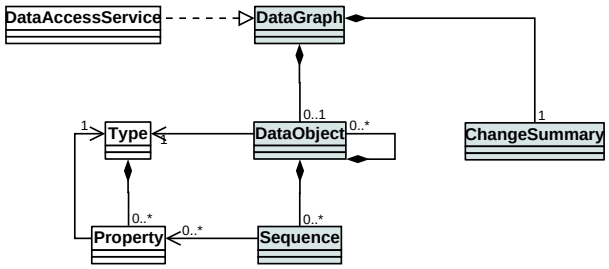

Figure 3: Service Data Object (SDO) Representation

When data needs to be exchanged between application components, sets of Data Objects are assembled into a Data Graph and sent from a DataAccessService to its final destination. Data Graphs can also keep track of all changes or modifications made to the graph over time in a Change Summary.

The choice of SDO for data interfaces reduces the impact on developers and integrators that are due to the manner in which data may be accessed. SDO translators can be written for each particular legacy data source and re-used for each instantiation of that source.

Additionally, our solution adopted the use Web Services and protocols, such as SOAP [9] to interoperate with agents or services from external systems.

3.3 Managing Workflows

The third core principle from was support for workflows, particularly those following the Observation-Interpretation-Action cycle of programmed system responses to dynamic events. Here again we are fortunate that the choice of JADE as the agent development framework provides us with a good starting point to build up from. There exists a complementary product to JADE that is called the Workflows and Agents Development Environment (WADE). WADE is built on top of JADE, as shown in Figure 4.

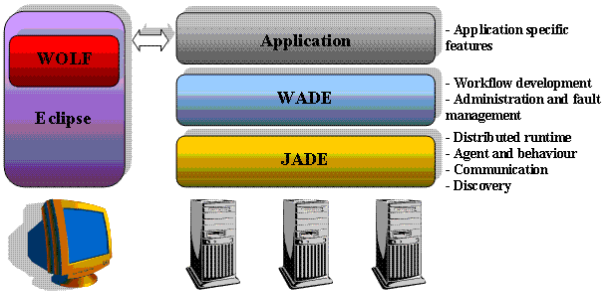

Figure 4: WADE Overview

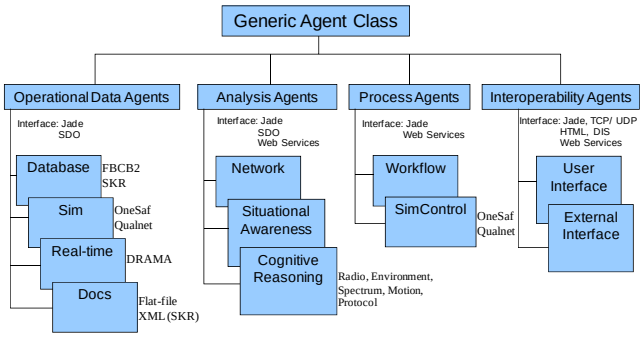

Figure 5: Agent Types for the CARET Agent Framework

3.4 Agent Classes

Based on JADE concepts, data handling approaches, agent interoperability mechanisms, and workflow orchestration concepts discussed above, this effort developed a basic agent structure from which all CARET agents could be derived. All CARET agents are derived from a Generic Agent Class as shown in Figure 5. This generic agent class provides a basic JADE agent structure with inherent data handling and processing features. The CARET Generic Agent class was used to develop four types of agents that were further derived to provide for the different agent capabilities required by the CARET Agent Framework. These agent types include Operational Data Agents (ODAs), Analysis Agents (AAs), Process Agents (PAs), and Interoperability Agents (IAs) [3][4].

Operational Data Agents are responsible for capturing or extracting data for a variety of sources in the CARET environment. Such sources may be SQL databases, real-time data sources, documents such as flat-files or XML schemas, or simulation environments. Process Agents are used to implement some type of process over time such as triggering or calibrating multiple simulation runs or managing the flow of data between agents. Analysis Agents are responsible for performing some type of analysis of data in the CARET environment, including performing the analysis of simulation results, analysis of intelligence, surveillance, or reconnaissance sensor data from the operational world, predictive analysis of trends with regard to missions or network configurations supporting those missions, and analyses of particular alternative or "what-if" scenarios in addressing a particular mission objective. AAs possess JADE, SDO and web service interfaces. Interoperability Agents (IAs) are responsible for interoperating with external systems or user interfaces and possess JADE, HTML, SDO, Web Service, TCP / UDP and DIS interfaces.

4 CARET Agent Framework Implementation

As mentioned, our implementation of the CARET Agent Framework is based on JADE. JADE uses topics so other agents can subscribe, where only one agent can be the publisher. While the topics are maintained by the main JADE container, but conceptually the flow of data between the different components is depicted in Figure 6 [5]. Ovals depict agent instances and data flows are color-coded by topic as follows:

- DISDATA
- CONFIG
- ENTITYLOC
- EXPERIMENT-SETUP
- EXPERIMENT-RESULTS

The dashed lines represent an external interaction from the JADE system

The CARET implementation uses seven intelligent agents, derived from the agent types presented in Figure 5. An overview of these agents is discussed as follows:

- DISBridgeAgent: This is an Interoperability Agent-External Systems (IA-ES) agent that processes Distributed Interactive Simulation (DIS) PDUs outputted by OneSAF Objective System [10]. OneSAF is use to simulate mission activities. For a operational use, this simulator is replaced by GPS sensors.

- IdentityAgent: This Interoperability Agent-User Interface (IA-UI) allows participants and signal planners to select, via a User Interface, the participants that he/she is interested in.

- EntityServerAgent: This Analysis Agent-Situational Awareness (AA-SA) is configured by IA-UIs and filters sensor data that pertains to entities of interest.

- AnalysisControlAgent: This Interoperability Agent-User Interface (IA-UI) agent interacts with a graphical user interface that allows the user to select parameters for the analysis.

- RemoteProcessAgent: This Process Agent-SimControl (PA-SC) agent is used to control the network analysis performed.

- SocketClientAgent: Interoperability Agent-External Systems (IA-ES) is used to provide entity information to the GoogleEarth application..

- RemoteCoverageAgent: This IA-ES agent is use to provide coverage overlay information to the GoogleEarth application

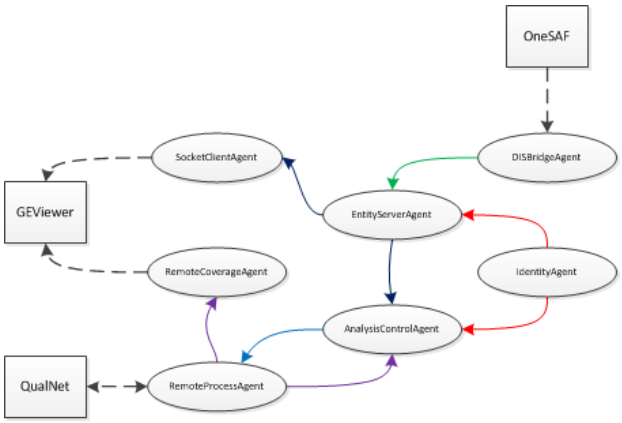

Figure 6: CARET Agent Framework Implementation

5 Statistical and Cognitive Modeling

Two key capabilities that CARET provides signal planners are a capability to analyze and diagnose issues related to network performance as a mission proceeds, and a capability to analyze and diagnose issues related to network performance as a mission is projected forward from a given point in time (using simulation) in order to identify potential unintended outcomes and assess various mission alternatives.

To provide such a capability to signal planners, CARET utilizes PA-SC agents. The PA-SC agent works by controlling the network simulation to perform an experiment around the selected participants. The PA-SC agent conducts these experiments to generate simulated network data based on the expected position of the participant in question. This data is then assembled as a coverage overlay to enable the participant or signal planner to visual the coverage patterns, or is used as input to cognitive reasoning approaches that compare the simulated data with actual network metrics to "diagnose" the cause of potential shortfalls using sets of rules, such as a fuzzy rule base, statistical analysis, and/or through the use of inference techniques.

Initial designs for these agents focused on the use of rule bases and statistical approaches as a way of identifying potential problems for the network in comparison to the expected performance. The statistical metrics were generated through the use of multiple simulations of the support network, with tweaks added to various parameters to gain an understanding of the state space amidst a variety of problems including radio degradation, platform position, and environmental effects. The rule sets were then used to diagnose the cause of specific shortfalls based on observed network behavior.

5.1 Statistical Model Development – Radial Coverage

For the first cognitive model, a statistical modeling approach was used. This modeling approach started with the idealized network topology, emitters, and receivers supporting a mission and simulated the expected coverage and QoS for that topology. Next, the statistical approach involved adjusting each of the radios (transmitters and receivers) involved in the scenario/topology with regard to their location and a variety of additional parameters while running QualNet simulations to generate an expected coverage profile for different parametric off-shoots of the mission. It should be noted that in generating the baseline coverage profiles, the prototype uses existing agent types that we developed for CARET. These agents were used because they facilitated information transfer and processing across CARET applications and alleviated the need for manual simulation execution and results extraction. To generate this coverage map, we implemented a PA-SC for Radial Coverage PA-SC RC, which runs experiments called the coverage-test. The PA-SC RC works by passing an input message defining the coverage experiment that specifies parameters required for the coverage test as follows:

1. Parameter to be varied: FREQUENCY or POWER
2. Minimum, maximum, and increment for the parameter
3. Id and latitude-longitude location of the subject-node
4. Minimum and maximum range (min_r, max_r) for the coverage test
5. Number of N concentric circles to generate
6. Number M of test nodes to place on the inner-most circle

This information is entered via the Analysis Control Agent (an IA-UI), shown in Figure 7, which subsequently passes the simulation control data to the PA-SC RC.

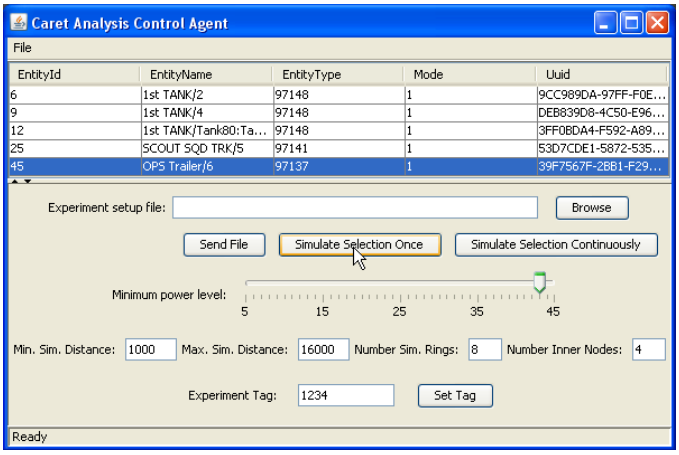

Figure 7: Agent Control using CARET Analysis Agent – Control Agent

As shown in Figure 8, the PA-SC RC creates network nodes (probe-nodes) and places them at evenly spaced

intervals on each of N concentric circles, centered at the subject-node. The radii of the N circles start at min_r and increment at even intervals to max_r. The inner-most circle is given M nodes, and the number of nodes placed in each successively larger circle is the largest integer less than M (r / min_r). This ensures that the arc-length between nodes is roughly the same from one circle to the next.

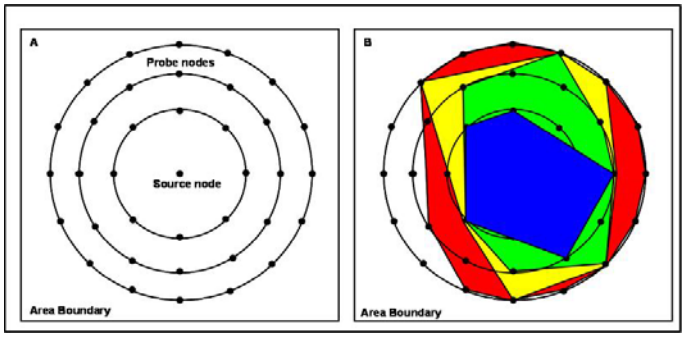

Figure 8: Node Locations for the Radial Coverage Test, N=3, M=8

The PA-SC RC runs QualNet once for each value of the target-parameter, and for each run, the PA-SC RC must generate a scenario-file for QualNet. The QualNet scenario-file has parameters specifying:

- The type of radios used
- Specifications of the communication protocol to be used
- Propagation model
- Specification of frequency
- Location of the DEM files for the area terrain
- QualNet "app" filename specifying transmit parameters

Each time the PA-SC RC runs QualNet, it modifies the scenario-file with the current value of this parameter. After the run completes, QualNet outputs a stat-file containing numerous statistics. When all runs have completed, the PA-SC RC filters all the stats files to determine the number of packets were transmitted to each probe-node and the number that it actually received. The PA-SC RC places this information into a results-file that can be read by the client application.

The result of this experiment is a map that details expected network coverage and QoS for the mission. When actual or simulated network coverage data is available, it is compared to this map to determine what types of network shortfalls may be occurring in a statistical fashion. It should be noted that the results of the PA-SC RC can be viewed by the analyst through graphical analysis. This process is described below.

5.2 Graphical Analysis

In order to gain an understanding of the statistical coverage for the network/mission at hand, the coverage-test results can be passed to a Google Earth viewer in order to gain an appreciation for the coverage bands. In this case, the coverage results are forwarded from the AA-CR RC to the IA-UI Google Earth (GE) viewer [11]. The GE viewer performs following formats the data for display as follows:

- The percentages are classified via thresholds the results into performance categories to be represented by color codes: EXCELLENT (blue), GOOD (green), FAIR (yellow), POOR (red), and none.

- Using the EXCELLENT performance threshold (EXCELLENT), it starts at the innermost probe-nodes and works outwards, forming a coverage-set for by taking the convex hull of the region containing the probe-points whose reception meet or exceed the threshold.

- This reception region is colored blue

- Still working outward from the center, the algorithm determines the convex hull of the region containing probe-nodes that meet or exceed the GOOD threshold. This will contain the previous region, so the difference between the two is colored green.

- The procedure continues likewise to determine the FAIR, and POOR regions which are colored yellow and red respectively.

The GE viewer is a wrapper for the Google Earth (GE) application. It overlays the color-coded coverage area from the graphics analysis onto a topological map of the area produced by GE. The overall use of CARET together with pertinent interfaces, are described below.

The final component in the system is the use of Google Earth [11] as the visual representation of both the entity positions/movements from OneSAF and the results of the simulations from QualNet. CARET is primarily concerned with diagnosing the obstacles to maintaining communications in a mission. The most effective way of conveying problems is with a visual representation. With QualNet, a grid around a desired entity is setup that determines in the areas around the entity where communications can be maintained. This information is then processed and displayed as a colored coverage map in Google Earth. The CARET Agent Framework User Interface is shown in Figure 9. Note that in this image the coverage maps are rendered on the right side in a simple 2D panel, however, this has been extended into a 3D Google Earth viewer (Figures 10).

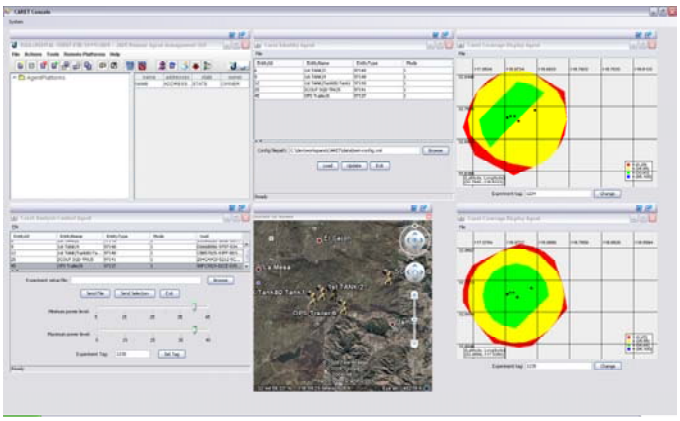

Figure 9: CARET Agent Framework User Interface

Figure 10: Scenario Coverage Depicted Through Agent-Driven Google Earth Overlayfor 85% Threshold

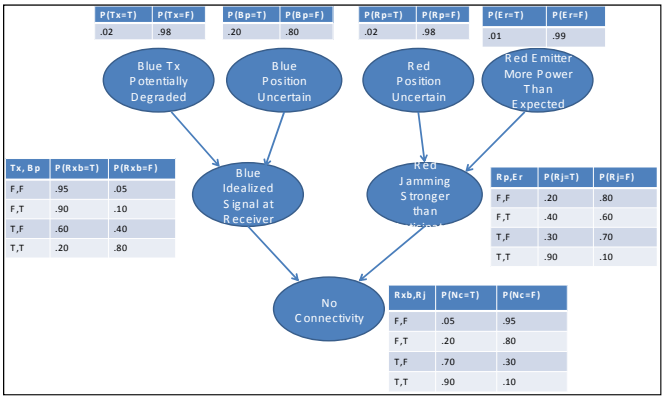

Figure 11: Statistical Metrics Used to Populate Bayesian Networks

5.3 Extending to Cognitive Reasoning

Once sets of rules and statistics were gathered in support of the cognitive analyses, an Analysis Agent – Cognitive Reasoning (AA-CR) can then be used for more advanced techniques, such as inferencing techniques, to gain further knowledge and guide the Signal Planner about the cause of certain phenomena. Our efforts researched a variety of approaches for implementing such reflective cognitive models required by this effort [12][13][14][15][16] that considered the use of neural networks, genetic algorithms, simulated annealing approaches, Bayesian networks, and Markov Models.

In this particular case, the statistical analysis of simulated radial coverage can be taken as the input or configuration data for Bayesian Network Models as shown in Figure 11, where we are considering an example where a Blue Transmitter is fixed but its transmission capability is not 100% certain, the Blue entity holding the receiver is potentially out of position, and the adversary jamming capabilities may be affected by more powerful jammers or a change in position.

For this case, we set the initial probabilities for the Blue Transmission capabilities (Tx), Blue Position Uncertainty (Bp), Red Position Uncertainty (Rp), Red Emitter Power (Re) and expected conditional probabilities for the Idealized Blue Signal Capability (Rxb) and Red Jamming Strength at the Receiver (Rj). Subsequent simulation runs (for the COAA and Network Analysis simulations) are run to refine the conditional probabilities for several of these nodes and used to diagnose the cause of particular shortfalls.

6 Conclusions

This paper has presented an approach performing mobile network coverage analysis to assist mission participants and signal planners with visualizing and understanding causes and potential remedies for network deficiencies during operations. The paper has presented an intelligent agent framework, known as CARET, which is used to integrate a variety of data sources, applications, and services. The paper also presents techniques for performing statistical analysis of anticipated coverage for various participants using GOTS/COTS simulation tools that are controlled through the use of our intelligent agents.

8 Biography

Robert M. McGraw co-founded RAM Laboratories, Inc. in 1997 and is now its Vice-President and Chief Technology Officer. Dr. McGraw's interests lie in the areas of multi-resolution modeling, cyber security, and distributed information management. He is currently overseeing RAM Laboratories efforts in developing an Application Security Analyzer for MDA and enhancing the CARET Agent Framework. Dr. McGraw received his B.S. in Physics and Electronics Engineering from the University of Scranton, and received his M.S. and Ph.D. in Electrical Engineering from the University of Virginia.

Richard A. MacDonald co-founded RAM Laboratories, Inc. in 1997 and has been serving in the capacity of President and Chief Executive Officer since the company's inception. With twenty years experience in high technology and defense businesses, Dr. MacDonald has overseen the strategic planning and growth of RAM Laboratories into a recognized defense technology leader with a national customer base spanning coast-to-coast, supporting multiple branches of the Department of Defense including the Army, Navy, Air Force, Coast Guard and the Department of Homeland Security. Dr. MacDonald earned both a Ph.D. and Masters of Science (M.S.) in Electrical Engineering from the University of Virginia, and a Bachelor of Science (B.S.) degree in Computer Engineering from the University of Michigan.

Cognitive RF Systems and EM Fratricide

Gerard T. Capraro and Ivan Bradaric
Capraro Technologies, Inc., 2118 Beechgrove Place, Utica, NY 13501 USA

Abstract

In many parts of our world the radio frequency (RF) spectrum is overcrowded. The Department of Defense and researchers throughout the US have been addressing this problem by developing cognitive radios, networks, and radar systems to intelligently choose frequencies, waveform parameters, antenna beam patterns, etc. to operate with conventional receivers without causing electromagnetic (EM) fratricide. In most of the documented work that addresses EM fratricide to date, there is an inherent assumption that the cognitive system knows when and where the fratricide occurs. However, the authors usually do not make known how this information is obtained. In this paper we propose two approaches of how the victim receivers can work together with cognitive systems and share the knowledge of their EM status.

1.0 Introduction

We are informed via many articles and studies that the radio frequency (RF) spectrum is crowded and more space is needed for wireless internet access, communications, and for military usage. Just recently the US Congress passed a bill to open up more spectra [1] to auction off RF frequencies belonging to the television broadcast industries. However, this alone will not solve spectrum crowding. When the frequency spectrum is measured over time, technologists have shown that the spectrum is underutilized. Recognizing this, there have been numerous research projects funded by the US Department of Defense (DOD). These research efforts go back many years to the USAF investigating software programmable radios. The Defense Agency Research Project Agency (DARPA) has probably funded the most projects in this area. Through this research, we now have two distinct users defined as the primary user (PU) (i.e. those who own the license for the frequency range) and the cognitive user (CU) (i.e. those users trying to share the spectra either by using broadband signals or sampling the spectra in time and transmitting when the PU is not transmitting). Most significant projects in this area include the DARPA XG program and the Wireless Network after Next (WNaN) program. In addition to these efforts, there has been a move to apply Cognitive Radio (CR) technologies to the radar domain (Cognitive Radar efforts) and radio networks. Some of these systems sample the spectrum and transmit if no one else is transmitting at any given frequency. This approach can cause electromagnetic interference (EMI) in nearby receivers. Many people have recognized this problem and have addressed it in many different ways [2 - 6]. Many of their solutions inherently assume they know information about the victim receiver, but do not address how this information is obtained. We propose herein two different approaches to solve this problem.

The paper is organized as follows. Section 2 briefly describes some cognitive radio and radar efforts. Section 3 defines the problem we address in this paper. Section 4 presents some potential solutions. Section 5 provides our conclusions and highlights some topics for future work.

2.0 Some Cognitive Efforts

Next Generation (XG) Program

The XG (neXt Generation Communications) program is developing an architecture that will open up the spectrum for more use by first sensing and then using unused portions of the spectrum. Some early goals of the XG program were:

1. Demonstrate through technological innovation the ability to utilize available (unused, as opposed to unallocated) spectrum more efficiently.
2. Develop the underlying architecture and framework required to enable the practical application of such technological advances.

Figure 1 from [7] is a logical functional diagram of the concept of operations of XG's policy-agile spectrum user, which uses a computer understandable spectrum policy capability. The major components are the Sensor (which senses the environment for determining its availability), Radio (the communications device that can dynamically change its emission and

reception characteristics), Policy Reasoner (manages spectrum policy information), and System Strategy Reasoner (manages the multiple radios on a platform).

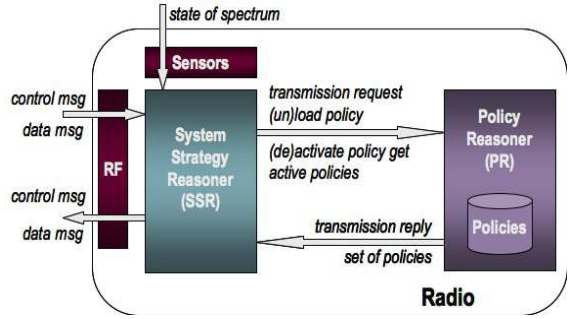

Figure 1.0 Policy-Agile Operation of XG Spectrum-Agile Radio

The last two components are of particular interest in that they utilize Semantic Web technologies. Operating a radio in different parts of the world requires that radios abide by the policies in the area where they are located. The XG program has developed its own XG policy language (XGPL) which uses OWL as its standard representation and will be implemented within the Policy Reasoner.

The Wireless after Next (WNaN)

The WNaN being performed by Raytheon BBN Technologies and funded by DARPA [8] is developing a scalable, adaptive, ad hoc network capability that will provide reliable communications to the military. The basic ingredients of their design are composed of a Dynamic Spectrum Address capability based upon the XG program. It also has 4 multiple transceivers and a disruptive tolerant networking (DTN) capability. The four transceivers provide fault tolerance and allows the system to pick the best channel for communications. The DTN capability allows the nodes to store packets temporarily during link outages. The WNaN also has content based access that allows users to query the network to find information and allow the system to store critical data at locations to minimize time and bandwidth. The system also has multicast voice with quality of service and the network protocols are designed for battery operated handheld devices with energy conserving capabilities.

Cognitive Radio

Another effort related to communications, and having similar goals to the XG program, is the Cognitive Radio [9]. Its objectives are to efficiently utilize the radio frequency (RF) spectrum and to provide reliable communications at all times. A basic cognitive cycle view of the radio is illustrated in Figure 2. A general overview and projections of the Cognitive Radio in our society can be found in [10].

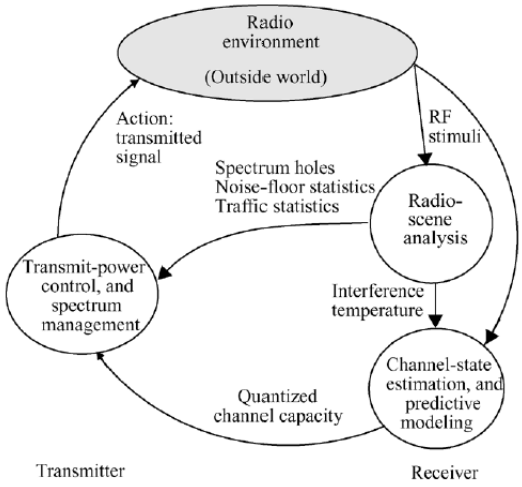

Figure 2.0 Basic Cognitive Cycle

Cognitive Radar

Interest in cognitive radar is growing in the radar community. Figure 3 describes a recent architecture we are currently working on while an earlier version is described in [11]. Figure 4 describes a cognitive radar that is primarily concerned with the tracking stages of a radar [12]. In Figure 5 a cognitive radar architecture is shown from the first textbook written on this subject [13]. The commonality of these designs are the feedback loop between the transmitter and receiver, use of outside sources of information, and the implementation of a learning process.

3.0 Problem Definition

In all of the above programs and many others, the CU chooses which frequency to transmit using frequency policy rules based upon location and whether someone is currently transmitting within the range of interest. There are at least three issues with this approach. The first is related to the sensing of the environment. What happens if a nearby receiver is not transmitting but is waiting to receive a signal at frequency f1, for example a bistatic radar receiver or an electronic warfare receiver? They don't transmit, they just receive. The second issue relates to the following scenario. Let us assume that one decides to transmit broadband signals below the sensitivity levels of any nearby receivers. As the number of CR increases, the signals within a nearby receiver's passband may exceed the noise floor and interfere with the performance of the receiver [14]. The third issue occurs when a CR decides to transmit at a particular frequency because there are no signals present. The chosen frequency is based upon a linear relationship between the frequency chosen and the sensed environment. The decision policy does not take into effect the nonlinearities between the chosen frequency and other nearby frequencies which can mix nonlinearly and cause receiver intermodulation or mix within the receiver's frontend and cause spurious responses. Most electromagnetic interference (EMI) situations are nonlinear and we must protect our own receivers.

If we are going to deploy cognitive radios and radars nearby conventional receivers we may have to rethink our current CR policy rules. To meet the challenges of the future we need to change.

EM Compatibility Paradigm Shift

EM fratricide is the situation where we degrade the performance of our own system(s) with our own system(s), e.g. an onboard radar's energy is received by an onboard communication receiver and that degrades the receiver's performance. This is a serious problem, since there are multiple sensor and communication systems onboard platforms. Military weapon systems are engineered to prevent such phenomena between hardware located in close proximity. The military has standards for describing how to build and test hardware for EMC, and how to test weapon system platforms for EMC, e.g. Military Standards 461E and 464. The DOD has also developed EMC prediction tools to assess the EMC of its weapon systems. These tools were developed during the 1970s and 1980s and have been enhanced and are used today. They were developed according to military standards to assure proper system's testing was performed, because most of the systems developed then were deployed in space where fixing EMI problems is not practical. Using software tools to perform EM measurements in the 1970s was a major paradigm shift for the EMC community.

Just as we needed a change by using software tools to assess a system's EMC in the 1970s, we now need to rethink how to build complex systems that employ waveform diversity and some of the proposed XG and cognitive radio and radar spectrum management concepts. Whereas in the 1970s we required software tools to predict where to hone our measurements, we now need to use software to help determine when EMI may occur in real-time, and manage the EM spectrum while the platform increases its total performance. This performance gain is not related to just one system onboard the platform, but to a system performance measure of the total platform, where the platform may contain communications, navigation, radar sensors, etc. The EMC tools used today assess the performance of an individual stovepipe system, e.g. the increase in bit error rate of communications equipment and the decrease in probability of detection for a radar. The predictions made by these performance measures are

usually related to the signal to noise plus interference ratios computed for each transmitter coupled to each receiver. The tools also compute the sum or integration of all transmitters' coupling into a receiver(s) along with a hypothesized EM spectrum, to represent the environment, and to predict an integrated or total EM ratio which can be related to a receiver's performance. This method identifies the performance of each receiver, but it does not alert us to the degradation of the total weapon system's performance. In addition, each computation is performed for a fixed set of operating conditions for each transmitter and receiver of EM energy. This approach is acceptable when analyzing a weapon system with conventional equipment, where each system's performance is assessed independent of all others. However, this is not acceptable for a weapon system or platform with a global performance requirement(s) or when the waveform parameters of one or more of its systems are changing in real-time e.g. a cognitive radio or radar. Our methods of building EMC systems must change to meet this dynamic environment.

4.0 Potential Solutions

To solve the issues discussed above some people are looking to change the beam pattern of the transmitter so that the power coupled to a victim receiver is reduced, some wish to change the transmitted signal's polarization, and of course, there is the attenuation gained by employing orthogonal waveforms. All these solutions help reduce the amount of degradation caused to a friendly receiver. However, these techniques inherently are assuming that one knows that the receiver is being degraded. How would a cognitive radar, radio or a WNaN know about the receiver?

There are currently two scenarios where one can implement a capability to solve the fratricide issue. One is on a single platform such as an aircraft, ship, or a complex weapon system where multiple conventional and cognitive EM equipment reside. The second scenario is concerned with WNaN where we propose to extend its capability and add a gateway to communicate with non cognitive radios as developed under another DARPA program. The EMC paradigm shift for both scenarios requires that the equipment report to a node that is managing the EMC of the platform or the total network.

Let us consider the single platform scenario first. The system strategy reasoner in Figure 1 and the strategy creator in Figure 3 need to be extended to handle our total platform with information being obtained from all the non cognitive receivers on or near the platform. We need a cognitive sensor platform network that can create strategies, evaluate them, learn and modify strategies as the platform sensor system operates. This learning should also be transferrable to other instantiations of the same type of platform.

The single platform scenario requires sharing information among sensors. Each of the sensors has its own signal and data processing capability. An intelligent processor is needed to address fusion, control, and communication between sensors. The goal is to be able to build this capability so that it can interface with any sensor and communicate using ontological descriptions via an intelligent platform network. The intelligent network will be able to coordinate the communications between the on-board and off-platform sensor systems. There are also communications issues that need to be addressed for the sharing of information and for minimizing the potential of EM fratricide. The intelligent platform should determine if there is EM interference potential when a sensor varies its signal characteristics which may cause interference to a receiving sensor. Rather than have each sensor on a platform operate as an independent system, one needs to design our platform as a system of sensors with multiple goals managed by an intelligent platform network that can manage the dynamics of each sensor to hopefully meet the common goals of the platform. This approach will require modifying current platform weapon systems which maybe very costly to implement.

Let us now consider the WNaN scenario of a Mobile Ad Hoc Networks (MANET) [8]. How will we know that the nodes on the network are causing fratricide to a nearby non cognitive receiver? One method is to communicate with friendly receivers similar to the first scenario discussed above. The second method is to use the research findings of another DARPA program called the US Army's Future Combat Systems Communications (FCS-C). This program has developed a Gateway [15] for conventional receivers. "*DARPA demonstrated that previously incompatible tactical radios can communicate seamlessly by using the network's Internet protocol layer. This method offers the potential for more affordable military communications between legacy and coalition radios in the future.*" If we add this approach to the WNaN system it will be possible to know when we are interfering with conventional receivers. According to [8], a capability to collect data as to the number of

packets sent for each node, priority type, emitted frequency by each node, etc. has been built. There exists over 300 statistics that can be gathered. If we fuse the gateway from the FCS-C program with the statistics gathering capability of the WNaN we may be able to infer when there is EMI caused to conventional receivers connected to either the WNaN system or the FCS-C system.

One approach would modify the conventional receivers to report when they are suffering EMI to the cognitive networks via the gateway. Another, and possibly less costly, approach is to infer when EMI has occurred by monitoring statistics at the gateway where the number of packet errors and resends are requested by the conventional receivers. A smart node could infer based upon the conventional receiver's tuned frequency and the nearby emitter frequencies, power levels, antenna gain patterns, etc. which non linear EMI situation is causing the fratricide. This cognitive approach can learn on the fly and restrict certain EM scenarios to alleviate the interference. If either of these approaches are implemented then another needed EMC paradigm shift will occur.

5.0 Conclusions and Future Work

Cognitive radios, radar and networks are a fascinating area of research. Once they are fielded they will unclutter the RF spectrum for future use. More research is needed to make these systems compatible with conventional transceivers. The potential solutions presented herein should be pursued so that systems and networks can self heal from any EM fratricide that can occur. However, to do so the system must know that a receiver is being degraded. To make this happen one needs to study the FCS-C gateway approach, the WNaN gathered statistics, the logic to process these statistics to determine whether EM interference is occurring, how it was caused, how to eliminate the interference, learn from the process, and change the strategy. We also need to study how we can easily modify current systems such as an aircraft or ship and add an intelligence capability that will allow cognitive radios and radar systems to work compatibly with conventional transceivers while maximizing the performance of the total platform.

Ontological Decision-Making for Disaster Response Operation Planning

Aaron Wheeler, Jim Dike, and Michael Winburn
3 Sigma Research, Indialantic, Florida, USA

Abstract – *Disaster response operation planners could benefit from a software tool to assist them in extracting individual mission information from various operation tasking orders, determining resources able to carry out the operation, construct a number of alternative operation plans, alert them to mission-critical changes to these plans, and allow them to quickly replan when problems occur. Within the context of aircraft operation planning for disaster relief, we use an ontological approach to solve these problems that includes modeling the air coordination plan (ACP) knowledge domain with OWL and SWRL, making inferences about the capabilities of real-world resources using an automated reasoner, retrieving relevant operation planning resources with SPARQL, then building multiple plans from the results of the queries. We also use SPARQL queries of the operation planning ontology database to provide alerts to operation planners of potential mission-critical changes to resources. Our results show that this approach allows operation planners to generate and monitor aircraft operation plans having dependencies on aircraft and pilot availability, weather effects on payload effectiveness, flight route distance, and fuel availability. We conclude that an ontological approach to aircraft operation planning does work and also supports broader goals of data transparency, information sharing, and domain knowledge persistence.*

Keywords: ontology, decision-making, operation planning, disaster response

1 Introduction

Large-scale disasters come from many sources, ranging from natural events like hurricanes, tornadoes, earthquakes, fires, famines, volcanic eruptions, or tsunamis; to human-made crises like nuclear accidents or political unrest. Aircraft provide a critical component to first response and longer term disaster recovery.

This research focuses on operation planning of air support for disaster recovery from natural and human-made disasters and political unrest. Specifically, we introduce a methodology for automated reasoning about operation plans to support disaster response decision-making.

Because of their ability to avoid ground obstacles, aircraft provided critical components to disaster recovery, including communication, aerial reconnaissance, supplies, and evacuation. Consider the following disaster recover scenario.

Suppose that a category five hurricane strikes a major population center on the coastal United States. Winds and flooding destroy communication and transportation networks, while people lack food, water, shelter, and medical care. Disaster response operation planners use aircraft to provide a number of basic needs. They deploy a drone aircraft to circle the affected area with a payload to provide an ad hoc private cellular network to first responders. Helicopters bring smart phones to emergency responders already on the ground so they can collect and share situational awareness data (GPS linked text, audio, still pictures, and video) with each other and with the command center located outside the affected area. Other drone aircraft provide aerial reconnaissance to assess damage and look for victims. Operation planners send helicopters to evacuate victims. Both helicopters and fixed-wing aircraft drop supplies to those stranded but not in immediate danger.

Unplanned changes to aircraft status and pilot availability, supply shortages, weather conditions, and scheduling conflicts, to name but a few complications, require operation planners to have a number of contingency plans and to know quickly when the current plan cannot succeed and replanning must occur.

Section 2 of this paper provides background information about our proposed system architecture, how ontologies can support emergency operation planning, and specific ontologies for aircraft operation planning. Section 3 describe the steps for generating primary and contingency operation plans using our ontological approach. Section 4 discusses our main findings, and section 5 concludes with a brief description of a current project that we intend to apply these transformations, and also a discussion of future research directions.

2 Background

This section introduces the Semantic Emergency operation planning with Ontological Reasoning (SEMPOR) system architecture and the Semantic Web technologies used by SEMPOR to reason about aircraft operation plans.

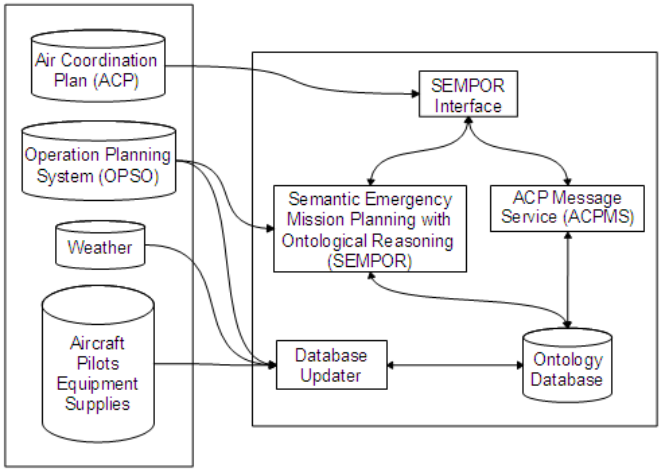
Aircraft operation planning for disaster response and for military operations share a number of similarities. Therefore,

we leverage the same terminology when appropriate. This has the advantage of supporting cross-domain information exchange and coordination, especially important during emergency situations.

2.1 System Architecture

Figure 1 below shows the SEMPOR system architecture. The left set of components represent the various data sources from which SEMPOR will extract relevant data in order to construct and update operation plans. SEMPOR itself comprises the components to the right.

Figure 1. SEMPOR System Architecture.



The Air Coordination Plan (ACP) database stores the current air coordination plans. The Operation Planning System (OPS) provides flight route details to the reasoner. Other data sources provide up-to-the-minute weather status, as well as details about mission-critical assets like aircraft, pilots, equipment, and supplies. SEMPOR may interactively query these data sources for specific information instead of using all possible information available about each operation asset.

Disaster response operation planners interact with SEMPOR and the ACP Message Service (ACPMS) through a graphical user interface. Both SEMPOR and ACPMS retrieve information from an ontology database. The ontology database contains specially formatted data collected from a variety of data sources that SEMPOR needs to generate operation plans.

2.2 Ontologies

The Extensible Markup Language (XML) provides language for describing the structure of information to support automated processing [8]. The XML Schema Definition (XSD) language contains type and element definitions that describe characteristics of well-formed elements and attributes of XML documents [9]. However, the XSD language does not express semantics [14] and so creates difficulties for Semantic Web technologies.

An ontology provides a formal description of a domain of discourse [1] and represents a core component of the Semantic Web. The World Wide Web Consortium (W3C) has recommendations for expressing ontologies using RDF [10], RDFS [11], and OWL [2].

The Resource Description Framework (RDF) represents a W3C standard for the Semantic Web that makes statements using subject-predicate-object triples [10]. RDF Schema (RDFS) extends RDF by allowing for the definition of classes and properties that describe other classes and properties [11].

Both RDF and the OWL 2 Web Ontology Language provide a formal semantics for interpreting ontology structures. OWL extends RDF and RDFS with terminology to express ontologies using description logic, a decidable fragment of first order logic [12]. OWL DL ontologies belongs to subset of OWL ontologies that satisfy the expressive requirements of a description logic. The expressiveness, completeness, and decidability of OWL DL makes it possible for automated reasoning engines to discover new information implied by ontology structures [13].

SEMPOR uses several Semantic Web languages to represent, reason about, and query for data needed to construct aircraft operation plans.

SEMPOR uses the Web Ontology Language (OWL) to describe our aircraft operation planning domain and the real-world resources needed for operation plans. OWL-DL, a subset of the full OWL specification, allows us to describe aircraft operation planning concepts and resources using a decidable and complete subset of first-order logic called description logic (DL). OWL-DL semantics allow for automated reasoning about classes and properties of things [2].

OWL allows us to make inferences about additional class memberships and properties of entities. However, we cannot automatically create relations between individuals based on comparisons of their explicit or inferred properties. In order to accomplish this type of reasoning, we use the Semantic Web Rule Language (SWRL) [3]. Rules in SWRL resemble production rules (e.g. "if X and Y then Z") in that individuals that match a conjunction of conditions will trigger or fire another set of conditions from which we can infer still more class membership and property relations for the individuals.

SEMPOR uses the SPARQL Protocol and RDF Query Language (SPARQL) to retrieve data from the inferred data model. The Resource Description Framework (RDF) provides a formalism for making statements about resources in terms of subject-predicate-object triples. SPARQL resembles

Structured Query language (SQL) used for querying relational databases, but includes Uniform Resource Identifiers (URI) for globally unambiguous queries [4].

An ontological representation of aircraft operation planning supports the W3C Decisions and Decision-Making Community Group objective of developing a semantic representation of decision-making concepts to improve sharing and use of decision information across diverse systems [7].

2.3 Ontologies for Operation Planning

SEMPOR uses several domain ontologies expressed using OWL and SWRL. Some of these ontologies we constructed specifically for SEMPOR, while others represent OWL versions of XML schema already developed to express ACP and related resources. We use a semi-automated approach to make the transformation from XML to OWL.

The Air Operations Community of Interest (AOCOI) has developed a number of XML schemas to describe air operations resources and concepts. They developed these schema with the intent of "enabling data transparency across the Air Operations domain, enable standard data-driven services for managers at all levels and reduce data entry, homegrown systems, and the need for record re-creation" [5]. We have chosen to use their vocabulary, taxonomy, and semantics in SEMPOR to support this effort and provide a foundation for better coordination between civilian and military responders during times of crisis.

The AOCOI has XML schemas (version 1.0.15.2) for Airspace, Common Mission Description (CMD), Friendly Order of Battle (FrOB), Mission Task Request (MTR), and Reference [5]. We have transformed to OWL the CMD and FrOB XML schemas to use in our prototype some of the terms these schemas contain. The CMD ontology provides use with concepts like ConfigurationItem and RampFuel, while the FrOB ontology gives us terms like BurnRate.

The Operation Planning Ontology contains concepts and properties specific to operation planning and also a representation of operation planner knowledge and reasoning. The Operation Asset Ontology contains representations of all operation assets not already represented by other ontologies.

3 Operation Planning

Now we enumerate the steps that operation planners and SEMPOR will follow during the course of generating air operation plans.

1. Collect information relevant to the operation from the ACP and other data sources.
2. Create in the ontology database a prototype operation plan.
3. Apply a reasoner to the ontology to infer candidate operation plan elements.
4. Build operation plan alternatives from these candidate elements.
5. Rank the operation plan alternatives from most to least preferred.

We will describe each of these steps in more detail in the sections to follow.

3.1 Data Acquisition

Collect information relevant to the operation from the ACP. Data relevant to the operation gets retrieved from their respective data sources and stored in the ontology database using OWL classes, relations, and values. This data acquisition strategy allows us to use heterogeneous data sources.

3.2 Operation Plan Prototype

SEMPOR assumes that the operation planner will create a high level description of an operation plan as part of the operation planning process. This high level specification will describe abstract planning elements from which SEMPOR can infer real elements using OWL and SWRL.

Figure 2 below shows an example of the information contained in the operation plan prototype. The operation planner provides an abstract description of each class of thing that could serve in the role of a particular operation plan element. In this example, the operation plan needs only one element. Classes of things that could perform the role required of this element appear in ***option1***. This entity has relations to two configurations, one specifying a hoist for lifting people and equipment and the other a cellular base station payload. Anything that SEMPOR can infer has one or both of these configurations can become an element in this operation plan.

Figure 2. Operation plan prototype data.

```
operation_plan
   startTime
   endTime
   flightTime
   needsElement value option1

option1
   hasConfiguration value proto_conf_hoist_4
   hasConfiguration value proto_conf_cellular_2
```

Note that SEMPOR interprets multiple needsElement and hasConfiguration differently. SEMPOR interprets multiple needsElement relations using a logical AND, meaning the operation plan must have "this element AND this

element AND ...". However, SEMPOR interprets multiple hasConfiguration relations using a logical XOR, meaning the aircraft operation plan must have only one of "this configuration OR this configuration OR ...". SPARQL queries and post-processing that we describe later will exploit these logical constructs to generate final operation plan alternatives.

3.3 Ontological Reasoning with OWL and SWRL

Describing operation planning resources and concepts with OWL-DL and SWRL allows us to use automated reasoners to make inferences over the logical structure of the knowledge representation. OWL-DL reasoners make it possible to discover implied relationships between real-world entities and use these to infer the suitability of aircraft and pilot for the air operation. We use the Pellet OWL 2 reasoner because it has a Java API, supports the latest version of OWL 2, and allows for most SWRL builtins [6].

We create in the ontology a class called ***Conf_Hoist_4*** to represent the set of things having a particular hoist configuration. We define the class by stating that individual entities belong to the set if they have both a ***has_ConfigurationItemObj*** relation to an individual that belongs to the set of ***Hoist*** things and a ***has_capacity*** property value of at least 500 pounds. Figure 3 below shows this graphically as a Venn diagram.

Figure 3. Logical AND with ontology concepts.

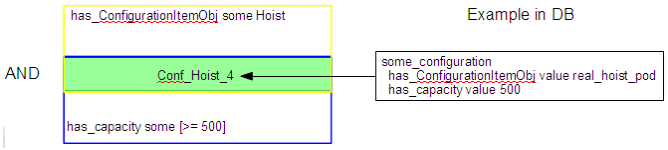


Figure 4 below shows a similar diagram, but for inference by logical OR. In this example, we define a class called ***AirAmbulance*** to represent the set of things with equipment capable of providing emergency medical support. Air ambulances can come equipped with a variety of medical payloads so we use a logical OR to capture them all in the definition of the set.

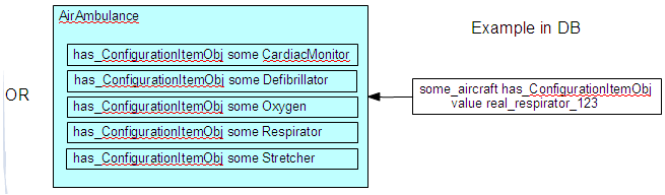
Figure 4. Logical OR with ontology concepts.



In both examples above, we could further specify that things that belong to one of the sets, either ***Conf_Hoist_500*** or ***AirAmbulance***, also have additional property values or relations to other individuals or types of things. In this way we can extend the number of inference steps that the reasoner can make, which could result in long and elaborate chains of reasoning that automatically find not so obvious classes, relations, and property values for individual entities needed for aircraft operation planning.

While OWL allows us to infer set memberships and additional property relations for individual entities, SWRL allows us to compare set memberships, relations, and property values of individuals then create relationships or assign property values. Figure 5 below shows a sequence of rules in SWRL that we use to assign additional characteristics to operation planning resources. The figure shows in words what the left-hand side (LHS) of each rule does and then shows on the right-hand side (RHS) in SWRL syntax the binding that results if the conditions on the LHS get triggered.

Figure 5. Sequence of rules for inferring additional properties.

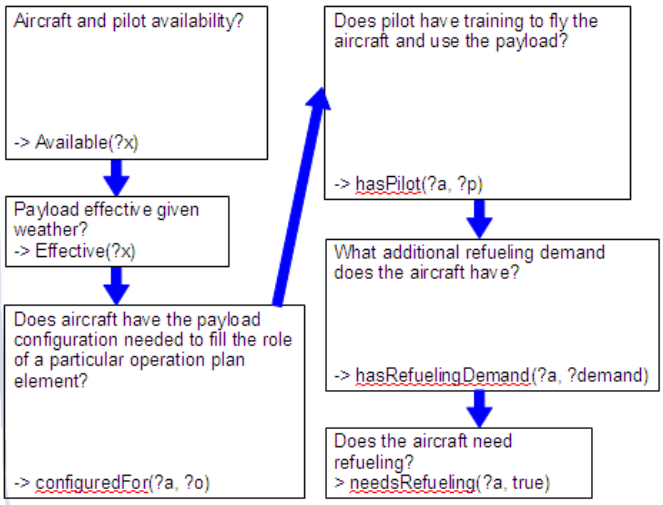


Figure 6 shows the LHS conditions in the SWRL syntax. For example, ***Available(?x)*** means that an individual instantiated on the LHS with variable ***?x*** belongs to the set of ***Available*** things. For another example, ***hasPilot(?a,?p)*** means that when the conditions on the LHS of the rule fire, the aircraft entity instantiated as the variable ***?a*** has a ***hasPilot*** relation to a pilot entity instantiated on the LHS with the variable ***?p***.

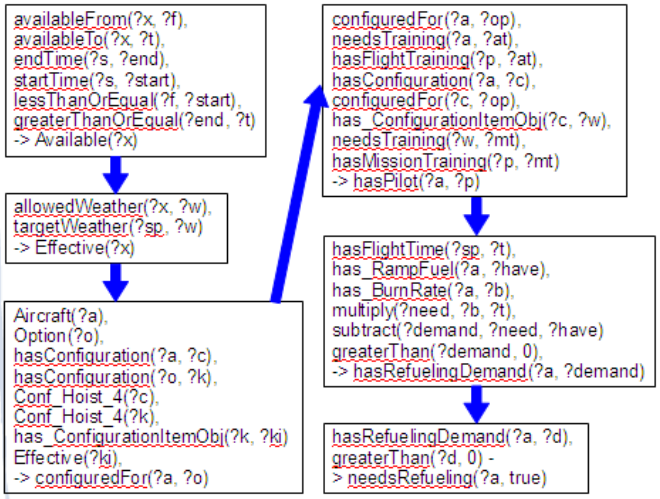
Figure 6. SWRL rules for inferring additional properties.



3.4 Ontology Database Queries with SPARQL

Automated reasoner, like Pellet load the explicit data model described with OWL and SWRL then makes an inferred model that contains statements implied by the logical structure of the explicit data model. SEMPOR uses database queries expresses with SPARQL to retrieve information from this inferred model.

Specifically, SEMPOR uses a SPARQL query to select for each inferred operation element the following values:

1. Operation element (e.g. option1)
2. Aircraft
3. Pilot
4. Configuration item (e.g. hoist_1)
5. Refueling demand

Figure 7 below shows the SPARQL query used by SEMPOR to retrieve these records from the inferred data model.

Figure 7. SPARQL query to retrieve operation elements.

```
select ?o ?a ?p ?ci ?rd
where {
      ?a a sp:OperationElement .
      ?a sp:configuredFor ?o .
      ?a sp:hasConfiguration ?c .
      ?c sp:configuredFor ?o .
      ?c cmd:has_ConfigurationItemObj ?ci .
      ?a sp:hasPilot ?p .
      ?p a sp:Available .
      ?a sp:hasRefuelingDemand ?rd .
}
```

SEMPOR uses the information obtained from the SPARQL query to construct aircraft operation plans, which we describe in the next section.

3.5 Aircraft Operation Plan Construction

SEMPOR now has a set of records from the SPARQL query from which it can construct aircraft operation plans with real resources that fit the requirements for operation elements requested by the operation planner in the prototype plan. The algorithm proceeds as follows.

First, divide the query results into separate lists based on the option. Each option represents a choice SEMPOR makes for a particular operation plan element. A prototype operation plan with two elements should have two options and two lists containing at least one record. This assumes at least one real resource exists that meets the requirements for the operation plan element. Next, pick one record from each list and generate an aircraft operation plan. Finally, repeat for every combination of records from each list.

For example, suppose we have a prototype operation plan that specifies two elements. The results of the SPARQL query give us aircraft1 and aircraft2 for option1; and aircraft3 and aircraft4 for option2. The algorithm creates operation plans from all combinations taken from these two lists. Specifically, SEMPOR creates the following combinations of operation plan elements:

- aircraft1 and aircraft3
- aircraft1 and aircraft4
- aircraft2 and aircraft3
- aircraft2 and aircraft4

Each of the combinations of elements above becomes part of an operation plan specification that gets returned by SEMPOR to the operation planner.

3.6 Real-Time Alerts

The ACP Message Service (ACPMS) provides real-time alerts to operation planners to keep them informed of changes in the status of both resources belonging to existing primary or contingency operation plans and to resources that could allow for new aircraft operation plans.

ACPMS monitors for changes to the ontology database. When the ontology database gets updated, ACPMS performs a number of SPARQL queries using the named entities in the primary and contingency operation plans.

Currently, ACPMS applies SPARQL queries to he ontology database to verify the following remain true;

- pilot available
- aircraft available
- aircraft has the required equipment configuration
- equipment remains effective for the weather conditions at the target
- aircraft has the same refueling demand

ACPMS alerts the operation planner to any deviations in the above conditions, as well as notifying the operation planner that more resources might have become available. The operation planner can then replan or select a different contingency plan.

4 Discussion

Our research efforts thus far show that we can

1. Represent mission-critical real-world resources with OWL and SWRL Semantic Web languages.
2. Capture operation planning knowledge and reasoning using OWL, SWRL, and SPARQL.
3. Use automated reasoning to infer implied relationships in an explicit data model of operation planning concepts and resources.
4. Query the inferred data model to obtain candidate operation plan elements.
5. Construct a primary operation plan and several contingency plans.
6. Recognize changes to operation plan elements and to the operation planning resource database that could affect existing operation plans or provide additional operation plan alternatives.
7. Alert operation planners to changes in near real-time.

5 Conclusions

We conducted research using an automated reasoner on an ontological data model of operation planning resources and concepts to determine the feasibility of the approach for ultimately developing a software tool able to meet the needs of operation planners. Among these needs include the ability to extract specific operation information for Air Coordination Plan (ACP), collect and organize data required for each mission, and verify the suitability and availability of all resources, both people and equipment, needed to carry out the air operation.

The results of our investigation show that our approach can indeed meet the needs of operation planners in their task of building and maintaining multiple operation plans. Through our research we have demonstrated that our ontological approach allows operation planners to generate and monitor aircraft operation plans having dependencies on aircraft and pilot availability, weather effects on aircraft and equipment, flight route distance, and fuel available.

In addition to satisfying these requirements, our approach has a number of additional advantages. First, the ontologies we use derive from AOCOI XML schema. This means our work supports AOCOI efforts to provide data transparency and sharing across both civilian and military Air Operations domains. Second, the ontological reasoning uses set theory in ways similar to how operation planners might combine pieces of information to construct operation plans. Third, the ontological models we develop capture the operation planning thought process in a form readable by both people and computers. Finally, having captured operation planning knowledge in an open data standard, our approach allows for the preservation and conveyance of operation planning decision-making in support of the W3C Decisions and Decision-Making Community Group [7].

Abductive Requery

Joshua Powers, David Skowronski and Tony Stirtzinger
Securboration Inc., Melbourne, FL, USA

Abstract – *We present an abductive approach to query formulation based on ontology and semantic rule content. Traditional Decision Logic ontologies offer scant opportunity for the application of abductive inference. When augmented by semantic rule languages such as SPIN, however, abduction becomes an attractive possibility for the targeted exploration of potentially large or virtual data sources. We describe a method of pre-processing such rules for use in abductive reasoning. We also describe rule selection and re-query formulation methods once a set of A-Box statements is presented to the abductive reasoner. Our approach assumes that the majority of A-Box content is virtual, ie, not realized until specifically asked for from non-ontology sources such as databases and/or unstructured text documents.*

Keywords: Abduction, Ontology, Query Generation

1 Introduction

Web Ontology Language (OWL)-based query languages such as Semantic Web Rules Language (SWRL)[1] and SPARQL[2] (and its SPIN[3] expression) provide the ability to both query an ontology for facts, and assert new facts in the ontology based on existing statements. This latter style of constructive rules is an attractive mechanism for obtaining some of the deductive benefits of OWL-Full reasoning while keeping the T-Box ontology expressed at the easier to manage OWL Lite or OWL-DL levels.

Such rules in and of themselves are still purely deductive in execution, usually possessing a large number of antecedents which must be matched by some A-Box statements in order to license the production of their consequent statements. However, this population of antecedent/consequent groups has great potential for the application of abductive reasoning.

Traditional abductive reasoning 'works backward' from discovering that something which is a consequent of a rule is true, to 'guessing' that the antecedent(s) are true. We propose an extension of this reasoning to work from some reasonable subset of antecedents and consequents to produce both new statements licensed by the rule, as well as new queries which are more specific in nature than the original rule. Such queries, if satisfied by further deductive reasoning over the A-Box or by providing direction to a fact extraction capability over source data, would potentially corroborate or invalidate the abductive step.

This paper describes an approach to preparing a large population of SPIN CONSTRUCT-style rules for this expanded abductive reasoning. We describe a mechanism for selecting such rules given a set of input OWL statements, and reformulating them into both abductive conclusions and further queries. We report some early results using these techniques, and suggest several directions for future research.

2 Motivation

The motivation for our work derives from two situations regarding ontology-based reasoning. The approach we describe is largely dependent on these factors being present. First, the basic OWL statements of the ontology in question are augmented by a reasonable population of SPIN language rules. Second, the A-Box is incomplete, and not fully realized without expensive querying of non-RDF data sources such as databases and/or natural language extraction results. This last motivator separates our use case from much of the theoretical work in this field, but makes it directly applicable to many scenarios faced by RDF-based analytical capabilities.

In working with large OWL ontologies, we have found that asserting logic via the construction of complex, anonymous Restrictions is frequently unwieldy for a variety of reasons. First, they are difficult to document and interpret between human authors and users of ontologies, and are thus likely to be the cause of unexpected and difficult-to-debug deductive inferences. Second, they are 'baked in' to the ontology, and are hard to suppress from reasoning as a result. This makes it difficult to be selective on which kinds of statements we wish to create via invocation of the reasoner. Third, depending on which flavors and versions of OWL we have chosen to use, we may not be allowed to state the logic we would like to express.

To alleviate these difficulties, it is often desirable to express such logic as CONSTRUCT rules in the SPIN language, and use a rule engine to produce new deductions when desired. Such rules are easy to document and read, can be invoked at will, and allow a wide range of expressivity, even if the underlying T-Box they are executed against is a simple flavor of OWL such as OWL-Lite.

SPIN rules with explicit antecedent-consequent structure often place a large set of very detailed requirements in the

antecedents, including rdf:type statements about entities and object properties holding between them. When working with incomplete data sets, we often wish to know what facts could be likely given a set of assertions, even if every detail about them is not currently known. Further, we would like to know what additional queries we might execute against a data set if we wanted to be more certain of the likely new facts. This is especially useful in situations where our source data is contained in non-RDF data stores and/or unstructured text sources which must be selectively processed with expensive entity and relation extraction capabilities in order to populate our A-Box with potentially corroborating information.

3 Related Work

Elsenbroich et. al. (4) call for the development of abductive approaches to reasoning over ontologies and knowledge bases. They define several attractive qualities of such reasoning: Consistency, Minimality, Relevance and Explanatoriness. The approach described in our paper cannot guarantee any of these qualities, but uses the ontology's T-Box statements and the content of the SPIN rules in a way compatible with their spirit.

Kiefer (5) gives a very thorough overview of many potential abductive approaches to reasoning in the Semantic Web context. We have not incorporated probabilistic reasoning in our current design, although this is frequently done in abductive approached.

Du et. al. (6) wish to adhere quite strictly to the Minimality and Consistency qualities, and define a logic programming approach to a subset of OWL which can satisfy these goals.

Kevorchian (7) describes some features of query-initiated abduction which have a parallel to the context assumptions we make in our approach.

4 Approach

We decided early on not to adhere strictly to the consequent → antecedent path which is the strict definition of abduction. We also wanted to cover cases where many but not all of a SPIN rule's antecedents were present in the input statements, and to produce subsequent queries which would search for both the remaining antecedents as well as the consequents.

We approach the abductive requery task in two parts: An indexing phase where SPIN rules are analyzed for potentially useful groups of statements which may appear in initial queries; And a query-time phase when initial queries are compared to this index on the SPIN rules and additional queries are constructed.

4.1 Indexing Phase

We calculate SPIN rule **fragments** which are all combinations of SPIN rule statements sizes 2-n where n is the number of statements in the original SPIN rule. We consider antecedent and consequent statements together, with no differentiation. Pure abduction would, of course, require at least one consequent statement be present in each fragment, but due to the potential incompleteness of the data, we would like to be more forgiving with respect to potential input queries. The total number of fragments is thus:

Clearly, this produces a large number of fragments, many of which are unlikely to produce useful abductive results. We would like to prune the fragments before we attempt to use them in the query-time phase.

4.1.1 Example

The following SPIN rule states the antecedents required to conclude that a person is a grandmother:

```
CONSTRUCT {
  ?p1 grandmotherOf ?p2 . }
WHERE {
  ?p1 parentOf ?p3 .
  ?p3 parentOf ?p2 .
  ?p1 rdf:type Person .
  ?p2 rdf:type Person .
  ?p3 rdf:type Person .
  ?p1 gender Female . }
```

This rule produces 120 fragments, among which are those that follow, which are annotated with their intuitive abductive use:

Fragment 1:

```
{ ?p1 grandmotherOf ?p2 .
  ?p3 parentOf ?p2 . }
```

"If we know that there is a grandmother of a parent of a child, then we suspect that the grandmother could be the parent of that child's parent. We furthermore suspect that the grandmother is Female."

Fragment 2:

```
{ ?p1 rdf:type Person .
  ?p2 rdf:type Person . }
```

"If we know there are two People, then we suspect the first Person could be a grandmother, the second Person could be a parent, and that there is a third Person who is their grandchild and child, respectively."

Intuitively, the likelihood and usefulness of the abductive interpretation of the first fragment is much greater than that of the second. To exploit this intuition, we assign weights to the statements of each fragment. Weights are based on the subclass or subproperty depth of any Properties, Classes or Individuals in the statement. Subclass depth is calculated as the number of direct subClassOf assertions

from the named Class to owl:Thing in the ontology. Subproperty depth is composed of three parts: 1) the number of direct subPropertyOf assertions from the named Property to ObjectProperty or DatatypeProperty in the ontology; 2) The subclass depth of the domain constraint of the named Property, if any; 3) The subclass depth of the range constraint of the named Property, if any. Individuals have the subclass weight of the deepest parent for which there is an explicit rdf:type statement in the ontology. We then weight the fragment with the sum of its statements' weights.

4.1.2 Example

In our example, the grandmotherOf and parentOf Properties are 2 levels deep in the ObjectProperty hierarchy and have domain and range constraints of Person, which has a subclass depth of 3. Our weighted example fragments from Example 4.1.1 thus become:

Fragment 1 (weight = 16):

{ ?p1 grandmotherOf ?p2 . (weight = 8)

?p3 parentOf ?p2 . (weight = 8) }

Fragment 2 (weight = 8):

{ ?p1 rdf:type Person . (weight = 4)

?p2 rdf:type Person . (weight = 4) }

Fragments with a weight below a given threshold are removed from consideration. The rest are stored in the index which contains the weighted statements and pointers to the rules they came from. Note that in a large collection of SPIN rules, it is likely that multiple rules will contain some of the same fragments. Each fragment is indexed in turn with any named Classes, Properties and Individuals found in its statements. The index is now ready for use in the query-time phase.

4.2 Query Phase

The input to this phase is a collection of statements. As mentioned in Section 2, these statements may be a partially resolved SPARQL query still containing some open variables, or they may be ABox statements generated by some inference, extraction or other analytical process. For our purposes, they are considered to be true statements upon which we will base our abductive assumptions.

The first step of resolving the query is to find the fragments which use the same named Classes, Properties and Individuals as can be found in the input statements. The depths of the statements found in the fragments are then used to rank those fragments.

4.2.1 Example

Given the following input statements:

UID1 grandmotherOf UID2 .

UID1 rdf:type Person .

UID1 hairColor Red .

The rule fragments we have seen during the indexing phase in Section 4.1 are partial matches for this set of input statements. Specifically, Fragment 1 matches because of the grandmotherOf statement in the input query, and is thus given weight 8. Both of Fragment 2's statements match because of the same tdf:type Person statement in the input query. Because they both match the same input query statement, they are only counted once, to provide weight 4. The input query statement about hairColor does not match any fragment, and provides no weight.

Fragment 1 (weight 8):

{ **?p1 grandmotherOf ?p2 . (weight = 8)**

?p3 parentOf ?p2 . (weight = 8) }

Fragment 2 (weight 4):

{ **?p1 rdf:type Person . (weight = 4)**

?p2 rdf:type Person . (weight = 4) }

In this simple example, there is not support from multiple input query statements to fragments, but this support would be additive if it existed.

Fragments are then sorted by their weighting against the input query statements, and the full SPIN rules they are found in are then weighted by the contributions of the fragment weightings. In the example, both Fragments 1 and 2 come from the same SPIN rule for grandmothers, so this rule is assigned a weight of 12.

Now with a list of weighted SPIN rules and the input query statements, we produce a version of the SPIN rule with as many open variables bound to Individuals, Classes and Properties as possible from the input. This binding process can be potentially computationally expensive if there are many candidate input Individuals which could validly bind to open variables in the SPIN rule. Our current approach is to prune rules which would produce more than a handful of SPIN rule interpretations.

4.2.2 Example

Our example input and rule share the unique grandmotherOf assertion which limits open variable binding ambiguity. The individuals used in the input statement take the place of the open variables in the SPIN rule:

CONSTRUCT {

UID1 grandmotherOf UID2 . }

WHERE {

UID1 parentOf ?p3 .

?p3 parentOf UID2 .

UID1 rdf:type Person .

UID2 rdf:type Person .

?p3 rdf:type Person .

UID1 gender Female . }

Two sets of information are now available: fully bound statements from the original SPIN rule which can be taken as abductive inferences; and a new, more specific SPIN rule which can be issued as a SPARQL query against data sources which may result in further variable bindings and abductive processes. Of the two bolded statements above, the knowledge that UID2 is a Person could of course have been determined by deductive inference using the range constraint of the grandmotherOf Property. The knowledge that UID1 has the gender Female is something which may only have been possible to discover by referring to the SPIN rule, although in many ontologies, Restrictions are used to produce these kinds of inferences. The more specific version of the SPIN rule which is to be used as a SPARQL query is constructed as follows:

```
SELECT ?p3
WHERE {
  UID1 parentOf ?p3 .
  ?p3 parentOf UID2 .
  ?p3 rdf:type Person . }
```

UID1 and UID2 are assumed to have been named in the data source(s) from which the original input was taken, and are thus available as query elements. The additional information about their relationship to each other does not need to be restated in the next query. Intuitively, we have determined that to gain more complete knowledge of the situation, we should search our data for some Person who is both the child of the grandmother and the parent of the grandchild.

5 Results

To test our approach, we generated a basic familial relations ontology which included Class and Property hierarchies. We then built a population of 20 SPIN rules describing family relationship structures as well as family events such as marriages. We aligned this ontology to the Basic Formal Ontology[8] to give some reasonable depth characteristics of our Classes and Properties. The shape of the ontology is summarized in Table 1.

Metric	*Measurement*
Classes	6
ObjectProperties	12
Avg Class Depth	7.5
Avg Property Depth	3
SPIN Rules	20
Avg Consequent Statements	1.8
Avg Antecedent Statements	8.5

Table 1: Test Ontology Metrics

5.1 Index Phase Results

We set the threshold for fragment depth relatively low so that we could avoid 'trivial' fragments that contained only rdf:type statements for mid- or high-level classes such as Agent, Entity, etc. Table 2 presents the nature of the resulting rule fragments and index produced for the test ontology.

Metric	*Measurement*
Raw Rule Fragments	1054
Average Fragment Weight	40
Fragment Threshold	20
Fragments Passing Threshold	728

Table 2: Review Metrics for Wine Ontology

We used an HBase database to store the index contents.

5.2 Query Phase Results

To date, we have not integrated our approach with capabilities which could issue our reformulated queries against live external data sources. We constructed a number of statement sets which were representative of possible starting queries a client might have. We then queried the fragment index and calculated the subsequent requeries as we described in Section 4.2.

Results appeared reasonable when manually reviewed. Predictably, we found that the more vague the starting point, the larger the number of suggested subsequent queries. When input statements were about specific consequents, the suggested subsequent queries supported finding evidence about the antecedents.

6 Conclusions and Future Work

We believe our approach has merit in scenarios where: the T-Box is primarily Class and Property hierarchies; there is a large population of semantic rules; and the full population of the A-Box is impossible to achieve 'all at once,' and must be built iteratively using contextually relevant query and extraction processes.

Clearly, we intend to integrate the abductive requery approach with a system including a large but incomplete A-Box and a query mechanism for extracting or discovering new statements based on some kind of requerying. We believe that there are many use cases in areas such as social networking, unstructured text mining and Big Data exploration.

More focused areas for expansion of our work are described in the following sections.

6.1 Incorporating Restrictions

Until the development and use of OWL-compatible semantic rule languages, OWL Restrictions were the primary method of stating rule-like information by using subclass and equivalent class statements in conjunction

with quantification on properties. We intend to 'convert' these constructs to antecedent-consequent structures and add them to the index and requery process.

6.2 Further Exploiting Class and Property Hierarchies

We have not incorporated basic Class and Property subsumption in our query phase approach, relying on input statements to be asserted at the same 'level' in the ontology as the SPIN rule statements are asserted. In our context of an incomplete A-Box, we intend to explore both generalizing: if input statements are either 'a Person has an email address' or 'an Organization has a mailing address', we want to match a SPIN rule which requires 'an Agent has an Address'. But we also want to explore 'unmotivated' specialization such as matching an input statement which says 'an Organization has a Budget' to a SPIN rule which requires 'a Public Company has a Budget.'

Preliminary Experiments on Literature Based Discovery using the Semantic Vectors Package

M. Heidi McClure
Intelligent Software Solutions, Inc
Colorado Springs, CO 80919

Abstract— *This paper presents a literature based discovery (LBD) implementation that uses Lucene for indexing, the Semantic Vectors (SV) package for latent semantic analysis, Neo4j for graph database storage, Gephi for visual representation along with custom code written by the author. The approach of using a latent semantic analysis based systems like SV to do LBD is not new, but going the next steps of examining related concepts and using a graph database representation for finding candidate linking terms is. The LBD system is a framework where relation extraction experiments may be performed. This paper presents work that is in progress.*

Keywords: literature based discovery, semantic vectors package, relation extraction

1. Introduction

Literature based discovery (LBD) has been around since the 1980's when D. R. Swanson first defined LBD as a means to discover previously unknown knowledge by examining term occurrences across multiple documents [16]. This paper presents an implementation that uses variations on latent semantic analysis (LSA) to perform LBD-style discovery. Studies of using LSA to do LBD have been documented by various authors, among them are *[14], [11], [19].* LSA discovers semantically related concepts giving stronger correlation scores to more strongly related concepts. When a pair of concepts that have a significant semantic relatedness score from LSA and that are never mentioned in the same document or documents, you have an LBD candidate pair. The other pairs of candidate related concepts are that are mentioned in one or more of the same documents may also provide important information. These two sets - LBD candidate pairs and share-document-mention (SDM) pairs present data that allows a next level of discovery which is the discovery of candidate linking terms. The process of using graph database navigation across all related concepts found with LSA to discover new linking-concept candidates for an LBD candidate pair is the new approach presented in this paper.

The system presented in this paper handles these tasks: corpus generation, candidate related entities discovery and relationship analysis. The corpus generation retrieves document data from databases or from text files (including XML). All data is pre-processed by applying various normalization tasks to the data. The pre-processed data is placed on the filesystem where each document is in a separate text file. Candidate related entities discovery task indexes the data, performs forms of LSA and identifies the concept pairs with the highest relatedness scores. Relationship analysis is the final task of identifying the candidate linking concepts. This is done by first retrieving all documents relating to a candidate pair, determining which are LBD and which are SDM candidate pairs. Then the concept linked to concept as an LBD or an SDM pair is captured in a graph database. Last candidate linking terms are discovered by traversing the graph database. This work is not complete and is a work in progress and will provide the framework system on which more advanced relationship discovery will be performed.

The rest of this paper presents some background information on LBD, LSA, and Random and Reflective Indexing (RI and RRI) which are enhancements to LSA. It presents some details of software components and data used in the design and test of the system including the Semantic Vectors (SV) package, Lucene, Neo4J, Gephi and the MEDLINE data set. It presents the design of the system and discussion of the results. The end of this paper presents some conclusions and ideas for the future directions of this work.

2. Background

2.1 Literature Based Discovery

LBD is the discovery of hidden knowledge in large sets of documents where the discoveries relate concepts A and C together. In LBD, a single document in the corpus will not contain the discovery. Sometimes a linking term, B, may be the means by which A and C are discovered and B would be in all documents containing A or C. In statistical approaches to LBD, there may not be a linking B term in the discovery - instead, A and C are discovered by semantic relatedness of the documents using, for example, latent semantic analysis (LSA) techniques. Once candidate discoveries are found, experiments may be performed to prove or disprove the hypotheses.

As various works state, Don R. Swanson [16] is considered to be the first to have mentioned the LBD style of discovery [13], [10], [15]. Swanson manually reviewed medical journals in one of his studies and found mentions of Raynaud's syndrome and its relation to various blood issues like problems with blood

viscosity, platelet function and vascular reactivity. Then he looked for discussions of these blood issues in articles that did not mention Raynaud's and found associations between the blood problems and fish oil. The connection made is that, perhaps, Raynaud's syndrome could be treated with fish oil. Medical studies have since been able to validate this discovery.

Since his initial study, Swanson and many other researchers started to apply automation to the task of LBD. Initially works would look for candidate B linking terms simply by their co-occurrence in the A-term documents then use these B terms to candidate documents where A is not mentioned. Then would try to find, again with co-occurrence, candidate C terms in the new set of documents. They sometimes used lists of words (vocabularies) to restrict which words they considered in each search - when list is used for both A and C concepts, the LBD system is called a closed system. An open system considers a a list of words only for the starting concept, A. [10]

This initial work is a closed LBD work, but future work plans to use the open approach.

2.2 Latent Semantic Analysis

LSA came initially from the Latent Semantic Indexing (LSI) work done by Scott Deerwester, Susan Dumais and and others [9] and used in LBD by Michael Gordon and Dumais [11] - LSA does not require, necessarily, a vocabulary, but, instead, finds similar documents based on LSI. LSA assumes that if terms or concepts are found in similar sets of text (not always the same text) then these terms or concepts may be related, the same or similar concepts. The mathematics behind LSI uses singular value decomposition (SVD) to reduce the dimensions of extremely large matrices by getting rid of less interesting data and to discover the related terms in documents. LSI proved to be more efficient than previous methods and has been moderately successful, however, it's still slow and computationally expensive.

2.3 Random and Reflective Random Indexing

More recently, Cohen, et al. [8] experimented with random indexing (RI) - a more scalable version of LSI - and extended the RI concepts to support indirect inference. Indirect inferences is what Cohen, et al. sometimes call LBD. RI is uses a random approach to further reduce the size of matrices being analyzed to discover similar terms in documents. Instead of a full term by document matrix, documents are placed into small sets of columns. For example, if there are 10,000 documents, a document may be assigned to 20 randomly chosen columns. Each document's term frequency information is tallied in each of its columns along with any other document that was randomly assigned [12]. Cohen, et al. also experimented with variations of RI - Sliding windows on RI, Term based Reflective Random Indexing (RRI), and Document based RRI. RRI uses RI but does it using results from one RI process and feeding it into another pass of RRI. Term and document based RRI vary how the random indexing is chosen - by term or by document in various passes through the RRI. Their claim is that these techniques provide more related terms/concepts that may not co-occur in the same document but are possibly related. They state that their use of RRI techniques is better suited for LBD.

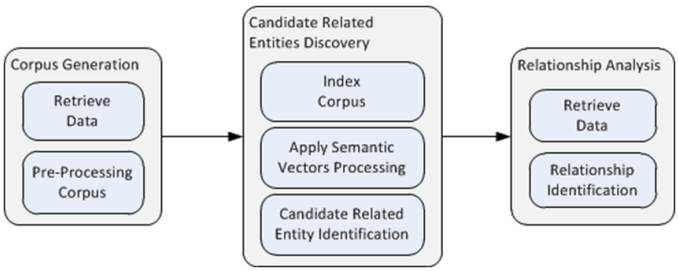

Fig. 1: Architecture

3. Design

This section describes the general design of the SV-based LBD system. There are multiple steps performed that ultimately present pairs of entities that may be related and presents candidate linking terms. The general architecture of the system is shown in Figure 1.

The steps noted below align with the small boxes in the architecture diagram.

1) **Retrieve data** and place each document into a separate text file on the computer filesystem. The data tested so far, has been in database as reports summarizing, for example, news articles, as web pages or as other text data. Data also has been in databases as copies of emails and has been in large XML files which needed to be broken up to get text documents. An example of XML files is the MEDLINE data presented in this paper where the resulting document pulled from the XML is just the abstract of the article.
2) **Pre-process the corpus** mostly to identify the concepts we wish to analyze. This makes a copy of the original filesystem documents and tags the new documents as necessary. Today this consists of doing some simple normalization of the data turning "John Doe" into "johnxxxdoe" so that the next step of indexing doesn't need to have custom indexing capabilities implemented. In other words, multi-word tokens have been turned into single words. Lowercase is being used because the SV package works best with all concepts in lower case.
3) **Index the corpus** using Lucene indexing as described in the semantic vectors package. The SV package uses the Lucene index to help build the SV vector files. See [6] for more information on Lucene.
4) **Apply semantic vectors processing** to create document and term vector files. Term vectors are not simple word

count per document vectors. They are vectors where the entries represent a term's relatedness to random sets of documents. Comparing the vector for two different terms (i.e. concepts) presents a score that gives the LSA relatedness of the two terms.

5) **Candidate related entity identification** is performed by comparing the term vectors for each entity as discussed in previous step. Some term pairs come up with a 1.0 score indicating the strongest relatedness - since there's probably nothing new to discover with this pair, these terms are ignored in LBD processing. Similarly, terms with zero or negative scores are also ignored.
6) **Retrieve documents** for the related entities. Finding these documents is done by going back to the original Lucene index created before SV processing. Returned are documents that mention either of the entities or both. At this time, identification of LBD candidates is done by finding the pairs of related entities that are never mentioned in the same documents.
7) **Relationship Identification** involves
   a) examining documents where entities appear together
   b) when entities are LBD candidates, identify candidate linking B terms. This may be done navigating the graph looking for terms that are linked to both the A and the C terms. There are examples of this presented in the results section.

   Explaining why entities may be related is the primary area of future work planned by the author.

In the next subsections, a small amount of detail is provided about some of the tools and API's used in this work.

3.1 Semantic Vectors Package

A byproduct of Cohen's work to improve LSI [8] is the Semantic Vectors (SV) package. This open source java software initially written by Cohen's co-author, Dominic Widdows, and now maintained by he and many others under a Google code project - [18]. SV provides a library of capabilities that perform random indexing which performs much faster than SVD. SVD is an N x N problem where matrices will get to a size that current computing capabilities will now allow them to be computed. RI can do LSA-like analysis on millions of documents. For this work, terms are compared to identify relatedness.

3.2 Lucene indexing

Lucene [6] is a set of java libraries that, among other things, allows for the searching of terms and phrases in sets of text documents or other representations of text like PDF's, HTML, Microsoft Word, etc. Lucene creates index files that contain the necessary information to not only find terms or phases quickly that may be contained in a corpus, it also is able to indicate where in the document the terms or phrases are. Lucene provides fast and efficient search capabilities.

In the LBD solution presented here, Lucene indexes are created first and then the Semantic Vectors package is used to find candidate LBD pairs. Once pairs are found, the Lucene indexes are again referenced to find the documents in which entities are mentioned.

3.3 Graph database - neo4j

Running SV with term comparisons across a set of documents discovers pairs of concepts that may be related. A graph database that represents node X, node Y and the link joining node X and Y is a good choice for storing results of SV or any other results of latent semantic analysis. Graph databases are sometimes called NoSQL databases since data is not stored in a traditional table structure. Neo4j is an open source light weight graph database [7].

For this project, nodes are the concepts (for example, A, B and C concepts) and the links are either an LBD link where the nodes on either side of the link are never mentioned in the same document or a shared document link where the nodes on either side are both mentioned in one or more documents.

3.4 Visualization - Gephi

Once data is stored in a neo4j database, visualizing that data is important in order to assist in the analysis of results. Gephi is an open source graph visualization tool [5]. Martin Skurla created a neo4j plugin into Gephi during Google's summer of code, 2010. [4]

Once a neo4j database is loaded into Gephi you can show only LBD relationships (links) or show only shared common document relationships. The graph (link) pictures shown in this paper were created from snapshots of Gephi displays of neo4j databases.

4. Experimentation and Results

4.1 Data Sets

The current application allows flexibility in what steps of the LBD process are run and flexibility in what data are used. For example, MEDLINE data used in experiments presented here are pulled out of XML files using python scripts that place each abstract into a separate file on the filesystem. Data may come from, for example, an Enron email corpus that may be in a database or may just be files on a filesystem [1], [3]. When data comes from database queries, the "document" data usually is read from large text fields or sets of fields - the system presented here places this data onto the filesystem - one file per document.

MEDLINE is a National Library of Medicine database of biomedical literature that includes, among other things, the

```

Fig. 4: Sample Candidate B Terms

titles and abstracts of over 21 million articles from over 5000 different journals and publications [2]. This data is stored in many XML files. For this effort, the python script used pulled each abstract for the years of interest and placed each into a file on the filesystem. Initial experimentation used all the abstracts from 1980-1984 which simulates rough dates used by Don Swanson in his initial LBD work [16]. This date range created 692,382 total file documents.

4.2 Output

MEDLINE data was analyzed by the system using approximately 190 candidate A and C concepts that were gathered from two papers - one that discussed fish oil and Raynaud's [11] and the other that discussed both fish oil - Raynaud's connection and migraines and magnesium connection [17].

During the processing of results, a neo4j database was created that ultimately allows for visual display of results. The Neo4j database contains nodes that represent documents and links that are named either an LBD relationship or a share-document-mention (SDM) relationship. If the relationship between two nodes is an LBD relationship, that means the nodes were never mentioned together in the same document.

The system also creates summary results in a set of text output files. In order to keep the number of result pairs to consider a manageable size, an algorithm is currently used that returns either a hard number of results or a percentage of total pairs discovered. Some of the generated output files contain:

1) All related pairs - pairs that share mentions in documents and those that don't. The ones that don't will be LBD pairs. The SV score is also captured for each pair. See Figure 2
2) All LBD pairs - in order to discover the LBD pairs, the Lucene index is queried to find all documents in which the terms are mentioned. If there are no documents in common (bothAandCDocs = 0 in the LBD Pairs output), then this is an LBD pair. For preliminary work, only a maximum of 100 document matches is allowed for this result reporting. See Figure 3
3) All candidate linking terms - this file is the result of navigating the Neo4j graph database to find candidate B linking terms between the LBD pairs reported in the second list (All LBD Pairs). The first two terms are the LBD pair, the last is the candidate B term. See Figure 4

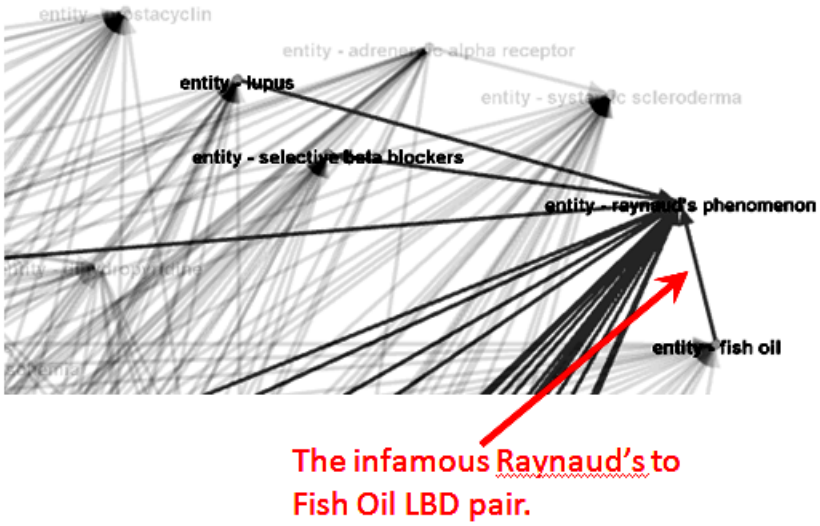

Fig. 5: Highlight Raynaud's and see LBD candidate pairs

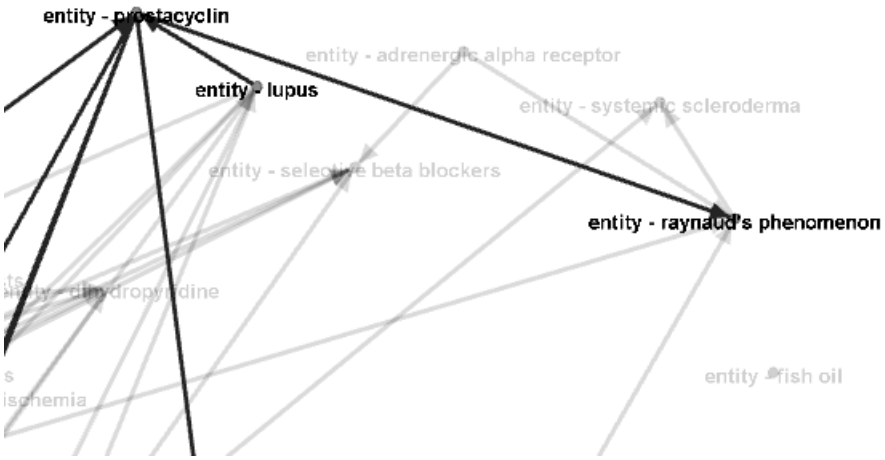

Fig. 6: Terms that share document references - A and C concepts, Lupus and Raynaud's, linked by B concept, Prostacyclin

4.3 Analysis

In addition to the text file results, the Neo4j database loaded into Gephi, the graph visualization tool, provides help in visualizing what's in the data. In Figure 5, all of the medical concepts that had an LBD relationship with Raynaud's phenomenon are highlighted. Simply mousing over the Raynaud's node performs this highlighting. From this visualization, we see that Raynaud's phenomenon is related, via LBD, to Lupus, selective beta blockers and fish oil - again, it's LBD because the links shown are only the LBD candidate pairs. As in Swanson's work [16], fish oil and Raynaud's phenomenon are never mentioned in the same documents. In Figure 6, only links where the entities actually are mentioned in the same documents are shown. This particular view where prostacyclin is highlighted shows that prostacyclin may be a linking B concept between the A and C concepts - Lupus and Raynaud's phenomenon. In Figure 7, we can see that adrenergic alpha receptor is a concept relating selective beta blockers and Raynaud's phenomenon together. In this same diagram, we notice that fish oil had no candidate linking terms to Raynaud's - this is probably due to the small subset of A and C concepts analyzed in this early testing (as noted earlier, approximately 190 terms were used for candidate A and C concepts).

5. Conclusion

I have presented an approach to discovering hidden knowledge in documents using a latent semantic analysis variant from the semantic vectors package. My approach discovers candidate

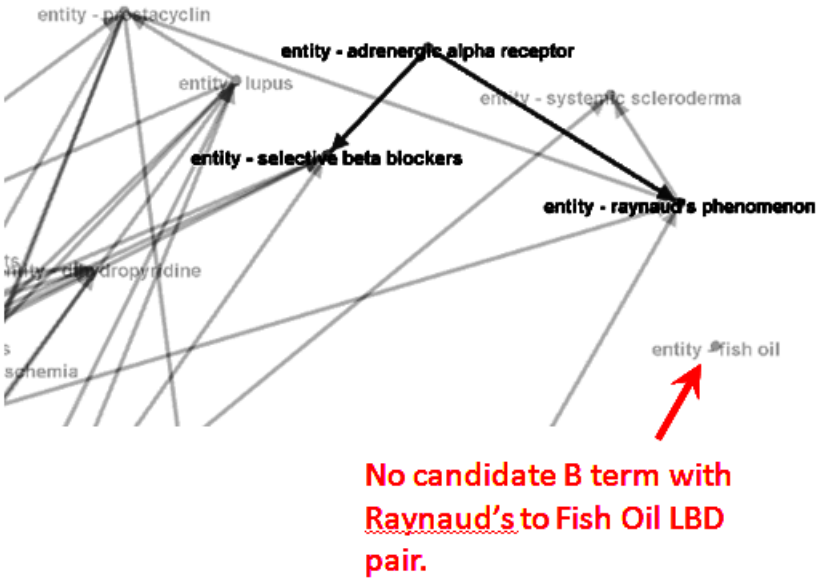

Fig. 7: Terms that share document references - A and C concepts, selective beta blockers and Raynaud's, linked by B concept, adrenergic alpha receptor. Note that no candidate term found between Raynaud's and fish oil.

A and C concepts or terms which, although never mentioned in the same document, may be related. I have also discovered candidate linking or B terms that relate the A and C. To the best of my knowledge and research, identifying the linking B terms from the LSA results is something that has not previously been done.

This system provides the platform on which alternative approaches may be tried to improve the quality of the discovered pairs.

6. Future

I hope to complete the following major tasks.

6.1 Complete the Reproduction of Swanson Results

In order to test the results of this system, I have successfully shown that fish oil and Raynaud's are semantically related and are never mentioned in the same documents in the 1980-1984 corpus. Using the evaluation methodology described by Meliha Yetisgen-Yildiz and Wanda Pratt [20], the next step is to examine the corpus of documents after 1984 to see if the LDB candidates are mentioned in the same documents, thus, perhaps, proving that there is now a confirmed and important relationship between the LBD candidate pairs. There are other published results based on MEDLINE that use LBD to discover previously unknown related concepts. I may try to recreate those discoveries, also.

6.2 Making Operational Solution

I plan to examine how analysts, scientists or other users might use the capabilities of the system presented in this paper. If I can refine the system so that fewer false positives are presented, users may find great benefit in the kind of discoveries that LBD presents - that is, the previously unknown and hidden knowledge that is in existing data.

6.3 Relationship Extraction - Discovering the Why

I plan to take the results - the candidate LBD pairs and perhaps the linking B terms - and try to figure out why the concepts are related. That is, try to explain the relations. Initially, I plan to try relationship extraction approaches that have already been published with the hopes of refining these techniques to fit with that data and to provide more accurate results.

6.4 Open LBD

The approach I have taken to date is a closed LBD solution where we know what A and C concepts to study. The next step is to expand this work to perform Open LBD where the C concepts are not known. To do this, candidate C concepts are discovered using natural language processing (NLP) named-entity (NE) extraction techniques to identify the kinds of concepts we are interested in. For example, when using medical domains, drugs, diseases, symptoms or side effects will be tagged by NLP NE extraction and then used as candidate C

concepts. When studying, for example, the Enron email corpus, people, places, organizations or events will be tagged.

Semi-Autonomous Hierarchical Document Classification Using an Interactive Grounding Framework

Jacob Staples[1], **Attila Ondi**[1], **and Tony Stirtzinger**[1]
[1]Securboration, Inc., 1050 W. NASA Blvd., Melbourne, FL, USA

Abstract - *Organizations must evolve internally over time to better fulfill their missions. The structural complexity inherent in a large organization can impede an agile evolutionary process, however. In this work we describe a tool created to ease the process of structural evolution within a large, complex and hierarchically organized organization. This tool analyzes request for change documents provided by low-level personnel unfamiliar with the overall organizational structure and determines which portions of the organization will be affected. This task is accomplished using natural language processing to extract relevant textual features from request for change documents and machine learning techniques to ground these features to relevant concepts corresponding to affected portions of the hierarchy. The initial groundings are refined through an interactive question-answer session with the user providing the request for change document. The tool is shown to have desirable convergence traits and a high degree of accuracy.*

Keywords: Machine learning, NLP, Neural networks, Hierarchical document classification, Automatic document classification

1 Introduction

Organizations must evolve internally over time to better fulfill their missions. The larger the organization, the more thoroughly a potential change to its structure must be vetted as even a minor change requires significant monetary and policy commitment. In this work we propose a mechanism for easing the interaction between the low-level users who are most readily able to recognize the inefficiencies in an organization and the high-level managers who are most able to remedy them. This mechanism will be discussed in the context of a hypothetical system representing a simplified version of a real-world product.

In this system, users who notice an inefficiency or unaddressed need in their day-to-day operations may electronically submit a request for change (RFC) document to a managerial team with a good understanding of the organization's structure. The managerial team then reviews these RFC documents and determines what action to take on them. One significant problem with this process is that the content typically provided by users who create RFCs is poorly aligned to the information a reviewer needs to quickly analyze the impact of the RFC. For example, RFC authors are typically most concerned with their individual ability to improve day-to-day operations whereas RFC reviewers are more interested in the impact on the organization as a whole. In this work we describe a mechanism for determining the organizational impact of RFC documents automatically for an organization whose structure is ontologically modeled. This means that users need not spend valuable time researching information which will not directly benefit their daily activities and managers need not delve too deeply into the minutiae of daily operations. The communication between the two groups can therefore be conducted much more efficiently because users write RFCs using language they understand and reviewers receive a summary of the information they need which has been automatically derived from the user's RFC.

The determination of organizational impact is conducted in two phases. The first is performed autonomously using NLP and machine learning techniques to determine the document content and compute an initially large number of potential areas of impact within the organization. The second is an interactive state where questions are asked of the user to refine the coarse results obtained during the first phase. The final result of these two phases is a document which can be quickly and easily scanned by a RFC reviewer to determine the impact of a proposed request for change within the organization.

2 Related Work

A common and well-established problem in machine learning is automatic document classification [1] in which a text T is categorized as applying to one of several concepts (topics). A simple extension of this problem is to ground T to a set of concepts C by some numerical measure of the relative strength of the correlation between T and each concept $c \in C$ present in the text. For example, if we ground text instance Tx to a set of four concepts {*concept1*, *concept2*, *concept3*, *concept4*} then Tx might ground to *concept1* with a weight of 0.4, *concept2* with a weight of 0.9, *concept3* with a weight of 0.05 and *concept4* with a weight of 0. The magnitude of these weights implies the quality of the grounding relative to the other links (in this example, *concept1* is grounded 8 times as strongly as *concept3* by Tx). This process is commonly referred to as multi-topic text classification [2].

Many automatic text classification systems are naïve in that they make the following assumptions about the text documents on which they operate:

1. The probability of a feature occurring in a text is independent of the length of the text
2. The probability of a feature occurring in a text is independent of the existence of other features in the text

For very large numbers of documents concerning a large number of unique topics produced by a large number of unique individuals, these assumptions are a close enough approximation to average behavior that naïve Bayesian or similar classifiers are often quite accurate. Our application is significantly different from such scenarios, however. We observed lengthy Request for Change documents to frequently contain many of the same words, a violation of the first assumption listed above. For example, nearly 20% of the RFC documents longer than 100 words contained some form of the word "requirement" as a noun compared to just 3% for those shorter than 50 words. Additionally, because the RFC documents typically deal with similar subject matter, the second assumption listed above is often violated. For example, a document containing the word "money" is significantly more likely to contain the word "expenditure" than a document which does not. With too few training examples to average out the violations listed above, the discrepancies between the naïve assumptions of simple classifiers (such as Naïve Bayes) and reality are greatly exaggerated. For these reasons, our initial attempts to utilize a naïve Bayes classifier for this application were unsuccessful and we turned to a new type of supervised learning classifier.

3 Approach

To automatically determine the organizational categories embodied by an RFC document, a text-to-concept grounding engine was developed incorporating elements of natural language processing, machine learning and similarity testing. The classifier portion of the engine analyzes the natural language content of the RFC document and, based on the key features identified, prompts the document submitter for answers to clarifying questions. The answers provided by the user help to narrow down the candidate categories for the reviewers, reducing or eliminating the need for follow-up communication.

The organizational model is quite complex with a total of 687 organizational area concepts hierarchically organized under ten main branches with a maximum depth of seven children. RFC reviewers desire the most applicable concept nodes to be returned regardless of their position in the hierarchy (i.e., leaf nodes are not favored above internal nodes simply because they are lower in the hierarchy).

3.1 Grounding abstraction

At its most fundamental level, our classification system operates on a set of features F extracted from a given text T and a set of relevant concepts C' to produce a score mapping function $M:\{c \in C'\} \rightarrow R$ which generates the affinity of the text for each relevant concept $c \in C'$. This mapping function comprises our grounding of the text T.

Our grounding mechanism (classifier) operates in a similar fashion to a 2-layer neural network [3][4] where the input nodes are features observed in text and the output nodes are concepts in the hierarchy. As mentioned earlier, features can be any structure recognizable in text such as words, phrases, sentences, word groups, etc. The features we utilize are stemmed lemma/POS pairings although any feature type or combination thereof is theoretically possible. Links between features and concepts are numerical relationships reflecting the affinity of a feature for a concept. A single feature can have multiple links (directed edges) to concepts but there is only ever one link between a single feature and a single concept. Links have a weight associated with them as mentioned earlier but they have an additional component called inertia which ensures that over time the link weight will become harder to change. This inertial property is analogous to the decaying training coefficient in neural networks and is useful because without it the link weights would oscillate wildly around spurious training instances.

3.1.1 Feature extraction

The features used by the classifier are extracted from the change request documents using a Natural Language Processing pipeline implemented using the UIMA [5] framework with OpenNlp [6] components augmented by a heuristic lemmatizer based on an extended WordNet [7] dictionary enhanced with the ability to recognize custom jargon terms which do not exist in a standard dictionary. The detailed description of the feature extraction algorithm can be found elsewhere [8]. Although the grounding mechanism suggested in this work supports nearly any conceivable variety of feature types and combinations of features, we achieved satisfactory results using only a single simple feature type created by appending the lemma and part of speech category for each non trivial word in the text.

3.1.2 Feature extraction

The features used by the classifier are extracted from the change request documents using a Natural Language Processing pipeline implemented using the UIMA [5] framework with OpenNlp [6] components augmented by a heuristic lemmatizer based on an extended WordNet [7] dictionary enhanced with the ability to recognize custom jargon terms which do not exist in a standard dictionary. The detailed description of the feature extraction algorithm can be

found elsewhere [8]. Although the grounding mechanism suggested in this work supports nearly any conceivable variety of feature types and combinations of features, we achieved satisfactory results using only a single simple feature type created by appending the lemma and part of speech category for each non trivial word in the text.

3.1.3 Grounding Engine

As mentioned earlier the classifier utilized in this work is a supervised learner operating on human generated text. Thus there are effectively two phases to document classification. During training, link weights between features observable in text and concepts corresponding to those features are created and evolved. During grounding, previously learned link weights are used to compute the most likely candidates.

Pseudocode of the training algorithm

```
TRAIN(GroundingNetwork g,
  TrainInst[] trainingDataset):
 for(TrainInst i:trainingDataset)
  Feature[] features =
    NLPEngine.parse(i.Text)
  Concept[] concepts =
    i.CorrectConcepts
  for(Feature feature:features)
   for(Concept concept:concepts)
    g.updateLink(feature,concept,
      trainingDelta)
   end for
  end for
 end for
END

GroundingNetwork.updateLink(
  Feature f, Concept c, Weight w):
 Link link =
  f.getOrCreateLinkToConcept(c)
 linkUpdates = link.getUpdateCount()
 m = 1/(linkUpdates+1)
 link.weight =
  m*(link.weight * linkUpdates +
     w * inertia(linkUpdates))
 link.incrementUpdateCount()
END
```

The inertia function should monotonically decrease as link updates increase to encourage link weight convergence. We found a simple linear inertial function to work well. Feedback to the classifier can be provided in an online fashion any time new training data is obtained (even after the initial training phase is complete). Similarly to a neural network, feedback training instances must account for the difference between false positive and false negative errors, a minor modification to the above algorithm reflected by the *trainingDelta* variable.

During classification, the learned links and weights obtained during training are utilized to compute which concepts are relevant to the text.

Pseudocode of the classification algorithm

```
CLASSIFY(GroundingNetwork g,
  Text t):
 Feature[] features =
  NLPEngine.parse(t)
 ScoreMap scores
 for(Feature f:features)
  Concept[] concepts =
   f.getLinkedConcepts
  for(Concept c:concepts)
   scores.addScore(
     f.getLinkWeight(c))
  end for
 end for
 return scores.normalize()
END
```

The scores for each concept grounded by at least one feature in the text are computed as the normalized weighted sum of the feature to concept link weights in the grounding network. This is similar to node scoring in a neural network.

3.2 Interactive refinement

After scoring, we obtain a score distribution for concepts as shown in *Figure 1* below for two sample documents. The case-1 document is lengthy at over 150 words and the case-2 document is quite brief consisting of only three key words. It is interesting to note that the case-1 document has a relatively smooth distribution of scores for higher scoring concepts which are grounded by many feature to concept links but this distribution becomes more discontinuous for the lower scoring concepts which are grounded by fewer and fewer words. The case-2 document has a discontinuous distribution over its entire concept space.

Ideally this distribution would have a few concepts with very high normalized scores which could be classified as "correct" and the remaining concepts would have scores of zero and could be classified as "incorrect." As the distributions above indicate, however, the reality is more complex in that there may be dozens of scores within a single standard deviation of the best score. We observed that the top five to ten highest scoring concepts had a very high likelihood of being close to a correct concept in the hierarchy but had a lower probability of being absolutely correct. We also observed that in some instances the initially suggested concepts after thresholding were incorrect either because the language used in the RFC document was significantly different than the language on which the classifier was trained or because of ambiguous links between features and concepts as discussed later.

To handle both cases, after obtaining the grounding weights for each concept in the hierarchy for a given RFC document, we select a set B of the k best scoring concepts to use as a starting point for interactive refinement, or elicitation, which attempts to determine which concepts are actually correct. It is important to note that the choice of k is entirely arbitrary but we select it to be large enough to ensure a high degree of recall at the cost of low precision (experimental results revealed that for our purposes this occurred around k=10). This coarse set is then refined via a multi-question interaction with the user.

There are two phases in the elicitation process. In the first, the classifier assumes the initial candidate nodes are close to the correct concepts but are not exact matches (this is a good assumption since the classifier is tuned to achieve high recall but low precision). For each initial candidate, a neighborhood of nodes whose geodesic distance is less than $\boldsymbol{\delta}$ from the initial candidate (which becomes the centroid of the neighborhood) is created. The objective of phase I elicitation is to eliminate one or more of these neighborhoods. In phase II, the classifier zeroes in on a single neighborhood (the one determined to be best after analyzing the user responses from phase I) and attempts to eliminate individual concept nodes.

Questions are built using features and are of the form "*Which of the following are pertinent to your requirement?*" followed by a pick $\boldsymbol{s}$ of $\boldsymbol{n}$ multiple choice question with various features which were not found in the text but which the classifier can use to best complete its objective for the current elicitation phase. For example, question options could include "*vision*", "*computer maintenance*", and "*operations overhead*". Elicitation begins in phase I and after either an arbitrary number of questions or some trigger condition is met relating to the number of candidate centroids eliminated, elicitation enters phase II. After each question is answered, the features selected are virtually added to the RFC list of features with some additional weight $\boldsymbol{\beta}$>1 relative to an original text feature.

The features selected for these questions could be randomly selected from a history of past features observed in text. The knowledge gained from these random features, however, would typically be quite small in the context of a centroid or specific concept since the features might not have ever been observed to be associated with the concepts in the neighborhood around the centroid. Our selection process for features therefore involves scoring each possible feature in terms of the relevance of the feature to the concept(s) needed in the current question phase, the coverage of the concepts by the feature, and the specificity of the feature to the concepts.

4 Results

To gauge the effectiveness of the proposed classifier in its problem domain we utilize an experimental dataset of 63 instances of RFC documents c whose correct classifications are known. These correct classifications cover a set of 97 of 687 total concepts arranged in a hierarchy. These classifications were carefully derived by hand by organizational subject matter experts and are the gold standard against which we compare document classifications. From this dataset, an arbitrary set of $\boldsymbol{t}$ training and $\boldsymbol{v}$ validation instances are randomly selected. Note that if $|t| + |v| > 63$ there is necessarily some overlap between training and validation instances (i.e., a document is validated over at least one instance on which it was previously trained). If $|t| + |v| \leq 63$ we ensure that no validation is performed on a document which was previously used for training.

The classifier is trained over each document in t using the correct classifications. The classifier is then tasked with classifying each validation instance v' in v. For each validation instance v' the classifier is invoked on the document text and the λ best-scoring concepts are interpreted as suggested classifications. These suggested classifications are decomposed into one of the following categories:

I. Exact match—the classifier selects a concept identified by the subject matter experts
II. Close match—the classifier selects a concept within δ hops in the concept hierarchy of a concept identified by subject matter experts
III. False positive—the classifier selects a concept which is not a close or exact match

Additionally, each of the concepts in the correct concept set is placed into one of the following categories:

I. Exact matched concept—the classifier selected this concept
II. Close matched concept—the classifier selected at least one concept within δ hops in the concept hierarchy of an objective concept.
III. False negative—the concept was neither an exact nor a close match

From these classifications we can determine the precision, recall, and fscore of the classifier's suggested classifications. We compute absolute precision and recall in terms of the number of concepts partitioned into each of the above categories as shown in the equations below.

$$P_{abs} = \frac{exact\ match}{exact\ match \cup close\ match \cup false\ pos.} \quad (1)$$

$$R_{abs} = \frac{exact\ match}{exact\ match \cup close\ match \cup false\ neg.} \quad (2)$$

The absolute F1-score, a metric which accounts for the compromise between precision and recall, is then computed by taking the harmonic mean of absolute recall and precision as shown below.

$$F_{abs} = \frac{2 \cdot P_{abs} \cdot R_{abs}}{P_{abs} + R_{abs}} \quad (3)$$

For each of the above metrics we also compute a closeness measure in which the set of exact matches is unioned with the number of close matches (in the case of precision) or close matched concepts (in the case of recall). Note that concept *c'* is close to concept *c''* if and only if the geodesic distance in the concept hierarchy between *c'* and *c''* is $\leq \delta$.

$$P_{close} = \frac{exact \cup close\ matched}{exact \cup close\ matched \cup false\ positive} \quad (4)$$

$$R_{close} = \frac{exact \cup close\ matched}{exact \cup close\ matched \cup false\ negative} \quad (5)$$

$$F_{close} = \frac{2 \cdot P_{close} \cdot R_{close}}{P_{close} + R_{close}} \quad (6)$$

We compute average classifier performance in terms of these metrics over 50 such randomly generated runs and additionally present the variance between runs for all metrics.

4.1 Ideal case behavior

Our first experiment is to gauge the best-case behavior of the learning algorithm. To do so we train the classifier using all of the correctly classified documents in *c* and subsequently task the classifier with classifying all of the documents in *c*. In this experiment we set λ to 10. An ideal learner would achieve perfect recall and precision after such training. The results of this experiment are shown below:

Table 1: Ideal-case classifier behavior for various performance metrics

δ=0, λ=10

	recall	precision	fscore
arithmetic mean	0.9649	0.3411	0.5040
harmonic mean	0.9649	0.3411	0.5040
variance	0.0000	0.0000	0.0000

δ=2, λ=10

	recall	precision	fscore
arithmetic mean	0.9781	0.7566	0.8532
harmonic mean	0.9781	0.7566	0.8532
variance	0.0000	0.0000	0.0000

We see that our classifier's absolute recall (δ=0) is quite high but not perfect. This is because during training many features were observed to become ambiguously linked to multiple concepts (i.e., multiple concepts had links from a single feature). Any document containing such an ambiguous feature has a nonzero probability of incorrectly grounding one or more of these ambiguously linked concepts in place of a correct concept, reducing recall. The precision of 0.34 for the δ=0 configuration indicates a high percentage of false positives and is an artifact of setting λ to a significantly higher value than average number of correct concepts per document, which was around 3.6 in this experiment (note that λ was set to 10). In the δ=2 configuration, precision improves because it accounts for concepts whose geodesic distance within the concept hierarchy is up to 2 nodes away from the classifier suggested node. We will study the impact of varying λ in more detail later. Note that there is no variance in these initial results because there is only one way to select 63 training and validation instances as described earlier (thus each run has identical results).

4.2 Real-world performance

Next we examine the impact of varying the training and validation set sizes. To understand the classifier's learning capability we utilize a validation set on which the classifier has not been previously trained. This simulates the more realistic case where knowledge acquired during training must be generalized to new instances in order to achieve correct classifications. An ideal classifier would generalize the results of the training set and achieve perfect precision and recall on a disjoint validation set whose entries were not previously encountered. The performance of our classifier over these more difficult cases is shown in the tables below.

Table 2: Real-world behavior

V=10, T=50 (δ=0)

	recall	precision	fscore
arithmetic mean	0.8241	0.2920	0.4259
harmonic mean	0.8160	0.2773	0.4139
variance	0.0067	0.0044	0.0039

V=10, T=50 (δ=2)

	recall	precision	fscore
arithmetic mean	0.9173	0.6064	0.7257
harmonic mean	0.9142	0.5942	0.7202
variance	0.0028	0.0071	0.0039

V=20, T=40 (δ=2)

	recall	precision	fscore
arithmetic mean	0.7803	0.3441	0.4686
harmonic mean	0.7714	0.3199	0.4523
variance	0.0068	0.0074	0.0070

Table 3: λ Impact on precision and recall

δ=0, λ=40

	recall	precision	fscore
arithmetic mean	0.9751	0.0878	0.1603
harmonic mean	0.9730	0.0825	0.1521
variance	0.0019	0.0005	0.0014

δ=0, λ=5

	recall	precision	fscore
arithmetic mean	0.7447	0.5212	0.6034
harmonic mean	0.7246	0.5064	0.5962
variance	0.0141	0.0077	0.0044

Although we observe a noticeable drop in recall versus the ideal case in all three of the above experiments, we see that the classifier consistently achieves good close recall (δ=2) provided the training set has good coverage of the concept hierarchy. By altering the λ parameter we can explore the tradeoff between recall and precision as shown below.

The results above were obtained on a 50T/10V configuration. As expected, at λ=40 we observe a significant improvement in recall (from 82 percent at λ=10 to 97 percent at λ=40) at significant cost in terms of degraded precision (29 percent to 9 percent). At λ=5 we observe the opposite trend—an increase in precision and a decrease in recall compared to the λ=10 configuration. At λ=5 we approach the maximum accuracy of the unaided classifier which was roughly 52%. Because this level of accuracy is not acceptable for our application, the approach we take is to set λ to a conservative value and refine our coarse results through elicitation.

4.3 Elicitation performance

As described earlier, the elicitation process effectively reshapes the score distribution curve. As an example, the impact of elicitation on a score distribution for the case-1 document described earlier can be seen in *Figure 1* below. Note that the concepts are ranked in descending order by score and are not ordered between runs. The highest scoring concept after elicitation was the 45th highest after a purely lexical analysis of the text (although a concept one node away in the concept hierarchy was the third highest scoring and would have been suggested anyway). The highest scoring concept after elicitation was aligned with subject matter expert opinion.

In general we observed elicitation to significantly improve the quality of the initially suggested concepts. This is because the close match recall of grounding engine is quite high but absolute precision is low. The elicitation process attempts to arrive at the correct concepts using the initial close-match concepts as a starting point.

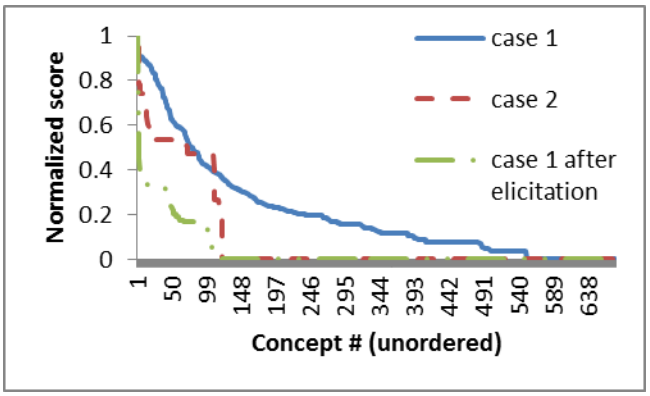

Figure 1: normalized score distributions for two sample documents

5 Conclusions and Future Work

We have demonstrated that the proposed document classification system is effective at determining the organizational impact of human produced RFC documents. We observed that the automatic classifications produced by the supervised learning classification system achieved good recall but low precision and these results were significantly improved through an interactive refinement with the user submitting the RFC document.

Although we achieved good results using simple word/part of speech features extracted from text, we believe our classification accuracy could be improved by using more advanced features such as phrases or WordNet synsets. Additionally, when selecting the initial neighborhood centroids for elicitation we utilized static thresholding with a fixed λ but it may be beneficial to arbitrarily adjust λ based on the distribution of scores returned after the initial classification. These are simple extensions of the system described.

[1]Securboration, Inc. 1050 W. NASA Blvd, Melbourne, FL, USA

Abstract - *Supervised machine learning algorithms, particularly those operating on free text, depend upon the quality of their training datasets to correctly classify unlabeled text instances. In many cases where the classification task is nontrivial, it is difficult to obtain a large enough set of training data to achieve good classification accuracy. In this work we examine one such case in the context of a system designed to ground free text to an organizational hierarchy which is ontologically modeled. We explore the impact of utilizing information garnered from a highly customized Natural Language Processing (NLP) analysis of this ontology to augment a very sparse initial training dataset and compare this to a more labor intensive extraction of a small set of key words and phrases associated with each concept. We demonstrate an approach with significant improvement in classifier performance for concepts having little or no initial training data coverage.*

1 Introduction

In this work we describe a software classification system which employs NLP analysis and machine learning algorithms to automatically determine whether a human produced text applies to one or more of a set of concepts. The machine learning portion of this system is essentially a supervised learner whose accuracy relies heavily upon the quality of the training instances it has encountered. Unfortunately the concept space over which this solution is deployed is sufficiently large that it was not feasible to obtain a large quantity of high-quality training instances. In fact, many concepts were observed to never be explicitly referenced by training instances. Although the classification portion of the system evolves dynamically to improve its classifications over time, the initial classifications produced by the system were of poor quality due to this deficiency of initial training data.

We discuss several approaches taken to improve these initial classifications and construct knowledge in the face of limited or absent training data. We compare two mechanisms of capturing expert user knowledge in terms of their impact on classifier accuracy and recall and how well they interact with traditional training instances.

2 Related Work

From a machine learning perspective, this work deals with the well-studied field of supervised learning algorithms [1]. There is a wide body of research related to applying such algorithms to human produced text, for an overview see [2]. Of particular relevance is the multi-topic document classification problem [3] in which a document is analyzed by a machine classifier and determined to be applicable or not applicable to a list of topics.

The sparseness of labeled training instances is by no means unique to this problem domain. Significant research has been conducted in the area of semi-supervised learners which attempt to generalize a small amount of labeled training data to a larger amount of unlabeled data which can subsequently be used for training. For a thorough overview of semi supervised techniques see [4].

In this work we examine a somewhat different position than that in which most semi-supervised systems are deployed, however, because we assume access to a limited number of labeled training instances but do not assume the existence of unlabeled training instances. Instead we assume access to expert generated knowledge either in the form of an ontology [5] modeling the structure of concepts in the concept space or in the form of a key-word document, either of which we attempt to derive unlabeled instances from and whose instance labels are trivial to reverse engineer from the ontology structure.

3 Approach

We explore two unique options to expand the initial classifier knowledge. The first is to exploit the knowledge of subject matter experts by hand-populating a database of key phrases they have determined likely to be associated with each concept in the concept space. The second approach is to utilize an expert-created ontology describing the nature and relationship between the concepts in the concept space to determine which lexical features are associated with what concepts by making the assumption that the definition of a

concept will contain language similar to the documents associated with that concept.

Though their angles of attack on this problem are quite different, it is important to keep in mind that these approaches are attempting to do fundamentally the same thing—derive new training instances which can be provided to the classifier. Before describing the mechanics behind generating these instances, we will give a brief overview of the classifier and its operation.

3.1 Classifier

The minutiae of the supervised learning classification algorithm utilized in this work are not germane to this discussion and are described elsewhere [10]. For the purposes of this paper, it is sufficient to understand the grounding engine mechanics for two key operations the classifier performs: classification and training.

Classification is an operation performed on a text document to determine which concepts are present in it. In order to classify a given document as exhibiting or not exhibiting a set of concepts, the document is first decomposed into features using Natural Language Processing (NLP) techniques described later. These features are provided as input to the grounding engine. The output of the grounding engine is a label for each concept indicating how confident the classifier is that the concept exists in the document whose features were provided. Note that the features passed to the classifier are either sense-ambiguous (for example a stemmed form of a word with some notion of its part of speech) or sense-specific (for example a WordNet synset identifier). In this work we explore the implications of each feature type.

Training is an operation performed on a text document and a set of labeled concepts indicating which are correctly or incorrectly associated with the text. When updated with a training instance, the classifier internally adjusts its structure such that in the future the features provided will be more likely to be associated with the concepts labeled "correct" and less likely to be associated with the concepts labeled "incorrect".

For clarity, we now introduce a logically distinct type of training, called bootstrap training, which differs slightly from the training described above. *Bootstrap training* is unique in that it is always performed before any standard training instances are encountered and is used to construct the initial body of knowledge needed to very roughly associate features with concepts. Because the bootstrap training labels in this work were implicitly derived, we could not make any assumptions about false negative concepts using a bootstrapping instance. When a bootstrap training instance was encountered, the classifier therefore only considered the concept arguments labeled as "correct" for the given text.

Bootstrapping is useful because, as mentioned earlier, for many of the concept types on which our classification system operated, there were a significant number of concepts having a trivial number of training instances (or none at all). Without some form of correction, these holes in the initial knowledge of the classifier meant that the classification algorithm would always assign some concepts zero confidence. Bootstrapping is less crude than the typical approach of assigning each concept a small virtual probability.

3.2 Feature extraction using Natural Language Processing

The features used as input to the classifier were extracted from document text via a NLP pipeline using the UIMA [6] framework and OpenNlp [7] components. The results of the OpenNlp components were augmented by a heuristic lemmatizer based on an extended WordNet [8] dictionary.

3.2.1 Custom WordNet dictionary

WordNet is a machine-usable dictionary of words organized into synonym sets (synsets). Each word in the dictionary is associated with a sense, which is captured by a synset; and each synset is associated with a textual description, along with the words belonging to this synset. In this sense the WordNet dictionary assumes the role of a thesaurus as well.

We modified WordNet in two ways to better fit the needs of the effort described here.

The first modification was at the content level—the dictionary lookup logic was modified to support customized synsets stored in a file. The addition of this custom read logic enables us to fully modify the WordNet dictionary by removing, altering, or creating new synsets in the dictionary. Nearly 1200 field-specific jargon and acronym terms were added to the dictionary. These 1200 terms were selected because they were important words previously discarded by the lemmatizer using a standard WordNet dictionary. After implementing the changes to WordNet the lemmatizer was able to recognize these terms as words.

The second modification was at the software level—the custom dictionary read logic was modified such that it loads all dictionary entries into memory (requiring around 350MB in our implementation). This change resulted in significant speedup over the file-based MIT implementation packaged with the dictionary for random word lookups. We observed a speedup of roughly 11x for random synset retrievals and 1.5x

for repeated synset retrievals compared to MIT's implementation. The lower speedup for repeated lookups is due to the use of caching in the MIT implementation, which mitigates costly file access times for dictionary entries which are frequently accessed.

3.2.2 Lemmatizer

Although the standard OpenNlp components provide reasonable accuracy for determining the correct part-of-speech (PoS) tags for words appearing in the document, the process is not perfect. To attempt to correct the erroneous PoS tags, we developed a custom component that uses simple heuristic rules to guess the potential textual form of the lemma of the word along with the correct PoS tag.

The lemma of a word is simply the base form of the word that forms the head of an entry in a dictionary (e.g. the lemmas of the words "ate" and "mice" are "eat" and "mouse", respectively). Our heuristic for finding the actual PoS tag for a word observed in a document uses the OpenNlp PoS tag guess for the word and the PoS tag of the previous non-filler word. If the custom dictionary contains a lemma/PoS pair matching the known lemma and OpenNlp PoS tag guess, the OpenNlp tag guess is assumed to be correct. Otherwise, we consult the dictionary using the following PoS tags (in the given order): verb, noun, adjective and adverb. The first matching PoS from this list when paired with the lemma is returned as correct. Note that the heuristic rules of calculating the lemma from the textual form of the word change based on the current PoS tag candidate. If no lemma/PoS tag matches an entry in the custom dictionary then the OpenNlp tag guess is assumed to be correct and the lemma is assigned the textual form of the word.

3.2.3 Sense disambiguation

The sense disambiguation scheme utilized is based on the Lesk algorithm described in [9]. The algorithm outlined below operates on sentences extracted from the document, performing the steps for each unprocessed word in the sentence. If, at any step in the algorithm, only one viable sense of the word/PoS remains, that sense is selected and the following steps are not performed.

First, exclude senses that are hyponyms of non-applicable senses (e.g. sport terms).

Second, check if senses from the current and another word are part of the same synset hierarchy; if yes, the corresponding senses are selected for both words.

Third, check if the current and the neighboring word are related to each other via lexical parallelism. Two words exhibit lexical parallelism if there exists a hypernym/hyponym (for nouns), similar-to (for adjectives), pertains-to or morphological similarity (for adverb) relationship between any of their possible senses. If lexical parallelism is observed, the senses in relation are selected for the corresponding words.

Fourth, if the current word is a verb, check if it is collocated with any of the neighboring word lemmas. A verb lemma is collocated with another lemma if the verb has a lemma in any of its hypernym synsets that is morphologically similar to the other lemma.

Fifth, perform the Lesk algorithm: check for maximum lemma overlap between the current sentence and the textual description of the possible senses.

Sixth, extract example usage from the sysnset textual definition and check for patterns with the neighboring words.

If all steps were successfully performed and there are still multiple candidate synsets associated with the word, all the remaining synsets are accepted as equally likely correct senses.

3.3 Bootstrapping mechanisms

We explored two options for generating the bootstrapping training set. For both options, we attempted to use both sense-ambiguous (lemma/PoS pair) and sense-specific (synset ID) features. In the sense-specific case we resolved the senses of the bootstrapping training set manually and employed the automatic sense disambiguation mechanism described above during training.

3.3.1 Bootstrapping based on keyword mapping

The first bootstrapping approach we took was to utilize a keyword mapping document which describes the key words and phrases associated with each concept in the concept space. To generate the bootstrapping training set, we created a set of single-feature training documents derived from the keyword mapping document. The label for the training instance contained in each of these documents was simply a list of the concepts correctly associated with the keyword.

This approach scales poorly because a domain expert must distill each concept into a list of the most important phrases and terms associated with that concept. Furthermore, it is important that these phrases and words not overlap to provide maximum differentiation between the concepts. Avoiding overlap becomes increasingly difficult as the size of the concept space grows. Additionally, it is not clear whether the few key words or phrases selected by the expert will have sufficient lexical overlap with the contents of an arbitrary document to produce meaningful classification results.

3.3.2 Bootstrapping based on ontology lexicalization

The second bootstrapping approach we explored was to utilize an ontology created by a domain expert that described the concepts in the concept space. To generate the training set, we created a single virtual training document for each concept. The training document consisted of the definition, description and other descriptive textual information extracted from the ontology describing the associated concept. The classification label associated with that document was the label of the concept from which the information was extracted. This approach scales better than manually generating the key word mapping document because the ontology is required to contain textual information (e.g. description) associated with each concept. The downside is that the training instances generated in this fashion may contain misleading knowledge since non-keywords may be included in the ontology text fields. As an example of this: the definition of a concept might always begin with the word "Definition" which will lead classified documents containing the word "Definition" to be erroneously grounded to all concepts.

4 Results

To gauge the performance of the various proposed mechanisms for training the classifier we conducted 50 runs with randomly generated training (T) and validation (V) sets for each run. Each validation set consisted of *V* randomly selected classification instances from a pool of *C* correctly classified documents (*C* = 63). The remaining *T* classification instances were used for training the classifier. The training and validation sets were selected such that they were guaranteed to be disjoint if possible (i.e., no document was validated using a classification instance previously used for training in the same run unless $|C| < |T|+|V|$). The training set was augmented with instances derived using various combinations of the following approaches:

1. No bootstrapping
2. Human-created concept keywords
3. Lexicalized ontology

For each validation instance the top 10 scoring concepts after classification were selected and the remainder was rejected. These 10 concepts were compared to the correct concept labels and the recall, precision, and fscore (the harmonic mean of the former two) values were computed as arithmetic averages over all runs.

To more clearly demonstrate the problem we faced with limited training data, we first examine the impact of decreasing the size of the training set with no training augmentation.

	63T,10V	50T,10V	30T,10V	10T,10V	1T,10V
recall	0.97	0.96	0.75	0.35	0.05
precision	0.34	0.34	0.25	0.06	0.02
fscore	0.51	0.50	0.38	0.10	0.03

Figure 1: Impact of training set size on classifier performance with no training augmentation

As expected, decreasing the size of the training set had a deleterious effect on precision, recall and fscore. Note that with the 1T/10V configuration the classifier's performance was actually slightly worse than if 10 concepts had been selected from the roughly 600 in the hierarchy at random. This worse-than-random behavior was due primarily to incomplete coverage of the concept space by the single training instance.

Because our classification system frequently encountered instances where there were few or no initial training instances as in the 1T/10V configuration, we clearly needed a mechanism for bootstrapping classifier knowledge.

To understand how effective bootstrapping can be on its own and with standard training, we tested the following training configurations:

- B: bootstrap training only
- B+T: bootstrap training followed by standard training
- T: standard training only

We also explored the impact of sense disambiguation during parsing using the following bootstrapping configurations:

- Dk: hand disambiguation of keyword senses, automatic disambiguation of training instances
- Dd: hand disambiguation of concept ontology descriptions, automatic disambiguation of training instances

- Ak: ambiguous keywords (no disambiguation of training instances)
- Ad: ambiguous concept ontology descriptions (no disambiguation of training instances)

Note that the Dk and Dd configurations above employed sense disambiguation. To maximize the benefit of sense disambiguation, we manually disambiguated the bootstrapping data.

Figure 2 shows the performance of various training configurations in terms of their fscores normalized to the un-bootstrapped 63T/10V case from *Figure 1*. In *Figure 2*, we observe that bootstrapping alone (B) performs poorly relative to the training alone (T) and both (B+T) configurations. This is expected because the quality of the bootstrapping training instances is significantly lower than the quality of real-world generated training instances.

It is clear from *Figure 2* that bootstrapping alone is a poor substitute for quality training data but does provide significantly better recall than simply guessing (which would produce a recall of 3.3% on average). On its own the best performing bootstrapping configuration was (Dk) which utilized the hand generated key word document.

We also observe that sense disambiguation (used in the Dk and Dd cases) only provided a benefit over using ambiguous features when bootstrapping alone (B) was used. The benefit of sense disambiguation in this case is 46% greater for keyword (Dk) than with lexicalized ontology (Dd) bootstrapping. This significant improvement over lexicalized ontology bootstrapping is a direct result of the highly targeted and minimally overlapping language used in the keyword document whereas the lexicalized ontology bootstrap instances were observed to contain many overlapping terms and phrases between unique concepts.

The next interesting observation from *Figure 2* is that the bootstrapping and training configuration (B+T) performed better than training alone (T). This indicates that bootstrapping was beneficial even for concepts covered by labeled training instances. To quantify the interaction between bootstrapping and normal training, we next varied the training set size and examined the performance of the (Ad, B+T) case above. Note that no sense disambiguation was used during bootstrapping or training and that lexicalized ontology bootstrapping was used. These results are shown in *Figure 3* as improvement factors for recall, precision and fscore relative to the corresponding values for the training only (T) case from *Figure 1*.

	Dk	Dd	Ak	Ad
B	0.60	0.41	0.42	0.40
T	0.81	0.70	0.86	0.87
B+T	0.98	0.93	1.00	1.00

Figure 2 : Impact of training configuration on classifier performance (63T/10V)

	63T,10V	50T,10V	30T,10V	10T,10V	1T,10V
recall	0.97	2.37	2.76	2.96	15.26
precision	1.32	2.42	2.78	3.34	16.92
fscore	1.15	2.40	2.77	3.17	16.26

Figure 3: Relative performance of lexicalized ontology bootstrapping + training compared to training alone

For all of the tested training set sizes shown above, bootstrapping resulted in a significant improvement in fscore relative to the trained only case. Intuitively, the benefit of bootstrapping decreases as the training set increases in size and this was also observed.

It is interesting to note that bootstrapping improved precision appreciably more than recall in all cases. This is because, during the post bootstrapping training process, exact concept matches were fed back to the system with higher weights than close concept matches.

It should be noted that while the relative improvements in recall, precision, and fscore for the 1T/10V case were large, classifier recall, precision, and fscore at that point were roughly 32%, 74% and 45%, respectively. Although still far from perfect, this result was significantly better than the results obtained with few or no initial training instances.

5 Conclusion and Future Work

We have explored several approaches which can be used to generate initial training data using domain expert knowledge. The most effective of these was building a bootstrapping training set using a lexicalization of an expert generated ontology describing the concept space. Our lexicalized bootstrapping mechanism was able to achieve an fscore of 40% even with no initial training instances present. Additionally, we observed 15% improvement in fscore values using bootstrapping and training together even for the most trained configuration tested.

One possible improvement to the techniques described in this work would be to experiment with more sophisticated sense disambiguation schemes. Our efforts to leverage WordNet to exploit synset relationships such as hypernyms and hyponyms were unsuccessful largely because we were unable to accurately map words in text to WordNet synsets automatically. In such a system it would be possible to derive a large number of similar words to those in the bootstrapping training set using the synset hypernym and hyponym relational links and we anticipate improved performance for bootstrapping using these approaches.

Novel Scan Engines and Intelligent Microagents to Detect Malware

Brian H. Xu, Ph.D., Principal Computer Scientist
Honeywell Aerospace, 1985 Douglas Dr. N., Golden Valley, MN 55422 USA

Abstract. *Existing cyber security technologies and COTS products are becoming less effective to detect modern malware, because such malware becomes increasingly sophisticated. In fact malware metamorphic and polymorphic methods are outpacing current signature based anti-malware products. To address these problems, novel Scan Engines and Intelligent Microagents (SEIMs) are presented in this paper for effective malware detection and mitigation. The SEIMs are based on innovative intelligent microagents, fast scan engines, and their synergic combination. (1) SEIM microagents autonomously sift through networks, use scan engines, COTS tools, reasoners, and machine learning algorithms to quickly detect and mitigate both known and unknown malware. (2) SEIM scan engines quickly search and detect malware digital genomes at byte level with high speed (over 50 MB/S). Our experiments have proven that the SEIM technologies can successfully detect the real malware. The SEIMs can be matured into effective and scalable commercial cyber security products.*

Keywords: Microagent, Scan engine, Cyber security, Malware detection, Malware genome, Botnet.

1 Introduction

There are currently over 286 millions malicious software (malware) threats (www.venturebeat.com) in cyberspace. Bots are malware programs that are stealthily installed across a targeted network, allowing an unauthorized user to remotely control the compromised computers for various malicious purposes [1]. Botnets are networks of the machines compromised by bots so that they are controlled by the bot maters (e.g., hackers, adversaries, etc.). Botnets are capable of acting on instructions, and organized networks of malware. It is well known that these malware (botnets, rootkits, etc.) attack our cyberspace using distributed DoS, key logging, phishing, spamming, and other malicious actions. The malware also cause root problems of spam bots, click fraud, large-scale identity theft, disabling antivirus software such as McAfee and Symantec products, and breaking through military and government networks [2]. A collection of servers infected with botnets are often under a single command and control (C&C) channel such as an IRC channel and/or P2P. The malware can attack against computers and networks in coordinated ways. Botnets and malware in cyberspace can take many forms including the following common ones:

- Top botnets include TDL (Botnet A), RogueAV, Koobface.A, and Zeus (Zbot) that can be made by DIY (Do-It-Yourself) tools [8].
- Agobot, Phatbot, Forbot, XtremBot are known bots written in C++. Agobot is the only bot that uses a control protocol other than IRC. It uses a fork via the distributed organized WASTE chat network.
- SDBot, RBot, UrBot, UrXBot are bots written in C.
- IRC-based bots are Global Threat bots, as popular IRC clients for Windows ("*.mrc").
- The Dataspy Network X (DSNX) bots (C++).
- Q8bot is a very small bot with 926 lines of C code.
- The Kaiten bot is written for UNIX and Linux machines.
- Perl-based bots consisting of a few hundred lines of Perl code, etc.

Botnets pose serious threats to our cyber security by compromising many computers (e.g., 1,000 to 5,000 computers) in networks. Even a small botnet with 500 bots can cause great damages in our cyberspace. Furthermore, current malware can have many different forms or variations. However existing malware detection products and technologies are primarily based on signatures, they are not effective to detect these malware. In addition, new malware become stealthier to propagate through software vulnerabilities, Internet, IT systems, and public clouds, which make them more difficult to be detected.

Widely used anti-malware COTS tools such as Symantec (www.symantec.com), McAfee (www.mcafee.com) and others are designed primarily to deal with viruses, spyware, and adware rather than bots and botnets. They are inadequate in detecting and mitigating botnets. As a result, botnet victims are increased 654% in 2011 [8].

Symantec Digital Immune System (DIS licensed from IBM) and other anti-malware technologies are ineffective in identifying polymorphic viruses and malware. They are also incapable of detecting any new or unknown malware that has not been seen by the antivirus labs, or any 0-day attacks. In addition, current technologies do not adequately address the increasing sophistication, stealth and encrypted C&C channels and fast-flux DNS for botnets [3, 4]. In fact, no single COTS software products can ensure cyber security of a computer network against such malware.

However, key weaknesses of botnets have been found. First, bots propagation mechanisms are a key cause of background noise on the Internet, especially on TCP ports 445/TCP (Microsoft-DS Service), 135/TCP (Microsoft Remote Procedure Call, Port 139/TCP (NetBIOS Session

Service), and Port 137/UDP (NetBIOS Name Service). These mechanisms account for more than 80% of all traffic captured. Windows XP and 2000 are the most affected software platforms [5]. These ports are limited as a weakness of the bots; we focus on TCP ports 445, 135, 139, and 137, block their propagation, and track the bots. Second, the following weaknesses are also found:

(1) Botnet-makers or bot-masters reuse existing source codes for new versions of the malware. The core algorithms of the malware are usually limited to metamorphic code, polymorphic code, and other self-modifying code. The core algorithms of the malware do not change, so identifying these algorithms can help us to detect new or unknown malware;
(2) Identifiable common patterns exist in almost all botnets for us to detect, since they are primarily generated by the same core algorithms;
(3) Botnet makers are too aggressive in compromising more networked computers to tell their trappers (like Honeypots [6]). We can detect and track the makers.
(4) Bot command and control (C&C) is mostly centralized on one or more IRC servers. Deleting the C&C channel can destroy or eradicate the botnet; and
(5) Botnet makers can expose other weaknesses of their malware including the address (not stealthy), and using a single rallying point (not robust); and having hard-coded addresses (not mobile).

Based on these identified malware weaknesses, we developed the novel fast Scan Engines and Intelligent Microagents (SEIMs) for malware detection and mitigation (see Figure 1). In this paper, we introduce the SEIM approach that is based on innovative intelligent microagents, fast scan engines and their synergic combination, in order to effectively detect and mitigate malware. Using the SEIMs, multiple scan engines are designed and developed for pattern matching, online learning using our neural networks [7], malware genome based detection and machine learning algorithms, dynamic behavior analysis, and inline sniffing mechanisms for real-time traffic monitoring, in order to detect both known and unknown malware (including zero-day malware, etc.). We developed and tested the SEIM prototype in a network with different physical machines and various operating systems (like a cloud through massive virtualization). Real bots from the authorized source [6] and many real malware from another source (over **32,000** malware executables and codes) [9] have been used to conduct technical experiments. The SEIM toolset scanned extremely fast (about 50 MB/S) and successfully detected these real bots and malware in the experiments. The remainder of this paper is organized as follows: the architecture of the novel SEIM approach is introduced in Section 2. The details of the SEIM technologies are briefly described in section 3. Selected experimental results are shown in Section 4. The conclusions are given in Section 5.

2 System Overview

The SEIM system consists of multiple intelligent microagents and fast scan engines (see Figure 1) establish multiple cyber defense layers by agile microagents (anti-botnet, anti-bot, antivirus, anti-worm, antimalware, etc.) and novel scan engines to detect malware by identifying digital patterns inherited from the malware families, in order to defeat various cyber attacks. The SEIM monitoring module monitors network traffic and port activities and the detection and analysis module report the detected malware to the SEIM users (cyber operators, warfighters, etc.). The specialized microagents reside in and move across hosts and networks. They use the scan engines to scan digital patterns in data files in various formats (e.g., binary, ASCII, Unicode, etc.), detect and mitigate malware by identifying their digital genomes and/or coding patterns. They also sniff network traffic in network structures and act on suspicious activities.

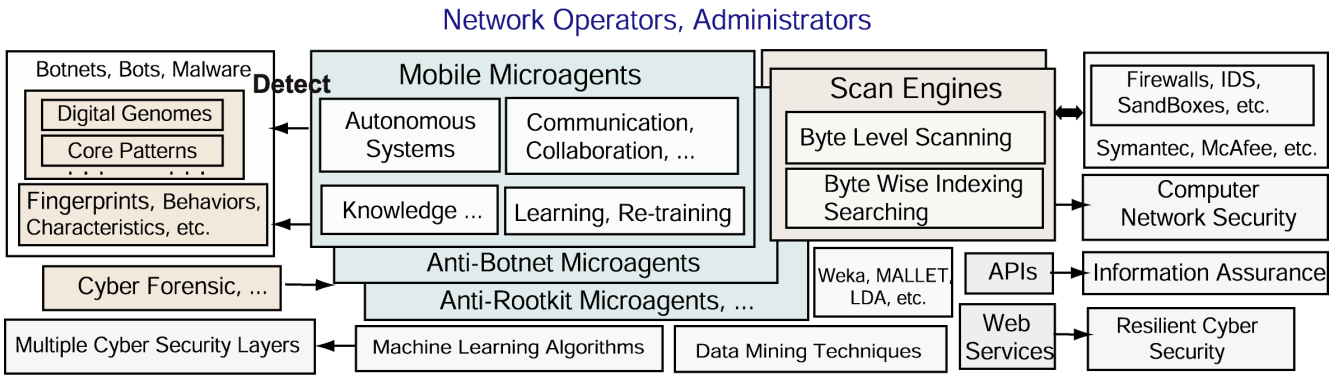

Figure 1. SEIM System Architecture and CONOPs.

The microagents (5 KB to 20 KB) need minimal network computing resources by leveraging existing defense software analysis, and by collaborating each other and work with other cyber security software agents and tools to build distributed or net-centric cyber defense systems. Each scan engine makes decisions based on the flexible

binary tree architecture that keeps the size of microagents minimal. As a result, the SEIM is able to detect and identify malware and botnets with minimal penetration rates and exploit the malware weaknesses to significantly reduce potential damages. The architecture of SEIM system architecture and con-ops are illustrated in Figure 1.

The SEIM technologies have the following advantages over existing malware detection technologies:

- Capable of adapting to new environments and dealing with new malware, because all intelligent microagents can be updated automatically by retraining our neural networks [7] and updating the digital genetics bases.
- Increased cyber security by (a) using our algorithms which can be available to critical infrastructure providers, and (b) deploying proactive microagents that collaborate to construct multiple cyber defense layers to defeat various malware families.
- Virtually boundary free operation—SEIM agile microagents patrol or move across networks, to search, detect, and eradicate malware in our cyberspace.
- Interoperable via Web services to distribute SEIM services, capabilities and functionalities to virtually all cyber systems from hypervisors to applications
- Enlarged application scope and reusability, as SEIM technologies and software are compiled as software components and web services with software APIs and Web APIs for IT systems and applications of industries, military and government agencies.

3 SEIM Design and Implementation

In general, the SEIM techniques can be applied to full-spectrum cyber security enhancement, detection, and mitigation of malware from computer networks (over 170 millions of Windows-based computers alone):

- Scan engines supported by microagents in SEIM proactively and successfully detect and mitigate malware in real time.
- Intelligent and agile microagents move across nodes and networks, they work with SEIM scan engines to detect and mitigate malware.
- SEIM fast scan engines are designed and built by developing unique capabilities to detect core digital patterns extracted and identified from sources of real botnets [1] and malware [9], based on our unique byte wise indexing search technique.
- Unique machine learning and data mining learning algorithms are developed to enhance SEIM capabilities to detect new and/or unknown malware, by adding new digital patterns that are genomes and/or digital genetics of the malware families [1, 2].

SEIM microagents are (1) lightweight (about 5 KB to 50 KB) to minimize computing resources and attack surfaces; (2) agile to move fast across nodes. They are intelligent by using distributed reasoning engines; they leverage SEIM scan engines to detect malware and can work with COTS and GOTS tools for resilient cyber security. By updating the configuration file with control instructions (in XML), the SEIMs construct a smart cyber sensor grid across computer networks of interest. They add full spectrum cyber protection to significantly enhance cyber security. SEIM microagents can be specialized in anti-botnet, anti-malware, and information assurance to form multiple cyber security layers. A sufficient number of SEIM microagents can be launched and deployed to detect malware across boundaries in cyberspace.

3.1 Fast Scan Engines

Core digital genomes and/or algorithms of computer malware (botnets, rootkits, viruses, etc.) do not change, because makers (hackers, black hat developers, etc.) of the malware continuously reuse their source codes in order to reduce the costs and time for new malware releases. The digital genomes or genetics are inherited from the source codes. The core algorithms may use metamorphic and polymorphic methods, as well as self-modifying or hiding tricks. However, these algorithms can generate variations only, not the genomes.

A sufficient number of malware source codes (over 32,000) are available for research [6, 9]. We have identified, extracted and reused some core genomes and patterns in both ASCII (scripts) and binary (executables) formats. SEIM scan engines are designed and prototyped to detect these genomes and patterns (e.g., 0xA5E3, etc.), by matching them bytes by bytes, using our rapid byte wise indexing search technique. Whenever core genomes and/or patterns are matched, the malware are detected. Immediately, the agile microagents save them to our malware repository in a database (SQL server or MySQL) for enhancing scan engines and retraining microagents and delete them from the networks based on their roles and privileges.

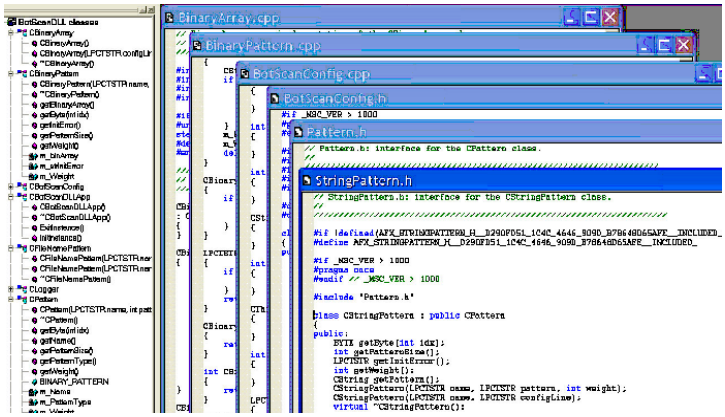

Figure 2. SEIM scan engine design, development and implementation in C++.

The Scan Engine is implanted in C++ for fastest speed. The software development environment and partial source code (classes, functions, etc.) are illustrated in Figure 2 and Listing 1, respectively.

Listing 1. Source Code Segment of the Scan Engine: BotScanDLL.cpp

```
... if ( schSCManager )
    { schService = CreateService(
      schSCManager, // SCManager database
      TEXT(SZSERVICENAME), // name of service
      TEXT(SZSERVICEDISPLAYNAME),
      SERVICE_ALL_ACCESS,    // desired access
      SERVICE_WIN32_OWN_PROCESS,
... ...
```

The scan engines are designed to search though executables (or scripts in Python, etc.) for the genetic patterns at byte level. These patterns can be extracted from real malware sources [6, 9]. For instance, the digital genomes (e.g. 0xA5E3, etc. in Hex) are malicious code specimens. SEIM scan engines search for the digital genomes through a selected executable to determine whether the executable is a malware or not. The scan engines are implemented in C++ for high computing speed. Listing 2 is a segment of the source code for prototyping the SEIM scan engines.

Listing 2. Partial Source Code in the Scan Engine.

```
... ...
class CBinaryPattern : public CPattern
 { public:
        int getWeight();
        BYTE getByte(int idx);
        int getPatternSize();
        CBinaryArray *getBinaryArray();
        LPCTSTR getInitError();
        CBinaryPattern(LPCTSTR name, LPCTSTR
        configLine);
        virtual ~CBinaryPattern();
 private:
        CString m_strInitError;
        int m_Weight;
        CBinaryArray * m_binArray; };
... ...
```

A sufficient number of the networked microagents can be deployed in a network to proactively detect and mitigate malware in parallel across networks, individually and collaboratively (without a central control site) to maximize performance and efficiency.

One of the innovative SEIM advantages is to use unanchored business objects to build components of scan engines and microagents to move the unanchored objects around applications on the computers in networks and clouds (e.g., DoD GID, DISA cloud, etc.).

The SEIM scan engines and microagents can be deployed and used on any platform, including UNIX, AIX, and Linux. The novel scan engines have successfully detected real malware; see sample experiments in Section 4.

3.2 Intelligent and Agile Microagents

The SEIM microagents have basic software agent features to (1) function with little or no user intervention; (2) communicate with their users and other agents; and (3) react to their environments or events without instruction from their users; and **novel** features to (4) move across any network to any host with the given security privilege; (5) avoid being attacked by malware due their minimal sizes, (6) learn to accomplish new tasks by leveraging existing tools (e.g., reasoning engines, scan engines, etc.), analytic algorithms and COTS (e.g., machine learning, data mining); and (7) exploit significant domain knowledge by using new rules and collect more patterns by cyber forensic and deception tools (e.g., OllyDbg, Honeypots, etc.). In addition, intelligent microagents use their neural nets [7] to learn and use their scan engines to dig into and penetrate through various malware codes. Specifically, they have unique features and capabilities in the following:

- SEIM intelligent microagents work collectively to establish a smart cyber sensor grid across entire computer networks. They add full-scale network protection on top of existing cyber security systems. They can also be integrated into current cyber defense systems through Web services and APIs.
- SEIM microagents patrol through enterprise networks and detect malware with nearly no performance degradation, because they are too lightweight to use much computing and networking resources.
- SEIM microagents collaborate with each other and interact with their users to establish collaborative intelligence; they can enhance cyber security on large networks, because they can cooperate with other cyber security defense agents and tools.
- Because SEIM microagents are all specialized in their fields such as anti-botnets, anti-malware, data leak prevention, they build multiple cyber defense layers for resilient cyberspace.
- Every SEIM microagent can use scan engines, reasoners, and analytic algorithms, so it is intelligent enough to learn and detect new malware.
- SEIM microagents launch from any network platform. They patrol and detect malware across boundaries and applications in both networks and clouds.
- All intelligent microagents can be re-trainable to adapt to a new environment and learn to detect new or unknown malware like zero-day threats.
- All intelligent microagents detect and mitigate malware individually and collaboratively under the supervision of their users (network operators, warfighters), who remotely control them from a management console.

The SEIM architecture supports sophisticated intrusion detection, botnet detection and eradication, and digital evidence gathering functions. As illustrated in Figure 1, the network administrators can manage and control their microagents from a remote network location such as a management console. The novel microagents are developed and implemented using Java, JDK in the JRE, because the Java Runtime Environment (JRE) can support operations on all platform computers on a network. The development environment and source code segment of these microagents are shown in Figure 3.

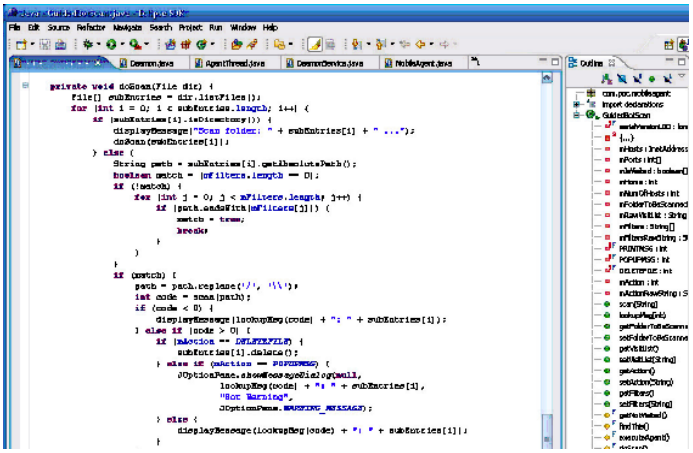

Figure 3. Design and implementation (in Java) of the SEIM microagents.

The microagents' capabilities are updated by updating the digital genomes and by editing the updatable instructions in an XML file to control the microagents. A small portion of the configuration file is illustrated in Listing 3.

Listing 3. Source Code Segment for a User to Configure Microagents and their team.

```

        <property name="visitList"
value="BrianXu:7788,alex:7788"/>
        <property name="filters" value=""/>
        <property name="action" value="print"/>
… …
```

Mobility of the microagents is implemented by using unanchored and/or mobile objects. It can also be implemented by Java socket programming and object serialization. A code segment for mobility is shown in Listing 4. The intelligent microagents can use distributed rules or knowledge bases to accomplish tasks. They use Snort rules to identify new malware; new rules can be made to deal with new malware based on their new patterns, accordingly. As an example of the rules, IRC bots are detected because they use *PRIVMSG*, *Exploit*, etc. as shown in Listing 5.

4 Experimental Evaluations

4.1 Prototyping and Experimental Setup

The novel Scan Engines and Intelligent Microagents (SEIMs) have been successfully prototyped for malware detection and mitigation. The SEIMs have also been successfully tested and proven to effectively detect malware automatically across all computers on networks. SEIM microagents significantly improve the effectiveness of cyberspace security and automate malware detection and network protection without requiring installation of a malware detection software package on every computer in a network. A single SEIM microagent can patrol many (hundreds or thousands) computers on networks when its security privilege is granted. This capability alone can minimize the costs of purchasing many (hundreds or thousands) anti-malware software licenses, and the costs of maintenance and upgrade service. Manual installations on all individual computers are not required, and neither manual start-up nor shut-down processes. Users simply set up a small configuration file to manage which computers or even which folders need to be scanned by the cross-domain agile microagents.

We developed our IRC microagents to extend detection areas, by integrating our scan engines and microagents

with open source Snort (www.snort.org) to add network traffic sniffing. SEIM intelligent microagents have been proven effective as IRC guard agents to sniff network traffic, detect IRC-based botnets, and delete the botnets and malware by sending an SEIM microagent to scan through the bot-residence computer based on a sniff alert. SEIM microagents have effectively detected IRC botnets and deleted the botnets and malware in our lab network, by sniffing the network traffic and monitoring IRC alerts. In addition, SEIMs can also detect non-IRC botnets, by monitoring the 2LD/3LD (second level domain/third level domain) ratio online and by analyzing sniffed network traffic data. The non-IRC botnet detection capability was added to our SEIM system on top of existing IRC botnet detection capability. By combining these two capabilities, SEIM microagents and search engines can effectively detect both IRC-based and non-IRC-based botnets. A novel Network Intrusion Detection (NID) analyzer is designed in our SEIMs by integrating the scan engines and microagents with WinDump (www.windump.com). WinDump is utilized to sniff network traffic in log data files, and the NID analyzer uses and analyzes the data to visually show us the 2LD/3LD ratio graph and traffic distributions among all recorded Internet sites.

4.2 Experimental Results

The SEIM prototype was tested in a lab network consisting of physical machines running various operating systems through virtualizations. We then spread real world bots [6] in the lab network for experimental investigations. The SEIM toolset scanned at speed of about 50 MB per second and successfully detected all real bots [6] and real malware [9] in all experiments. A few experiments are demonstrated in the following scenarios:

1. SEIM microagents patrol and detect real botnets [6] and real malware [9] in all computers across the network, as illustrated in Figures 4 and 5.
2. SEIM microagents instantly detect IRC-based botnets in all computers in the network based on real-time Snort network sniffing, as illustrated in Figure 6.
3. SEIM NID analyzer monitors the 2LD/3LD ratio based on WinDump log files and triggers SEIM microagents to detect non-IRC-based botnets.
4. Working as a Windows service, see Figure 7, an SEIM search engine monitors and detects malware.

The innovative SEIMs are capable of scanning, identifying and detecting any digital patterns or genomes in computer data files. Current applications of the SEIM tools include to detect malware (viruses, Trojans, rootkits, spyware, worms, etc.) in binary (e.g., executables, DLLS, etc., see Figure 5) and ASCII or Unicode (e.g., scripts, any programming languages, etc., see Figure 4). In addition, the SEIM technologies can be applied to empower the effectiveness of analysis tools, reasoning engines and other COTS and GOTS in industry, military and government applications.

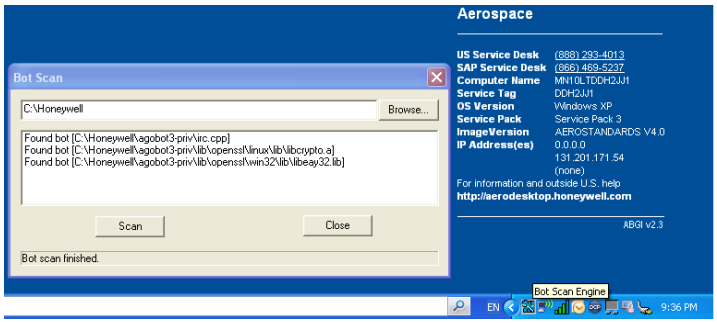

Figure 4. SEIM scan engine successfully detected real bots and botnets [6] in the machine.

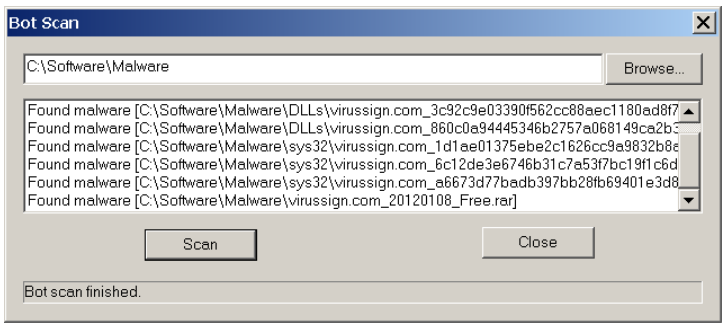

Figure 5. SEIM microagent patrolled and detected the real malware [9].

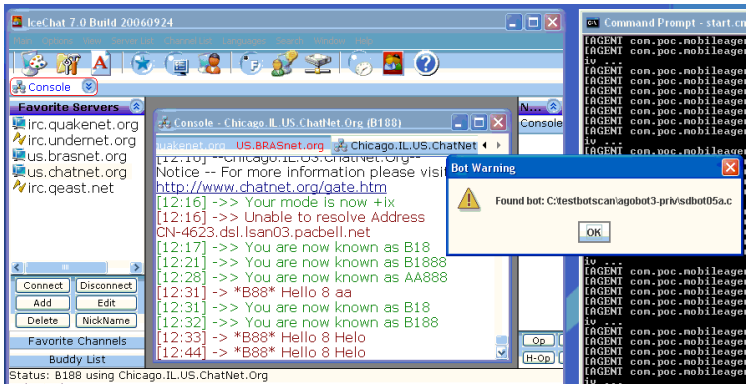

Figure 6. An IRC-based botnet was detected by the SEIM successfully.

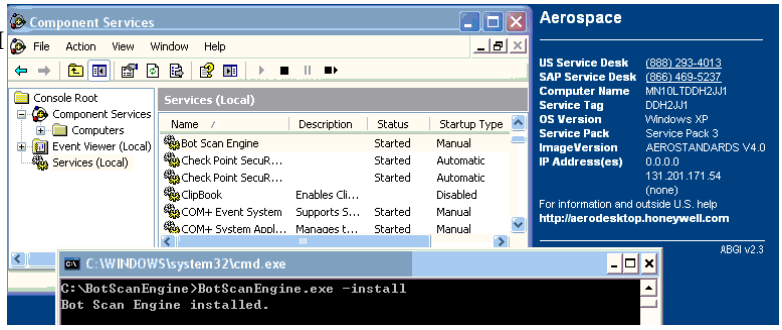

Figure 7. SEIM is running as a Window Service to protect the computer in real time.

5 Conclusions

In this paper, the novel Scan Engines and Intelligent Microagents (SEIMs) are presented for malware detection and mitigation. The SEIMs are based on novel microagents that automatically learn the behaviors of bots and botnets residing on hosts and networks to effectively stop their malicious activities. SEIM scan engines use genetic or genomic pattern matching, neural networks [7] for online learning, to detect both unknown and known malware, and use an inline sniffing mechanism for real-time traffic monitoring. The SEIMs have been prototyped (in C++ and Java) and tested in the lab network. SEIMs scanned at speed of about 50 MB/S and successfully detected real world bots [6] and real malware [9]. Specifically, experimental demonstrations have proven that SEIMs (1) detect bots, botnets, and malware across networks; (2) instantly detect IRC botnets on networked computers in parallel based on real-time network sniffing; (3) monitor 2LD/3LD ratio and detect non-IRC botnets; (4) detect malicious codes and executables in real time; and (5) scan and detect malware throughout all networked computers.

Importantly, the SEIM technologies can be applied to empower the effectiveness of guided data mining (where to mine what data, etc.), analytic tools, machine learning algorithms, and other COTS and GOTS. The digital patterns they can detect include not only malware genomes, but also key concepts and insights of humans. They can be applied to industry (business intelligence, analytic applications, cyber security, etc.), military (C2, ISR, C4IR, counter-insurgency, etc.), and government (homeland security, anti-terrorists, etc.) applications, respectively. The first goal is to advance the SEIM prototypes into fully functional and commercial software products for cyber security.

Abstract—*Automatically assigning semantic class labels such as WindSpeed, Flight Number and Address to data obtained from structured sources including databases or web pages is an important problem in data integration since it enables the researchers to identify the contents of these sources. Automatic semantic annotation is difficult because of the variety of formats used for each semantic type (e.g., Date) as well as the similarity between different semantic types (e.g., Humidity and Chance of Precipitation). In this paper, we show that by exploiting different kinds of latent structure within data we can perform this task accurately. We show that this improvement happens in spite of higher complexity in terms of both the inference procedure and the increased number of labels. We study how increasing the amount of structure taken into account by the model improves accuracy of semantic labeling. Finally, we show that when exploiting all the relationships, we obtain a significant improvement in field labeling accuracy over the regular-expression-based approach, while still keeping the complexity low.*

Keywords: Supervised learning, Graphical models, Semantic web

1. Introduction

Automatic semantic annotation of structured data elements is an important problem in information integration. It helps in identifying the contents of various sources so that further operations can be performed on them. For instance, once the semantic type of the data in different sources is known, these sources can be joined together. Each domain has some common semantic types defined in them. For example, the weather domain presents information about *Temperature*, *Humidity*, and *Visibility*, the flights domain presents information about *Flight Number*, *Airport*, and *Time of Arrival* and the spatial domain presents information about *Address*, *Latitude*, and *Longitude*. The first column of Table 1 shows a sequence of fields extracted from a weather forecast website and its second column shows their semantic types or labels. Formally defined, the task of semantic annotation is to assign these semantic labels to the sequence of fields when their identity is unknown.

Automatic semantic annotation is difficult to perform accurately. There are two main reasons for this. First, the semantic types have many different formats in which they can be written. Table 2 shows some of the various ways of writing the value of 9 $miles$ for *Visibility*. There are variations in the choice of the unit, its abbreviation, the precision of the numeric value, and even in the representation of a particular edge case value as a non-numeric term (for example, *Clear*). Therefore, even if the model has seen examples of a few formats, a new format may not be recognized by the model. Second, several semantic types can look similar to each other. *Humidity* and *ChanceOfPrecipitation* are two such semantic classes. Both of them are percentage values, written as a numeric value followed by a percent symbol (e.g., *40%*). This makes it hard for the model to discriminate between these semantic types.

Researchers have used CRFs to perform semantic annotation in the past. Zhu et al. [17] used CRFs to labels objects on a webpage by exploiting the relationship between adjacent items. Tang et al. [15] used tree-structured CRFs to identify different information elements such as *Telephone Number* and *Secretary Name* in official reports. Both of these approaches exploit the relationships among the field labels. The problem with this approach is that in the presence of many semantic types and weak dependencies between adjacent fields, these approaches do not perform as well. Instead, we propose to exploit the structure within the fields by modeling the relationship between the labels of the field and the labels of their tokens as well as the relationships among the adjacent tokens to achieve high field labeling accuracy. In this paper, we show that as we exploit more and more of the latent structure within the data, we can achieve higher field labeling accuracy. We show that this holds true even when the complexity of the inference increases and we add many more labels that the model has to choose from. We also show that our graph structure keeps a low limit on the complexity of the inference algorithm which is proportional to $L_f \times L_t^2$, where L_f is the number of field labels and L_t

Table 1: A sample data tuple extracted from a weather forecast website. The table shows the fields, their corresponding semantic classes, their tokens (generate by our lexer) and their semantic classes.

Fields	**Field labels**	**Tokens**	**Token labels**

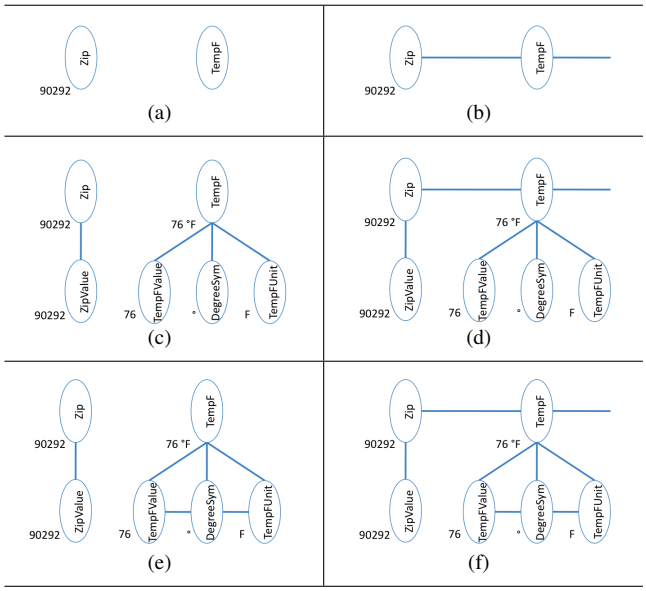
The rest of the paper is structured as follows: In section 2, we give a brief overview of the CRF models. In section 3, we first explain our method of generating tokens from the fields and extracting features from them, which is common to all graph structures. Then we present different graph structures that we build incrementally to exploit more structure within the data. We describe how we generate these graphs, how we train the CRF models from them and our method of performing prediction on unlabeled graphs. We also discuss the complexity of each graph structure. In section 4, we present the results of our experiments and in section 5, we discuss the related work. We conclude in section 6.

2. Conditional random field models for labeling data

Conditional Random Field-based models [4] learn the probability distribution of labels conditioned on the evidence. The variables and their mutual probabilistic dependence is presented as nodes and edges respectively. Therefore, the training examples are in the form of labeled graphs and prediction involves assigning values to the nodes of an unlabeled graph.

Fig. 1: Six graph structures that capture the various probabilistic dependencies between the data elements.



CRF models represent the relationships between the labels and the evidence and the relationships between mutually dependent variables (those that are connected via edges) in terms of feature functions. A feature function applies on a fully connected subgraph, called a clique. A feature function that applies on only one node is called a one-node feature function and that which applies on two nodes is called a two-node feature function. A feature function when applied on a clique, takes as input one label value for each node in the clique and checks if those values are the ones that it expects. It also considers the features of the evidence around those nodes. It returns a value of 1 or 0 depending on whether the required conditions are satisfied or not, respectively. Learning the model entails learning appropriate weights for these feature functions.

More formally, let the features of the evidence be represented by a feature vector, X, the labels be presented by the feature vector, $Y = \{y_i\}$, the feature functions be represented by $F = \{f_i\}$, and their weights by $W = \{w_i\}$. The potential for a clique is defined as:

$$\phi(clique) = exp\Big(\sum_i f_i(y_{clique}|x)\Big) \qquad (1)$$

The potential of the whole graph is the product of the potentials of all the cliques. The sum of the graph potential for all possible label assignments is called the partition function and represented by $Z(X)$. The likelihood of a particular label assignment to the random variables $P(Y = y|X = x)$ is defined as the ratio of the graph potential for

that label assignment to the partition function as follows:

$$1/Z(x) * exp\big(\sum_c \big(\sum_k w_k f_k(y_c, x)\big)\big) \quad (2)$$

CRFs do not have a closed form solution for the weights. The weights are found by numerical optimization techniques such as gradient based approaches [8]. The gradient with respect to the weight w_k is given below. The term $p(y_c = y|x)$ is the marginal probability of the clique variables. These marginals are found using inference algorithms such as belief propagation [10]. The labels are predicted for an unlabeled graph using potential maximization algorithms, such as the Viterbi algorithm [16].

$$\sum_c f_k(y_c = y_k, x) - \sum_c \sum_y p(y_c = y|x) f_k(y_c, x) \quad (3)$$

3. Exploiting structure within data for accurate labeling

There are three kinds of probabilistic dependencies that are generally seen among various data elements in structured data. They are as follows: 1) The dependency between the labels of neighboring fields, 2) The dependency between field labels and their token labels, and 3) The dependency between neighboring tokens within a field.

We can exploit all of these dependencies through different graph structures used for training the CRF models. Since a CRF graph represents the relationship between two random variables by means of edges between their nodes, it means that the more relationships one exploits, the more complex the graph structure becomes. A more complex graph structure also requires higher computational complexity inference techniques. Therefore, there is a trade-off between the numbers of relationships one exploits and the complexity and hence the time required to perform inference on these graphs.

In this work, we present six different graph structures constructed from the structured data by incrementally exploiting more structure within the data. These graphs are shown in figure 1. The simplest graph is one where there is only one node corresponding to each field. The purpose of the CRF model that uses this graph is to learn to predict the label for each field independently. This graph structure is show in figure 2(a) and is discussed in section 3.2. There is only one kind of label-to-label dependency that can be exploited here, the one between adjacent field nodes. The corresponding graph structure is shown in figure 2(b).

In addition to fields, the model can also take tokens into account for each field. These graphs are shown in figure 2(c) and 2(d) and are discussed in section 3.3.

Finally, we can also take into account the relationships between tokens. These graphs are show in figure 2(e) and 2(f) and are discussed in section 3.4.

In the following subsection, we discuss the process of tokenization of these fields and the extraction of features from the tokens.

3.1 Tokenization and Extraction of features

We generate the tokens from the fields using our own lexical analyzer. This lexical analyzer splits the field string at whitespaces and then splits the resultant parts in such a way that each token is either purely alphabetic (e.g., Cloudy), purely numeric (e.g., 76, -4.5), or a single symbol character (e.g., °, %).

Once the tokens have been generated, we assign features to each token. There are three different classes of features, the ones that apply to purely alphabetic tokens, the ones that apply to purely numeric tokens, and the ones that apply to symbol tokens. Table 3 lists all the features that we use. Some of the features listed are generic features, whose particular instance is generated based on the token from which it is generated. For example, the feature *Starts_With_Alpha_⟨X⟩* is a generic feature and its particular instance for the token *Cloudy* will be *Starts_With_Alpha_C*. One of the important features is the identity of the token itself. Since CRF models assign weights to features based on their frequency of appearance, this feature is useful for those semantic types that consist of a small lexicon of terms (e.g., *Country Names*). The features used by us are generic and can apply to any domain. We have picked features that capture the basic properties of any token. It is very easy to add new domain specific features to this set of features, if it is so required. However, all our experiments use only these features.

Table 3: Features used to characterize the tokens.

Features	Description
Alphabetic features	
$Alpha\_Length\_\langle N\rangle$	Length. N = 1,2, ...
$Starts\_With\_Alpha\_\langle X\rangle$	First character. X = A, a, B, ...
$Capitalized\_Token$	Token is capitalized.
$All\_Uppercase\_Token$	Whole token is uppercase.
$Alpha\_Id\_\langle Token\rangle$	Token itself is feature. $Token$ = California, NW
Numeric features	
$Num\_Length\_\langle N\rangle$	Length. N = 1,2, ...
$Before\_Decimal\_Len\_\langle N\rangle$	# of digits before decimal.
$After\_Decimal\_Len\_\langle N\rangle$	# of digits after decimal.
$Negative\_Num$	Number is negative.
$Starting\_Digit\_\langle N\rangle$	First digit. N = 0, 1,2, ...
$Unit\_Place\_Digit\_\langle N\rangle$	Units place digit. N = 0, 1,2, ...
$Tenth\_Place\_Digit\_\langle N\rangle$	Tenth place digit. N = 0, 1,2, ...
Symbol features	
$Symbol\_\langle Sym\rangle$	Symbol itself is feature. Sym = %, :, °

3.2 Graphs with field nodes only

Figure 2(a) shows the simplest graph structure generated from the data. Each field has a separate graph which contains only one node. This node represents the random variable associated with the field label. We tokenize the field into tokens, extract features for each token and then combine them into one set of features. These features are assigned to the field node. For example, the field node for '76°F' will have the features, Num_Length_2, $Starting\_Digit\_7$, $Symbol\_°$, $Alpha\_Length\_1$ and others, where the first two features have been extracted from token '76', the third feature has been extracted from '°' and the fourth feature has been extracted from the token 'F'.

We use only one class of feature functions for this graph structure. These feature functions are of the form:

$$f(field\_node, field\_label) \tag{4}$$

These feature functions return the value 1 if the field node has a feature p_m and input value $field\_label$ is some l_j. We find the marginals for a field node by finding the potential of the node for each value of label l_j and then dividing the potentials by the sum of the potentials, $Z(x)$. Once the marginals are calculated, the gradient can be calculated from them. We train our model in this way.

We predict the most likely label for a new field node by finding the label l_j for which the potential of the node and therefore of the graph (since the graph consists of only one node) is the highest. The complexity of the inference method as well as the labeling method is $O(L_f)$, where L_f is the number of field labels.

In every domain, it is generally the case that there is some order to the fields. This means that a field is immediately followed by one of a small set of fields. For example, the $Temperature$ field type is generally followed by $SkyCondition$ and a $WindSpeed$ field is generally followed by $WindDirection$. We exploit this relationship in the graph structure shown in 2(b). This graph is formed by connecting the fields in a linear chain. We capture this relationship using the following feature function:

$$f(field\_node1, field\_node2, field\_label1, field\_label2) \tag{5}$$

where it returns 1 if the input $field\_label1$ is some label l_j and input $field\_label2$ is some label l_k. Otherwise, it returns the value 0. Therefore, this graph uses the two classes of feature functions shown in equation 4 and 5.

We perform inference on this graph using the belief propagation algorithm [10]. We predict the most likely label assignment to the field nodes using the Viterbi algorithm [16]. The complexity of performing inference on this graph is again $O(L_f)$. Yet, the model uses more feature functions for these graphs. This graph structure better represents the field labels since they consider both the features of the fields as well as the neighboring fields. Our experiments show that these graph structures indeed give higher field labeling acurracy. This happens because the neighborhood information helps disambiguate between similar fields. For example, the fact that *Humidity* and *Sky Condition* are generally reported together prevented the model from mislabeling some of the *Humidity* values as *Chance Of Precipitation* because these values appeared close to a *Sky Condition* value. The model based on the graph structure in figure 2(a) did make some of these mistakes.

3.3 Adding token nodes to the field nodes

The features used to represent the fields in the models described above are derived from the tokens of the fields. It seems more appropriate to predict the identity of the tokens based on their own features and derive the identity of the field based on the tokens. For example, the field type $Temperature$ can have token types *TemperatureValue*, *DegreeSymbol*, and *TemperatureUnit* and the field type $Time$ can have the constituent token types $Hours$, $TimeSeparator$, $Minutes$ and $Seconds$. We create a new graph structure, where each field node will have token nodes as it children.

The graph structures shown in figures 2(c) and 2(d) show how these graphs look. We do not exploit the field-label-to-field-label relationship in the left figure, while we do so in the right figure.

The graph shown in figure 2(c) does not have any features belonging to the field node itself. Instead the features belong to the token nodes. We use two new classes of feature functions to represent relationships in these graphs. The first class of feature functions are written as:

$$f(token\_node, token\_label) \tag{6}$$

These feature functions take a $token\_label$ and a $token\_node$ as inputs and returns 1 if the $token\_node$ has a feature p_m and the $token\_label$ is some label l_j. These feature functions represent the dependency of the labels of token nodes on their features.

The second class of feature functions are written as:

$$f(field\_node, token\_node, field\_label, token\_label) \tag{7}$$

These feature functions take a $field\_label$ for a $field\_node$ and a $token\_label$ for a $token\_node$ and return 1 if the $field\_label$ is some label l_j and the $token\_label$ is some label l_k. These feature functions represent the co-occurence of the field labels with their token labels.

We use belief propagation to perform inference on these graphs. The graphs are already in the form of a tree, as required by the algorithm. The prediction for a new graph is made using a modified Viterbi algorithm called the max-sum algorithm [3]. This algorithm maximizes the sum of the log of the potentials of the various cliques in the graph.

Compared with the graph structure in figure 2(a), this graph is more natural because it finds the labels of each

token based on its own features and then finds the label of the field based on the labels assigned to its tokens. Yet, this graph introduces more nodes to be labeled and also introduces a large set of token labels to chose from. This increases the ambiguity while training as well as during prediction. As we show in our experiments, this graph structure gives higher field labeling accuracy than the graph structure that has only one node in the graph. This happens because when the features of the tokens are combined into one set (as in figure 2(a) and 2(b)), most of the features from different semantic types are similar. For example, if we look at the semantic type $Temperature$ and $Humidity$, both these types have numeric values, and the values are between 0 and 100. The main difference appears in the fact that $Temperature$ values end with a F or a C, but $Humidity$ ends with a percentage ($\%$) symbol. But, when these features are distributed over their own tokens, the most distinguishing tokens namely the F or C in one and the $\%$ symbol in the other have very distinct features. The CRF model can differentiate between these much better. With high confidence on these tokens, the field labels tend to be correctly assigned due to their co-occurence relationship with these tokens labels (e.g., the strong co-occurence of $Temperature$ with $TemperatureUnit$).

In addition, this graph structure also solves an important problem of identifying the semantic types of the various components within a field. For example, in order to compare two $Date$ fields that are written in different formats, (e.g., 07/21/2011 and 21 July, 2011), it is required that the semantic meaning of the various components of each date string are known so that they can be compared effectively. Therefore, the graph structure described here improves the accuracy of labeling while solving a larger problem.

The graph shown in figure 2(d) is an extension on the graph described above. In this graph, we also join the field nodes via edges. We exploit the neighboring relationships among the field nodes in the same manner as we did in the graph in figure 2(b) via the feature function presented in equation 5.

In order to perform inference in these graphs, we first need to convert them into a tree structure. We perform this conversion as follows: we make the first (leftmost) field node the root of the whole graph. All its token nodes are already its children. We also make the field node to its right, its child. This is repeated at each field node. This gives us a tree, where each node has one parent and each node can have zero or more children. We then apply belief propagation algorithm to this graph to perform inference.

Prediction on a new unlabeled graph is performed by first converting it into a tree structure as described above and then applying the max-sum algorithm [3] starting from the leaf nodes to find the most likely joint assignment of labels to all the field and token nodes. This graph structure is more complex than the one described above. We show in our experiments that exploiting the field-node-to-field-node label dependency helps improve the field labeling accuracy over the simpler model that does not exploit these relationships, similar to the results obtained for the graph structures in figure 2(a) and 2(b).

3.4 Connecting the tokens with each other

There is an important relationship between neighboring tokens within a field. In general the order of the token types within a field remains roughly constant. For example, $Minutes$ always follows $Hours$ in every format of $Time$, *Temperature Unit* ('F' or 'C') always appears after the *Temperature Value* token within a $Temperature$ field and *State Name* always written after $CityName$ within an $Address$ field. To exploit these strong relationships, we connect the tokens within the fields together. Figures 2(e) and 2(f) show how the graphs look in this case. Figure 2(e) shows the graphs where we do not exploit the neighborhood relationships between fields, whereas figure 2(f) shows the graph structure where we do.

We represent the relationships between labels of neighboring token nodes by a new class of feature functions. These feature functions are written as:

$$f(token\_node1, token\_node2, token\_label1, token\_label2) \quad (8)$$

This function returns the value 1 only when $token\_label1$ is some token label l_j and $token\_label2$ is some token label l_k. Therefore, this graph has three classes of feature functions. Two of these classes are the same as we used in the graph structure shown in figure 2(c).

We cannot use belief propagation to perform inference on these graphs since they have cycles in them. Therefore, we convert each graph into a different graph called a junction tree [5]. A junction tree (JT) is formed by replacing all the three-node cycles in the original graph by a single junction tree node (JT node) and connecting the JT nodes that share at least one node in the original graph. See [5] for the detailed general algorithm for converting any graph into a junction tree. We convert our graphs into junction trees as follows: if the field has only one or two token nodes, then it is replaced by just one JT node. Otherwise, for each field, we take two token nodes at a time starting from the left and replace the three-node cycle formed by them and the field node with one JT node. Figure 2 shows the junction tree constructed from the CRF graph in figure 2(e). Since, the adjacent JT nodes share the field node and a token node, they are connected with each other. This always gives us a linear chain of $(N-1)$ JT nodes for N token nodes. Since this is a linear chain, we apply belief propagation to this graph. The possible states that a JT node can take is a power set of the labels that each node within the clique that they represent can take. Therefore the complexity of the belief propagation algorithm is equal to:

$$L_f \times L_t^2 \quad (9)$$

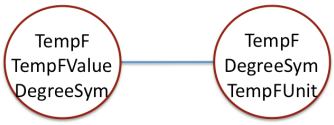


Fig. 2: The junction tree for one field and its tokens.

where L_f is the number of field labels and L_t is the number of token labels. This complexity is low enough to allow us to apply the belief propagation algorithm on graphs of practical sizes.

To label a new graph, we convert it into a junction tree, as explained above. We then use the Viterbi algorithm to find the most likely states for all the JT nodes. The Viterbi algorithm is constrained so that the states on the nodes that are shared by two adjacent JT nodes are the same. For example, since the two JT nodes in figure 2 share the field node and the middle token node, both JT nodes can only take values so that the labels values for the two shared nodes in the same.

Figure 2(f) is the most complex graph structure that we use. It exploits all the three dependencies among the field and the tokens. It uses the three feature functions used for the graph structure explained above. In addition it also uses the field label to field label feature function that we used in the graphs in figure 2(b) and 2(d) to exploit the neighborhood relationships among field labels.

Like in the previous graph, this graph also contains cycles. As a result we again convert these graphs into junction trees. Since the field nodes are connected to each other in a line, the two-node-cliques formed by consecutive field nodes are also converted into JT nodes for these graphs. These JT nodes share the field nodes with the JT nodes formed by token nodes under these field nodes (as explained for the previous graph). This results in a linear chain junction tree as shown in figure 3. Due to the linear structure, belief propagation algorithm can be applied to this graph. Since, the new JT nodes represent two field nodes, the number of states that they can take is:

$$L_f^2 \tag{10}$$

where the terms mean the same as before. Generally, this term will always be smaller than $L_f \times L_t^2$ since the total number of tokens is generally larger than the total number of fields. Therefore the complexity of performing inference on this algorithm remains bounded as before.

We similarly generate a CRF graph from unlabeled data, convert it into a linear chain junction tree and then use the Viterbi algorithm on it to predict the labels for fields and tokens.

4. Experiments on real world data

We tested the six graphical structures in three different domains: weather forecast, flight status and geocoding. For each domain, we scraped data[1] from 100 different web pages of four different web sites to obtain 400 tuples of data in each domain. We also defined a set of field level and token level semantic classes that we wanted to identify in each domain. We tokenized the fields in each tuple using our lexical analyzer. We then labeled all the fields and their tokens using the labels for the semantic classes already defined. We then extracted the features for each token. The average number of fields per tuple in the weather forecast domain was 31, in flight status domain it was 14 and in the geocoding domain it was 3.5. Table 4 shows the web sources used in each domain and also mentions the number of field and token semantic types in each domain.

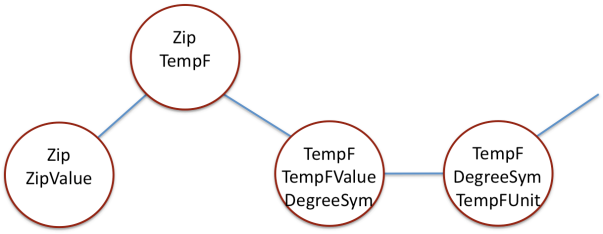

Fig. 3: The junction tree for the fully connected graph in figure 2(f). We have drawn the JT node formed from the field nodes' clique slightly elevated to differentiate it from the JT nodes formed from field and token nodes. Yet, this is a linear chain.

Table 4: Experimental setup

Domain	Details	**Data sources**
weather forecast	#field types = 15 #token types = 37	wunderground.com
		unisys.com
		weather.com
		noaa.com
flight status	#field types = 8 #token types = 17	flytecomm.com
		flightview.com
		continental.com
		delta.com
geocoding	#field types = 5 #token types = 12	geocoderus.com
		geocoderca.com
		geonames.com
		worldkit.com

We ran four experiments on every graph structure in each of the three domains. In each experiment, we trained a CRF model on the graphs created from 300 tuples from three sources and tested it by labeling the 100 tuples from the fourth source. We then averaged the field and token labeling accuracy for each graph structure. Table 5 shows the average field labeling accuracy for each graph structure in each domain. The geocoding domain is a relatively simple domain with only five field types. Therefore, even the simplest graph structure gives high field labeling accuracy and there is little scope for improvement as we take advantage of more

[1]We used a tool called AgentBuilder, from Fetch Technologies.

structure within the data. However, there is an improvement of 1% from the simplest graph structure to the most complex graph structure in the field labeling accuracy.

All the differences in the table for the other two domains are statistically significant for $p = 0.05$. The results for the weather forecast and the flight status domains show that the accuracy increases each time we exploit additional relationship among the labels. For example, the accuracy for graph structures where the relationship between the neighboring field labels is exploited (right column) is always more than the accuracy for the graph structures where it is not (left column), except in only one case for the flight status domain where the source *flytecomm.com* has dates that are in a very different format from other sources and also appear out of the normal order so that all of them get consistently mislabeled. The accuracy also increases when we exploit the relationship between the field labels and the token labels. Further, when we connect the adjacent token nodes to exploit their neighborhood relationships, we get a significant improvement in labeling accuracy. There is an improvement of 10% in the weather domain and 7% in the flight domain from the graph structure that has only one field node to the graph structure that has both the field and token nodes and all of them are connected. These results clearly show that exploiting each new relationship gives us a better model and hence higher field labeling accuracy. These experiments represent the real accuracy that one might achieve while using these graph structures since we never test our models on the same data that we trained it on. Yet, despite the fact that each new source uses its own formats and representations, the model is able to successfully identify the semantic labels for a high percentage of fields.

The following is an example of how the model exploits the inter-label relationships to correctly label a field that uses a format not seen before by it: The weather source, *unisys.com*, represents temperature in fahrenheit (*TemperatureF*) using only a numeric value and the unit, and without a degree symbol. (for example, '62 F'). None of the other three sources, on which the model was trained had such an example of this class. Yet, the model was able to assign the correct semantic label to these fields by taking advantage of the strong relationship between the field level label *TemperatureF* and the token level labels *TemperatureFValue* and *TemperatureFUnit*, and a strong correlation between the *TemperatureFUnit* token label and the feature *Alpha_Id_F*. In contrast, in the graph structure in figure 2(a), all such fields that had integer values were labeled as *Humidity* due to the lack of the differentiating feature $Symbol\_^{\circ}$ and a strong correlation between the label *Humidity* and the feature *After_Decimal_Len_0*.

Table 6 shows the token labeling accuracy results for the four graph structures in all three domains. There is an improvement in token labeling accuracy every time we add one more relationship to the model for use. There is an average improvement of 5% in the weather domain and 6% in the flights and geocoding domain between the simplest graph structure that involves tokens (figure 2(c)) and the graph structure that exploits all relationships (figure 2(f)). The average token labeling accuracy is around 85% across all the different graph structures and domains. This means that the model is able to correctly identify the semantic types of the tokens within the fields with high accuracy. Some of the tokens types are so similar to each other that it is difficult to differentiate between them. For example, the token types, $TemperatureValue$, $HumidityValue$, $PressureValue$, and $VisibilityValue$ all look very similar to each other and yet our models are able to use the identity of the neighboring fields and tokens to correctly identify them.

Table 5: Result of experiments on all six graph structures. The average field labeling accuracy improves as we exploit more structure within the tuple and the fields.

Domains		Fields not connected	Fields connected
Weather forecast	**Fields only**	0.79	0.83
	Field and tokens	0.80	0.85
	Tokens connected	0.85	**0.89**
Flight status	**Fields only**	0.90	0.88
	Field and tokens	0.90	0.93
	Tokens connected	0.93	**0.97**
Geo-coding	**Fields only**	0.97	0.97
	Field and tokens	0.98	0.98
	Tokens connected	0.98	**0.98**

Table 6: The average token labeling accuracy for experiments on all six graph structures.

Domains		Fields not connected	Fields connected
Weather forecast	**Field and tokens**	0.81	0.85
	Tokens connected	0.83	**0.86**
Flights status	**Field and tokens**	0.81	0.84
	Tokens connected	0.85	**0.87**
Geo-coding	**Field and tokens**	0.84	0.85
	Tokens connected	0.89	**0.90**

An alternate approach to assigning semantic labels to fields is based on matching unlabeled fields with regular expressions that are generally known to represent a particular semantic class. We compare a CRF model utilizing the graph structure in figure 2(f) with a sophisticated regular expression based pattern matching model proposed by us in [7]. In this work we generate regular expressions of varying generality to match the given labeled examples. For example, patterns such as 25, *2-digit*, and *numeric* are generated for a temperature value 25. The labels are assigned to unlabeled fields based on how well they match the regular expressions for each semantic type. We used the same experimental set up for running experiments on our previous approach. The average field labeling accuracy of both the approaches is presented in table 7.

In all the three domains, the labeling accuracy of the CRF model is much better than the accuracy for the regular

expression based approach. This is because the regular expression based approach it is unable to generalize the structure of a semantic class from the examples that it has seen. Therefore, even a slight change in the structure, such as the introduction of a dot after an abbreviated unit can mislead it. On the other hand, since our model learns many different types of dependencies among labels, even if some such relationships do not hold true due to changes in the structure, other dependencies such as the relationship with neighboring fields can still help the model make the right prediction.

Table 7: Comparison of our graph structure that exploits all the three relationships with a regular expression based approach. The new model performs much better on all domains.

Domains	Regular expression based model	CRF model
Weather	0.65	0.89
Flight status	0.42	0.97
Geocoding	0.36	0.98

5. Related Work

Semantic annotation is a problem that occurs in various domains and on various kinds of documents. Named entity extraction [9] is a form of semantic annotation problem where the task is to assign named entity tags to various words or phrases in a text document such as a news report. Similarly, semantic annotation can also be applied to reports, where the task is to identify the various pieces of information such as telephone numbers, etc. An example of semantic annotation in semi-structured sources is the problem of identifying the various information fields on webpages [6]. Finally, the semantic annotation of structured sources such as databases is performed under the name of schema matching [2]. In this paper, we solve the problem of assigning semantic labels to structured data obtained from databases or web pages. Unlike schema matching, we do not label entire columns of data. Instead we assign labels to all fields in a tuple, which corresponds to a row in a database table. The advantage of our approach is that it is applicable to sources with missing and optional fields since we do not need the data to be available in a regular tabular format.

CRF models were proposed by Lafferty et al. [4], where they presented experiments on linear chain graph structures for performing part-of-speech tagging of natural text. Researchers then applied the same structure to other problems such as noun phrase chunking [13] and extracting tables from documents [11]. Later researchers demonstrated the use of other graphical structures such as factorial graphs [14], two-dimensional grid structures [17] and tree-structured graphs [15]. In this paper, we use various kinds of graph structures, which include linear chain graphs, hierarchical tree structured graphs and also cyclic graphs. We compare their capability in exploiting the various patterns within data and also examine the computational complexity of performing inference on them. In addition, we also show that the cyclic hierarchical tree structure graph (Figure 2(f)) is well suited to accomplish the task of semantic annotation and achieves high accuracy both in field and token labeling.

There have been two main works using CRF models to perform semantic annotation. Zhu et al. [17] used the CRF model to assign semantic labels to the image, description, price and title of a product on a commercial product webpage. They mapped the web objects to two-dimensional grids and exploited the spatial proximity and relationship to assign labels to them. In the other work, Tang et al. [15] used tree-structured graphs to represent the layout of the information elements on semi-structured reports. In both these cases, the researchers exploit the dependence of the field labels on their structures and the relationship between adjacent field labels. In this paper, we present six different graph structures that exploit different combinations of inter-label relationships including the graph that only exploits the relationship between adjacent field labels (figure 2(b)). We show that we can achieve a significant improvement in the labeling accuracy if we exploit the relationships between the field labels and the token labels as well as the relationships among neighboring token labels.

One of the other advantages of our graph structures is that we also assign semantic labels to the tokens of the fields. This is essential in comparing data values from different sources which might be using different formats. Borkar et al. [1] used HMMs [12] to assign semantic labels to the tokens of US addresses. They trained a linear chain HMM model that learns the transition probabilities beween the various labels and the emission probability of the various kinds of tokens from these labels. The semantic types used by them are: *HouseNumber, StreetName, CityName, StateName, ZipCode*. In contrast to their approach, we use a more powerful model than HMMs, which allows the use of overlapping features. Also, we do not need to train a separate model for each field level semantic type. Instead our model can simultaneously identify the field level type of an item of data as well as the semantic types of its tokens. For example, in the geocoding domain, our model can identify the semantic type of a field as being *Latitude*, *Longitude* or *Address* and also identify their token labels such as *LatitudeDegree*, *LatitudeMinutes*, *HouseNumber*, and *StateName*.

An alternate approach to graphical models, such as CRFs and HMMs, that can be applied to the problem of semantic annotation involves learning the syntactic rules that describe the syntax of the semantic classes using regular expressions. We proposed this approach in [7]. In this approach, we generate regular expressions of varying generality from the examples of the semantic types and then match these with new unlabeled examples to predict their label. We presented

results comparing the approach proposed in this paper with our previous work and show that the new approach performs much better as compared to the previous approach. The previous approach could not handle variations in the formats easily and fails as soon as the format changes even slightly. In addition, it cannot take advantage of the information available about the neighboring fields and tokens. Since our model exploits many different classes of relationships and combines them in a probabilistic way, it can handle such variations because many of these relationships still hold true for the new format.

6. Conclusion

In this paper we have shown that we can get high labeling accuracy from CRF models by exploiting the latent structure within data. We showed that in spite of increased complexity and higher number of labels, exploiting more structure improved the labeling accuracy for fields as well as the tokens. We also showed that the complexity of the graph structure that exploits all three relationships is bounded by $L_f \times L_t^2$, where L_f is the total number of field labels and L_t is the total number of token labels.

There are many domains where entities have such hierarchical structure within them. For example, this approach can also be applied to assign part-of-speech labels to phrases within sentences, where the phrases can be split into words and the relationships between the labels of adjacent words can be used to achieve higher labeling accuracy for phrases. Similarly this approach can also be used for named entity recognition to identify top level entities such as *Address* as well as low level entities within them, such as, *City Name*, *State Name*, or *Country Name*.

One of the factors that impact the speed of training is the number of feature functions used in the model. Presently, we use all feature functions that can be generated from the training examples. In future, we will explore techniques of pruning this space to reduce the training time. We will also experiment with more complex feature functions that can be formed from conjunctions or disjunctions of elementary features functions. For example, a feature function that says that an *Hour* token can either have one or two digits is a better descriptor of this semantic type than two separate feature functions, one of which associates the feature of having one digit with the semantic type and the other associates the feature of having two digits with it. Both of the above mentioned directions can reduce the total number of feature functions used in the CRF model, while building more expressive CRF models.

Abstract - *This paper proposes a method of extracting Web search keywords of interest by gender, age, and day of the week. By using the results of such keywords, it is expected that suitably equipped robots will be able to offer appropriate topics of conversation to the person they are interacting with. In this study, we compiled Web search engine keywords based on rank using the Biglobe Search Shunkan Ranking system. However, such rankings cannot be used independently because the relevant words for a particular day will not be known until that day is over. Accordingly, our method uses Web search rankings compiled for the day prior to day in question to select keywords for use. Because of this, the method cannot determine keywords that appear on the actual day of the conversation. However, it can extract keywords that appear repeatedly in identifiable patterns, as well as topics of general interest to a certain age and gender. In our experiments, we experienced particularly good results by focusing on three concepts: keyword consolidation, forgetting factor, and short-term and long-term memory.*

1 Introduction

In recent years, electronic devices and various other machines have become increasingly sophisticated and intelligent. The shared future vision for these machines is for them to coexist seamlessly with human beings. Advancements toward this goal include the development of numerous robots, some of which are capable of walking on two legs, running, and even dancing [1][2]. Through such developments, machine forms are being created that appear increasingly humanlike. At this stage, in order to seamlessly and efficiently coexist with humanity, such machines have an increasing need for intelligence and the capacity to converse naturally with human beings. In the future, the ability to engage in conversation with human beings will be indispensable [3][4][5].

To accomplish this, such robots should to be able to offer appropriate topics to the person engaging them in conversation. Thus, it would be useful if such robots had the ability to collect news of interest to that person, which could then be used to help conversations proceed more smoothly.

When we first meet someone, learning the details of their personal interests is normally a challenge. However, we can usually make roughly accurate judgments of safe conversation topics by considering discernable factors such as age and gender. Thus, in such situations, we normally try to steer the conversation towards general topics we feel are appropriate to those factors, and which can be discussed without causing discomfort for either person, instead of asking for their address, hobbies or other personal information.

This paper does not address how to stimulate conversation with another person after learning the details of their personal preferences; instead, it describes a method of extracting topics of potential interest to an average person, based on their age and gender, using keywords and World Wide Web search engines. Since such search engines are designed to locate information of interest to the user, a robot equipped with this feature can determine appropriate topics based on relatively generic values.

Information of interest often varies depending on the age and gender of the person. For instance, Japanese women in their 20s tend to be more interested in TV dramas and traveling than Japanese men and women of other age ranges. Additionally, keyword search trends have been noted to vary depending on the day of week. For example, searches including Japanese Racing Association (JRA) and other entertainment-related keywords are more likely to be the subject of Web searches on Saturdays, while searches for "Town Work" and other job hunting related keywords are more prevalent on Mondays.

In view of the above, this paper proposes a method of extracting Web search keywords of interest by gender, age, and day of the week. By using the results of such keywords, it is expected that suitably equipped robots will be able to offer

appropriate topics of conversation to the person they are interacting with.

In this study, we compiled Web search engine keywords based on rank using the Biglobe Search Shunkan Ranking system[6]. However, such rankings cannot be used independently because the relevant words for a particular day will not be known until that day is over. Accordingly, our method uses Web search rankings compiled for the day prior to day in question to select keywords for use. Because of this, the method cannot determine keywords that appear on the actual day of the conversation. However, it can extract keywords that appear repeatedly in identifiable patterns, as well as topics of general interest to a certain age and gender.

2 Biglobe Search Shunkan Rankings

These rankings aggregate keyword searches entered into the Biglobe search engine and list the most popular keywords by gender and age in a ranking format from 1-20

Totals are aggregated once a day. As an example, Table 1 gives the Biglobe Search Shunkan Rankings for male users 10-19 and 20-29 ages on Thursday January 20, 2011. Table 2 gives the Biglobe Search Shunkan Rankings for male users 30-39, 40-49 and 50-59 ages on Thursday January 20, 2011.

Table 1: Biglobe Search Shunkan Rankings, male users 10-19 and 20-29 ages on Thursday, January 20, 2011

	10-19	20-29

3 Keyword Consolidation

“Youtube” spelled in the Roman alphabet and the Japanese spelling “Yu-Tyu-Bu” are two words that represent the same concept, but which are handled separately because they are displayed differently. There are also certain words that are subsets of other words, such as "employment" and "Rikunavi," (a popular Japanese recruiting site). In such cases, words representing the same concept, or that are included in a subset of another word, are consolidated.

In light of our objective of providing appropriate conversation topics, we believe it is useful to consolidate keywords with more generally related words. In the above example, a person searching for “Rikunavi” can be expected to plan on using the site to search for a job. Thus, it would be appropriate to offer topics and articles using the keyword "employment."

And, “Youtube” spelled in the Roman alphabet and the Japanese spelling “Yu-Tyu-Bu” are expected coherence a more popular word “Youtube”.

In this study, we also consolidate word selections using Google searches[7]. We began by searching for all ranked search keywords over a fixed cumulative period to determine the number of hits and the URL of the top hit for each

keyword. Next, we compared the URLs and separated keywords with the same URL into separate groups. The group name takes the word selection of the group member keyword with the most hits. Table 3 lists some examples of keywords for which the top URL is the same site.

Table 3: Keywords sharing the same top URL in search results

Search keyword	Hits
YouTube	4,650,000,000
Yu-Tyu-Bu (in Japanese)	18,900,000
Horseracing	18,000,000
JRA	8,330,000
Kakaku	1,130,000,000
Kakaku.com	21,700,000
Forums	193,000,000
2channel	25,700,000
Draft	2,720,000
Draft commission	422,000
Employment	24,100,000
Rikunavi	8,520,000

4 Forgetting curve

Human memory fades with the passing of time. Because of this, search rankings from one day ago cannot be treated the same as those from a month ago. Accordingly, our model uses a memory retention curve to account for the impermanence of human memory. The "forgetting curve", which shows the rate at which human memory fades, was created by German psychologist Hermann Ebbinghaus[8]. Ebbinghaus obtained the figures in Table 4 through experimentation, even though no numerical formula has been clarified.

Table 4: Ebbinghaus experiment results

Time Passage	Memory
20 Minutes	42%
1 Hour	56%
1 Day	74%
1 Week	77%
1 Month	79%

The model in this paper uses Formula (1), which approximates the forgetting curve from the five points shown in Table 4. The amount W(t) remembered over number of days *t* is as given below. Hereinafter, this is referred to as the forgetting factor.

$$W(t) = -0.1429t + 25.19 \qquad (1)$$

5 Memory Weighting

Previously accumulated keywords are used quantitatively to express degree of interest. First, search rankings 1-20 (by age and gender) are assigned points for each day accumulated. The top ranked keyword in the search rankings is given 20 points, the second is given 19 points, the third is given 18, and so on. Human memory can be broadly divided into short- and long-term memory. Short-term memory stores small amounts of information temporarily and is quickly forgotten. In contrast, long-term memory is the ongoing storage vessel for large amounts of information. In this study, points were adjusted and weighted based on the concepts of short- and long-term memory.

As will be described below, all accumulated keywords are weighted for short- or long-term memory, after which, the weight for the same keywords is consolidated. The system outputs keywords from 1-20 in order of highest total value.

5.1 Short-term Memory Weighting

Weighting for short-term memory is based on search rankings over the previous week. To accomplish this, we take the product of forgetting factors W_1-W_6 for all keywords, from one to six days previously. The weights are then totaled for the consolidated keywords. As an example, Figure 1 shows short-term memory weights for keywords selected on Saturday, January 24.

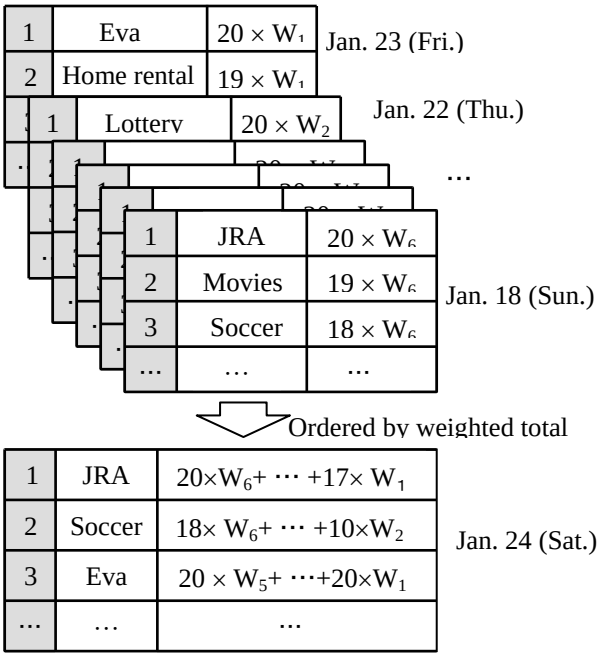

Figure 1: Weighting example for short-term memory

5.2 Long-term Memory Weighting

When creating weighting for long-term memory, data search information compiled on the same day of the week, over the past four weeks, is collected and analyzed. For example, if predicting the search rankings for a Saturday, the system would begin by compiling weighting data using the results from Saturdays seven days, 14 days, 21 days, and 28 days prior to the date the prediction is made. It would then apply the product of forgetting factors W_7, W_{14}, W_{21} and W_{28}. The weights are then recalculated for the consolidated keywords. Calculations follow the same technique described in Section 6.1.

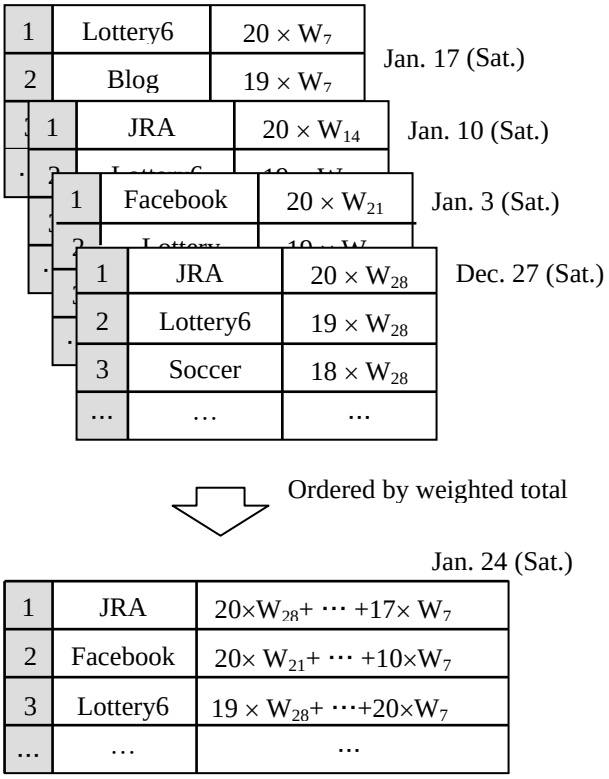

Figure 2: Weighting example for long-term memory

6 Experimental

6.1 Evaluation Method

As described previously, evaluations of the topic keywords obtained by the proposed method are compared to the actual Biglobe Search Shunkan Rankings obtained the next day. Note that the topics of a particular day will not be known until the following day.

Ranks for experiment results are given as *i*, and the actual rankings are given as *j*. Through visual inspection, the resulting keyword for rank *i* is compared to keywords *j* = 1-20 and given points *p*. Evaluation criteria have three levels: for the same concept $p = 1$, for related concepts $p = 0.5$, and for unrelated concepts $p = 0$. Equation 2 calculates the anticipated accuracy a_{ij} of the experiment result *i* and *j* = 1-20. The highest value between a_{i1}-a_{i20} is a_{ik}, which is used as the accuracy of result *i*.

$$a_{ij} = \frac{p}{i \times j} \qquad (2)$$

The above process is iterated 20 times for *i* = 1-20, and the average value for a_{ik} is taken as the average accuracy.

If an exact match exists, average accuracy is approximately 0.08. The higher the experiment results predict actual high-ranking keywords and related keywords to be ranked, the higher the average accuracy will be.

6.2 Experiment overview

In order to examine the usefulness of the created system, the following experiment was conducted:

・Period: June 4, 2010 (Fri.) - June 10, 2010 (Thurs.)

・Data for short-term memory: the past six days prior to the day of testing

・Data for long-term memory: the past four weeks

The compared data uses consolidated keywords and a keyword system to determine interests by gender and age, not accounting for short-term and long-term memory.

6.3 Experiment overview

6.3.1 Output Comparison

Table 5 lists an example of the actual rankings from our proposed system, as well as rankings from the comparison system for women in their 20s, for Monday, June 7.

In Table 5, it can be seen that the rankings obtained using the proposed method were close to the actual rankings, particularly in the higher ranks. Those results showed that women in their 20s are likely to search for recruitment-related keywords such as “Town Work” and “Hello Work” on Mondays. The system also predicted keywords close to the actual rankings in the lower ranks with similar word pairs like recipe and “Cookpad”, “Rakuten”, and Yahoo Auctions.

Table 5: Comparison of Actual Rankings and Results

Rank	Actual ranking	System from the present study	Comparison system
1	Town Work	Part time work	ARASHI
2	Hello Work	Hello Work	JRA
3	Maki Goto	Town Work	Part time work
4	Recruitment	Twitter	*YouTube*
5	Recipes	How to make	Entertainers
6	Search keywords	Youtube	One Piece
7	World Cup	Kaela Kimura	Hawaii
8	Ballroom dancing	Ameba blogs	Tumbling
9	Africa	Cookpad	One
10	Searching for a partner	Jalan	Uniqlo
11	FromA	AKB48	Mai Hosho
12	Okinawa	Recruitment	Youtube
13	Rakuten	JRA	How to make
14	Civil servant	Entertainers	Hairstyle
15	ANAP	Moon Lovers	Jalan
16	Principle	JTB	Shoujo Cosette
17	Post office	Yahoo Auctions	Wiki
18	MP3	TVXQ	JTB
19	Rent-a-car	General election	TVXQ
20	Ameba blogs	Kyoto	ANA

6.3.2 Evaluation Results

Figure 3 shows the evaluation results for male users in their 20s.

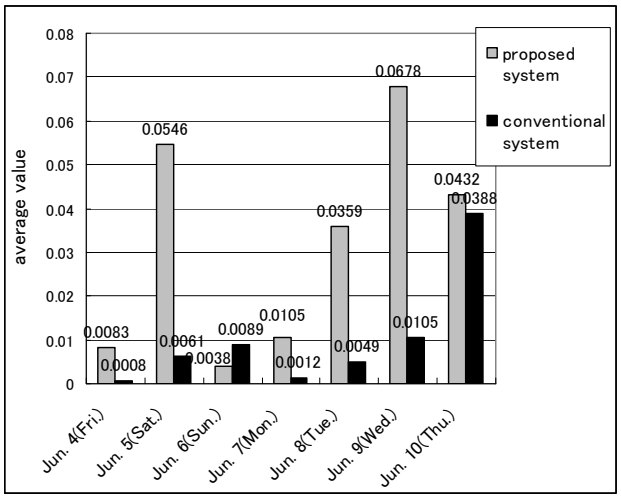

Figure 3: Results for male users in their 20s

Figure 4 shows the evaluation results for female users in their 20s.

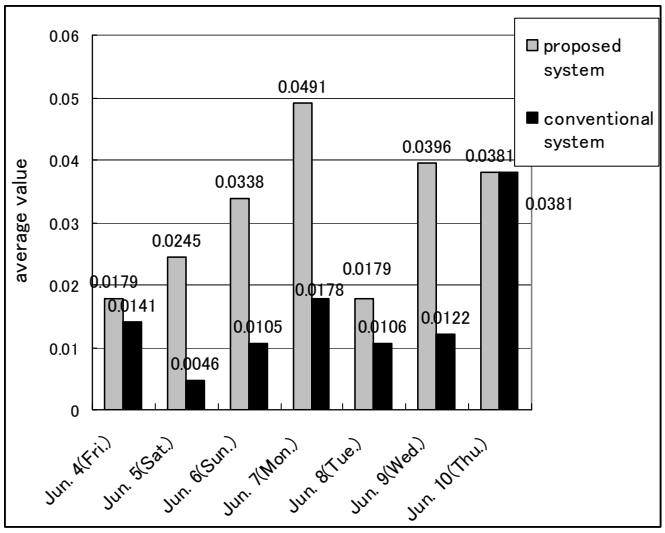

Figure 4: Results for female users in their 20s

Figure 5 shows the evaluation results for male users in their 30s.

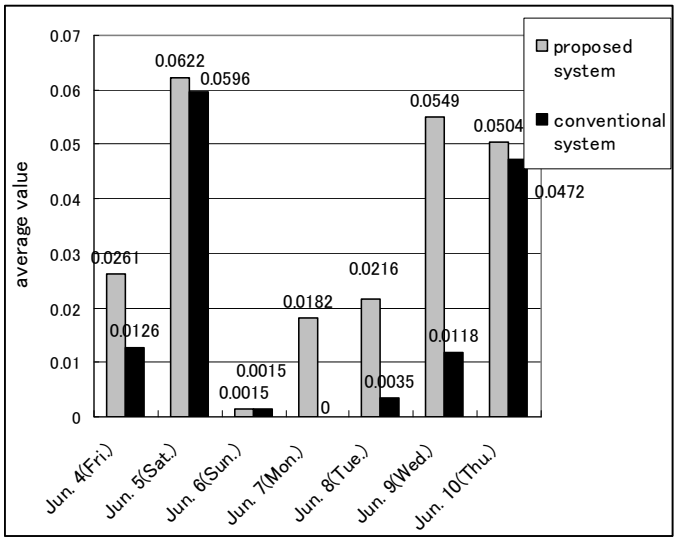

Figure 5: Results for male users in their 30s

Figure 6 shows the evaluation results for female users in their 30s.

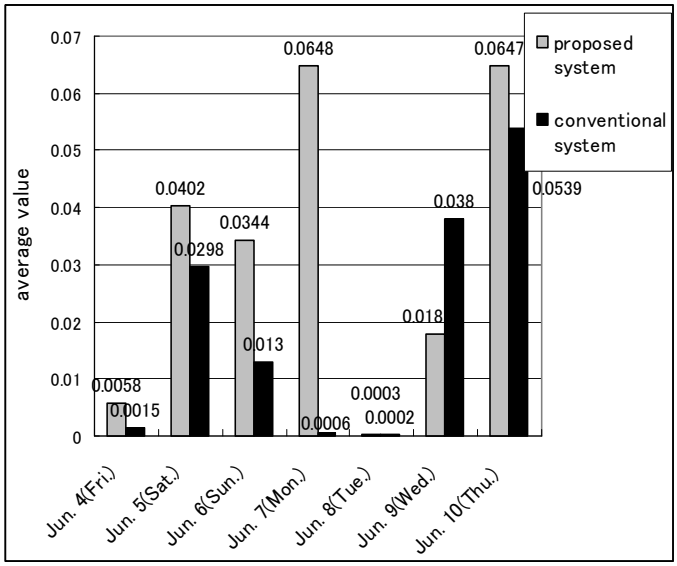

Figure 6: Results for female users in their 30s

6.3.3 Analysis

In order to determine the reasons for the increased accuracy, we analyzed the results for male users in their 20s under the following three conditions: excluding the forgetting factor, using only short-term memory, and using only long-term memory. The results are provided in Figure 7 and Table 6.

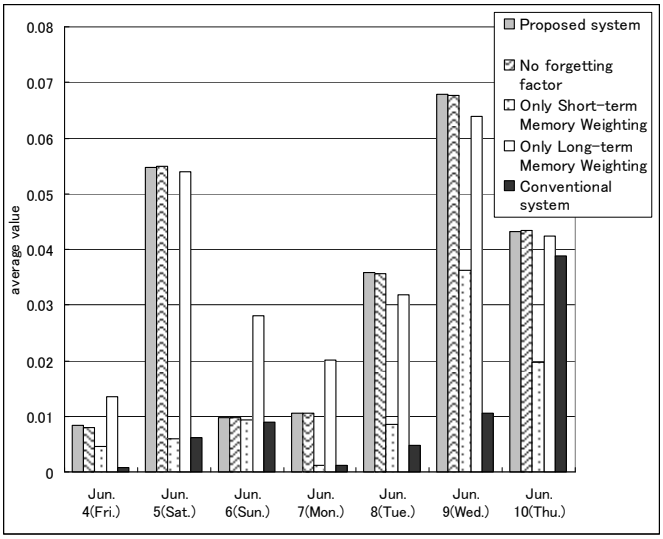

Figure 7: Analysis of results for male users in their 20s

7 Discussion

From Figure 3, it can be seen that average accuracy is high when using long-term memory only and low when using short-term memory only. Furthermore, when accounting for both short-term and long-term memory, accuracy was even higher than when only long-term memory was used on four out of the seven days. Thus, we believe that the accuracy of our system can be raised by weighting and adjusting for both short- and long-term memory.

Table 6: Analysis of results for male users in their 20s

	Present study	Forgetting factor excluded	Short-term memory only	Long-term memory only	Existing system
June 4	0.00823	0.05463	0.00981	0.01054	0.03586
June 5	0.00802	0.05499	0.00976	0.01052	0.0357
June 6	0.00463	0.00592	0.00927	0.00127	0.0086
June 7	0.01362	0.05403	0.02797	0.02018	0.03177
June 8	0.00084	0.00612	0.00892	0.00116	0.00486
June 9	0.00828	0.05463	0.00981	0.01054	0.03587
June 10	0.00802	0.05499	0.00976	0.01052	0.0357

Additionally, the forgetting factor did not appear to have any significant effect. We think this is because the system does not account for "recognition" [9] in the forgetting curve. Here, recognition refers to the ability to identify something that has been previously encountered. By nature, recognition of a previously encountered phenomenon (before it is completely forgotten) will flatten the slope of the forgetting curve. Thus, in the present study, it was necessary to devise ways to distinguish keywords that could be recognized from those that would be completely forgotten by flattening the forgetting curve slope for keywords with multiple search ranking entries.

8 Conclusion

In this paper, we proposed a method of extracting Web search keywords of interest to users by gender, age, and day of the week. In our experiments, we experienced particularly good results by focusing on three concepts: keyword consolidation, forgetting factor, and short-term and long-term memory. We believe that in the future, we will be able to obtain even better results by appropriately adjusting the weighting ratio for short- and long-term memory, and by including in the concept of recognition. Furthermore, it will be necessary to build a system that can search and suggest actual news articles based on the keywords extracted using the proposed method. Doing so should allow suitably equipped robots to autonomously introduce topics capable of stimulating rich intellectual conversation.

Application of Defeasible Domain-Specific Knowledge to the Description of Gothic Cathedrals in the ARC Project

Abstract - *The goal of the Architecture Represented Computationally (ARC) project is to build a complete system by which user input or written descriptions of Gothic cathedrals are automatically represented logically, allowing validation consistency, query-answering, and the generation of precise textual or visual descriptions.*

This paper will briefly cover the first major step in the implementation of this system, which is the knowledge representation and inference engine, with particular focus on the meta-programming and non-monotonicity of the application. The meta-programming allows users to define terminology, add facts, and create constraints without the need to understand Prolog. The non-monotonic knowledge representation allows the user to create rules about general concepts and conflicting rules about subsets of those concepts, from which the correct results are inferred. This ability of the ARC systems allows the user to "overgeneralize and then except," which is a basic aspect of natural description.

Keywords: Prolog, Gothic cathedral, architecture, Defeasible reasoning

1 Introduction

The ARC Logic system, implemented in Prolog, focuses on creating a system that is user-friendly through the use of two specific features. First, domain specific knowledge is represented in a manner similar to a natural method of description. Users can define terminology, assert facts, and create constraints with no programming experience. The second feature is the non-monotonicity of the knowledge representation and reasoning engine. Together, these two features narrow the gap between natural description and logical representation, which is advantageous for direct use of the system, as well as integration with automated natural language processing system. The ARC Logic user can approach a description already possessing a large amount of background knowledge and assumptions, explicitly stating only those things which vary from the background knowledge. Architecture, especially the architecture of Gothic cathedrals, is suited to this foray into description understanding because it generally follows a limited set of logical rules, and although individual cathedrals can vary, there are clear default models to work with [1].

Section 2 of this paper briefly discusses the way in which natural description uses default models, background information, and assumption from non-monotonic rules. Section 3 explains how this non-monotonic nature is modeled in the ARC Logic system as defeasible facts and rules, and how goals are derived with respect to defeasibility. Section 4 introduces the meta-programming predicates with which the user can create and customize domain information without Prolog expertise. Section 5 shows how the non-monotonic ARC system handles conflicting facts, and rebutting or undercutting constraints. The final section highlights the use of scope and the way a user can combine general and specific descriptions to naturally and logically model Gothic cathedrals.

2 Natural description

The goal of the ARC project is to allow users to easily create and use logical descriptions of Gothic cathedrals, and to eventually have an automated process by which usable logical descriptions can be extracted from natural language textual descriptions [2] [3]. The closer the logical system is to encapsulating the natural style of description, the more efficient and accurate it can be. Natural descriptions do not start in a void; they take into account the assumptions from generic models or sets of norms and then describe how a specific case varies from these generalities. As a result, a complex understanding of some specific cathedral can be

conveyed with little explicit description. A describer relies heavily on the ability of those receiving the description to fill in all the missing information by making assumptions based on their own knowledge. The describer makes assumptions about shared understandings of basic aspects of a cathedral, just as communication in general requires an assumption of shared understanding of each word used. This ability to work with assumptions also allows the user to ignore, at least explicitly, those aspects which fit expectations, and focus cognitive resources on analysis of only the deviations.

Because Gothic cathedrals follow relatively strict conventions, one can assume most of the knowledge about the structure of a specific building solely from the information that the building is a Gothic cathedral. The ARC Logic system allows users to create or use rules that apply generally to the domain, in addition to the information present explicitly in a given description. Users can describe columns, bays, choirs, or other information that is generally assumed background information in a description of Gothic cathedrals by creating constraints that apply to these general objects. Constraints can also be used to describe a complete logical model for an entire default Gothic cathedral. Just as assumption is necessary for filling in the gaps to understand a sparse natural description, a default model of a cathedral can fill in the logical gaps for all of the information not explicitly stated in a description of a specific cathedral. By modifying only the abnormalities or attributes which cannot be assumed by default, a complete logical description of a specific cathedral can be created with the small amount of explicit information.

The use of assumptions and background information in description requires the ability to hold rules that apply to a set of things, while holding conflicting rules that apply to subsets of those same things, and then reason with all of these rules appropriately. Since new information can override previous assumptions, the method of natural description is non-monotonic, and the ARC Logic system uses non-monotonic reasoning to model this.

3 Non-monotonic logic system

In monotonic logic, new information can only add new knowledge, not remove something previously derivable. If some sentence p is entailed by some set of sentences, then p must be entailed by that set and any additional sentences. The type of description modeled by the ARC project makes generalized statements and then exceptions to those generalities. Exceptions indicate that there are sentences entailed by the general rule but not by the general rule and the addition of those exceptions, so the system cannot be monotonic. Assumptions are a result of the necessity of working with uncertainty, and non-monotonic reasoning is a method of accounting for this uncertainty.

Defeasible reasoning is one of these non-monotonic methods. In defeasible reasoning, information can be classically true or false (indefeasible), but one can also work with information that should be assumed to be true or false (defeasible), unless there is a reason not to keep the assumption. This way, a user can create a defeasible rule, which can result in the derivation of defeasible facts, and then some or all of these facts, and even the rule itself, can be overridden, modified, or removed by additions to the knowledge base.

The ARC Logic system has three types of information: facts, rules from the logical properties of terms, and constraints. This system allows a user to specify, for each piece of information, the certainty of the knowledge being used. The inference engine then derives everything from the knowledge base that can be derived. Where valid inference in traditional logic is truth-preserving, valid inference in this system is certainty-of-truth-preserving, or defeasibility-preserving. Something derivable from only indefeasible premises is known indefeasibly, while derivations that require any defeasible premise can only have a defeasible conclusion.

Adding this functionality to standard Prolog for the ARC Logic system required two additions. First, ARC's logic system has a way to hold meta-information about facts, constraints, and rules from logical properties of terms. Secondly, the system has a defeasibility-preserving inference engine that uses this meta-information of facts and the defeasibility of rules.

3.1 Fact meta-information

In classical (monotonic) logic and traditional Prolog, proven consequents can be separated from their consequence relations. The set {A, A => B} entails B, so B can be used without continued consideration of the set that entailed it. In a defeasible system, however, the consequents of rules may "not be detachable even when their antecedents are derivable," [4] as one of these detached consequents could be defeated by additional information. The ARC Logic system is forward-chaining, filling the knowledge base with all the facts that can be inferred from the information in the knowledge base. To fill the knowledge base with independent facts requires detachment of the derivable consequents from their antecedents. This implementation circumvents the need to keep facts

tied to their method of proof by keeping two important pieces of metadata for each fact in the knowledge base.

The first piece of metadata is the defeasibility of the fact, which can either be defeasible or indefeasible. The ARC system's use of defeasibility could be considered a binary measure of certainty. If a fact is indefeasible, then it is known with certainty. If the fact is defeasible, then it is reasonable to assume it is true unless we have information to the contrary. The criterion for each assumption is completely up to the user, just as the semantic value of some logical fact or rule is. There is no measure of "how certain" or "how strongly to assume" in this implementation; something is considered defeasibly true if it is derivable, no matter how many defeasible facts and rules were used in this derivation.

The second piece of metadata stored with each fact is the origin of the fact, which can be either inferred or explicit. Because the system is non-monotonic, information already in the knowledge base is not necessarily safe from being removed with new knowledge. If some fact or rule in the knowledge base is modified, removed, or added, the system needs a way to expunge all the facts that required the now-missing information and all facts that were derivable because of the lack of the now-added information. The ARC Logic system uses a blunt method for removing information that is no longer derivable. When the inference engine is called, the first step is a retraction of all facts which are both defeasible and inferred. When the new inference is complete, all and only those facts that can be inferred from the known information are added back to the knowledge base. Explicitly-added defeasible facts can still be removed from contradictions, but it is important that they are differentiated from inferred facts, because their inclusion in the broad retraction could remove information with no way to recover it.

3.2 Defeasibility-preserving inference

The metadata holds information about the facts, but to add new facts with the correct defeasibility requires a defeasibility-preserving method of inference. The ARC system uses a predicate d_call/2, which is used in place of Prolog's regular call/1 functionality to answer queries or find all the facts that are derivable from the knowledge base. When d_call matches with a fact, it uses the defeasibility metadata about that fact. Of course the d_call predicate also uses Prolog rules, created from constraints and logical properties of terms, in order to prove goals. A constraint meaning "capitals are above shafts in every column," forms a rule in the knowledge base that essentially looks like above(A,B) :- object(capital, A), has(C,A), has(C,B), object(shaft, B). To prove above(A,B), each goal in the body has to be proven just like in a regular Prolog call. When there is a conjunction of terms in the body, the goal (head) is given the same defeasibility as the weakest link; if any one of the clauses is only provable defeasibly, the new fact must also be defeasible. If through backtracking, alternative proof methods are found, then the strongest defeasibility amongst these is assigned to the new information. In the ARC implementation, indefeasible vs. defeasible of d_call/2 works the same as true vs. false in classical logic; one false/defeasible clause makes the whole conjunction false/defeasible, and one true/indefeasible clause makes the whole disjunction true/indefeasible.

Prolog rules created from constraints and logical properties of term definitions also hold defeasibility, in that they each contain a goal in the body that is always defeasible or always indefeasible. If the constraint said "capitals are defeasibly above shafts," an always-defeasible goal would be included in the body of the rule, so the above fact would be defeasible, even if the capital and shaft objects are known indefeasibly.

4 Domain knowledge input

The logical representation of a cathedral comes from the facts about objects or their relationships, Prolog rules from the logical properties of relationship terms, and Prolog rules from the creation of constraints. These relationship terms and constraints are based on knowledge of a specific domain. The logic engine has no built-in rules for any specific relationship term or constraint, with the exception of the special relations has and contains. Instead, the system uses meta-programming methods to create Prolog rules from the domain-specific knowledge that users input. This approach allows users to define relationships (like above) and objects (like shaft and base), and to create constraints (to say "shafts are above bases"). These predicates allow users to create and modify complex ontologies in whatever domain they want, without the need to understand the Prolog programming language.

4.1 Term definitions

Term definitions are used to designate object and relationship terminology, and imbue the terms with the expected logical behavior. The predicates define_relationship/2, define_metarelationship/3, and define_object/3 take names and logical properties as the arguments and assert all the necessary Prolog

rules to the knowledge base at run-time. For example, a user describing Gothic cathedrals or any other architecture would likely want to use the relationship above. In most contexts, aboveness implies transitivity; the set {above(A,B), above(B,C)} should entail above(A,C). This entailment follows when a rule for the transitivity of above is added to the set. A user can implement this functionality by calling define_relationship(above, [transitive]). The first argument is the name of the relation, and the second argument is a list containing any combination of the values: symmetric, reflexive, transitive, or variations of these three. The appropriate Prolog rule (or rules) is created and asserted to the knowledge base at run-time for each of these properties in the list.

Negative versions of these logical properties are one type of variation. Standard Prolog does not have explicit negation; the \+ predicate designates negation by failure, and lack of some fact in the knowledge base means that proposition is defeasibly false. To define facts as indefeasibly false, the ARC system requires an explicit negation function. Negation is designated by an alteration of the name itself (adding or removing a 'not_' from the front of the predicate atom), so negative relationship facts are treated the same way by the ARC Logic system as positive facts.

A user can include any of the negative versions of the logical properties: asymmetric, irreflexive, and intransitive. The relationship of immediately above, for example, can be made explicitly intransitive by adding intransitive to the list of properties. This creates a rule with the same body as the transitive version would have, but with a head of the negated predicate, so that anything which can be derived from transitivity is explicitly negated.

A user could work with a taxonomy that avoids explicit negation altogether. If imm_above is created without any version of transitivity, the program would not be able to infer imm_above(A,C) from imm_above(A,B) and imm_above(B,C). Adding explicit negation could increase the thoroughness of the procedure for checking consistency.

These three positive and three negative logical properties each create indefeasible Prolog rules; if everything in the body can be proven indefeasibly, the goal is known indefeasibly. By adding 'd_' to the front of a property, the user can indicate it is a defeasible property, making 12 variations in total. It may be useful to assume that bears_weight_of is transitive, but should not be a certainty. Designating bears_weight_of as d_transitive creates the same rule as regular transitivity, except the always indefeasible goal in the body is replaced with an always defeasible one.

In addition to defining relationships between constants, the user can also define the relationships between these relationships with define_metarelationship/3. The first argument is either antonym or implies, and the next two arguments are previously-defined relationship terms. Synonymy is another logical meta-relation, but since it only creates redundancy, the user (or a natural language processing system) should decide on one naming convention. Antonymy in this implementation designates a converse relation, such that define_metarelationship(antonym, above, below) allows the system to infer below(B,A) from above(A,B), and vice-versa. define_metarelationship(implies, imm_above, above) allows the system to infer above(A,B) from imm_above(A,B). Defeasible properties are implemented in define_metarelationship/3 the same way. define_object/3 works very similarly to define_metarelationship/3, allowing users to designate subtypes and supertypes.

4.2 Defining constraints

Constraints are user-created statements that enforce existence of objects or relations between objects. Like term definitions, constraints are designed with the intention of striking a balance between versatility and usability for non-Prolog-programmers. The information given in constraints is used to automatically create Prolog rules which are asserted to the knowledge base.

The has and contains relations, which are parent and ancestor relations for objects, respectively, are the only relationships built into the ARC Logic system. These relationships are necessary for the description of objects and work differently with respect to objects than user-defined relations like above. Constraints that use the has relationship also work differently than constraints that use user-defined relationships.

If a user wants to add to the knowledge base the information that "each column has a base," the user only needs to input create_constraint(column, must, has, base). This lower arity version fills in the missing argument values with defaults, calling the complete query of create_constraint(X, object(column, X), must, has, 1, 1, base). This can be read as "For all x, if x is of type column, then it must have a minimum of one and a maximum of one base." The Prolog rule created from a has constraint checks that the minimum number (fifth argument) of objects of some type (last argument), are a part of any object that matches the condition of the first two arguments, and creates new objects if the minimum is not met.

Constraints can be written for any user-defined relation as well, but they work differently. A user-defined relation constraint can use any numbers for minimum and maximum, but the default value when not designated is all. The all value signals that the relation holds for any number of objects matching the conditions. create_constraint(X, object(shaft, X), must, above, all, all, base) means that every shaft object is above every base object where both objects belong to the same parent object (by a has relation). Constraints about user-defined relations create Prolog rules that only apply between sibling objects, as it would rarely make sense or be useful to say something like "the shaft in column 1 is above a base in column 2," and they only create new facts about relationships, not create new objects, if the minimum is not met.

The first and second arguments comprise the condition, and work the same way for any kind of relationship. The first argument is a universal quantifier and the second argument can contain any number of Prolog terms. The constraint applies to any object/constant in the knowledge base that meets the conditions. Since the most common condition is simply "all objects of some type," a user can write simpler queries by just giving a type name instead of the first two arguments, so create_constraint(column, must, has, 2, 3, base) calls create_constraint(X, object(column, X),must, has, 2, 3, base). Conditions can also be written with higher complexity. If, for example, a user wanted to make this constraint only apply to columns in the arcade level, they could enter create_constraint(X, (object(column, X), contains(Y,X), object(arcade_level, Y)), must, has, base).

Constraints of course also have defeasibility. A must value in the third argument adds an always-indefeasible clause to the dynamically-created Prolog rule, and a d_must value adds an always-defeasible clause so that all resulting facts are defeasible. This defeasibility also allows the constraint to be contradicted or altered.

5 Defeasible comparisons

This paper has explained how user-defined terms and user-created constraints are added as rules to the Prolog knowledge base dynamically, explained the way facts are stored in the knowledge base with their meta-information, and how the defeasibility-preserving d_call predicate works. Together these allow for all the information in the knowledge base to be labeled correctly as defeasible or indefeasible, but this paper has yet to demonstrate the use of this defeasibility information. The ARC system is non-monotonic and defeasibility-preserving so that it can appropriately handle conflicting information. This section briefly explains how conflicts, in facts and constraints, are resolved.

5.1 Comparing facts

The ARC system performs inference by using the d_call predicate to find every fact that can be derived and then attempts to assert each fact. It is "attempt to assert," not simply "assert," because the assertion of a derived fact into the knowledge base is not guaranteed. Whenever assert_fact/3 is called, the knowledge base is checked for matching and conflicting facts. If matching facts are found, the strongest version is kept. If conflicts are found, they are resolved as shown in Table 1.

Table 1. Fact Comparison

	New fact defeasible	New fact indefeasible
Old fact defeasible	Both facts removed	Old fact removed New fact asserted
Old fact indefeasible	New fact ignored	Requires fix

If the conflicting facts are both indefeasible, this is the same problem that arises with contradictions in classical logic. The ARC Logic system cannot automatically resolve this problem, and instead warns the user, because an indefeasible contradiction signals that either the user's ontology is self-inconsistent, or is constructed in a way that does not meet the specifications of the program.

5.2 Comparing constraints

The ARC system can resolve conflicting facts as long as at least one of them is defeasible. The same is true for constraints, but handling these conflicts is more complex. Constraints conflict if they have the same conditions and same object type for the consequent, but the relations are explicit contradictions, or the minimum of one constraint is greater than the maximum of the other.

The terminology used for conflicting constraints is adapted from John Pollock [5], who distinguished rebutting and undercutting defeaters. Defeaters make no positive claim; they only attack other defeasible assumptions. Rebutting defeaters give reason against some conclusion, while

undercutting defeaters give reason against some line of reasoning [5]. The ARC Logic implementation does not use defeaters, but regular constraints can defeat some or all of the results of defeasible constraints they conflict with. When the conditions are exactly the same, the constraints rebut each other, because the same antecedent conditions lead to contradictory conclusions. Resolution of rebutting constraints is the same as resolution of conflicting facts shown in Table 1.

Rebutting constraints can be useful, but in order to match the style of natural descriptions, which often overgeneralize and then make exceptions, the ability to create constraints that are general and other constraints which are exceptions is needed. If one constraint applies to a set of object instances, and a conflicting constraint applies to only a subset of those instances, then this second constraint undercuts the first.

If a user wanted to model "it should be assumed that each column has a base," but also "columns in the arcade level do not have a base," these would be created by create_constraint(X, object(column, X), d_must, has, 1, 1, base) and create_constraint(X, (object(column, X), contains(Y,X), object(arcade_level, Y)), must, has, 0, 0, base), respectively. The latter constraint undercuts the former, because the constraints have conflicting min-max values, the former constraint is defeasible, and the condition of the latter means the constraint applies to a subset of the former. This is the case regardless of the defeasibility of the undercutting constraint and the order in which the constraints were asserted.

To determine that the latter constraint undercuts the former, the program basically checks (with exceptions for subtypes and contains terms) if each term in the condition of the former constraint is inside the condition of latter constraint. If they are, then the latter undercuts the former. This check function also returns the difference between the two conditions. In the example above, the difference is ((contains, Y, X), object(arcade_level, Y)).

The ARC Logic system works with the natural assumption that more specific information takes precedence over more general information. When confronted with the information about columns in general and columns in the arcade level, a human being would assume that some specific column instance, which is in the arcade level, does not have a base. In natural human description, assuming other factors are equal, the more specific information has more justification. The ARC Logic system resolves undercutting constraints in a similar manner. The more specific constraint is added to the knowledge base without modification. The more general constraint, which was undercut, is retracted and modified before it is asserted back to the knowledge base. The modification turns the implicit exception, which the user does not need to indicate, into an explicit exception. The constraint is modified by adding the difference in a negation-by-failure predicate to the condition.

After the comparison, modification, and assertions, the knowledge base from this example contains two constraints (in their Prolog rules format) corresponding to constraint(X, (object(column, X), contains(Y,X), object(arcade_level, Y)), must, has, 0, 0, base) and constraint(X, (object(column, X), \+ (contains(Y,X), object(arcade_level, Y))), d_must, has, 1, 1, base). Upon inference, if there is a column in the knowledge base, the inference engine will ensure it has a base, unless d_call can prove that the column is contained in an arcade level. If later information shows that the particular object is part of the arcade level, the defeasible and inferred fact of having a base will have been removed, and not asserted back, on the next call to the inference engine.

6 Creating complete descriptions

The ability to create overgeneralizing constraints can be useful for describing generalizable concepts like columns, but this same functionality also allows the combining of constraints about general Gothic cathedrals with constraints and facts about specific cathedrals.

The number of stories in the nave of a Gothic cathedral is an important part of an architectural description, but this number varies from cathedral to cathedral. One could create a description of a generic, default, Gothic cathedral with constraints that say each cathedral indefeasibly has a nave, and that a nave indefeasibly has an arcade and clerestory, and defeasibly has a gallery and triforium, because these levels are not always or necessarily present in every Gothic cathedral. The vertical slices are called bays, and these can also vary in number depending on the cathedral. Constraints could state that each cathedral indefeasibly has a minimum of 4 bays and a maximum of twelve bays running along the side of the nave. Even though there has to be at least 4 bays, the generic model could contain the constraint that the nave defeasibly has a minimum and maximum of 7 bays running along the side. The ARC inference engine will create 4 indefeasible bays and an additional 3 defeasible ones.

To describe a specific cathedral, like Chartres, constraints can be added to the general constraints, to say that if something is a cathedral, and is chartres, no (a maximum of 0) gallery. This new constraint is in conflict with an old defeasible

constraint, but because it is more specific, it undercuts the old one. The resulting knowledge base ensures that a gallery will only be created for a cathedral object if there is no way to prove that that cathedral is chartres. This works the same way with the number of bays, and down to any level of detail.

To create a constraint that applies only to objects in chartres, the user would add contains(chartres, X) to the conditions of the constraints. Manually including this information in each constraint about the specific cathedral is not intuitive, especially if one is working with a set of general constraints already created, and is only writing constraints that apply to a specific Gothic cathedral. To correct this, the ARC logic system includes a way to alter the scope of the input data. In natural description, it is often very clear (to a human reader) if a description is referencing a concept in general or a specific instance that fits that concept. The user accesses this ability with the predicate set_scope/1. The scope indicates the outermost object that is being described. Whenever a constraint is created, a contains(Scope, X) is added to the condition, where Scope is the current scope set in the knowledge base and X matches the universal quantifier of the condition. If constraint A has the term contains(some_constant, X) in the condition and constraint B has the term contains(some_other_constant, X) in the condition (which is otherwise the same as A), then constraint B undercuts constraint A as long as contains(some_constant, some_other_constant) is derivable.

This same principle works with parts or sections of a Gothic cathedral just as well as differentiating between specific cathedrals or default models. The scope can be considered a "zooming" function that allows one to designate that the following constraints describe only a particular area of a cathedral, just as they can designate that some constraints only apply to Chartres Cathedral or Notre Dame de Paris.

The scope functionality of ARC system simplifies the user's ability to create a description of a specific cathedral, or part of a cathedral, or even a specific cathedral at a certain point in history, from a hierarchy of descriptions. Since this system can be used outside of the description of Gothic cathedrals, it might be useful to write constraints that apply to a generic building ("it has a floor, ceiling, and door," "the ceiling must be above the floor," etc.), then create a description of a generic place of worship by only describing the ways in which this would differ from a generic building. A description of generic Gothic cathedrals could be built from this description of a generic building of worship, or default Gothic cathedrals built in a particular century, or some other logical description models that would be useful for architectural historians. The user can also use this scope ability to describe and/or compare more than one cathedral in a single session.

The ARC logic system allows a user to add domain-specific knowledge to the system, creating a custom ontology and description without the need for expertise in Prolog or programming in general. The system also enables the user to combine any number of default and specific descriptions at different levels. These abilities, along with an inference engine that deals automatically and appropriately with defeasible information, capture an important element of natural description and natural intelligence, and form a solid foundation for the future ambitions of the ARC project as well as ventures into other related domains.

Abstract— *Most part of the document retrieval systems use defined keywords by the user to find documents. In the information retrieval, for some application, is important to have a system that, instead of putting a keyword, takes a complete document and gives us as output a set of documents more similar to the input document. This paper presents an approach to compare documents and proposes - through the use of MFS to represent the tokens - two heuristics that can be used together with TF-IDF algorithm in order to improve the results in the document retrieval. The results showed that the use of these heuristics improves the accuracy of the TF-IDF algorithm and generates smaller indexes for document representation.*

Keywords: document retrieval, vector-space model, term weighting, maximum frequent sequences

1. Introduction

Nowadays semi-structured data, especially text documents, represent a new challenge for researches in developing methods and tools for its indexing and retrieval. According to [1], the Internet is doubling its size every 5.32 years. Considering this growing rate and the value of the information, it becomes necessary the creation of new search engines based on new approaches for efficiently store and retrieving the information, as the use of text sequences in the representation of the content and new methods for evaluation of the importance of that content [2], [3].

Two other issues are relevant in the process of information retrieval when applied for document search: the size of the generated indexes for document, due to the necessity of storage space to keep that information available for researches, and the use of heuristics to improve the computation of the similarity between the documents that have a big impact in the performance and quality of the answers obtained from the system [4], [5]. Most of the systems that proposed to retrieve documents from a collection are based in the principle of comparing every document with some keys chosen by the user. This common approach has some deficiencies when the user needs to find documents more similar to one specific target document, because the user, after reading the target document, will determine its keywords and submit them to the retrieval system to obtain the most similar documents [6]. The system normally indexes and chooses the keywords for the documents in its database, and the way the system performs it rarely will be the same as the human uses [7].

In this paper, we propose one approach to improve the results obtained by search engines that use TD-IDF algorithm for indexing the documents through the use of MFS in two different and not exclusively ways: the first one weighs the MES by its size and the second weights the MFS accordingly to the region of the document that it appears. In the second approach, the human knowledge was mapped for a set of documents of one specific subject to establish the weights of the MFS according to the region of the document. One overview of the system is showed in Figure 1.

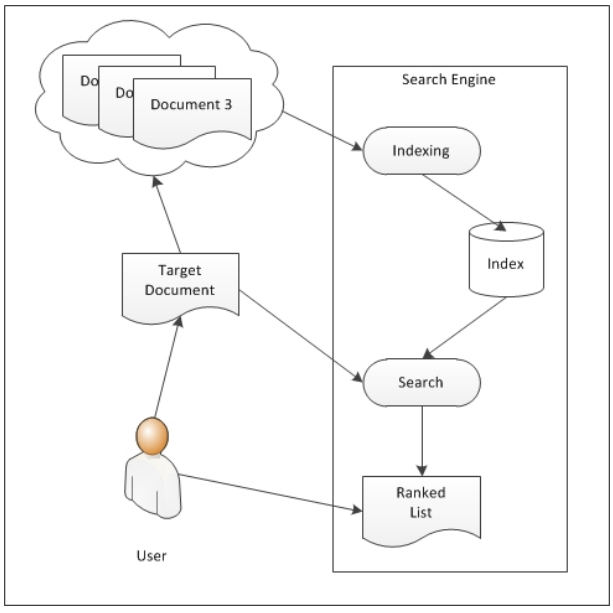

Fig. 1: Proposed Search Engine Architecture

2. Basic concepts

The classical, most used and still competitive Information Retrieval model is the Vector Space Model, created by [8], on which a document is represented as a vector and each

position of the vector is filled with the terms that compound the document. This approach begins by assuming words to be independent of each other. After this, statistics are collected for individual tokens, both in the query and in the documents that compound the collection [9]. Classical is the combination of term frequency (TF), [10], and inverse document frequency (IDF), called TF-IDF. TF is a measure of term relevance at analyzed documents or the query: the more often a term appears in a document, the more important term is to the document. IDF measures the term importance over all documents of the collection: terms that rarely appear over all documents are more important in discriminating the documents. There are some approaches to compare two documents, but the most widely used is one called Cosine Distance, that calculates the cosine measure between the angles formed by two points drawn in a cartesian plan. The main disadvantage is that this model does not take in account the word order

Here we propose his use, but instead of representing documents by using its single words, we will use word sequences, called Maximum Frequent Sequences, defined in [11], [12]. The three main characteristics that define MFS are: 1) Maximum because one MFS could not be a subsequence of another sequence, 2) Frequent in the document it occurs and 3) Sequence composed by terms of one phrase, from the same document, considering the order that the terms appear in the phrase and allowing gaps between the terms that it composes. In the process of extraction of MFS from a document, some parameters could be set, such as: maximum size accepted, minimum size, maximum gap, minimum threshold to be considered frequent. In order to evaluate the importance of the MFS, two new relevant metrics are proposed: the first one considers the size of the MFS and the second considers the region of the text it appears.

The objective is to create a methodology for document retrieval in which every document has its representation through MFS extracted for it, using the heuristics to improve the results and consider, in the evaluation, the information about the region of the document the MFS is found. The human knowledge will be merged with the other heuristics in order to provide the importance of one MFS according to the text region.

3. Related works

In [13], is pointed that, with the combined use of single words and word sequences, is not useful to apply the same relevance measures, as TF-IDF. This happens because usually the word sequences are less frequent than single words and this make them to have a not good relevance.

In[14], is proposed the use of MFS as document descriptors, using the vector space model, but they use the classical TF-IDF as weight measures and, as shown later on this paper, it is not the best way to measure the importance of a MFS.

4. Proposed relevance measures

Once the documents are represented according to the vector space and use tokens such as MFS, the next step is to define how to value the importance of each token. Here, the goal is to make the weight of an MFS reflect its content within the document in which it appears relative to its expression, representation and differentiation among the other documents that compose the collection. In order to compare and validate the results, the experiments will use the classical TF-IDF. The proposed metrics can be combined according to the representation in Figure 2 and, it is possible to use all of them together or choose other combinations of metrics along the document indexing process.

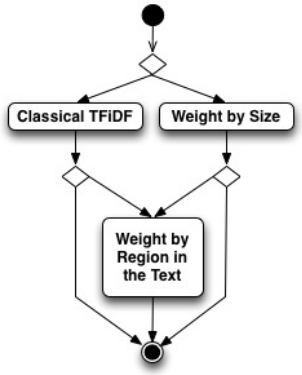

Fig. 2: Possible Combination of the Relevance Measures

4.1 Weight by size

The main idea is that the bigger the MFS is, the bigger its semantic value is and the better it can be used to describe the content of the document. In the same way, the bigger the MFS shared between a set of documents is, the bigger the similarity of that set of documents is if compared with the similarity between documents of another set that shares smaller MFS. The notion of bigger and smaller is represented in the Equation 1 and the value depends of the documents that compose the collection.

$$w = (ap \times tAp) \times (\frac{mfsSize^{IFactor}}{greatestMfsSize^{IFactor}}) \quad (1)$$

Where ap is the amount of times a MFS appears in the analyzed document; tAp is the amount of times that a MFS appears in all the documents that compound the collection; mfsSize is the size, in words, of MFS; $greatestMfsSize$ is the size of the biggest MFS that the indexed document has and $IFactor$ is the configurable parameter with any value, greater than zero, and is used to set the distance between

MFS from different sizes. In the tests we performed, it was used a value of 2.

4.2 Weight by region

In this approach, the objective is to evaluate the importance of one MFS according to the region it occurs in. For instance, one MFS that is present in the introduction is better than another one that appears in the middle of the text. To establish the weight, according to the region the MFS occurs, a set of human evaluators analyzed a set of documents from one particular subject, indicating what phrases in the content are more important to understand the document. The regions of the document are established according to the phrases that compose the document; one document with 35 phrases is divided in 35 regions. The data collected will be used to create a calculation memory for the documents of that particular subject and will be used for weighting the MFS, considering the region of the document, as showed in Equation 2.

$$weightForRegion = \frac{\sum_{i=1}^{n} regionWeight_i}{n} \quad (2)$$

Where $regionWeight_n$ is the weight, obtained from the calculation memory, from region i, where the MFS in question occurs. The weight of all regions is computed by a sum operation and an arithmetic average of the weights is computed.

The final value, $weightForRegion$, is multiplied with w, that can be obtained from the equation of the Weight By Size or by classic TF-IDF.

5. Data acquired

In order to evaluate the effectiveness of the proposed heuristics against the classic TF-IDF, we defined a methodology, creating 6 groups of evaluation. Each group had one target document and a collection of 5 other documents, composing a total of 30 documents. The documents chosen for the experiments are politics editorials from a Brazilian popular newspaper, with average size of 24 phrases and 602 words.

Given the target document, we ranked five documents in each respective group using the algorithms, sorting them according to their similarity with the target document. The ranked list created by the applications was compared with a ranked list generated from the human evaluation. The experiment was made with 9 journalism and media students, and a web application called AVALIA was developed to help the students through the evaluation process. We can split the collected data in two subsets: Data for Control and Calculation Memory.

5.1 Data for control

Collected from the human evaluations through the AVALIA system, represented in Figure 3, where the students sorted a list of given documents accordingly to their similarity with the target document.

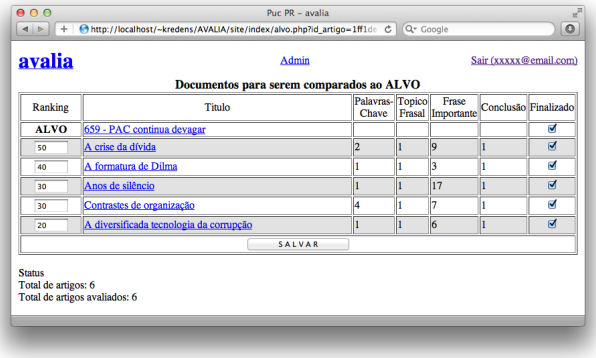

Fig. 3: AVALIA's screen shot, used by users to rank the documents.

This set of collected data was used to compare the efficiency of the heuristics proposed in this paper with the traditional methods for weighing tokens. The data was summarized for the 6 groups of documents, creating 6 rankings of documents, sorting them accordingly to the similarity with the respective target document. Table I shows the data from group 1, for which the target document was document 44.

Table 1: Consolidated ordenation of target 44

Evaluation 2, TARGET 44												
		Student - Adjusted Ordination										
Document		50	51	52	53	54	56	57	58	61	Σ	Average
3^o	23	5	1	3	1	4	1	5	3	2	25	2,778
4^o	26	3	4	2	4	2	1	3	2	4	25	2,778
5^o	41	1	0	1	5	1	1	4	1	1	15	1,667
1^o	43	4	3	5	3	3	2	2	4	3	29	3,222
2^o	45	2	2	4	2	5	3	1	4	5	28	3,111

5.2 Calculation memory

Using the ranking information provided by the evaluators about what phrases are most important in every document, the collected data was grouped and interpolated in order to determine what region of the texts is more important. This data will be used to weight the MFS accordingly to the region of the document it occurs, and a metric was created to determine what regions of the text are more important accordingly to human evaluation. Table II shows the values of the ranking obtained from the human evaluation for every group of documents and, in column Weight, is the arithmetic average from all groups ranked.

The distribution of the weights accordingly to the region of the document for the experiments is showed in Figure 4, where the graph representation was calculated considering an interval of confidence of 95%.

Table 2: Consolidated ordination of phrases from users perspective

	Evaluation						
Ordination	24	30	41	42	44	46	Weight
0	0	0	0	0	0	0	0
1	2,458	2,897	3,117	1,737	2,534	1,996	2,457
5	4,816	5,039	10,391	5,768	8,198	6,362	6,762
10	4,082	6,097	4,143	4,658	4,709	4,935	4,771

6. Results

In order to test and validate the proposed heuristics, 9 different experiments have been created with the merge of the proposed heuristics and classical methods, with special attention to the removal or not of stop words and type of tokens. The list of experiments is represented in Table 3. The combination and merge of the techniques, represented in all 9 experiments with the 6 groups of documents, generated a set of 54 tests and 324 different indexes. The basis of combinations proposed on this paper can be viewed in Figure 2.

After concluding the creation of indexes, the 6 target documents were ranked with the documents in each respective group, in order to create a ranked list with similarity of the target document over the other documents in the group. In all experiments, the cosine similarity measure was used. After this process, every one of the 6 groups of documents had 10 rankings of similarity: one based on human evaluations, and the 9 others on the combination of heuristics proposed in Table 3. To obtain the accuracy of every experiment, the Equation 3 was used.

Table 3: Experiments created to validate the proposed relevance measures

Experiment	Tokens	*Stopwords* remotion	Weight by Size	Weight for Region in the Text
1	MFS	yes	no	no
2	MFS	yes	no	yes
3	MFS	yes	yes	no
4	MFS	yes	yes	yes
5	MFS	no	no	no
6	MFS	no	no	yes
7	MFS	no	yes	no
8	MFS	no	yes	yes
9	Single Words	–	–	–

$$accuracy = \frac{\sum_{i=1}^{5} P_i}{5} \quad (3)$$

Where P_i is the position in the final ranking and receives the value accordingly to the distance between the values obtained in the experiments and human evaluation. When the article is in the same position of the human evaluation, the value is 1, in other cases, his value is decreased in 0.2 for every position dislocated to right or left.

In Table 4, we can observe the final results for the 9 experiments and the accuracy rate obtained in every one of the 6 groups of documents.

Table 4: Consolidated view from accuracy per evaluation

		Accuracy per Evaluation						
	Exper.	1	2	3	4	5	6	Final Accuracy
1^o	4	64%	84%	68%	64%	76%	68%	70,667%
2^o	2	84%	68%	68%	52%	76%	68%	69,333%
3^o	9	84%	60%	80%	68%	68%	52%	68,667%
4^o	3	64%	76%	68%	48%	76%	68%	66,667%
5^o	5	84%	92%	68%	40%	40%	68%	65,333%
6^o	6	84%	84%	68%	40%	40%	76%	65,333%
7^o	1	56%	68%	68%	52%	76%	68%	64,667%
8^o	7	68%	84%	60%	40%	40%	76%	61,333%
9^o	8	68%	84%	60%	40%	40%	76%	61,333%

The experiment with the best result is experiment 4, that uses tokens represented as MFS and the combination of two heuristics - weight by size and weight by region - proposed on this paper. In the second position, is experiment 2, that uses MFS and the heuristic weight by region only, and in the third place, is the classic method, that uses simple words to represent the documents and the TF-IDF method for weighting the tokens.

All the best 3 positions used stop-words removal and all worst 5 positions in the results did not use stop-words removal, what demonstrates that methods, which used stop-words removal, are more effective. The only exception is the experiment 1, which used stop-words removal, token as

MFS, but used only TF-IDF with no heuristics to weight the MFS and demonstrates that the use of MFS and TD-IDF without any heuristics is worst than using single words with TF-IDF.

The last analysis shows that is necessary to create more efficiently heuristics for the use of MFS to represent documents, and the results are easily understood, considering that the TD-IDF method was created to work with single words. The non-removal of the stop-words causes the generation of too specific MFS, representing more specifically the writer style of the document author, what gives to every document unique characteristics and decreases its similarity when compared to others.

Another interesting observation is that the uses of MFS created very small indexes for the documents, as showed in Table V, where we can observe that the index for experiment 9 is about 351% bigger than the indexes generated in experiments 2 and 4. This fact reveals the advantage of using MFS instead of single words, considering storage space necessary to keep the indexes, considering that the size, using MFS, was expressively smaller. That difference is explained considering the nature of the MFS representation, where one text sequence chosen as MFS needs to be maximal - can't be a subsequence of any other sequence in the document. We can have a MFS composed by one single word if this single word is frequent and it is not part of another frequent sequence bigger than it.

Table 5: Consolidated view from index sizes distribution

	Size of the Index per Evaluation (KB)						
Exper.	1	2	3	4	5	6	Average
1	16,4	17,7	21,8	19,7	17,8	15,9	18,21
2	16,4	17,7	21,8	19,7	17,8	15,9	18,21
3	16,4	17,7	21,8	19,7	17,8	15,9	18,21
4	16,4	17,7	21,8	19,7	17,8	15,9	18,21
5	26,4	39,9	35,9	29,7	27,1	25,7	30,78
6	26,4	39,9	35,9	29,7	27,1	25,7	30,78
7	26,4	39,9	35,9	29,7	27,1	25,7	30,78
8	26,4	39,9	35,9	29,7	27,1	25,7	30,78
9	69,5	64,1	66,3	64,7	57,7	61,8	64,01

Although it is not the subject of this study, during the tests, it was noted clearly that the indexing process, when the tokens were MFS, became 6-9 times longer. The extraction of MFS sub process ends up being slow as it tries to generate all possible sequences, according to the configures parameters. But in this process, as all the indexing is done only once for each document, and also the process of calculating the index, which needs to be rerun for each new document, is not affected in its final time and decreased as the final set of tokens is smaller. This can be seen when comparing the sizes of the final indexes.

7. Conclusion

An important contribution of this paper is the fact that the method proposed uses the approach of searching for documents more similar to one target document, instead of searching for documents more similar to one set of keywords defined by one user. This issue is more efficient for retrieval of documents in environments where is necessary to retrieve documents more similar to one specific document, because it considers the taxonomy of the entire target document and avoids human errors in the process of choosing the best keywords in the target document for later use in the search.

The use of MFS to represent and index documents in the process of information retrieval, using the vector space together with proposed heuristics on this paper, obtained best results than the use of single words in both metrics: accuracy and size of the indexes.

The size of the index created for one document also has a big impact in the performance of the retrieval system, because the smaller they are, the less computational resources will be necessary to compare and calculate the similarity between the documents. Also, a smaller index needs less space to be stored.

The metrics defined in TD-IDF algorithms with the use of the MFS, and using human evaluation of the documents to generate a background information about the importance of one MFS according to the region of the document where it is found, demonstrates that the traditional methods based on TF-IDF document retrieval can be improved and achieve better results.

Representational Choices for Problem Solving

Danny Kopec[1], **Christina Schweikert**[2], **Gavriel Yarmish**[1]

Abstract - *An important aspect of teaching is enabling students to analyze and solve problems in a manner most suitable for them. Some people can quickly visualize the effects of a formula. Others may first solve problems with a hands-on model approach, a diagram, or a wordy description. In this paper, we illustrate a variety of representational choices through two familiar problems / methods: the Towers of Hanoi problem and the Bucket Sort. In a broad sense, some representations of solutions may be viewed as "extensional," while others are "intensional." Depending on the predilections of the problem-solver, either approach, in general, may be preferred. We emphasize the importance of making good representational choices when attempting to solve problems. Hand in hand with the understanding of a problem, developing an algorithm for its solution, and the actual solution process and its testing, is awareness of the importance of representational choice. Such awareness is certain to enhance development of students' problem-solving skills.*

Keywords: knowledge representation, problem solving, computer science education

1 Background

It is apparent that during the past 20 years or so, we live in special times that have evolved coincident with the proliferation of the World Wide Web. It is easy to recognize the past two decades as the "Information Age," but the challenge is to convert that information into knowledge. Sowa called it the "Knowledge Soup" [6]. Ingredients of the knowledge soup, which we call the "Knowledge Pyramid," as depicted in Figure 1 may be viewed as the progression from *data*, to *facts*, to *information*, and finally to *knowledge*. Information is important for effective decision making, but knowledge, as has been said, "is golden." With knowledge, the deep understanding often necessary for problem solving can be achieved. Knowledge enables a number of different forms of problem solving including: the use of meta knowledge, analogies, cases, sub-problems, sub-goals, proof by contradiction, deduction, induction, etc.

It may be the case that students in the information age are not as well, or not sufficiently founded in the sciences, history, technology and its progress as might be expected. There seems to be great gaps in their understanding of invention and how the necessities of the times have impacted and promulgated progress.

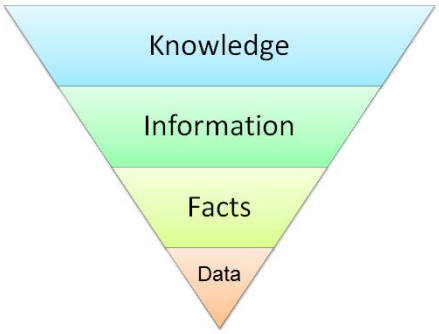

Figure 1: Knowledge hierarchy

How students learn has dramatically changed, and we must recognize that teaching techniques must change accordingly. The notion of "visualization" is not new to science education and it has been used to teach computer science algorithms and methods such as sorting for many years [2]. In many cases, the importance of representational choices, e.g. the choice of graphs, trees, semantic networks, production rules, etc., may be as integral to a problem solution, as the solution itself.

During the problem-solving process, certain choices of representation are likely to have a better impact on the memory of certain problem solvers. For example, a figure or sketch may be sufficient for some, while others may prefer a detailed, step by step description, pseudocode, or an abstract formula.

2 The Towers of Hanoi Problem

2.1 Description of the Towers of Hanoi Problem

In this game there are 3 'pegs' A, B and C and n disks, each with a different size diameter. The rule is that disks may be stacked on the pegs as long as a large disk is never placed on top of a smaller disk. In the following descriptions, a 'step' is defined as the movement of one disk from one peg to another peg. For example: A to B is a step and it means move the top disk on peg A to the top disk on peg B. Figure 2(a) illustrates the starting position for n=3. Problem: What is the minimum number of steps necessary to move all n disks from peg A to peg C and what are those steps?

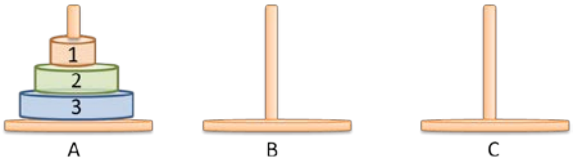

Figure 2(a): Towers of Hanoi start configuration

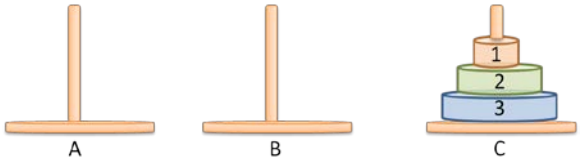

Figure 2(b): Goal state

2.2 Representations

This problem, whose ultimate solution is recursive, is quite difficult for someone who has not seen it before. It is therefore a good example for the idea of representation choices.

2.2.1 Extensional Representations

An extensional representation would be a complete set of steps describing a solution. It may be a description of a solution in words, or it may, for example, be a complete graphical representation of the solution (see Figure 2(c)) or a table (see Figure 3).

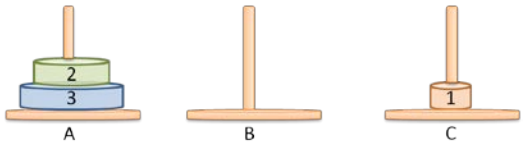
Hands-On/Pictorial

Hands-on simply means to play the game by hand with the pegs and varying numbers of disks. Alternatively, pictures may be used. The idea is to try and find patterns that connect the solution for different values of n. Figure 2(c) is a pictorial representation of the solution for n=3.

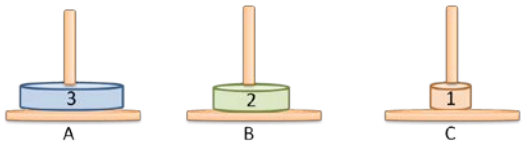
As the figure shows, the solution consists of the following 7 steps:

1. A to C
2. A to B
3. C to B
4. A to C (bottom disk)
5. B to A
6. B to C
7. A to C

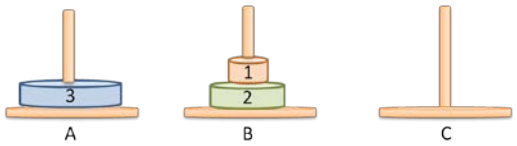
If we were to play the game with n=1, then with n=2 and so on until we play it with n=10 (in reality it would only be feasible to play this game up n=~5), we would find that the total number of moves approximately doubles for each additional disk, as demonstrated in Figure 3. This table is an example of an extensional representation of the problem since it is analyzing the solutions for Towers of Hanoi for different numbers of disks.



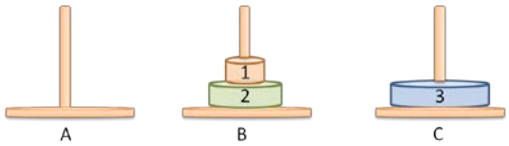
Step 1: Move disk 1 from peg A to peg C.



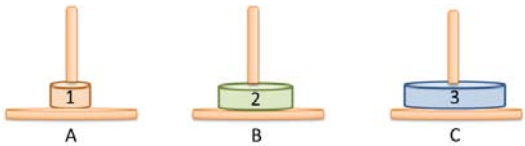
Step 2: Move disk 2 from peg A to peg B.



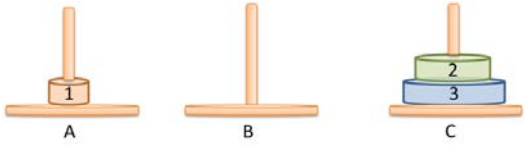
Step 3: Put disk 1 on top of disk 2.



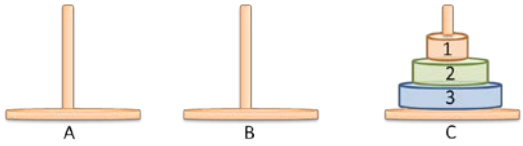
Step 4: Move disk 3 from peg A to peg C.



Step 5: Unravel - Move disk 1 from peg B to peg A.



Step 6: Move disk 2 from peg B to peg C.



Step 7: Put disk 1 on top of disk 2 – goal state reached.

Figure 2(c): Graphical solution of the Towers of Hanoi problem

Number of Disks	Moves to Temp Peg	Moves from Temp Peg to Goal	"Big" Disk Moved to Goal State (C)	Total Number of Moves
1	0	0	1	1
2	1	1	1	3
3	3	3	1	7
4	7	7	1	15
5	15	15	1	31
6	31	31	1	63
7	63	63	1	127
8	127	127	1	255
9	255	255	1	511
10	1023	1023	1	2047

Figure 3 – Table representing the total number of moves for varying numbers of disks

2.2.2 Intensional Representations

An intensional representation is a more compact description. A student may get this quickly or they may get to this point after first describing it in other intensional or extensional forms.

A student may describe the solution as follows: Isolate the bottom disk by moving the top n-1 disks from peg A to peg B. Then move the remaining (Big) disk from peg A to peg C. Finally, move the n-1 disks on peg B to peg C.

A more compact intensional representation:

1. Move n-1 disks to intermediary peg B. This will take 2^{n-1}-1 moves (see Figure 3).
2. Move the bottom disk from peg A to peg C.
3. Move n-1 disks from peg B to peg C.

Another intensional representation would be:

- For n disks on peg A, we must use (2^n-1) moves to peg B to reveal the bottom disk on peg A.
- 1 move to move the bottom disk from peg A to peg C.
- (2^n-1) moves to move the n-1 disks to the final peg.
- Total number of moves: $2(2^n-1) + 1$

Recurrence Relation

The following recurrence relation is another representation. It is unlikely that a student will use this. However, it is possible that for those who are mathematically inclined it may be most suitable.

$T(1) = 1$

$T(n) = 2T(n-1) + 1$

Solution of recurrence: $T(n) = 2^n - 1$.

Pseudocode Representation

This representation is that which Computer Science students may be most familiar with. Nevertheless, it is not necessarily the most intuitive to all students.

Pseudocode:

```
Define:   n = number of disks
          A = start peg
          B = intermediate peg
          C = goal peg
Towers(n, A, B, C):
  If n=1 move disk from A to C
   Else
          Towers(n-1, A, C, B)
          Towers(1, A, B, C)
          Towers(n-1, B, A, C)
  End If
```

3 The Bucket Sort Problem

3.1 Description of the Bucket Sort Problem

The bucket sort algorithm works by placing items to be sorted into buckets according to a value, or range of values, and then sorting each bucket - either by applying bucket sort recursively, or utilizing another sorting algorithm. Bucket sort can be applied to various kinds of data, including numerical and textual data, and its implementation would be tailored appropriately.

3.1.1 Extensional Representations

An extensional representation of an algorithm can be a demonstration or application of the algorithm for which its intensional definition holds. For bucket sort, we can use a variety of examples, visualizations, or data structures to illustrate its core concepts by example.

Pictorial / Visual

A step by step visualization of the bucket sort process is a sample extensional representation. If we apply bucket sort to a set of names, we can use graphics to illustrate the sorting process, as depicted in Figure 4. Since we are sorting strings,

we will assign the names to buckets according to the first character. For each bucket, we will recursively apply bucket sort and assign strings to buckets according to the second, third character, etc. until all buckets contain at most one name. The contents of the sub-buckets are then concatenated and returned their originating bucket, now in sorted order. The contents of the buckets are then appended to form the sorted list.

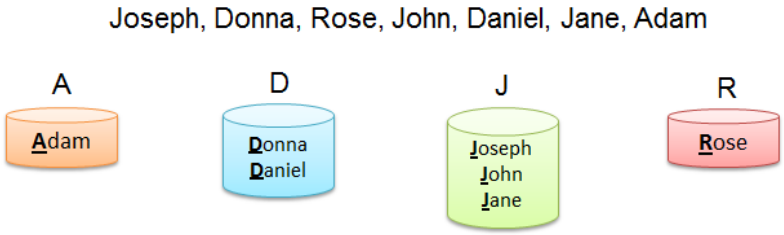


Figure 4(a): Assign strings to buckets according to first character

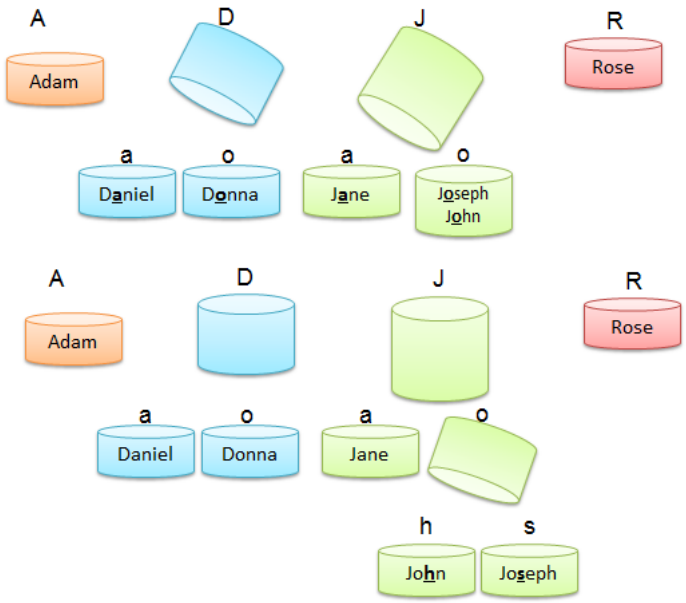

Figure 4(b): For those buckets with more than one string, assign strings to sub-buckets according to the next character, and repeat until all buckets contain one string

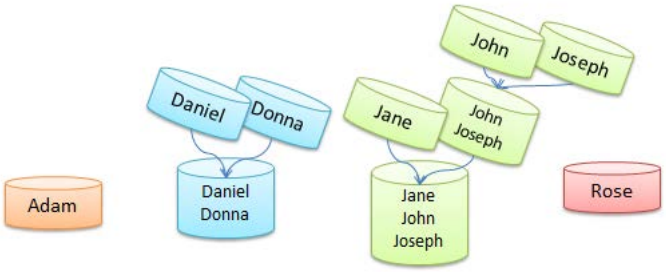

Figure 4(c): Build up the solution by filling original buckets from their sub-buckets

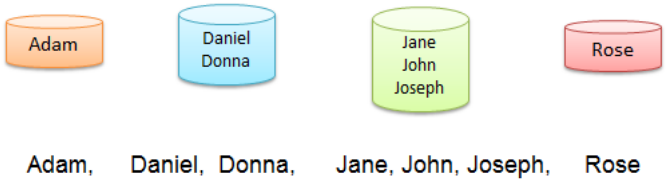

Figure 4(d): Concatenate the contents of the buckets to obtain the sorted list

Tree Structure

A tree can also be used as extensional representation of the bucket sort concept by organizing the tree according to keys. This kind of prefix tree, known as a "trie" from the term "retrieval", can be traversed in a pre-order manner to generate the sorted list of strings. A prefix tree representation for a set of sorted strings is depicted in Figure 5.

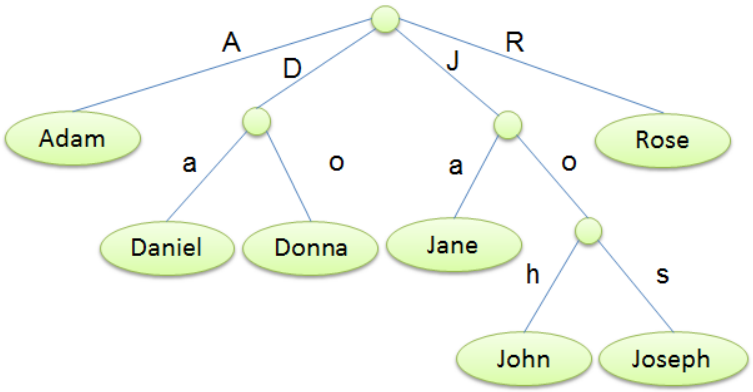

Figure 5: Prefix tree representation for a set of sorted strings

3.1.2 Intensional Representations

An intensional representation contains the most essential and intrinsic characteristics of a concept or, in this case, algorithm. For bucket sort, an abstract definition could be expressed as:

Bucket Sort Algorithm:

1. Create a set of empty buckets
2. Place each element in the input list into appropriate bucket
3. Sort each bucket
4. Concatenate the contents of the buckets in order and place into original list

This is considered an intensional definition because it provides the fundamental features of the algorithm, which can then be applied to generate a set of various extensional instances.

Pseudocode Representation

Bucket sort can be implemented with an array of lists - the array representing the set of buckets, and a list holding the contents of each bucket. The following is a sample pseudocode for bucket sort which takes an unsorted list U as input:

```
BucketSort(U):
  n = length of U
  B = new array of n lists
  for i = 1 to n
     do insert U[i] into list B[key(U[i])]
  for i = 1 to n
     do sort B[i] with insertion sort
  concatenate the lists B[0], B[1], ..., B[n-1]
```

The function key maps the range of elements in the array to bucket keys, for example converting characters to integers or floating point values to integers. A variation of this implementation could be to insert the elements into the buckets in order as they are being inserted into the lists, rather than applying insertion sort to all lists at the end. Another variant is to call BucketSort recursively. Taking this pseudocode and implementing it in specific programming languages such as C++ or Java and applying it to specific data sets would be an extension of this intensional representation.

4 Relevance to CS Education

One of the challenges faced in computer science education, and science education in general, is how to improve students' problem solving skills. In a typical computer science course, such as introductory programming, we may teach the concept behind a particular algorithm (i.e. exchange sorts), and then demonstrate it with a few examples (i.e. sorting a set of integers, characters, or words). The students then apply these algorithms to given data that is in a specified format. In a data structures course, students are taught algorithms along with their corresponding data structure, such as binary search and binary tree, or postfix evaluation and stack. Consequently, students often associate a particular problem solving method with a particular form of knowledge representation and specific types of problems.

To enrich this process, students should be exposed to diverse problem solving methods and a variety of knowledge representation choices, both intensional and extensional, depending on their preferences and learning styles. Students can be given a set of problems and then be asked to make decisions as to the most appropriate problem solving method(s) and knowledge representation(s). This will build students' experience in applying and transferring various techniques to different classes of problems.

5 Summary and Discussion

We have illustrated knowledge representation choices for students utilizing Towers of Hanoi as an example. It is a potentially complicated problem that can be approached from many representational angles – even if the ultimate solution is the same recursion. We also demonstrated extensional and intensional definitions for Bucket Sort. When approaching problem solving, we believe, that instead of only laying out one description of the answer, we should strive to work with each student so that they understand the solution in a way that is conducive to the best understanding for them.

With the desire for education to be effective in an interdisciplinary way, differences in the learning style of different students from different disciplines should be considered. For example, students with a mathematical background may prefer intensional representations, while students with an engineering background may prefer more visual or manipulative representations, and students with a computer science background may be comfortable with either approach.

Acknowledgement

The authors would like to acknowledge the late Donald Michie for the ideas about extensional and intentional solutions presented in this paper.

Abstract - *For a computer to perform intelligent information processing requires functions that can extract concepts from words, as humans do, and then associate those concepts with related concepts. In order to implement this association function, it is necessary to quantify the degree of association between two concepts. In the present paper, we propose a method for quantifying degree of association incorporating viewpoint that uses a concept base (a knowledge base that expresses concepts as a collection of pairs, each pair consisting of an attribute word used to describe the concept and a weighting that expresses the word's importance). Here, "Viewpoint" is the perspective from which a concept is viewed; for example, consider the degree of association between "airplane" and "automobile", and the degree of association between "airplane" and "bird". From the viewpoint of "vehicle", "airplane" and "automobile" are highly related, while from the viewpoint of "flight", "airplane" and "bird" are highly related. We present herein a comparison of two methods for calculating degree of association incorporating viewpoint, and demonstrate that the method involving modulation of attribute weightings based on viewpoint results in degree of association calculations that are closer to human senses.*

Keywords: degree of association, viewpoint, Concept-Base

1 Introduction

The remarkable advances in modern information-processing systems have made them indispensable across human society; however, much of this progress has been in terms of enhanced function or performance. While high functionality and performance are obviously essential for ease of use, convenience is also extremely important for information-processing systems. An information-processing system that can be used in the same way as human conversation is referred to as an intelligent information system. Realization of such a system would deliver unparalleled convenience, rendering reading of manuals and remembering operational procedures redundant.

Human conversations are based on correct interpretation of unclear information made possible by the "common sense" regarding language and underlying word concepts that is acquired through experience and learning. In short, the ability to extract a concept from a word, and then associate that concept with a variety of related concepts, plays an important role in human conversation.

The ability to make anthropomorphic common-sense judgments is a necessary component of developing an intelligent information system. Such a common-sense judgment system requires a means of associating related concepts as humans do. One proposed method is to assign a numerical value to the degree of association between concepts [1]. Degree of association is calculated using a concept base [2]. In the present paper, we expand this method to calculate degree of association incorporating viewpoint.

2 Concept-Base

A concept-base is a knowledge base comprised of terms (concepts) mechanically constructed from sources such as multiple Japanese language dictionaries and newspapers and terms (attributes) that express their semantic features. Concepts have

been given attributes along with a weighting, which expresses their importance. Approximately 90,000 concept notations have been compiled in the concept base, with an average of 30 attributes for one concept. A certain concept A has a pair of sets of attribute a_i and weighting w_i, as appear below.

$$A = \{(a_1, w_1), (a_2, w_2), \cdots, (a_m, w_m)\}$$

Any primary attribute a_i is composed of the terms contained in the set of concept notations in its concept base. Therefore, to ensure that a primary attribute matches a certain concept notation, that primary attribute can be further extracted. This is called a secondary attribute. In a concept base, a concept is defined by a chained set of attributes to the n-th order.

3 Degree of Association

Each concept is defined as a set of attributes and each attribute is also a concept as described above. In this paper, a method to derive the degree of association between concepts using up to second order attributes is used. The value of the degree of association ranges from 0.0 to 1.0.

3.1 Calculating the degree of matching

Let us assume that the primary attributes for any concepts A and B are a_i and b_j, respectively, and that their corresponding weightings are u_i and v_j. The number of attributes for concepts A and B shall be L attributes and M attributes ($L \leq M$).

$$A = \{(a_i, u_i) \mid i = 1 \sim L\}$$
$$B = \{(b_j, v_j) \mid j = 1 \sim M\}$$

In this situation, the degree of matching for concepts A and B, $Match(A,B)$, can be defined in the following equation.

$$Match(A, B) = \sum_{a_i = b_j} \min(u_i, v_j)$$

Where, the total sum of the weightings of each concept must be normalized to 1. If there is an attribute that becomes $a_i = b_j$ (concepts A and B have a common attribute), relative to attributes a_i and b_j of concepts A and B, the common portions of the weightings of the common attributes. This means that only the smallest portions of the weightings will effectively be considered to be in match, and their total shall be the degree of matching.

3.2 Calculating the degree of association

To find the degree of association, the relevance between two concepts is calculated as a numeric value based on the value found by calculating the degree of matching of the secondary attributes of the concepts. More specifically, of the two concepts to be calculated, let the one with the smallest number of primary attributes be A ($L \leq M$) and the primary attributes of concept A be the criteria.

$$A = \{(a_1, u_1), \cdots, (a_i, u_i), \cdots (a_L, u_L)\}$$

After that, rearrange the primary attributes of concept B so that the sum of the degree of matching, $Match(a_i, b_{xi})$, with each primary attribute of concept A is at a maximum.

$$B_x = \{(b_{x1}, v_{x1}), \cdots, (b_{xi}, v_{xi}), \cdots, (b_{xL}, v_{xL})\}$$

This will determine a correlating set for the primary attributes of concept A and the primary attributes of concept B. The primary attributes of concept B that exceed the correlation will be ignored. (There will be L attribute combinations at this time.) However, if some of the primary attributes are in agreement, meaning that their concept notations are the same (a_i=b_j), they will be handled separately. This is because there are about 90,000 concept notations in the concept base and the matching of attributes is considered to be rare. As a result, by handling the matching attributes separately, they are valued more highly when they match. More specifically, the size of the corresponding attribute weightings u_i and v_j will be aligned in the direction of the smallest weighting. When this takes place, the value of the attribute with the smallest weighting will be subtracted from the attribute with the largest weighting and once again be correlated to the other attributes. For example, if a_i=b_j and u_i=v_j+ α , then the correlation would be between (a_i, v_j) and (b_j, v_j), and (a_i, α) would once again be correlated to the other attributes. Let us assume the number of attribute combinations determined and correlated in this manner is T. The degree of association between concepts A and B in this case, $DoA(A,B)$, is defined in equation below.

$$DoA(A, B) = \sum_{i=1}^{T} \{Match(a_i, b_{xi}) \times (u_i + v_{xi}) \times (\min(u_i, v_{xi}) / \max(u_i, v_{xi})) / 2\}$$

The value of the degree of association expresses the strength of the relevance between concepts as a continuous value between 0 and 1. The closer the value is to 1, the stronger the relevance.

4 Calculating degree of association incorporating viewpoint

The associations drawn by humans between two concepts are judged based on several viewpoints. For example, consider the degree of association between "airplane" and "automobile", and the degree of association between "airplane" and "bird". Ordinarily, from the viewpoint of "vehicle", "airplane" and "automobile" are highly related, while from the viewpoint of "flight", "airplane" and "bird" are highly related. In short, the association between two concepts will vary depending on the viewpoint, which lies outside those two concepts.

With conventional methods, two concepts are always used to investigate degree of association, and the attributes and weighting of these concepts are defined in a concept-base and are thus always consistent. Application of a third concept to act as a viewpoint is required to judge degree of association incorporating viewpoint. The question of what viewpoint to apply also becomes an important issue during practical application of this method. While it may be necessary to extract a viewpoint automatically from conversational text or surrounding context, in the present paper, we assume that a relevant viewpoint is already being applied and consider what calculation method offers the best way to subsequently calculate degree of association incorporating viewpoint.

We examined two algorithms for calculating degree of association incorporating viewpoint. One determines the correspondence between attributes of two concepts, while the other modulates attribute weighting of two concepts.

4.1 Determining attribute correspondence based on viewpoint

A comparison of concepts *A* and *B* from viewpoint *V* is an investigation of the strength of association between the attributes of viewpoint *V* and of related concepts *A* and *B*. So if we assume that viewpoint *V* has attributes $\{v_1, v_2,\ldots v_n\}$, by looking for attributes in concepts *A* and *B* that relate to attribute v_1 (and likewise for v_2 and so on), we can regard that as calculating the degree of association incorporating viewpoint. The calculation for degree of association that uses this approach can be expressed as follows.

Algorithm for calculating degree of association incorporating viewpoint

Two concepts, *A* and *B*, and one viewpoint, *V*, are expressed as

$$A = \{(a_i, u_i) \mid i = 1\sim L\}$$
$$B = \{(b_j, v_j) \mid j = 1\sim M\}$$
$$V = \{(c_k, w_k) \mid k = 1\sim N\}$$

The attributes of viewpoint *V* are fixed as

$$V=((c_1,w_1),(c_2,w_2), \ldots,(c_N,w_N))$$

To maximize the total degree of matching with viewpoint *V*, the attributes of concepts *A* and *B* are rearranged respectively as

$$A=((a_{x1},u_{x1}),(a_{x2},u_{x2}), \ldots ,(a_{xN},u_{xN}))$$
$$B=((b_{y1},v_{y1}),(b_{y2},v_{y2}), \ldots ,(b_{yN},v_{yN}))$$

The degree of association between *A* and *B* as viewed from viewpoint *V*, $DoA(A,B|V)$ is defined as follows:

$$DoA(A,B|V) = \sum_{i=1}^{N} \frac{Match(c_i,a_{xi}) + Match(c_i,b_{yi})}{2} \times (w_i / wsum)$$

$$wsum = \sum_{i=1}^{N} w_i$$

4.2 Modulating attribute weighting based on viewpoint

In a concept base, the weightings applied to attributes can be considered typical weights for concepts. But when calculating degree of association, if we explicitly specify the viewpoint, the attribute weighting can be expected to change depending on the viewpoint. For example, when we investigate attributes for the concept "bird", attributes in order of weighting might be "avian", "poultry", and "chicken". But if we specify the viewpoint "flight", the attributes "wing" and "plumage" would be weighted more heavily than the attributes "poultry" and "chicken". Here, we propose methods using either degree of matching or degree of association for calculating degree of association incorporating viewpoint that modulates attribute weighting based on viewpoint.

Algorithm for modulating weighting based on viewpoint

Concept A and viewpoint V are expressed as follows:

$A = \{(a_i, u_i) \mid i = 1 \sim L\}$
$V = \{(c_k, w_k) \mid k = 1 \sim N\}$

The weighting u_i' of attribute a_i of concept A when viewpoint V is applied is defined as follows:

$$u_i' = Match(a_i, V)$$

(weighting by degree of matching)

$$u_i' = DoA(a_i, V)$$

(weighting by degree of association)

The weighting for concept B is similarly modulated. For concepts A and B with modulated weighting, degree of association is calculated similarly to the degree of association calculation expressed in Section 3.

A characteristic of this algorithm is that it modulates attribute weighting depending on the viewpoint. Tables 1, 2, and 3 show the weighting of attributes for the concept "bird" modulated from the viewpoint "flight."

Table 1: Weighting in the concept base

Avian	Poultry	Chicken	Bird	Egg-laying	…
223	193	156	132	123	…

Table 2: Weighting by degree of matching

Wing	Down	Feather	Wildlife	Pheasant	…
0.51	0.27	0.22	0	0	…

Table 3: Degree of association weighting

Wing	Down	Feather	Plumage	Skylark	…
0.27	0.15	0.11	0.027	0.024	…

Characteristic calculation times and weightings values differ between Tables 2 and 3. When degree of matching is used for weighting, calculation time is short because only first-order attributes are calculated. Conversely, when using degree of association for weighting, each time that degree of association is calculated for a single viewpoint, the calculation must be performed several times over for each attribute of both concepts A and B in conventional degree of association calculations. Therefore, calculation times are extremely long. In terms of the number of calculations, using degree of matching for weighting is clearly preferable. In terms of the weighting values, when we take degree of matching for weighting, only those attributes that clearly have strong associations with the viewpoint are applied to the weighting because calculations use only first-order attributes. When using degree of association for weighting, almost all the attributes are applied because they are extended to the second order (there are few attributes that do not match at least once when extended to the second order), so almost all attributes contribute to the weighting value. However, this does not necessarily mean that weighting by degree of association is suitable as some weighting will be applied to attributes even if a totally unrelated concept is used as the viewpoint when calculating degree of association for two concepts A and B.

5 Assessing calculations of degree of association incorporating viewpoint

Calculations of degree of association incorporating viewpoint were assessed in two ways. The first was to assess the accuracy of the calculation itself. This test used assessment data in which the magnitude relationship of the degree of association values should be reversed due to specification of a viewpoint. The other was to assess degree of association values when calculating degree of association incorporating no viewpoint. Explicitly specifying a relevant viewpoint for calculating the degree of association between two concepts should result in higher values than when no viewpoint is specified as the latter is a special variation of calculating degree of association incorporating viewpoint.

5.1 Assessing the accuracy of calculations of degree of association incorporating viewpoint

The data shown in Table 4 was used to assess the accuracy of calculations of degree of association incorporating viewpoint.

Table 4: Assessment data (partial)

Reference concept *X*	Concept *A*	Concept *B*	Viewpoint α	Viewpoint β
Stranger	Another person	Connection	Other	Relation
Shared	Public	Lineage	Public	Community
Ally	Comrade	Navy	Peer	Battle
…	…	…	…	…

The assessment data in Table 4 is a set of five concepts. Of the five concepts, three were used to investigate degree of association, with the remaining two being viewpoints specified when calculating degree of association. Concept *X*, which was used as a reference, is a concept that could be viewed as relevant from either viewpoint α or β. Concept *A* is a concept that could be viewed as relevant from viewpoint α; concept *B* is a concept that could be viewed as relevant from viewpoint β. The degree of association between Concept *X* and Concept *A* as viewed from viewpoint α can be expressed as *DoA* (*X*, *A* | α), so if the assessment data in Table 4 satisfies the following two equations, we can take that as calculating the degree of association incorporating viewpoint:

$$DoA(X, A \mid \alpha) > DoA(X, B \mid \alpha)$$
$$DoA(X, B \mid \beta) > DoA(X, A \mid \beta)$$

The assessment data in Table 4 was generated automatically using a thesaurus [3]. Following is a description of the method used to automatically generate the assessment data.

First, we looked for leaves that appeared twice in the thesaurus and used these as reference concept *X*. While there were a large number of leaves that appeared three or more times, these high-frequency leaves were classified within the thesaurus according to fine differences in meaning, and these differences were difficult to judge accurately. For this reason, the test was limited to terms appearing twice, which were comparatively easy to judge.

Next, we used the parent nodes for each leaf as viewpoints α and β. A leaf that was present under node/viewpoint α, but not present under node/viewpoint β, became concept *A*; one that was present under node/viewpoint β, but not present under node/viewpoint α, became concept *B*. Figure 1 shows the relationships of these five concepts in the thesaurus.

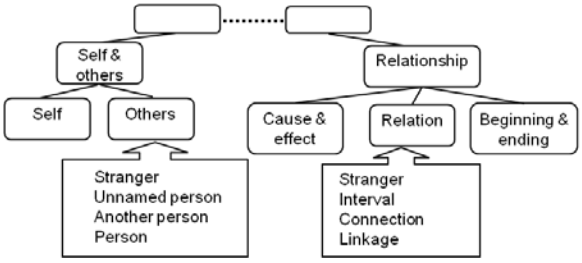

Figure 1: Positional relationships between assessment data terms in the thesaurus

Thus, by defining five concepts as shown in Table 4 as one set of data, we were able to mechanically create assessment data. We generated 3934 sets of assessment data in this way.

The assessment data in Table 4 comprises many complex data. This is because, although the thesaurus systematically classifies words, these classifications differ in range; the number of nodes present above leaves may vary, and even when the distance between two nodes is short, there may still be leaves that appear multiple times. However, as the mechanically generated data in Table 4 originates from a thesaurus, it can be considered objective. This assessment data is therefore suited to comparing the effectiveness of calculation methods based on increases or decreases in the correct answer rate rather than the achievement of a certain percentage of correct answers.

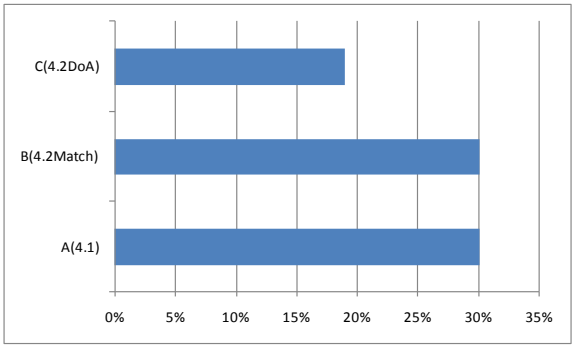

Figure 2: Assessment results
(percentage of correct answers)

Of the methods for modulating attribute weighting using viewpoint presented in Section 4.2, we found that weighting by degree of matching (B) gave more accurate results than weighting by degree of association (C). We attribute this to the qualitative difference of the weightings. We also found that

determining attribute correspondence by viewpoint (A) gave similar accuracy as weighting by degree of matching (B).

Figure 3 shows the percentage of incorrect answers from among the assessment data, where incorrect answers are defined as those that do not satisfy both of the equations in this section.

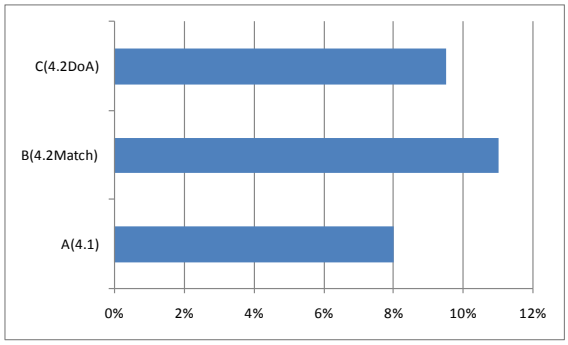

Figure 3: Assessment results
(percentage of incorrect answers)

Figure 3 shows that weighting by degree of matching (B) had the highest percentage of incorrect answers (performed worst), followed by weighting by degree of association (C); attribute correspondence by viewpoint (A) had the lowest percentage of incorrect answers. However, because the algorithm is understood to return higher values for degree of association when a relevant relationship has been specified, it is possible that there will be a high degree of association even with an irrelevant viewpoint. Further investigation is thus required to improve the algorithm.

5.2 Calculating degree of association incorporating no viewpoint and assessing compatibility

Next, let us compare the association between two concepts with no viewpoint with association using viewpoints. With regard to the concepts "airplane" and "bird", the degree of association is not necessarily high when no viewpoint is specified, but specifying the viewpoint "flight" results in a strong association. In other words, specifying a viewpoint that is relevant to both of the concepts involved in the degree of association calculation can produce a higher degree of association than when no viewpoint is specified. Also, if we investigate the degree of association between "airplane" and "flight" using a viewpoint clearly unrelated to either, such as "fluorescent light", the degree of association will naturally be lower than when no viewpoint has been specified.

Based on this, we performed an assessment using concept *X*, concept *A*, viewpoint α, and randomly selected viewpoint γ from Table 4, and took as correct answers anything that satisfied the following equation:

$$DoA(X, A \mid \alpha) > DoA(X, A) > DoA(X, A \mid \gamma)$$

Here again, we used 3934 sets of assessment data. Our results are shown in Figure 4.

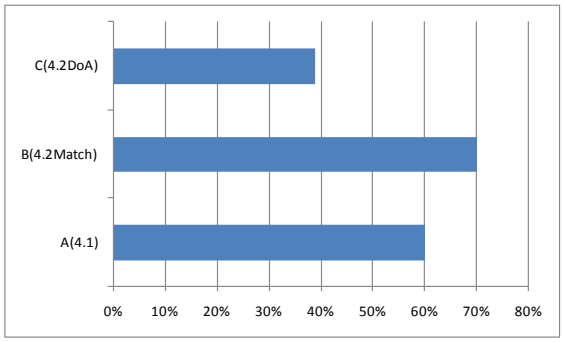

Figure 4: Assessment results (relationship to degree of association incorporating no viewpoint)

Figure 4 reveals that the best results were achieved by modulating weighting by degree of matching using viewpoint, which also yielded the best results in the assessment of accuracy. Accuracy was slightly low at approximately 70%, but as mentioned in Section 4.2, this is mechanically generated data, which is an important difference from other methods.

These findings indicate that weighting attributes by degree of matching based on viewpoint constitutes a suitable method for calculating degree of association incorporating viewpoint.

6 Conclusion

In the present paper, we examined methods for quantifying associations between two concepts, as a way to implement an association function using a concept base. In particular, we proposed and assessed

methods for calculating degree of association incorporating viewpoint. These methods permit associations more strictly related to meaning and are therefore effective tools in the endeavor to develop a intelligent common-sense judgment system.

Meta-RaPS with Q Learning Approach Intensified by Path Relinking for the 0-1 Multidimensional Knapsack Problem

Arif Arin, Ghaith Rabadi
Dept. of Engineering Management & Systems Engineering
Old Dominion University
241 Kaufman Hall, Norfolk, VA 23529 USA

Abstract - *Many successful metaheuristics employ intelligent procedures to obtain high quality solutions for optimization problems. Intelligence emerges in these metaheuristics via memory and learning. Meta-RaPS (Metaheuristic for Randomized Priority Search) which can produce promising solutions is classified as a memoryless metaheuristic. To improve its performance, Q learning and Path Relinking (PR) are selected as memory and learning mechanisms to be incorporated into Meta-RaPS. In the proposed algorithm, Meta-RaPS Q-PR, Q learning and PR approaches serve as mechanisms that learn the best policy to construct a solution, and learn "good" attributes of best solutions to reach the optimum solution while losing "bad" attributes of the current solution. The 0-1 multidimensional knapsack problem will be used to evaluate the Meta-RaPS Q-PR.*

Keywords: Q learning; Meta-RaPS; path relinking; memory; 0-1 multidimensional knapsack problem

1 Introduction

In some optimization problems whose output is a sequence of actions, finding the policy for the correct actions that gives the best solution for all states is important. Selection of best actions in intermediate states will not mostly lead to the optimum policy, and only the actions in the feasible policy can be accepted as correct actions. In these cases, reinforcement learning (RL) is one of the successful algorithms evaluating the goodness of policies and learning from the good action sequences to create a policy.

The modern science of RL has emerged from four different fields: classical dynamic programming, artificial intelligence (AI), stochastic approximation, and function approximation [1]. RL is in the class of machine learning along with supervised and unsupervised learning. While, in supervised learning, correct values are provided by a supervisor; in unsupervised learning, there is only input data and no supervisor. In the RL, unlike supervised leaning, the machine is not told which actions to take but has to discover which actions yield the most reward. Trial-and-error search and delayed reward are the two most important unique characteristics of RL [2].

The RL algorithm can be classified as model-based and model-free. In the model-free RL algorithm, there are two different cases: deterministic, where there is a single reward and next possible state, and non-deterministic where there are different rewards to move to different next states. This type of RL algorithm is called Q learning. In Q learning algorithm, models of the agent or the environment are not required [3]. Q learning can be employed even when the agent has no prior knowledge of how its actions affect its environment.

As machine learning, Computational Intelligence (CI) is another subfield of AI (also named scruffy or soft) techniques that involves approaches based on strategy and outcome, and includes adaptive and intelligence systems [4, 5]. Metaheuristics can be viewed as another name for the strategy-outcome perspective of scruffy AI. Glover and Laguna [6] define metaheuristics as "a master strategy that guides and modifies other heuristics to produce solutions beyond those that are normally generated in a quest for local optimality". Intelligence via memory and learning in metaheuristics represents the information extracted and stored during the search for better solutions.

Glover and Laguna [6] introduced a classification method for metaheuristic algorithms that depends on three design choices: the use of adaptive memory, the type of neighborhood exploration used, and the number of current solutions carried from one iteration to the next. Meta-RaPS (Meta-heuristic for Randomized Priority Search) can currently be classified as a memoryless metaheuristic and it should benefit from existing memory and learning mechanisms to increase its effectiveness. Thus, we propose incorporating memory and learning into Meta-RaPS to study whether such techniques can help it become "intelligent". Specifically, the Q learning and Path Relinking (PR) approaches will be incorporated into Meta-RaPS as memory mechanisms and the 0-1 multidimensional knapsack problem will be used as a testbed to evaluate the effectiveness of the proposed algorithm.

The 0-1 MKP is the generalized form of the classical knapsack problem (KP). In the KP there is a knapsack with the upper weight limit b, a set of n items with different profits c_j and weights a_j for item j. The problem is to select the items from the set such that the total profit of the selected items is maximized without exceeding the upper weight limit of the

knapsack. If the number of knapsacks in the KP is increased, this will lead to the MKP. In MKP there are *m* knapsacks with different upper weight limits, and item *j* has different weight for each knapsack *i*. The objective is to find a set of items with maximal profit such that the capacity of each knapsack is not exceeded [4]. The MKP can be formulated as in equations (1), (2), and (3):

$$\text{Maximize} \quad \sum_{j=1}^{n} c_j x_j \tag{1}$$

$$\text{Subject to} \quad \sum_{j=1}^{n} a_{ij} x_j \le b_i \quad i = 1, \ldots, m; j = 1, \ldots, n \tag{2}$$

$$x_j \in \{0,1\} \quad j = 1, \ldots, n \tag{3}$$

where x is a vector of binary variables such that $x_j = 1$ if item *j* is selected, and $x_j = 0$ otherwise. The 0-1 MKP is an NP-hard problem.

The 0-1 MKP is basically a resource allocation problem, which can be used to model many problems in the literature such as the capital budgeting, project selection, cutting stock and many loading problems.

2 Meta-RaPS

Moraga et al. [7] defines Meta-RaPS as "generic, high level search procedures that introduce randomness to a construction heuristic as a device to avoid getting trapped at a local optimal solution". Meta-RaPS combines the mechanisms of priority rules, randomness, and sampling. Meta-RAPS is a two-phase metaheuristic: a constructive phase to create feasible solutions and an improvement phase to improve them. In the constructive phase, a solution is built by repeatedly adding feasible components or activities to the current solution in an order that is based on their priority rules until the stopping criterion is satisfied. Generally, solutions obtained by implementing only constructive algorithms can reach mostly local optima, which can be avoided in Meta-RaPS by employing randomness in the constructive phase.

Meta-RaPS uses four parameters: number of iterations (I), the priority percentage (p%), the restriction percentage (r%), and the improvement percentage (i%). Meta-RaPS does not select the activity with the best priority value in every iteration. Instead, the algorithm may randomly accept an activity with a good priority value, but not necessarily the best one. The parameter p% is used to decide the percentage of time an activity with the best priority value will be added to the current partial solution, and (100 - p)% of time it will be randomly selected from a candidate list (CL) containing "good" activities. The CL is created by including items whose priority values are within r% of the best priority value. The construction phase of Meta-RaPS is completed when a feasible solution is produced. The improvement phase is performed if the feasible solutions generated in the construction phase are within i% of the best constructed solution value from the preceding iterations.

DePuy et al. [8] emphasized that the advantages of the Meta-RaPS over other metaheuristics are that run times for Meta-RaPS is not significantly affected by the size of the problem, it is easy to understand and implement, and can generate a feasible solution at every iteration. Pseudo code for Meta-RaPS is shown in the Figure 1.

```
Until stopping criteria met
do until feasible ConstructedSolution generated
   Find priority value for each feasible activity
   Find best priority value
   If rnd() ≤ %p
      then select the activity with best priority value
   else create CL from feasible activities with priority ≥ Limit
      Limit = MinPriority + %r · (MaxPriority - MinPriority)
      Select randomly an activity from CL
   If ConstructedSolution > BestConstructedSolution
      ConstructedSolution ← BestConstructedSolution
End Until
If ConstructedSolution ≤ %i · BestConstructedSolution
   then improve
   If ImprovedSolution > BestImprovedSolution
      ImprovedSolution ← BestImprovedSolution
End For
```

Figure 1. Pseudo Code of Meta-RaPS

Meta-RaPS has many successful applications for discrete optimization problems, such as the Resource Constrained Project Scheduling Problem [9], the Vehicle Routing Problem [10], the Traveling Salesman Problem [11], the 0-1 Multidimensional Knapsack Problem [12], the Parallel Machine Scheduling Problem with Setup Times [13], Early/Tardy Single Machine Scheduling Problem [14], Parallel Multiple-Area Spatial Scheduling Problem with Release Times [15] and Aerial Refueling Scheduling Problem (ARSP) [16].

3 Q Learning

In the Q learning algorithm, the term Q is basically represents the reward received immediately after selecting action *a* from state *s*, plus the value, discounted by γ, of following the optimal policy. If the agent learns the Q function, it will be able to select the action that maximizes Q(s, a) among available actions in its current state.

In the terminology of the Q learning, the decision maker is called "agent" and there are several possible "states" for the agent to move from one to another. The "environment" is the current state in which the agent interacts and makes decisions. The agent has a set of possible, or feasible, actions that affect both the "reward" and the next state. Once an action is taken, the state will be changed. For each action the agent receives feedback, called the "reward". The rewards are delayed, and required for the agent to learn the system. The sequence of actions from the first state to the terminal state is called episode. To solve the optimization problem the agent learns the best course of actions that have the maximum cumulative reward via Q learning transition equation (4).

$$Q(s_t, a_t) \leftarrow (1-\alpha)\ Q(s_t, a_t) + \alpha\left[r_{t+1} + \gamma \max_{a_{t+1}} Q(s_{t+1}, a_{t+1}) \right] \quad (4)$$

In (4), $Q(s_t, a_t)$ is nominated as the cumulative quality, or reward, of action a_t taken in state s_t for time t. r_{t+1} is the reward received when the action a is taken at time (t + 1). $Q(s_{t+1}, a_{t+1})$ is the value for the next state, and has a higher chance of being correct. α is the learning factor, $0 < \alpha < 1$, gradually decreased in time to converge; and γ is the discount factor, $0 \leq \gamma < 1$ [17]. We discount this value by γ because it will happen in the next step. As γ approaches to 1, future rewards are given greater emphasis relative to the immediate reward. The discount concept essentially measures the present value of the sum of the rewards earned in the future over an infinite time.

In the process of creating the Q learning matrix, initially all $Q(s_t, a_t) = 0$ for all actions in a lookup table. The $Q(s_t, a_t)$ values are calculated using equation (4) and stored in their state-action cells of the lookup table. This process will be repeated until the Q learning matrix converges, i.e. the differences between Q values are smaller or equal than a ε value accepted. It has been shown that as α is gradually decreased in time for convergence, this algorithm converges to the optimal Q* values [18]. The pseudo code for Q learning algorithm is presented in Figure 2.

```
initialize Q learning matrix with zeros
while Q learning matrix not converged
    for t = 1 until current episode is completed
        select first item a_t for state s_t randomly
        calculate Q(s_t, a_t) via Q learning transition equation
        update Q learning matrix
        t ← t + 1
    end for
end while
```

Figure 2. Pseudo Code of Q learning.

Q learning methods are the most widely used reinforcement learning methods, probably due to their great simplicity. They can benefit from the experience generated from interaction with an environment, and be applied with a minimal amount of computation [19].

After Q learning is introduced by Watkins [20], many successful applications based on Q learning are presented by researchers in the literature, such as weightings for optimal control and design problems [21], robot navigation [22], morphing Unmanned Air Vehicles [23] and scheduling [24]. More information about the Q-learning algorithm can be found in [19, 20, 25, 26].

4 Path Relinking

The approach is named Path Relinking because it generates a path between solutions linked by a series of moves during a search to incorporate attributes of the guiding solution while recording the objective function values [6]. PR was originally proposed by Glover [27] as a way to explore trajectories between elite solutions obtained by tabu search or scatter search. The PR generates new solutions by exploring trajectories connecting the initiating solution and the guiding solution. While following the path from the initiating towards the guiding solution the high-quality solutions are created by selecting moves with "good" attributes contained in the guiding solution [28]. At each iteration, the best move in terms of the objective function and decreasing the distance between the two solutions is selected. This is repeated until the distance is equal to 0 at which point the best solution found in the trajectory is returned by the algorithm.

In the PR approach for each pair of solutions, different alternatives exist in selecting the starting and the target solutions:

- Forward: The worst of both solutions is used as the starting solution.
- Backward: The better of both solutions is used as the starting solution. Since the starting solution' neighborhood is more explored than that of the target solution, the backward strategy is in general better than the forward one.
- Back and forward relinking: Two paths are constructed in parallel, using alternatively both solutions as the starting and the target solutions.
- Mixed relinking: Two paths are constructed in parallel from both solutions but the guiding solution is an intermediate solution at the same distance from both solutions.

Recent PR approaches have been developed to solve the problems such as large-scale global optimization [29], team orienteering problem [30] and scheduling [31]. There are many successful hybrid applications where PR is used to add a memory mechanism by integrating it into other algorithms; PR with GRASP [32, 33, 34]; TS [35], GA [36, 37], and memetic algorithm [38].

5 Meta-RaPS Q with Path Relinking

Meta-RaPS Q algorithm with PR is created three main phases: first, Q learning matrix is developed to obtain priorities of each item needed for Meta-RaPS; second, a solution is generated based on Meta-RaPS principles; and in the last phase, PR is applied to reach the best solution of Meta-RaPS Q-PR. Once the solution is produced, the Q learning matrix is updated using this solution.

5.1 Creating Q Learning Matrix Phase

In the Q learning algorithm, next item is selected according their Q values, i.e. the item with the maximum Q value. However, by accepting the item having the maximum Q value the algorithm may be stuck in local regions, and cannot explore other promising areas. Another risk with this strategy is that each cell in the Q learning matrix may not be filled in enough to converge because in theory there is no

equal chance to select each cell only by considering their maximum values. A precaution to remove these risks may be to select the next item randomly, instead of looking for the one with maximum Q value. The preliminary analysis of both approaches showed that, in selecting next item, randomness strategy is superior to elitist strategy. Thus, the transition equation of Q learning (4) is modified so that the algorithm can select randomly among the feasible items in the next state instead of accepting the feasible item with maximum Q value.

To begin the algorithm, first the lookup table for the Q learning matrix is created. The solution process begins randomly by selecting both the item as in the first state and next item for the next action. If we assume that the selected item for the first state, *t=1*, is 6, then the value Q(1, 6) is calculated using equation (4) based on all feasible actions after item 6 is selected. The Q learning matrix is updated by replacing new Q(1, 6) with the previous one. In this example, the learning factor α and discount factor γ are 0.7 and 0.1, respectively, and r_{t+1} is 19 which is the priority of the item 3 selected randomly in state *t+1*.

$$Q(1, 6) = (1 - 0.7)\, Q(1, 6) + 0.7\, [r_{t+1} + 0.1\ \text{random}\{Q(2,1), Q(2,2), Q(2,3), Q(2,4), Q(2,5), Q(2,7), Q(2,8)\}]$$

$$= (1-0.7)\ 0 + 0.7[19+0.1\text{random}\ \{0, 0, 0, 0, 0, 0, 0\}]$$

$$=13.3.$$

When there are no other feasible items to add to the solution the calculations are stopped for the current episode, and this process will be repeated until the Q learning matrix converges. The converged Q learning matrix will be used as the priority matrix to select items in the Meta-RaPS Q-PR algorithm.

5.2 Meta-RaPS Phase

In the construction phase of Meta-RaPS, a solution is built by repeatedly adding feasible items to the current solution (partial solution) in the order based on their priorities. In solving the 0-1 MKP instances, priorities of items are extracted from the cells representing state-action pairs in the Q learning matrix. In the improvement phase, two different algorithms will be employed: 2-opt and insertion algorithms. Whereas, in the 2-opt algorithm, the item in the solution is replaced with an item that is not in the solution in a systematic way, in the insertion algorithm, the selected item is inserted to the right or to the left of another item in the solution and items between the old and new places of inserted item shifted towards old place of inserted item in the same order [33].

5.3 Path Relinking Phase

The PR will be employed in Meta-RaPS Q-PR as an intensification procudure. In the PR algorithm a trajectory, or a path, is created between two solutions, called initial and guide, to find new solutions. While progressing, the initial solution transforms gradually in the guide solution by incorparating the attributes of the guide solution. In Meta-RaPS Q-PR algorithm, the improved solution found at the current iteration is accepted as the initial solution, and the best improved solution until the current iteration is assigned as the guide solution. To follow the PR process, the initial and guide solutions are first coded in a binary string. The positions containing same numbers in the initial and guide solutions are identified to keep their states and the numbers in the remaining positions are changed in a systematic way to create the neighborhood. The neighbor with the maximum profit is selected to build the path. At each step, the solutions become more similar to the guide solution and more different from the initial solution. While processing the solution found is replaced with the best improved solution only if it is better than the best improved solution.

For example, considering a 4-item 0-1 MKP problem, if items 3 and 4 are selected for the initial solution, and items 1, 2 and 4 for the guide solution, they will be coded as (0 0 1 1) and (1 1 0 1), respectively. Note that initial and guide solutions share only one item with the same state at the same position. The states of items in the other positions are switched from selected (1) to not selected (0), or not selected (0) to selected (1) to obtain the following neighbors: (1 0 1 1), (0 1 1 1) and (0 0 0 1). The best neighbor, i.e. the one with the maximum profit, is selected as the new initial solution which is now closer to the guide solution, having two items at the same position. This process is followed until the initial and guide solutions are totally identical. Table 1 summarizes the PR transforming process from the initial to guide solutions.

Table 1. PR Process

Initial	**Guide**	**Neighbors**		
0 0 1 **1**	1 1 0 **1**	1 0 1 1*	0 1 1 1	0 0 0 1
1 0 1 **1**	**1** 1 0 **1**	1 1 1 1	1 0 0 1*	
1 0 **0 1**	**1** 1 **0 1**	1 1 0 1*		
1 1 0 1	**1 1 0 1**			

Note that the PR phase of the Meta-RaPS Q-PR algorithm is not executed at the first iteration because the best improved solution to serve as the guide solution is not constituted yet. The Meta-RaPS Q-PR pseudo code is shown in Figure 3.

```
Create Q learning matrix to obtain priorities of items
Until stopping criteria met
BestImprovedSolution ← Meta-RaPS Q(ConstructedSolution,
                                   ImprovedSolution)

6 Computational Study

Meta-RaPS Q-PR is coded in C++ and solved the small/medium 0-1 MKP instances on the Intel i5 CPU 2.27 GHz PC, and the large instances on the HP Z600 CPU 2.40 GHz PC. A standard library of 0-1 MKP test instances available from the OR-Library [39] is used to evaluate the proposed algorithm. These test problems are developed by [40, 41, 42, 43].

The performance of the Meta-RaPS Q-PR will be evaluated in terms of solution quality, or deviation percentage. The deviations between solutions s (solution found in the current method) and s* (optimum solution or best solution found so far) is calculated using the following equation (5):

$$\frac{f(s^*)-f(s)}{f(s^*)} x100. \quad (5)$$

The stopping criteria are to run the Meta-RaPS Q-PR algorithm 10000 iterations or to stop whenever the percent deviation becomes 0, whichever comes first. Since there are many parts in the proposed algorithm where randomness plays very important role, the Meta-RaPS Q-PR will solve each instances 10 times, and their mean and standard deviations will be taken for the analysis. The values of parameters for Meta-RaPS are obtained by applying D-optimal design, a Design of Experiments method, which is an offline parameter tuning method [44]. The optimum parameter setting found for the Meta-RaPS Q-PR algorithm is in Table 2.

Table 2. Meta-RaPS Q-PR Parameters

Parameter	Value
Learning factor α	0.7
Discount factor γ	0.1
Priority (p)	0.4
Restriction (r)	0.2
Improvement (i)	0.1
Number of iterations (I)	10000

The results for the small/medium 0-1 MKP instances produced by the proposed algorithm are summarized in Table 3. The Meta-RaPS Q-PR approach could solve all instances, and find 9.02 times optimum solutions in 10 runs in average for all instances. The average deviation% of the solutions reached by the proposed algorithm is 0.016%.

Table 3. Meta-RaPS Q-PR Results for Small/Medium 0-1 MKP

Statistics	Dev.%	#Opt.	#Iteration	Time (Sec.)
Average	0.016	9.02	1176	258
Std. Dev.	0.037	2.06	1580	593

In solving the 0-1 MKP, Moraga et al. [12] employed the Meta-RaPS with Dynamic Greedy Rule (DGR) [10] as the priority rule in determining the priorities among items. Their average deviaton% was 0.003% for all instances. PETERSEN7 was the only instance for which Meta-RaPS DGR did not find the optimal solution for 10000 iterations, and their runtimes per instance was 115 seconds.

To reveal the contribution of the Q learning and PR to Meta-RaPS Q-PR, the number of optimum solutions found in the construction, improvement and PR phases are tracked for each instance. Since it is observed in the initial analysis that the role of PR is getting more important with the increasing number of items and knapsacks, the instances are put in the order of the size, which is defined here as the product of the number of items and number of knapsacks, as a possible sign of instance difficulty.

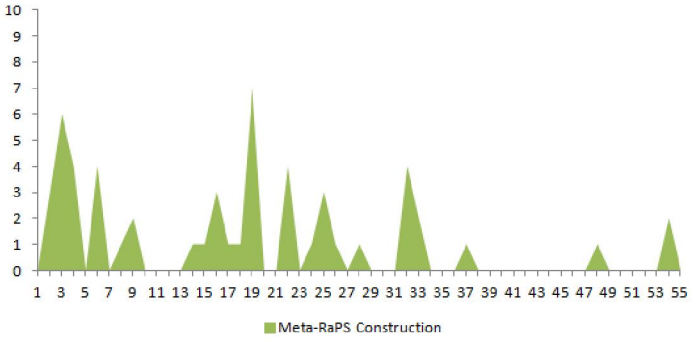

Figure 4. The number of optimum solutions found in the construction phase of Meta-RaPS Q-PR.

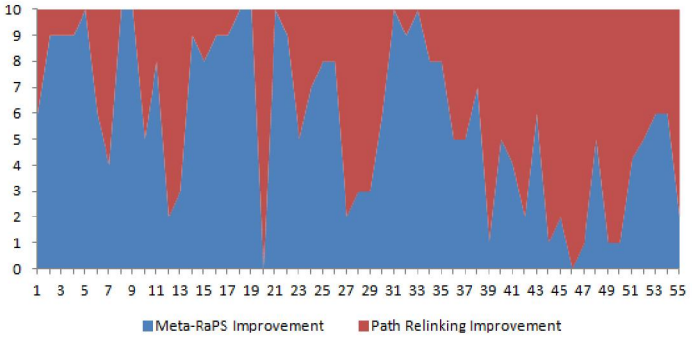

Figure 5. The distribution of solutions found in the improvement and PR phases of Meta-RaPS Q-PR in 10 replicates.

Figure 4 shows the distribution of the number of optimum solutions found in the construction phase. For the instances with lower size, Meta-RaPS could find optimum solutions even in the construction phase by using the priorities from Q learning matrix. For the remaining instances it is observed that the chance of reaching to optimum solutions is decreasing with the increasing size of the instances. The distributions of the number of optimum solutions found in the improvement and PR phases indicate the efficiency of the PR algorithm, in Figure 5. Especially for the instances with higher number of size, the role of PR in the proposed algorithm becomes clear; its share of the number of optimum or best solutions found in 10 runs for each instance is increasing.

It should remind that beside the parameter *number of iteration*, there is another stopping criterion that stops the algorithm whenever deviation% is equal to 0. For the instances with lower size, the algorithm can find the optimum solutions, and stops the solution process before it reaches to the PR phase. This is the reason why the PR phase seems not to produce optimal or best solutions for these instances. However, in solving the instances with higher size, Meta-RaPS requires employing the PR phase to obtain better results. To see the performance of the Meta-RaPS PR for larger size problems, the algorithm is also applied to solve the first 10 large size 0-1 MKP instances with 100 items and 5 knapsacks in OR Library [39]. The proposed algorithm could solve optimally 7 of 10 instances and its deviation% from optimum/best solutions is 0.14%, as seen in Table 4.

Table 2. Meta-RaPS Q-PR Results for Large 0-1 MKP

Statistics	Dev.%	#Opt	#Iteration	Time (Min.)
Average	0.14	3.2	3532	37.61
Std. Dev.	0.15	3.7	1010	13.13

Meta-RaPS Q-PR could reach better results than Meta-RaPS DGR proposed by Moraga et al. [12] whose average deviaton% was 0.60% for 0-1 MKP instances with 100 items and 5 knapsacks. Meta-RaPS DGR run times ranged from 7 to 35 minutes per problem.

7 Conclusion

According to Alpaydın [26], for a system to be intelligent, in a changing environment, it needs to have ability to memory and learn. And, learning is an intelligent process in which the basic unit of mutability is the idea [45]. "Good" adaptive ideas are maintained, much as good genes increase in a population, while poor ideas are forgotten. In similar manner, memory and learning mechanisms in metaheuristics can learn and remember "good" ideas related to the search process to make it possible to create high quality solutions for optimization problems by utilizing this information.

In the original form, Meta-RaPS has no information about the search history and begins every iteration from the same point due to its memoryless nature. In the proposed algorithm, Meta-RaPS Q-PR, the Q learning and PR approaches serve as mechanisms that learn the best policy to construct a solution, and learn "good" attributes of best solutions to reach the optimum solution while losing "bad" attributes of the current solution.

We showed that incorporating memory and learning mechanisms, such as Q learning and PR, into a memoryless metaheuristic can result in significant improvements to the metaheuristic's performance. Even though the proposed algorithm could solve all small/medium instances, the average deviatons% for proposed and original versions of Meta-RaPS are pretty small. However, the contribution of Q learning and PR becomes more clear when investigated the small set of large instances. Thus, for the future studies, the proposed algorithm should be applied to solve the remaining large 0-1 MKP instances in OR-Library to understand its true performance.

Abstract— *Web spam has become a big problem in the lives of Internet users, causing personal injury and economic losses. Although some approaches have been proposed to automatically detect and avoid this problem, the high speed the techniques employed by spammers are improved requires that the classifiers be more generic, efficient and highly adaptive. Despite of the fact that it is a common sense in the literature that neural based techniques have a high ability of generalization and adaptation, as far as we know there is no work that explore such method to avoid web spam. Given this scenario and to fill this important gap, this paper presents a performance evaluation of different models of artificial neural networks used to automatically classify and filter real samples of web spam based on their contents. The results indicate that some of evaluated approaches have a big potential since they are suitable to deal with the problem and clearly outperform the state-of-the-art techniques.*

Keywords: web spam; spam classifier; artificial neural network; pattern recognition

1. Introduction

The web has becoming an essential tool in the lives of their users. The steady growth in volume of available information requires the use of search engines that help users to find desired data and presenting the results in an organized, quick and efficient way. However, there are several malicious methods that try to circumvent the search engines by manipulating the relevance of web pages. This deteriorates the search results, leaves users frustrated and exposes them to inappropriate and insecure content. Such technique is known as web spamming [1].

Web spam is composed by *content spam* and/or *link spam*. According to Gyongyi and Garcia-Molina [2], a very simple example of content spam is a web page with pornography and thousands of invisible keywords that have no connection with the pornographic content. Sheng *et al.* [3] explain that link spam is a kind of web spamming with thousands of links to web pages that are intended to promote. Such method increases the relevance of pages in search engines that rank the importance of pages using the relation of the amount of links pointing to it.

The minor problems caused by web spamming is the nuisance offered by forging undeserved and unexpected answers, promoting the announcement of unwanted pages [3]. However, there are more serious problems that pose a significant threat to users, since the web spam may have malicious content that installs malwares on the computers of victims, promoting the discovery of bank passwords and other personal information, degrading the performance of computers and network, among others [4].

According to annual reports, the amount of web spam is frightfully increasing. Eiron *et al.* [5] have classified 100 million web pages and they found that, in average, 11 of the 20 best results were pornographic pages that achieved a high relevance through the manipulation of links. According to Gyongyi and Garcia-Molina [2], there are more than 20% of web spam in the search results. Furthermore, the same study has indicated that about 9% of the search results have at least one link from a spam page in the 10 best results, while 68% of all queries have some kind of spam in the four best results presented by the search engines [2].

Unlike the large amount of available approaches to deal with email spams [6], [7], [8], [9], [10], [11], [12], [13], [14], there few methods in the literature to automatically detect web spam. In general, all the techniques employ one of the following strategies:

- To analyze only the relation of web links [3], [15];
- To analyze only the content of the web pages [16], [17]; or
- To extract features from both contents and links [18], [19], [20].

Among all the approaches presented in the literature, machine learning methods are the most used ones, such as ensemble selection [21], [22], clustering [20], [23], random forest [21], boosting [21], [22], support vector machine [1], [24], and decision trees [15], [20]. However, the main conclusions presented in the literature indicate that the high speed the techniques employed by spammers are improved requires that the classifiers be more generic and adaptive.

To the best of our knowledge, the artificial neural network, that is the one of the most popular and successful technique for pattern recognition, has not been evaluated for classifying web spam. To fill this important gap, this paper presents a performance evaluation of different models of artificial

neural networks used to automatically classify and filter real and public samples of web spam.

This paper is organized as follows: Section 2 introduces the background of the evaluated artificial neural networks. The experiment protocol and main results are presented in Section 3. Finally, Section 4 offers the main conclusions and guidelines for future work.

2. Artificial neural network

Artificial neural network (ANN) is a parallel and distributed method made up of simple processing units called neurons, which has computational capacity of learning and generalization. In this system, the knowledge is acquired through a process called training or learning that is stored in strength of connections between neurons, called synaptic weights [25].

A basic model of ANN has the following components: a set of synapses, an integrator, an activation function, and a bias. So, there are different models of ANN depending on the choice of each component [25].

In the following, we briefly present each model we have evaluated in this work.

2.1 Multilayer perceptron neural network

A multilayer perceptron neural network (MLP) is a perceptron-type network that has a set of sensory units composed by an input layer, one or more intermediate (hidden) layers, and an output layer of neurons. This type of network is fully connected, in other words, all neurons in any layer are connected to all neurons of the previous layer [25].

By default, MLP is a supervised learning method that uses the backpropagation algorithm which can be summarized in two stages: *forward* and *backward*.

In the *forward* stage, the signal propagates through the network, layer by layer, as follows:

$$u_j^l(n) = \sum_{i=0}^{m^{l-1}} w_{ji}^l(n) y_i^{l-1}(n),$$

where $l = 0, 1, 2, ..., L$ are the indexes of network layers. So, $l = 0$ represents the input layer and $l = L$ represents the output layer. On the other hand, $y_i^{l-1}(n)$ is the output function relating to the neuron i in the previous layer, $l-1$, $w_{ji}^l(n)$ is the synaptic weight of neuron j in layer l and m^l corresponds to the number of neurons in layer l. For $i = 0$, $y_0^{l-1}(n) = +1$ and $w_{j0}^l(n)$ represent the bias applied to neuron j in layer l [25], [26].

The output of neuron j in layer l is given by:

$$y_j^l(n) = \varphi_j(u_j^l(n)),$$

where φ_j is the activation function of j. Then, the error can be calculated by:

$$e_j^l(n) = y_j^l(n) - d(n),$$

where $d(n)$ is the desired output for an input pattern $x(n)$.

In *backward* stage, the derivation of the backpropagation algorithm is performed starting from the output layer, as follows:

$$\delta_j^L(n) = \varphi'_j(u_j^L(n)) e_j^L(n),$$

where φ'_j is the derivative of the activation function. For $l = L, L-1, ..., 2$, is calculated:

$$\delta_j^{l-1}(n) = \varphi'_j(u_j^{l-1}(n)) \sum_{i=1}^{m^l} w_{ji}^l(n) * \delta_j^l(n),$$

for $j = 0, 1, ..., m^l - 1$ [25], [26].

According to Haykin [25], one of the most common stopping criteria for the MLPs and other types of ANNs is the amount of training iterations. The algorithm can also be stopped when the network reaches a minimum error, which can be calculated by the Mean Square Error:

$$MSE = \frac{1}{n} e^T e,$$

where n is the number of input patterns and e an array that stores the relative error for all input patterns in the network.

2.1.1 Levenberg-Marquardt algorithm

The Levenberg-Marquardt algorithm is usually employed to optimize and accelerate the convergence of the backpropagation algorithm [27]. It is considered a second order method because it uses information about the second derivative of the error function.

Considering that the error function is given by MSE, the equation used by Gauss-Newton method to update the network weights and to minimize the value of MSE is:

$$W_{i+1} = W_1 - H^{-1} \nabla f(W).$$

The gradient $\nabla f(W)$ can be represented by:

$$\nabla f(W) = J^T e$$

and the Hessian matrix can be calculated by:

$$\nabla^2 f(W) = J^T J + S,$$

where J is the Jacobian matrix

$$J = \begin{bmatrix} \frac{\partial e_1}{\partial x_1} & \frac{\partial e_1}{\partial x_2} & \cdots & \frac{\partial e_1}{\partial x_n} \\ \frac{\partial e_2}{\partial x_1} & \frac{\partial e_2}{\partial x_2} & \cdots & \frac{\partial e_2}{\partial x_3} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial e_n}{\partial x_1} & \frac{\partial e_n}{\partial x_2} & \cdots & \frac{\partial e_n}{\partial x_n} \end{bmatrix},$$

x_i is the i-th input pattern of the network and

$$S = \sum_{i=1}^{n} e_i \nabla^2 e_i.$$

It can be conclude that S is a small value when compared to the product of the Jacobian matrix, so the Hessian matrix can be represented by:

$$\nabla^2 f(W) \approx J^T J.$$

Therefore, updating the weights in Gauss-Newton method can be done by:

$$W_{i+1} = W_1 - (J^T J)^{-1} J^T e.$$

One limitation of the Gauss-Newton method is that a simplified Hessian matrix can not be reversed. Thus, the Levenberg-Marquardt algorithm updates the weights by:

$$W_{i+1} = W_i - (J^T J + \mu I)^{-1} J^T e,$$

where I is the identity matrix and μ a parameter that makes the Hessian a positive definite matrix.

More details about the Levenberg-Marquardt algorithm can be found at [26], [27], [28].

2.2 Kohonen's self-organizing map

The Kohonen's self-organizing map (SOM) is based on unsupervised competitive learning. Its main purpose is to transform an input pattern of arbitrary dimension in a one-dimensional or two-dimensional map in a topologically ordered fashion [25], [29].

The training algorithm for a SOM can be summarized in two stages: competition and cooperation [25], [29].

In the competition stage, a random input pattern (x_j) is chosen, the similarity between this pattern and all the neurons of the network is calculated by the Euclidean distance, defined by:

$$id = \arg \min_{\forall i} \|x_j - w_i\|,$$

where $i = 1, ...k$, and the index of the neuron with lowest distance is selected.

In the cooperation stage, the synaptic weights w_{id} that connect the winner neuron in the input pattern x_i is updated. The weights of neurons neighboring the winner neuron are also updated by:

$$w_i(t+1) = w_i(t) + \alpha(t) h(t) (x_i - w_i(t)),$$

where t is the number of training iterations, $w_i(t+1)$ is the new weight vector, $w_i(t)$ is the current weight vector, α is the learning rate, $h(t)$ is the neighborhood function and x_i is the input pattern.

The neighborhood function $h(t)$ is equal to 1 when the winner neuron is updated. This is because it determines the topological neighborhood around the winning neuron, defined by the neighborhood radius σ. The amplitude of this neighborhood function monotonically decreases as the lateral distance between the neighboring neuron and the winner neuron increases. There are several ways to calculate this neighborhood function, and one of the most common is the Gaussian function, defined by:

$$h_{ji}(t) = \exp\big(\frac{-d_{ji}^2}{2\sigma^2(t)}\big),$$

where d_{ji} is the lateral distance between winner neuron i and neuron j. The parameter $\sigma(t)$ defines the neighborhood radius and should be some monotonic function that decreases over the time. So, the exponential decay function

$$\sigma(t) = \sigma_0 \exp\big(-\frac{t}{\tau}\big)$$

can be used, where σ_0 is the initial value of σ, t is the current iteration number and τ is a time constant of the SOM, defined by

$$\tau = \frac{1000}{\log \sigma_0}.$$

The competition and cooperation stages are carried out for all the input patterns. Then, the neighborhood radius σ and learning rate α are updated. This parameter should decrease with time and can be calculated by:

$$\alpha(t) = \alpha_0 \exp\big(-\frac{t}{\tau}\big),$$

where α_0 is the initial value of α, t is the current iteration number and τ is a time constant of the SOM which can be calculated as presented in the cooperation stage.

2.3 Learning vector quantization

The learning vector quantization (LVQ) is a supervised learning technique that aims to improve the quality of the classifier decision regions, by adjusting the feature map through the use of information about the classes [25].

According to Kohonen [29], the SOM can be used to initialize the feature map by defining the set of weight vectors w_{ij}. The next step is to assign labels to neurons. This assignment can be made by majority vote, in other words, each neuron receives the class label in that it is more activated.

After this initial step, the LVQ algorithm can be employed. Although, the training process is similar to the SOM one, it does not use neighborly relations and updates only the winner neuron. Therefore, it is checked if the class label of the input vector x is equal to the label of the winner neuron. If the labels are equal, this neuron is moved towards the input vector x by:

$$w_{id}(t+1) = w_{id}(t) + \alpha(t)(x_i - w_{id}(t)),$$

where α is the learning rate, id is the index of the winner neuron and t is the current iteration number. However, if the label of the winner neuron is different from the label of the input pattern x, then it is moved away by:

$$w_{id}(t+1) = w_{id}(t) - \alpha(t)(x_i - w_{id}(t)).$$

2.4 Radial basis function neural network

A radial basis function neural network (RBF), in its most basic form, has three layers. The first one is the input layer which has sensory units connecting the network to its environment. The second layer is hidden and composed by a set of neurons that use radial basis functions to group the input patterns in clusters. The third layer is the output one, which is linear and provides a network response to the activation function applied to the input layer [25].

The activation functions consists of radial basis functions whose values increase or decrease in relation to the distance for a central point. The decreasing radial basis function most common is the Gaussian, defined by:

$$h(x) = \exp\left(-\frac{(x-c)^2}{r^2}\right),$$

where x is the input vector, c is the center point and r is the width of the function. On the other hand, the increasing radial basis function generally is represented by a multiquadric function, defined by [30]:

$$h(x) = \frac{\sqrt{r^2 + (x-c)^2}}{r}.$$

The procedure for training a RBF is performed in two stages. In the first one, the parameters of the basic functions related to the hidden layer are determined through some method of unsupervised training, as K-means.

In the second training phase, the weights of the output layer are adjusted, which corresponds to solve a linear problem [27]. According to Bishop [27], considering an input vector $x = [x_1, x_2, ..., x_n]$, the network output is calculated by:

$$y_k = \sum_{j=1}^{m} w_{kj} h_j,$$

where $x = [w_{k1}, w_{k2}, ..., x_{km}]$ are the weights, $h = [h_1, h_2, ..., h_m]$ are the radial basis functions, calculated by a function of radial basis activation.

After calculating the outputs, the weights should be updated. A formal solution to calculate the weights is given by:

$$w = h^{\dagger} d,$$

where h is the matrix of basis functions, $h^{\dagger}$ represents the pseudo-inverse of h and d is a vector with the desired responses [27].

Consult [25], [27], [30] for more information.

3. Experiments and results

To give credibility to the found results and in order to make the experiment completely reproducible, all the tests were performed with the public and well-known WEBSPAM-UK2006 collection[1]. It is composed by a set of 105,896,555 web pages hosted in 114,529 hosts in the UK domains. It is important to note that this corpus was used in *Web Spam Challenge Track*[2] *I* and *II*, that are the most known competitions of web spam detection techniques.

In our experiments, we have followed the same competition guidelines. In this way, we have used a set of 8,487 feature vectors employed to discriminate the hosts as spam or ham. This kind of information was provided by the organizers. Each feature vector is composed by 96 features proposed by Castilho *et al.* [20], where 24 features were extracted from the host home page, other 24 ones from the page with the highest PageRank, 24 ones from the mean of these values for all pages, and the remaining 24 ones from the variance of all web pages. Furthermore, each host is labeled as spam, not spam (ham) or indefinite. Thus, the vectors related to hosts that are labeled as undefined were discarded.

3.1 Protocol

We evaluated the following well-known artificial neural networks (ANNs) algorithms to automatically detect web spam based on its content: multilayer perceptron (MLP) trained with the gradient descent and Levenberg-Marquardt methods, Kohonen's self-organizing map (SOM) with learning vector quantization (LVQ) and radial basis function neural network (RBF).

We have implemented all the ANNs with a single hidden layer and with one neuron in the output layer. In addition, we have employed a linear activation function for the neuron of output layer and an hyperbolic tangent activation function for the neurons of the intermediate layer. Thus, we have initialized the weights and biases with random values between $+1$ and -1, and normalized the data to this interval.

The desired output for all networks is -1 (ham) or $+1$ (spam). So, for RBFs and MLPs, if the output is greater than or equal to 0, the host is considered spam, otherwise it is considered ham. The same not happens with SOMs since the data receive the same label of the neuron that represents them.

Regarding the parameters, in all simulations, we have employed the following stopping criteria: maximum number of iterations be greater than a threshold θ, the mean square error (MSE) of the training set be smaller than a threshold γ or when the MSE of the validation set increases (checked every 10 iterations).

[1] *Yahoo! Research: "Web Spam Collections"*. Available at `http://barcelona.research.yahoo.net/webspam/datasets/`.

[2] *Web Spam Challenge:* `http://webspam.lip6.fr/`

The parameters used for each ANN model were empirically calibrated and are the following:

- Multilayer perceptron with gradient descent method:
  - $\theta = 10,000$
  - $\gamma = 0.001$
  - Step learning $\alpha = 0.005$
  - Number of neurons in the hidden layer: 100
- Multilayer perceptron with Levemberg-Marquardt method:
  - $\theta = 500$
  - $\gamma = 0.001$
  - Step learning $\alpha = 0.001$
  - Number of neurons in the hidden layer: 50
- Kohonen's self-organizing map with learning vector quantization:
  - Competition stage:
    - One-dimensional neighborhood function with initial radius $\sigma = 4$
  - Cooperation stage:
    - $\theta = 2,000$
    - Step learning $\alpha = 0.01$
    - Number of neurons in the hidden layer: 120
- Radial basis function neural network:
  - Number of neurons in the hidden layer: 10

Note that, for the simulations using the RBFs, we have not employed any stopping criteria because the training method is not iterative, as pointed out in Section 2.4.

To address the algorithms performance, we divided each simulation in 10 tests and calculated the arithmetic mean and standard deviation of the following well-known measures: accuracy rate (Acc%), spam recall rate (Rcl%), specificity (Spc%), spam precision rate (Pcs%), and F-measure (FM). In each test, we have randomly selected 80% of the samples of each class to be presented to the algorithms in the training stage and the remaining ones were separated for testing.

3.2 Results

In this section, we report the main results of our evaluation. Table 1 presents the performance achieved by each artificial neural network. Bold values indicate the highest score.

Table 1: Results achieved by each evaluated artificial neural network for WEBSPAM-UK2006 dataset.

	Gradient	Levenberg	RBF	SOM + LVQ
	Mean	Mean	Mean	Mean
Acc	86.2±1.2	**88.6**±1.4	79.7±0.6	80.6±0.8
Rcl	57.0±4.6	**69.3**±4.2	26.7±2.8	29.2±2.6
Spc	95.0±0.4	94.2±1.2	95.8±0.7	**96.3**±0.6
Pcs	77.5±2.7	**77.6**±4.6	65.8±3.3	70.4±4.0
FM	0.656±0.039	**0.731**±0.032	0.379±0.030	0.412±0.030

According to the results, it is clear that the MLP trained with Levenberg-Marquardt method achieved the best performance. On the other hand, the Kohonen's self-organizing map and radial basis function neural network acquired the worst performances with a very low spam recall rate. Furthermore, in all results we noted the contrast between the high specificity rate and a not too high spam recall rate, which indicates that the classifiers have more successful to identify ham hosts than spam ones.

Based on these first results, we considered the hypothesis that there are redundancies in the feature vectors that could be affecting the classifiers performance. In this way, we employed the principal component analysis (PCA) [25] to analyze and reduce the dimensionality of the feature space. Using the PCA, we observed that with only 23 dimensions is possible to represent about 99% of the information presented in the original 96 feature vectors. According to the analysis, the most relevant information are in the first 21 dimensions. Therefore, it is possible to conclude that just the attributes extracted from the host home page have enough information to characterize the host as spam or ham.

After reducing the feature vectors from 96 to 23 dimensions, we performed a new simulation. The found results are presented in Table 2.

Table 2: Results achieved by each evaluated artificial neural network for WEBSPAM-UK2006 dataset after a step of dimensionality reduction using principal component analysis.

	Gradient	Levenberg	RBF	SOM + LVQ
	Mean	Mean	Mean	Mean
Acc	81.0±0.6	**85.5**±1.5	76.9±0.4	77.3±0.2
Rcl	38.8±2.4	**55.5**±3.4	2.5±1.3	3.1±0.8
Spc	95.1±0.6	94.8±1.2	99.5±0.3	**99.8**±0.1
Pcs	71.1±2.8	77.0±4.0	58.6±19.8	**88.3**±6.5
FM	0.502±0.024	**0.644**±0.027	0.047±0.024	0.060±0.014

Based on the found results we can see that, although PCA indicates that the new feature vectors represent more than 99% of the information of the original data, reducing the dimensionality of the feature space clearly affected the classifiers performance for all evaluated techniques, mainly for Kohonen's self-organizing map and radial basis function neural network which achieved spam recall rate lower than 5%. Therefore, it is conclusive that in this scenario reducing the dimensionality of the feature space is not indicated.

Analyzing the results achieved in all experiments, we also suspected that the difference between the achieved high specificity rates and low spam recall rates for all evaluated techniques could be explained by the large difference between the number of ham over the amount of spam samples. This could be doing the classifiers more specialized to identify ham hosts. Thus, to test this hypothesis, we decided to present to the classifiers the same number of data in the two classes during the training process. In this way, 1,978 samples of each class were randomly selected to be trained.

With this new setup, we performed a new simulation using again all the feature vectors. Table 3 presents the classification results.

Table 3: Results achieved by each evaluated artificial neural network for WEBSPAM-UK2006 dataset using classes of equal size in the training stage.

	Gradient	Levenberg	RBF	SOM + LVQ
	Mean	Mean	Mean	Mean
Acc	84.7±1.6	**87.6**±1.5	63.6±1.3	66.9±0.7
Rcl	82.9±2.0	**86.5**±2.0	45.6±1.9	59.7±5.9
Spc	86.4±2.4	**88.8**±1.9	81.6±1.5	74.2±5.5
Pcs	86.1±2.4	**89.1**±2.4	71.3±2.1	70.1±2.9
FM	0.845±0.015	**0.877**±0.017	0.556±0.016	0.642±0.026

The last results indicate that training the artificial neural networks with the same number of samples in each class clearly improved the performance of all classifiers. Note that, if we compare the new results with the ones presented in Table 1, as it was expected, the cost for the lower specificity rate worth if we consider the great improvement in the spam recall rate. It can be also confirmed by the improvement in the F-measure for all evaluated techniques. It is important to note that the MLP with the Levemberg-Marquardt method achieved very good results and the best performance when compared with the other evaluated methods.

To show that the evaluated artificial neural networks are really competitive, in Table 4 we present a comparison between the best results achieved by the evaluated artificial neural networks and the top performance techniques employed to classify web spam available in the literature.

Table 4: Comparison between the results achieved by the evaluated artificial neural networks and the top performance classifiers available in the literature.

Classifiers	Pcs	Rcl	FM
Top performance methods available in the literature			
Decision trees [20] - content	-	-	0.683
Decision trees [20] - content and links	-	-	0.763
Support Vector Machine [1] - content	60.0	36.4	-
Bagging [16] - content	84.4	**91.2**	-
Boosting [16] - content	86.2	91.1	-
Best results achieved by each artificial neural network			
MLP + Gradient - content	86.1	82.9	0.845
MLP + Levenberg - content	**89.1**	86.5	**0.877**
RBF - content	88.3	45.6	0.556
SOM + LVQ - content	64.2	59.7	0.642

The comparison indicates that the MLP with Levemberg-Marquardt method is very competitive and suitable to deal with the problem. Note that, although the Bagging algorithm presented by Ntoulas *et al.* [16] achieved higher spam recall rate, the spam precision rate is lower and, consequently, the specificity rate is also lower than those one achieved by MLP. Furthermore, the results indicate that the MLP neural networks outperformed established methods as the decision trees proposed by Castilho *et al.* [20] and SVM presented by Svore *et al.* [1].

4. Conclusions and future work

In this paper, we have presented a performance evaluation of different models of artificial neural networks used to automatically classify real samples of web spam based on their contents.

The results indicate that the multilayer perceptron neural network trained with the Levenberg-Marquardt method is the best evaluated model. Such a method also outperformed established techniques available in the literature such as decision trees [20] and support vector machine [1].

Furthermore, since the data is unbalanced, the results also indicate that all the evaluated techniques are superior when trained with the same amount of samples of each class. It is because the models tend to converge to the benefit of the class with the largest number of representatives, which increases the rate of false positives or false negatives.

We have also observed that the Kohonen's self-organizing map and radial basis function neural network were inferior than the multilayer perceptron neural networks in all simulations. So, we can conclude that such a models are not indicated to classify web spam.

Finally, an analysis on the feature vectors originally proposed by Castilho *et al.* [20] indicate that they have many redundancies, since with the principal component analysis is possible to reduce them from 96 to 23 dimensions that represents about 99% of the information presented in the original feature set. However, using the reduced feature vectors clearly hurts the classifiers accuracy.

For future work, we intend to propose new features to enhance the classifiers prediction, and hence increase its ability to discriminate the hosts as spam or ham. In this way, we aim to use the relation of links presented in the web pages.

Abstract: *This work explored the application of Group Method of Data Handling (GMDH) and Radial Basis Functions Generalized Regression Neural Network (RBFGRNN) for a multi-class data classification with real valued attributes. The Dataset employed has 336 instances, with each instance consisting of a name and seven predictive inputs and one of five different classes. The Karhunen Loeve Transformation (KLT) technique is used to avoid redundancy in the data keeping more than 95% of the information in the original data. A four layer GMDH network with six best error outputs passed to the succeeding layer gave the best result. Before applying a multi-dimensional RBFGRNN network, a DIANA like hierarchical clustering algorithm has been employed to determine the number of cluster centers and organize the data around those centers. Finally, the multi-dimensional RBFGRNN is applied on the transformed data and the performance of the network is evaluated. The regressed output of the network highly resembles the actual desired class outputs.*

Keywords: GMDH, RBFGRNN, KLT, classification, clustering.

1. Introduction

A classification problem can be described as identifying an unknown object as a member of a known class of objects. The large volume of biological sequences, like DNA and protein sequences, available in public databases in recent times has created great interest in the area of development of computational techniques for automatic classification of those data sequences. In literatures, several algorithms have been suggested for a multivariate classification problem. Traditional sequence classification algorithms like K-nearest neighbor based techniques and machine learning algorithms like support vector machines (SVM) have been studied and implemented in this effort of sequence-based classification [1]. Over the years, algorithms based on Markov models, and Hidden Markov models have been used extensively for solving various problems in computational biology [2, 3]. Deshpand and Karypis specifically evaluated different classification algorithms applied on five different datasets, including E. coli, and found out that the SVM-based approaches provide better accuracy than Markov model or K-nearest based methods [1]. Machine learning algorithms learn from experience or observed examples based on some class of tasks and performance measure [4]. Because of the algorithm's learning ability to construct classifiers, machine learning techniques are appropriate for biological data classification problem. In machine learning, there are in general two types of learning approaches: supervised learning in which the learner has some prior knowledge of the data, and unsupervised learning where no prior information is given to the learner regarding the data or the output [5]. Neural networks are one of the most widely applied classification techniques for solving problems in human-like manner [5, 6]. After sufficient training, the neural structure uses the knowledge it stores in the connection weights to recall patterns.

This paper investigates the application of GMDH and RBFGRNN neural networks for classifying a multivariate class problem. Neural networks in general assume fairly independent sets of attribute values to avoid garbage-in garbage-out scenario. So, preprocessing of training data is very crucial to guarantee linearly independent sets of inputs to the network. For this purpose, KLT technique is applied to transform the high dimensional data to a lower dimension by avoiding a redundancy in the original data. In addition, the order of the training data is randomized at each epoch and the inputs are normalized so that all the inputs to the network will have a balanced impact on the network. The transformed data needs to be categorized in to a set of clusters before using the RBFGRNN. In most literatures, K-mean clustering algorithm was used to cluster the data in to K number of clusters. K-mean clustering is famous and simple to implement. In most circumstances however, the number of clusters that prevail in the data is not known apriori. Instead, we applied a hierarchical DIANA like clustering algorithm that starts with one big cluster and continuously divides the cluster until the diameter of the cluster is less than a threshold value. The feasibility of the algorithms for a multi-class data classification is verified using an E. coli data set obtained from the database of UCI's machine learning laboratory [7]. The E.coli (formally known as Escherichia coli) are named after a German paediatrician and bacteriologist Theodor Escherich who first discovered it in 1885 [8]. The E. coli dataset has 336 real valued instances with 8 attributes (7 predictive, 1 name). In the implementation we considered only the 7 predictive

This material is based in part upon work supported by the National Science Foundation under Cooperative Agreement No. DBI-0939454.

input attributes as the name is simply an ID that does not contribute for classification.

The rest of the paper is organized as follows: In sections 2 and 3 we present a detailed algorithmic description of GMDH and RBFGRNN networks respectively. Section 4 presents the methodology followed. The KLT dimensionality reduction and the DIANA like clustering algorithm techniques are also briefly explained here. Section 5 discusses the simulation results obtained and the last section concludes the paper by highlighting major achievements obtained and pointing future research directions. Finally, the appendix section displays the simulation results in tabular form.

2. GMDH

The GMDH neural network, invented by Alexey G. Ivakhnenko at the institute of cybernetics in Ukraine in 1968 [9], is based on a polynomial theory of complex systems. GMDH polynomial neural networks are self-organizing networks. The connections between neurons in the network vary during the training process so as to optimize the performance of the network [10]. The network starts only with input neurons. During the training process, neurons are selected from a pool of candidates and added to the hidden layers. Hence, the number of layers in the network is automatically selected to produce maximum accuracy without over fitting. GMDH does not require presetting of the neural network structure and it allows presenting a classification rule as a concise set of short-term polynomials. Ivakhnenko originally developed the GMDH for the purpose of building more accurate predictive models of the fish populations in rivers and oceans [9]. It is a self-organizing method which is based on sorting-out gradually complicated functional models (not necessarily polynomials) utilizing an external criterion in their evaluation on separate cross-validation data samples. The original intent of the GMDH lies in the field of forecasting, extrapolation of multivariate processes, pattern recognition, knowledge discovery and data mining. When used in its polynomial form, the GMDH answers the age-old question of how to fit a polynomial to data without over fitting [11]. Figure 1 illustrates the structure of a basic GMDH network using polynomial functions of two variables.

The first layer (at the top) presents one input for each predictor variable. Each neuron in the second layer draws its inputs from two of the input variables. The neurons in the third layer draw their inputs from two of the neurons in the previous layer and progresses through each layer in the same fashion. The layer at the very bottom draws its two inputs from the one just before it and generates a single value as an output of the network. Traditional GMDH neural networks use complete quadratic polynomials of two variables as transfer functions in the neurons.

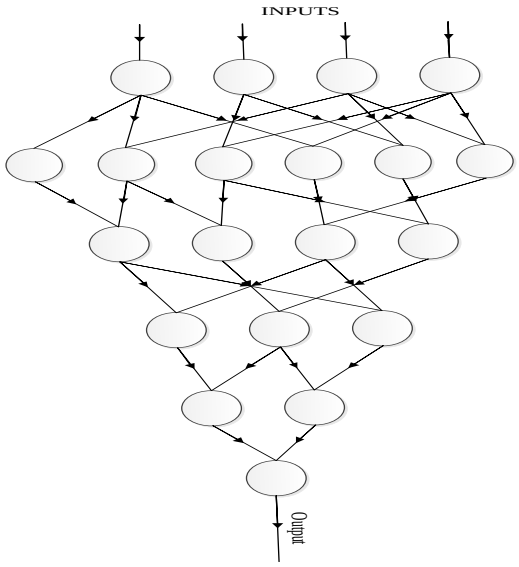

Figure 1: The structure of a basic GMDH network using polynomial functions of two variables.

A second order polynomial equation of the GMDH neural network model is shown in Equation 1. The coefficients are the values for the weight of the neuron with x1 and x2 as inputs y as an output.

$$y = a_0 + a_1 x_1 + a_2 x_2 + a_3 x_1^2 + a_4 x_2^2 + a_5 x_1 x_2 \quad (1)$$

A more simplified version of GMDH can be obtained by ignoring the square terms in equation (1). Our implementation considered both versions and the results for the simplified version are portrayed in Figures 4 to 7. And the weights and combinations of input for each of the four layers are as shown in Tables 1 to 4.

3. RBFGRNN

The RBFGRNN is an adaptation of the traditional GRNN (the Nadaraya-Watson kernel regression approximator) that was developed by Donald Specht [12]. This network is akin to the RBF network in which there is a hidden unit centered at each cluster center. These RBF units in the hidden layer are called "Gaussian Displacement Units (GDUs)" and correspond to kernel functions in the Nadaraya-Watson kernel regression approximator (see Figure 2). RBFGRNN can be used for prediction by analyzing and modeling the relation between inputs and outputs of large amount of data [13]. The KLT (also termed Principal Component Analysis in some literatures) is a linear projection technique where a high dimensional data is transformed into a lower dimension. It is a key element of many signal processing and communication tasks, including approximation, compression, and

classification. Figure 2 shows the schematic diagram of a typical RBFGRNN network.

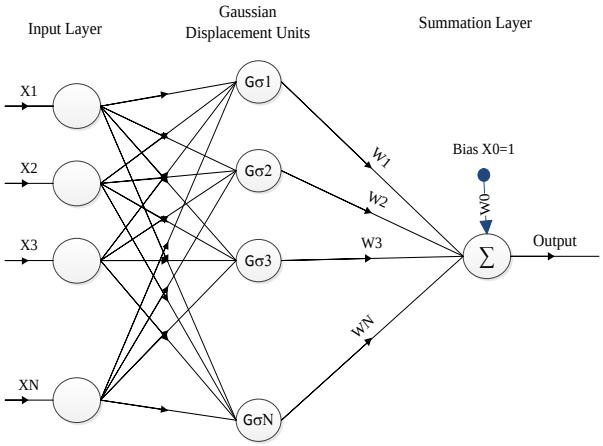

Figure 2: Architecture of a typical RBFGRNN.

The output of the GDUs is computed using equation (2).

$$g(x, c_k) = \exp(-0.5 * (x - c_k)^T Z^{-1} * (x - c_k)) \quad (2)$$

Where, the c_ks are the cluster centers and Z is the covariance matrix.

4. Methodology

The implementation is organized in to the following subsections.

4.1. Data Formatting

First, the original data downloaded from the UCI's website is formatted in a way it is suitable for training. The data is then divided in to training and testing in a 1:3 ratio (25% testing). In addition, the sequence of the events in the data is randomized for fair generalization outcome by the network. Each of the classes instances are reshuffled and equal percentage representation is maintained for each class both in the training and testing data set.

4.2. Dimensionality Reduction

The original data is transformed into a lower dimension using the KLT technique. First the covariance matrix is computed using equation (3). The Eigen values and Eigen vectors of the covariance matrix are then obtained using octave (see equation 4).

$$\text{cov } X = \frac{1}{N-1} X^T * X - mean(X)^T * mean(X) \quad (3)$$

$$[eigenvecto\,r, eigvalue] = eig(\text{cov } X) \quad (4)$$

Once the Eigen vectors and Eigen values are computed, the next step is to find the top "*dim*" Eigen values that keep 95% of the information in the original data using equation (5).

$$\frac{\sum_{i=1}^{\dim} lamda_i}{\sum_{i=1}^{N} lamda_i} >= 0.95 \quad (5)$$

Where, *dim* is the dimension of the transformed data, $lamda_i$ is the i^{th} eigen value and *N* is the number of eigen vectors. The first "*dim*" Eigen vectors satisfying equation (5) are used to form the transformation matrix *phi* given in equation (6). The *phi* matrix will be used to transform the data using equation (7)

$$phi = eigvector(:, \quad 1:\dim) \quad (6)$$

$$transformedData = X * phi \quad (7)$$

4.3. DIANA

A DIvisive ANAlysis (DIANA) is a hierarchical clustering technique that constructs the hierarchy starting with one big cluster that contains all the events, i.e. initially there is one large cluster consisting of all the objects. A DIANA like clustering algorithm is used for clustering the transformed data. At each subsequent step, the largest available cluster is split into two clusters until a stopping criterion is met. By trial and error a threshold value of 20 times the smallest nonzero distance between any two events in the data set gives the best performance and is used as stopping criteria.

Algorithmic description:

a. All vectors start out as one cluster on the buffer list.
b. Calculate the smallest none zero distance (LB) between any two events in the one cluster.
c. Divide Cluster:

For each cluster on the buffer list

i. Find the vectors (m, n) in the one cluster whose distance equals the cluster's diameter. The diameter of a cluster is defined as the largest distance between any two vectors in the cluster.
ii. For all other vectors
If vector k is closer to m, place it in group-1, otherwise place it in group-2
iii. Check Condition
If the diameter of vectors in group-1 is larger than the threshold, then place group-1 on the buffer list, otherwise place group-1 on the final list. And do the same for group-2.
iv. Remove the parent cluster from the buffer list

d. Repeat step c until no clusters exist in the buffer list.

4.4. GMDH

The GMDH network training algorithm proceeds as follows:

1. Initialize the training and testing data, iteration constant and the maximum number of layers parameters.
2. Construct the first layer which simply presents each of the input predictor variable values.
3. Construct all possible functions using combinations of inputs from the previous layer and predict the weight values.
4. Compute the Mean Absolute Error (MAE) between the regressed output at the K^{th} layer and the desired output.
5. Sort the candidate neurons in order of increasing MAE.
6. Select the best (smallest MAE) neurons from the candidate set for the next layer. A model-building parameter specifies how many neurons are used in each layer.
7. Compare the best MAE at the K^{th} layer with the best MAE at the $(K\text{-}1)^{th}$ layer.
8. Check condition
   If the error for the best neuron in the K^{th} layer is better than the error from the best neuron in the previous layer and the maximum number of layers has not been reached, then set the output of the K^{th} layer to the input of the $(K+1)^{th}$ layer and go back to step 3 to construct the next layer. Otherwise, stop the training.

When over fitting begins, the error as measured with the control data will begin to increase. Training the network should stop at this point. Figure 3 shows the layout of the program flow for the GMDH implementation.

4.5. RBFGRNN

In the RBFGRNN, the GDUs require the sample covariance matrix from the training data as well as the input cluster centers. The output of the hidden layer is fed into an optimal linear regression network to map the GDU outputs to the target training data (see figure 2). First, the KLT is applied to check linear dependency in the training data by transforming the original high dimensional data to a form that is linearly independent. Then, the transformed data is categorized into clusters around the cluster centers obtained using the DIANA like algorithm. RBFGRNN is a one pass neural network where the connection weights are computed using equation (8).

$$W = (G^T * G)^{-1} * G^T * Y_D \qquad (8)$$

Where, G is a GDU matrix whose values are computed using equation (2) and Y_D is the desired output vectors.

Once the values for the weights are determined, the regressed output of the network is calculated using equation (9).

$$Net\_Out = G * W + w_0 * bias \qquad (9)$$

Where, w_0 is the weight value associated with the bias input.

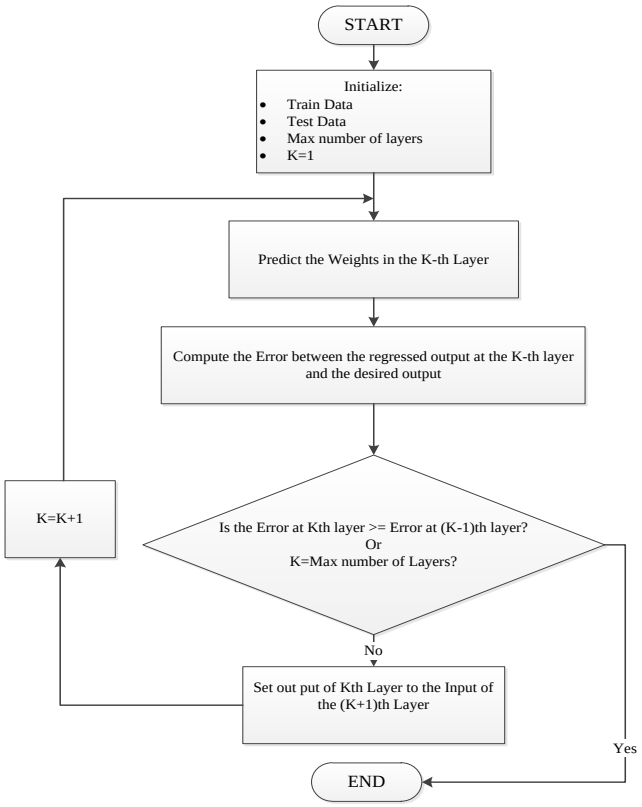

Figure 3: Program Flow Layout for GMDH.

5. Results

The performance of the two networks for solving a multi-dimensional real valued data classification is tested on an E-coli data set. The GMDH network was attempted for different best outputs (based on top best MAE values). The estimated output of the GMDH network fits with the given datasets. The performance of the network is evaluated based on the MAE for the testing date. How the network behaves for the data it has seen during the training phase is also considered. Training of the network is stopped when the MAE curve starts to increase or stops decreasing (see Figure 4). Accordingly, four layers are found to be sufficient for classifying the data. The values for the weights at each of the four layers are given in the tables in the appendix section (see Tables 1 to 4). The values for the eight cluster centers are shown in Table 5. The elbow curve (Figure 4) displays the MAE versus the number of layers for both the training and testing data. Figures 5 and 6 show a comparison of the response of the network with the desired output for the training and testing data respectively. The final architecture of the GMDH network is shown in Figure 7. Each neuron is

constrained to two inputs and one output. The a_{ij} vectors are the weights for the i^{th} and j^{th} input combinations. The input combinations are ordered by the MAE (for instance combination of inputs 1 and 3 gives the least MAE at layer 1).

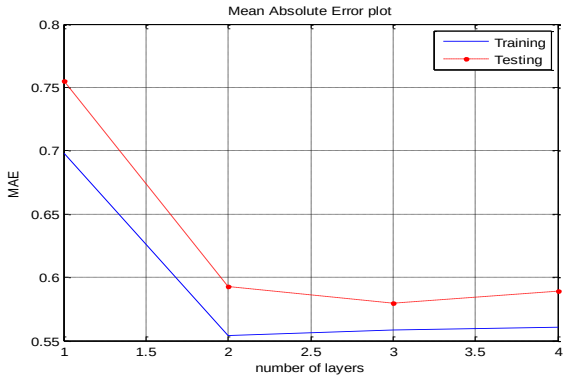

Figure 4: Mean Absolute Error (MAE) plot for the training and testing data using 6 layers.

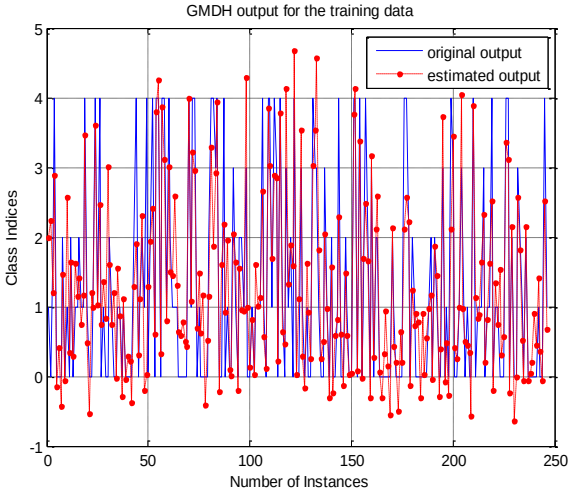

Figure 5: Actual values of the training dataset and corresponding GMDH-estimated output.

The KLT reduced the dimension of the original data from 7 to 4. It is found out that four of the Eigen values constitute more than 95% of the information in the data. Thus, the true dimension of the E. coli dataset is four. After applying the DIANA like clustering algorithm, eight cluster centers have prevailed and the data is organized around those centers based on its distance closeness. Finally, multi dimensional RBFGRNN is applied on the transformed data. The network response for the training and testing data is shown in Figures 8 and 9. The dataset has 5 classes indexed using integer numbers from 0 to 4. As can be seen from the performance curves (Figures 5, 6, 8 and 9), the output of both networks pretty much resembles the desired class indices.

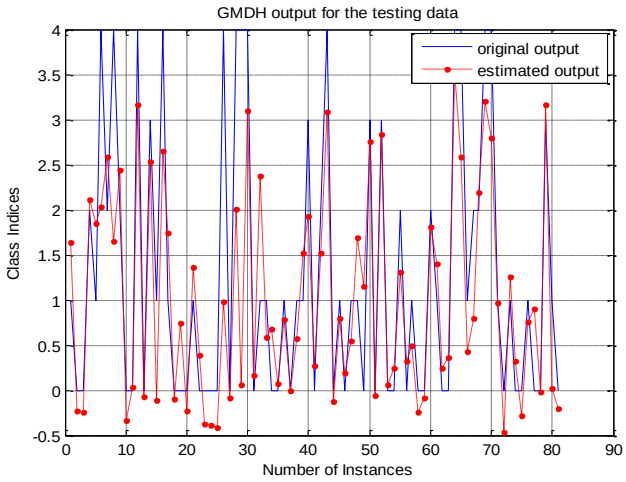

Figure 6: GMDH-estimated output versus actual values for the testing dataset.

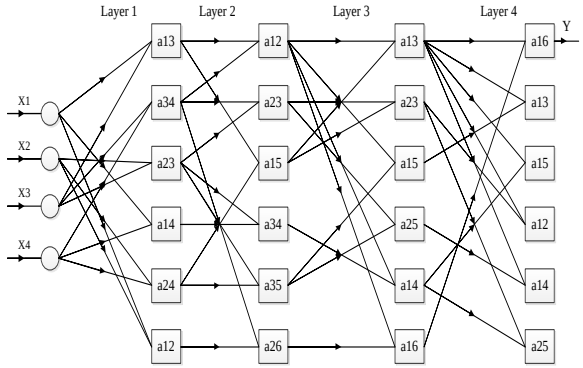

Figure 7: The architecture of the final GMDH Network after the training

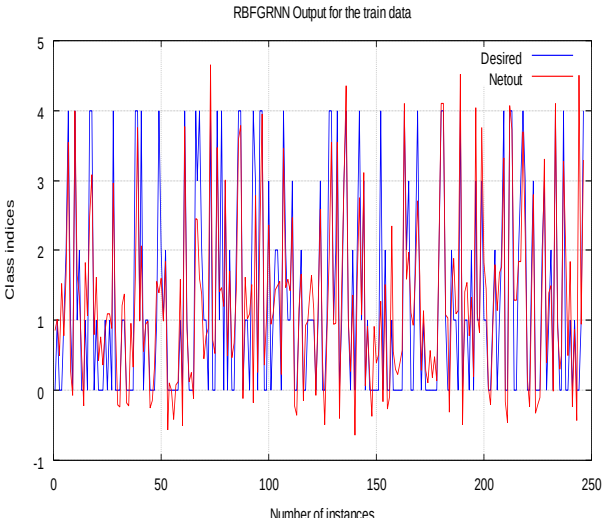

Figure 8: RBFGRNN-estimated output versus actual values for the training dataset.

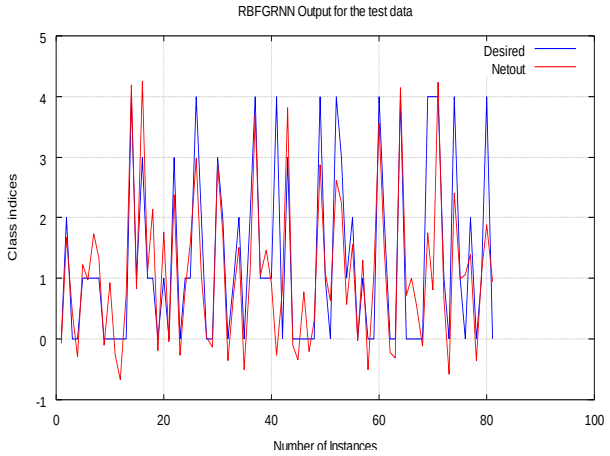

Figure 9: Output of the RBFGRNN for the test data.

As can be seen from Figure 9, the network output for the test data fairly follows the desired output. The discrepancies at some points are due to scarce training events for generalization and inadequate validation data.

6. Conclusion

This work has shown the feasibility of GMDH and RBFGRNN neural networks for classifying a multi-attribute real valued data set. The Karhunen-Loeve Transformation technique was used to avoid redundant data set in the input columns. Accordingly, the true dimension of the data was found out to be four. Considering the fitting of GMDH estimated values to given values in the database, as well as the best values of the errors as shown in the training and testing error curves, the GMDH network with six best outputs passing to the succeeding layer produced the best result. Also, it is observed that RBFGRNN is very efficient in solving a multi-dimensional classification problem as it does in approximating smooth functions. A DIANA like hierarchical clustering algorithm is used to cluster the data. The simulation results obtained proved that the regressed output of the network pretty much resembles the actual desired values. So, given enough data and an appropriately sized GDU layer, RBFGRNN and GMDH networks are very effective for classifying a multi-class data at a high precision.

Abstract:-

Predicting stock price is always a challenging task. In this paper we are trying to predict the next day's highest price for eight different companies individually. For this we are using different feature sets to predict the price. It is observed that the Volume+Company and Nasdaq+S & P 500 +Company sets performed better than any other feature sets used. Also these features were very helpful for predicting stock price using sequential minimal optimization (SMO) and bagging approach. Comparing different methods, the best results were obtained using SMO and bagging.

Keywords:

Machine learning,stock market, sequential minimal optimization, bagging,

I. Introduction

For many years considerable research was devoted to stock market prediction. During the last decade we have relied on various types of intelligent systems to predict stock prices to make trading decisions. Thus numerous models have been depicted to provide the investors with more precise predictions. It has been observed that the stock price of any company does not necessarily depend on the economic situation of the country. It is no more directly linked with the economic development of the country or particular area. Thus the stock price prediction has become even more difficult than before.

These days stock prices are affected by many factors like company related news, political events, natural disasters … etc. The fast data processing of these events with the help of improved technology and communication systems has caused the stock prices to fluctuate very fast. Thus many banks, financial institutions, large-scale investors and stockbrokers have to buy and sell stocks within the shortest possible time. Thus a time span of even a few hours between buying and selling is not unusual.

Kyoung-jae [11] used support vector machines for prediction of stock price index as a time series problem. In this the effect of the value of the upper bound C and the kernel parameter δ^2 in SVM was investigated. It was observed that SVM actually performs better than back propagation and case based reasoning. This is due to the fact that SVM implements the structural risk minimization principle, which leads to better generalization than conventional techniques. Ping-Feng Pai and Chih-Sheng Lin developed a hybrid model, which is a combination of SVM and autoregressive moving average (ARIMA). This actually exploits the individual strengths of both models. Both ARIMA and SVM capture the data characteristics of linear and non-linear domains respectively. This hybrid model performs better when compared with these individual models alone.

Frank Cross [16] tries to find the relationship that could exist between stock price changes on Mondays and Fridays in the stock market. It has been observed that prices on Friday have risen more often than any other day. It has also been observed that on Monday the prices have least often risen compared to other days. Boris Podobnik [17] tries to find cross-correlation between volume change and price change. For the stock prices to changes it takes volume to move the stock price. They found two major empirical results. One is the power law cross-correlation between logarithmic price change and logarithmic volume change and the other is that the logarithmic volume change follows the same cubic law as logarithmic price change.

Many machine-learning techniques are used for predicting different target values [5,6,10]. This could be even to predict stock price. The genetic algorithm has been used for prediction and extraction important features [1,4]. Lot of analysis has been done on what are the factors that affect stock prices and financial market [2,3,8,9]. There are different ways by which stock prices can be predicted. One way is to reduce the complexity by extracting best features or by feature selection [7,13,14]. This approach will help us predict stock prices with better accuracy as the complexity reduces.

The people who invest money in the stock market usually focus only on a particular sector. For example people who want to invest money in Microsoft would not be interested in investing in a chemical industry as they cannot usually have knowledge about two different sectors. Only beginners would be interested in doing something weird like that. Thus the objective of this project is finding the relation between different companies of the same sector so that we can predict stock prices using different machine learning techniques.

II. Feature extraction based prediction

In this project we are trying to predict the highest price of the stocks of a particular company on everyday basis. There are a total of eight companies used for this experiment. These are Adobe, Apple, Google, IBM, Microsoft, Oracle, Sony and Symantec. For each company six different attributes are used. The highest stock prices for next day of these companies will be predicted using different machine learning techniques. For predicting the stock price of each company we are using eight different feature extraction techniques. These eight feature extraction techniques are explained below:-

1) Top 3 companies:-

In this type of feature extraction we are predicting the stock price of each company by finding a relation between different companies. This inter-relation between these companies will be used to predict the stock prices of a particular company in a better way. Each company's data will be individually used to predict each other company's stock price. The top three companies, which can predict a particular company with higher accuracy, will be used together to predict the stock price of a particular company. Along with the top three companies the NASDAQ index and the S&P 500 index would be used in each case.

2) Previous 3 days:-

In this the data of the previous three days for the company whose highest price we are trying to predict is used.

3) Previous 5 days:-

Similarly in this the data of the previous five days for the company whose highest price we are predicting is used.

4) Top 7 attributes:-

In this the top 7 attributes are evaluated using the ReliefFAttributeEval feature selection method. ReliefF algorithm is an extension of Relief. It is not limited to two class problems and is more robust to deal with incomplete and noisy data. The idea of ReliefF is to evaluate partitioning power of attributes according to how well their values distinguish between similar instances. An attribute is given a high score if its values separate similar observations with different class and do not separate similar instances with the same class values. For this the data of all eight companies and NASDAQ index and the S & P 500 index were used.

5) Top 10 attributes:-

In this similarly the top 10 attributes are evaluated using the ReliefFAttributeEval feature selection method. For this also the data of all eight companies and Nasdaq and S & P 500 were used.

6) Volume + Company:-

In this the volume attribute of stock purchased for each of the companies and both stock indexes i.e. NASDAQ index and the S & P 500 indexes are used. Along with this, the data of the company whose highest stock price for next day we are predicting is used for prediction.

7) Nasdaq + S & P + Company :-

In this as the name suggests, we use the NASDAQ index, the S & P 500 index and the data of the company whose highest price we are trying to predict.

8) Company alone:-

In this only the data of the company whose highest price we are predicting is used. So total attributes used in this case are six. These are the opening price, closing price, highest price, lowest price, volume and adjusted closing price.

The different machine learning techniques used for the experiments are briefly explained below:-

1) Neural Network:-

It is inspired from biological neural networks. It consists of interconnected neurons, which process information using a connectionist approach. The network adapts itself according to the information flowing into the network and tries to predict the required data.

2) Sequential Minimal optimization (SMO):-

The sequential minimal optimization solves the QP problem without any extra matrix storages and without using numerical QP optimization steps at all. The SMO decomposes the overall QP problem into QP sub-problems. It is a linear classifier that tries to find the maximum margin i.e. the distance between the classifier and the nearest data points [10,11,12].

3) Bagging using sequential minimal optimization:-

Bagging is a popular re-sampling ensemble method that generates and combines a diversity of classifiers using the same learning algorithm for the base-classifier. The learning algorithm used in this case is sequential minimal optimization. In this a standard training dataset is used which generates new training datasets using sampling. Thus we can learn different models based on the new training datasets generated. These models are combined by averaging the output or by voting to

predict the desired output. In each model the learning algorithm used is sequential minimal optimization.

4) M5P:-

For M5P, a decision-tree induction algorithm is used to build a model tree. To build this tree model divide and conquer approach is used. Secondly, the tree is pruned back from each leaf. To avoid discontinuities between the sub-trees in the model it is smoothened by combining the leaf model prediction with each node along the path back to the root, smoothing it at each of these nodes by combining it with the value predicted by the linear model for that node.

III. Experimental Setup:-

The dataset used for this experiment consists of the stock data for the last five years. Six attributes for each company are used for prediction. These are the Opening price, closing price, highest price, lowest price, volume and adjusted closing price. The values of the NASDAQ and S&P 500 indexes for the last five years are also used. These indexes also have the same six attributes. So there are a total of sixty attributes used for the experiments.

The whole data is divided into three equal sized datasets. These three datasets are sequential. So we train using the first dataset and then use the second dataset for testing. Similarly we train using the second dataset and test using the third dataset.

IV. Results:-

The prices of the stocks were predicted using mainly the four machine-learning techniques mentioned above. The results obtained by these methods are analyzed as given below:-

1) Predicting stock prices using neural network:-

When the neural network is used to predict the highest price for each company, it is observed that the feature extraction from the Company alone performed the best compared with the other feature extraction methods. The results obtained for the different datasets is given in Figures 1 and 2.

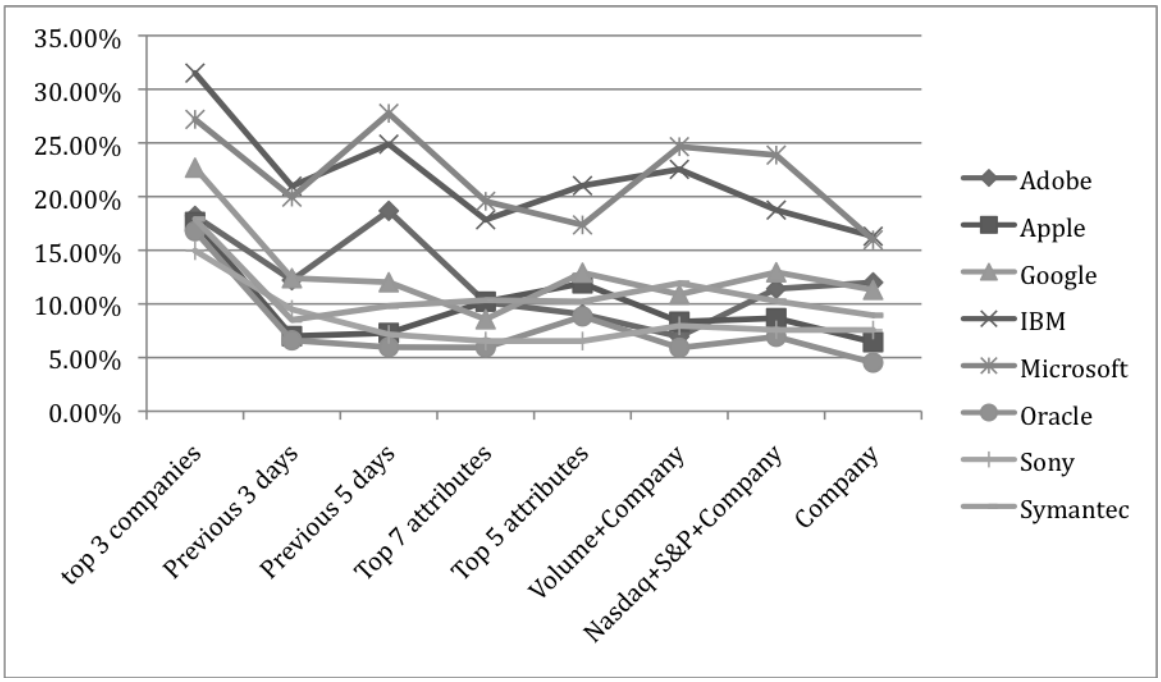

Fig 1:- This figure shows relative absolute error for predicting the highest price for eight companies using neural network. The second dataset is used as testing set in this case

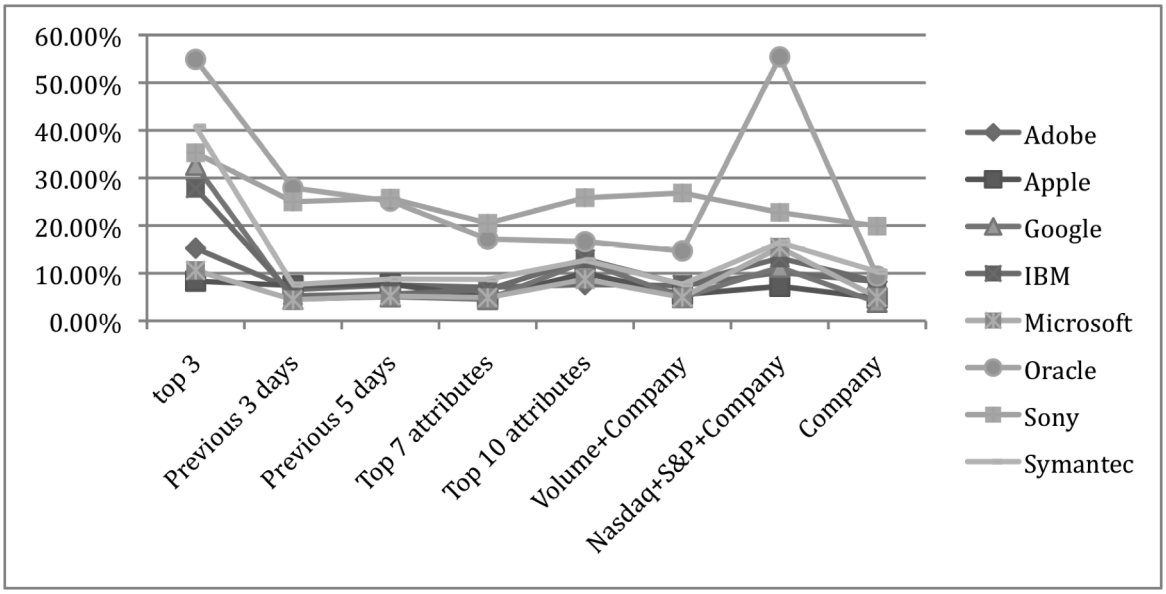

Fig 2:- This figure shows relative absolute error for predicting the highest price for eight companies using neural network. The third dataset is used as testing set in this case.

2) **Predicting stock prices using sequential minimal optimization (SMO):-**

When sequential minimal optimization is used to predict the highest price for each company, it is observed that the feature extraction methods Company + Volume and Company + NASDAQ +S & P has performed the best when compared with other feature extraction method. In this case these extraction techniques performed better than Company alone which was not the case for neural network. The other two are previous 3 days and previous 5 days. The results obtained for the different datasets are given in Figures 3 and 4.

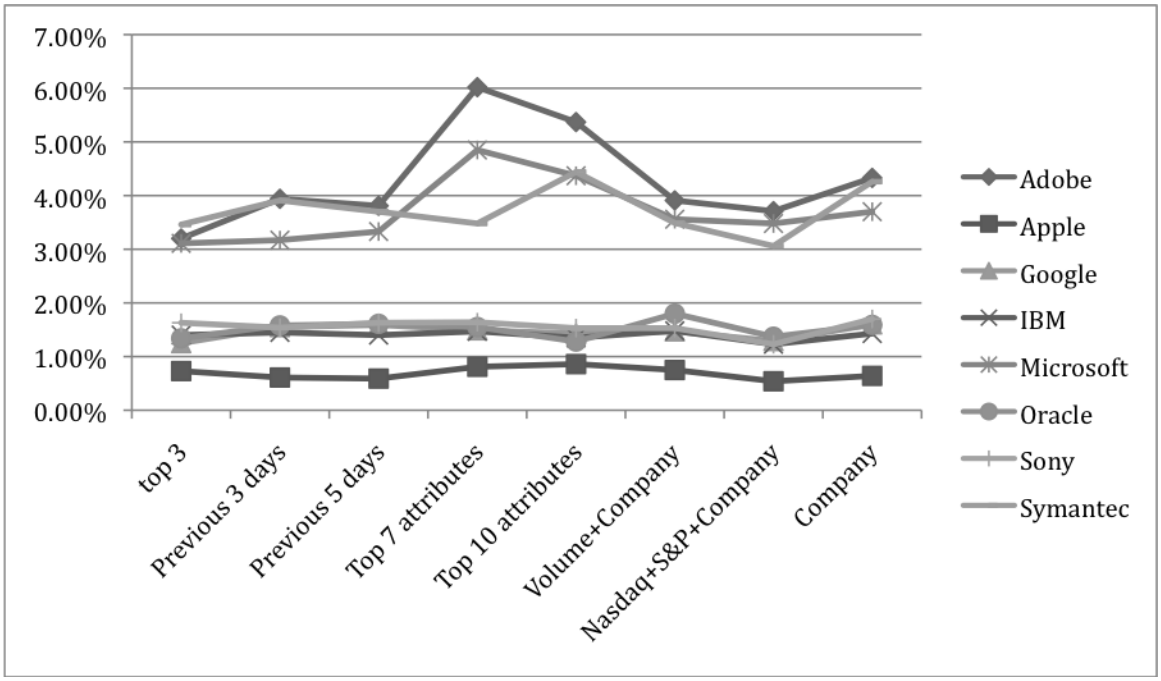

Fig 3:- This figure shows relative absolute error for predicting highest price for eight companies using sequential minimal optimization. The second dataset is used as testing set in this case.

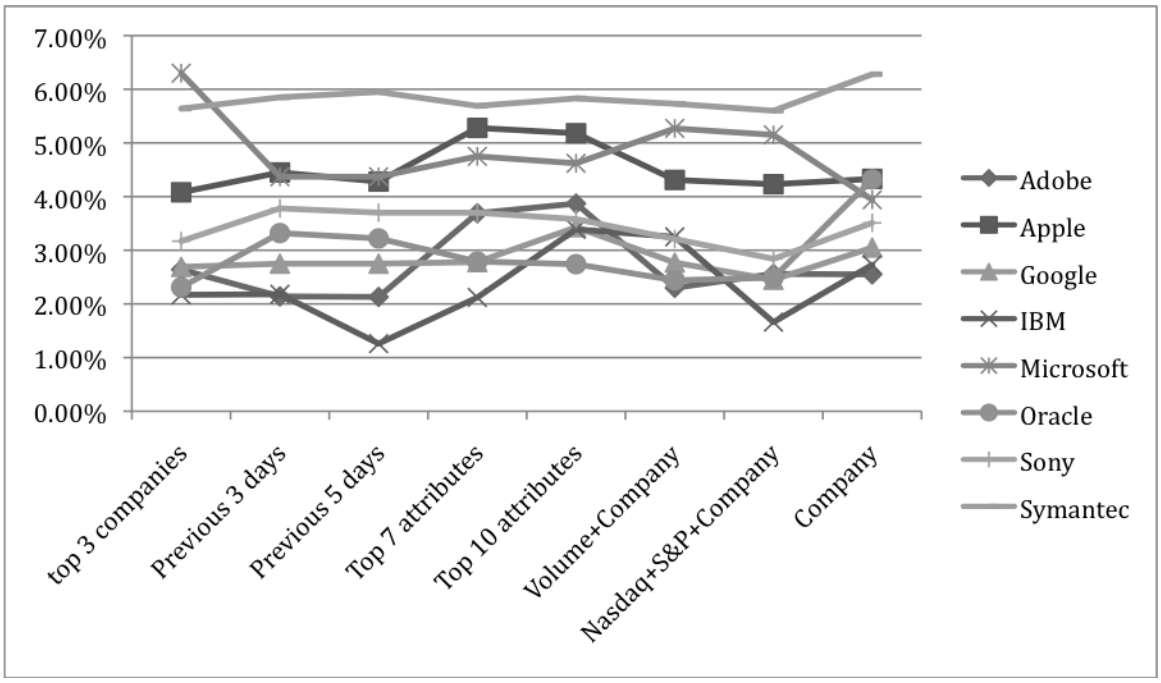

Fig 4:- This figure shows relative absolute error for predicting highest price for eight companies using sequential minimal optimization. The third dataset is used as testing set in this case.

3) Predicting stock prices using bagging:-

When bagging is used to predict the highest price for each company, it is observed that the feature extraction methods Company + Volume and Company + Nasdaq +S & P performed the best when compared with other feature extraction methods. Similar results were observed when we tried to predict the stock market using sequential minimal optimization. The results obtained for different datasets are given in Figures 5 and 6. The SMO algorithm was used internally to predict the stock price of each company.

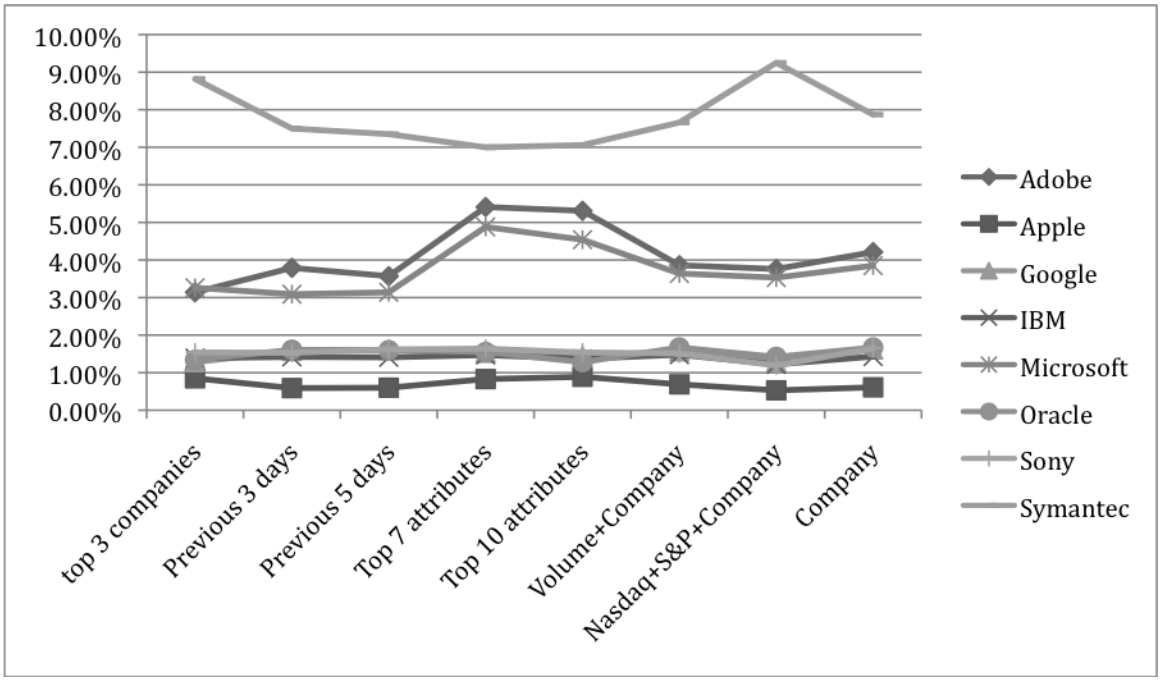

Fig 5:- This figure shows relative absolute error for predicting highest price for eight companies using bagging approach. The second dataset is used as testing set in this case.

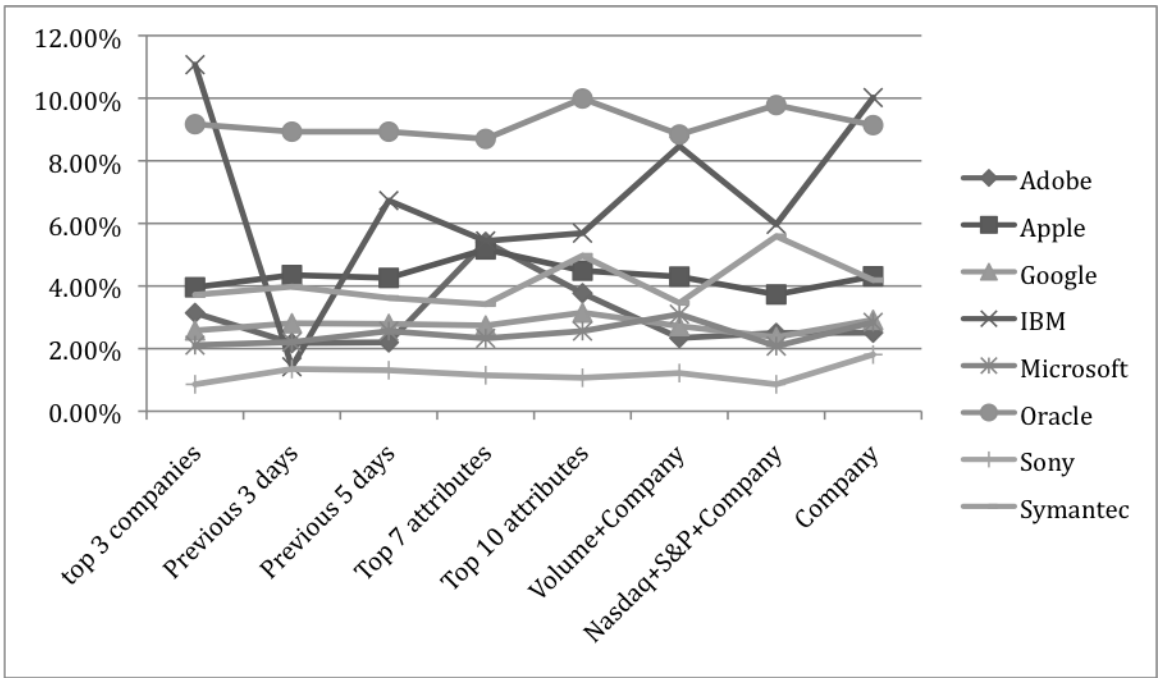

Fig 6:- This figure shows relative absolute error for predicting highest price for eight companies using bagging approach. The third dataset is used as testing set in this case.

4) **Predicting stock prices using M5P:-**

When M5P is used to predict the highest price for each company, it is observed that the feature extraction methods "Company + Volume" and "Previous 3 days" performed the best when compared with other feature extraction methods. The third best feature extraction method is Company alone. The results obtained for the different datasets are given in Figures 7 and 8.

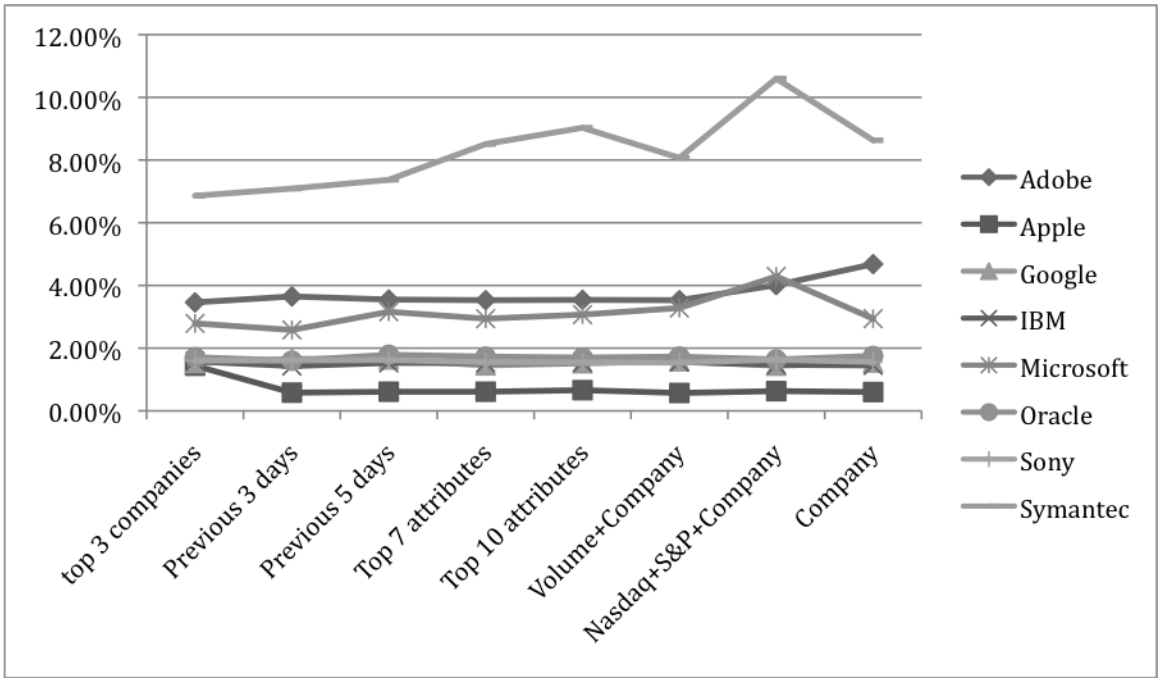

Fig 7:- This figure shows relative absolute error for predicting highest price for eight companies using M5P. The second dataset is used as testing set in this case.

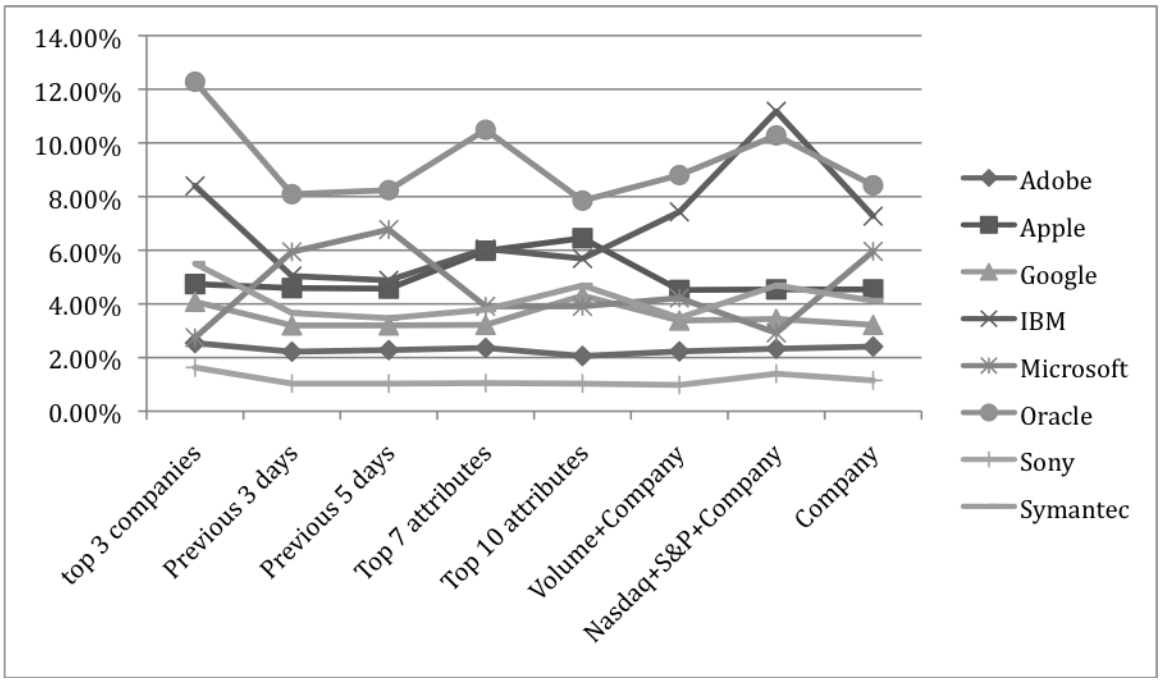

Fig 8:- This figure shows relative absolute error for predicting highest price for eight companies using M5P. The third dataset is used as testing set in this case.

V. Conclusion:-

It can be observed from Figures 1 through 8 that the best machine learning techniques for predicting the stock price are sequential minimal optimization and bagging using SMO. Using these methods the best features extracted to predict stock prices are "Volume + Company" and "Nasdaq + S & P +Company". Thus when the volume attributes of all eight companies are used along with individual data of the company whose price we are trying to predict will represent "Volume +Company". Similarly the whole data for Nasdaq, S & P 500 and individual companies data will represent "Nasdaq + S & P +Company".

Generally neural networks perform well but in this case the performance is not satisfactory. Also the results obtained using neural networks do not match the trends of the remaining learning techniques. Hence proper tuning of the different parameters is required so that neural networks may perform well like the other three learning algorithms.

ABSTRACT

The Course Generation System (CGS) is a system that generates a course accommodate to the teaching material, student status and learning goal. In this paper we present a framework for authoring/course generation system using ontology and an HTN planning technique called PANDA.TUTOR. This system allows the author to prepare the course structure and content, enriched with classification information without need to define the adaptation rules or specify configurations for each student, aiming to keep all the authoring process low in terms of time and effort. The course generation system, which is basically an HTN planning system, introduces a personality based planning approach, in which the course structure and the course content are generated and adapted according to students' personality and state. The system enriches with different learning scenarios, teaching strategies and learning styles. The student's personality type taken as a guide to select an appropriate scenario, teaching strategy, and learning style in order to regulate the current emotional and motivational state of student.

1. INTRODUCTION

Intelligent Tutoring System (ITS) is computer based learning which assists students in their learning process. Thus, it has the ability to be adaptable according to the needs of students. During the learning process, it is important to individualize the given course and teach students according to their personality types, cognitive capabilities and current emotional and motivational states, to achieve the learning goal efficiently. Thus, students with various personality types differ in their behavior. The process of arranging personalized adaptations is usually complex. Consequently, the current platforms usually do not provide more than a relatively simple way of personalization and adaptation. Although most of course generation systems generate a suitable course according to the student's cognitive ability, and gives some consideration to the motivation and emotion. The student's personality type, emotional appraisal and coping ways and different regulation strategies for each personality type have not been considered so far.

Course generation has long been a research field which is also known as curriculum sequencing. Two main approaches are defined in course generation field [1]: the adaptive course generation and the dynamic course generation. In the first approach, the course is generated before it delivers to the student. Indeed, it could help the student to realize the complete view about the requested concept and provides free navigation ability through the presented part. In the second approach, the student progress is observed during the interaction with the presented course, then, the presented part is adapted according to the student goals and progress. Although, this approach is appropriate with the changeable state of student, it may cause confusion for the student when s/he moves from one part to another and may not get the complete idea. Thus, our system follows the first approach.

In this paper we will introduce our system PANDA.TUTOR, a new approach of course generation in ITS, that generates a personalized course as a structured representation of the subject based on Task-Centered Instruction Strategy. The objective of our system is to build a general Authoring/Course Generation system. Thus, the course content consists of a textual description, examples, exercise and the like is prepared by the author and enriched with classification information. The course generation system is an HTN planning system. It generates the course by tailoring the learning content to an individual learner, considering the student's goal, the current emotional and motivational state of the student. Therefore, PANDA.TUTOR includes different learning strategies, learning styles and regulation strategies which help the planner to construct high individualized courses, and help students to build up their knowledge. In addition, it has the ability to adjust or maintain the student emotion.

The authoring part in our approach is defined over the course module and the course generation part is defined over the pedagogical module. Moreover, the aim of authoring phase is to

International **C**onference on **A**rtificial **I**ntelligence (ICAI-2012).

keep all the authoring process low in terms of time and effort. So, we will introduce an ontology that describes the course content module of our system. Thus, developing of the course ontology is a step toward creation shared and reusable adaptive educational systems. Also, the ontology permits the retrieval of learning materials after the pedagogical module generates the course. The proposed ontology model is a general educational ontology based on knowledge objects and the Instruction Design theory, which are introduced by Merrill [2]. Furthermore, we have considered a separation between the course Content reusability and the learning objects reusability. The authorized course afterwards is considered during the pedagogical module to construct a personalized lesson for the student.
Before introducing our proposed architecture in section 3, we will define the course generation, the relation between them and personality and learning styles in Section 2. In section 4, we will demonstrate the course ontology in our approach. Section 5 demonstrates how the HTN planning paradigm can be used to generate the personalized course. The paper ends with some concluding remarks in section 6.

2. ONTOLOGY AND E-LEARNING

The use of ontologies is a way of describing the semantics of information on the Web. Ontology provides a set of terms which should be shared among the authors, and hence could be used as well-structured shared vocabulary. Ontology is a research domain helping us to overcome the most common problems in intelligent tutoring systems[3, 4]. It enables the ontology designer and the author to share a common course structure, and the educational materials to be reused. Besides, It allows us to specify formally and explicitly the concepts that appear in a concrete domain, their property and their relationships. Aroyo et al. [5] describe how an assistant layer uses an ontology to support the complete authoring. For the course structure, Henze et al.[6] propose an approach that describes the features of the domain ontology and the learner ontology, as well as observations about the learner's interactions. Urllich[7] used the ontology to assemble the learning resources to generate a curriculum , taken into account the knowledge state of the student, the preferences an learning goals. On the other hand, there are standard meta-data, which are used to describe index, and search teaching materials; for instance,IEEE LOM, SCORM and IMS. However, these standards do not include any domain ontologies which can be specified, building on formalisms. In addition, Possible types of learning resources in LOM (Diagram, Figure, Table, Exercise, Text, Exam), mix instructional forms and resource type. On the other hand, many non-SCORM systems such as DCG [8], [9] support the pedagogical approaches but they lack the interoperability and flexibility, and they are do not support the reusability of educational materials. The contribution of our model is to build a general cognitive and constructive conceptual construction of the ontology that can be used in different types of courses. We consider a new approach to construct our ontology based on Instruction design theory of Merrill[2] as we will explain in the next sections.

3. LEARNING STYLES

learning styles are defined as "the term learning styles is used to describe the attitudes and behavior that determine an individual's preferred way of learning" [10]. Honey and Mumford itemize four learning styles as follows:

- **Active learning styles:** they prefer activity-oriented learning materials with high interactivity level, and become bored with repetition.
- **Reflective:** they like to deliberate on their experiences and study the situation from different perspectives, as well as collecting and analyzing the data before taking action. Those students prefer example-oriented learning material.
- **Theorists:** They strain to formulate their experiences in theoretical or logical form, and motive trying on ideas, theories, and experiments. they prefer exercise-oriented learning material.
- **Pragmatists:** they are eager to try out new materials, but concentrate on the concept that can help them to achieve their task, and prefer to explore and discover concepts by more abstract level. The theory-oriented learning materials are convenient for this type.

3.1. Personality and Learning Styles

The term Personality is defined as a permanent pattern of characteristics that discriminates between people in their felling thought and behavior. In PANDA.TUTOR we considered the personality types of Vollrath [11]. He defines eight types of personality based on three types Extroversion(E), Neuroticism(N), and Conscientiousness(C). The Neuroticism and Extroversion are related to stress, while conscientiousness is related to the ability of coping. These types as follows; **Spectator***(low E, low N, low C)*, **Insecure** *(low E, high N, low C)*, **Sceptic** *(low E, low N, high C)*, **Brooder** *(low E, high N, high C)*, **Hedonist***(high E, low N, low C)*, **Impulsive***(high E, high N, low C)*, **Entrepreneur***(high E, low N, high C)*, **Complicated** *(high E, high N, high C)*.
There is no single learning style that is best for all students. Many studies attempt to investigate the relation between the personality type and learning styles. Furnham [12]links between the big five factor of personality (OCEAN) and learning styles. He investigates that the Extroverts are fairly conversant with Activists and pragmatists learning style, while the introverts are reflectors. The Neuroticism is more probably theorists and reflector, and Conscientiousness interacted

positively with Activists style and negatively with theorist learning style.

4. SYSTEM ARCHITECTURE

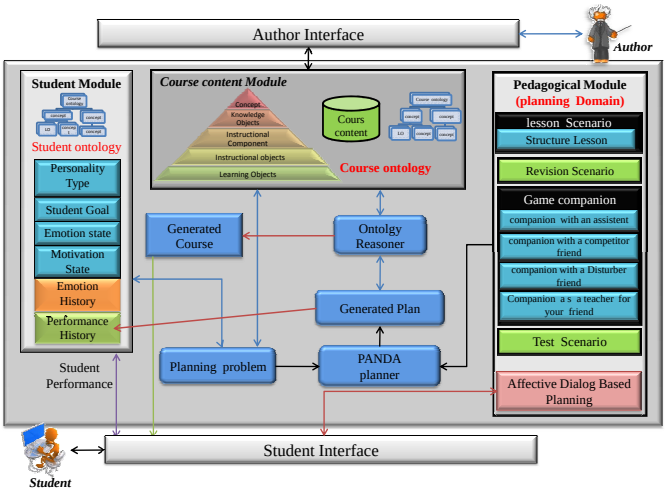

Fig. 1. The system Architecture

As depicted graphically in Figure 1, our architecture consists of three main modules: course module, student module, and pedagogical module. An authoring phase is defined over the course module and course generation phase is defined over the pedagogical module. So we have developed general educational ontologies for the student module and course module that can be used for different domains. Ontologies help us to share, reuse and reason about information. During the pedagogical module two main process are defined; the dialog process and the course generation process based on planning technique that generates the course, regarding the course module and student module.

The generated plan will be a set of querying statements that query the course ontology to retrieve the learning objects to generate the course for students.

PANDA.TUTOR includes four types of scenarios; Lesson scenario, revision scenario, companion games scenario and test scenario. The term scenario means a discrete sequence of steps inside the learning process. In these scenarios the emotional and motivational state are considered for generating the course for the concept goal.

5. COURSE ONTOLOGY IN PANDA.TUTOR

Merrill[2] defines a set of knowledge objects to describe the subject matter content or knowledge to be taught. These knowledge objects are considered as a framework to organize the knowledge base of content resources. The components of Knowledge objects are not specific to a particular subject matter domain, the same knowledge object components can be used for representing a variety of domains *(e.g. mathematics, science, humanities, technical skills, etc.)*. He describes the contents in a way that they could be manipulated in a computer system to automatically create instruction from the content. Thus, he defines five types of knowledge objects *information_about, parts_of, kinds_of(subconcept(s)), how_to (Process), and what_happens(condition or principle)*.

For each knowledge object, two levels of information are defined; *information_Level (generality)* and *a portrayal_Level*. By considering these Information levels, four instructional strategies are defined; *(Presentation (TELL)and Demonstration (SHOW))* for *Information_Level*, and *Activation (RECALL) and Application(DO))* for portrayal level.

The course space in our approach has two main sub-spaces; the course structure as the course domain space and the course content as the media space. The domain space consists of the most important concepts of course domain with different cognitive levels and relationships between them. In our work we considered the concept map approach for developing our course ontology. Concept mapping is a technique for representing concepts and their hierarchical interrelationship as a graph, which nodes represent concepts and arcs represent relationships among them [13]. While, the media space is a semantic network that is named the resource network, which is used to represent learning objects of course content. Learning objects is a unit of content of digital resources that can be shared and reused to support teaching and learning process[14].

The proposed domain is a framework for instructional design of knowledge objects from the viewpoint of ontology and semantic web. The domain ontology has been developed under OWL language. We have developed general educational ontology that can be used for different courses. This ontology is considered during the course generation to generate an adapted and personalized course. The protege 4.1 framework has been selected to edit and construct the contents.

Consequently, in our ontology six main classes are defined as a hierarchical fashion, The course space, the course concepts, the knowledge objects, the instructional strategy components, instructional objects and learning objects. Indeed, for each course, a set of concepts should be defined. For each concept different types of knowledge objects could be defined, for each knowledge object (KO) different instruction components (IC) can be defined, different instruction objects can be specified for each instruction component according to the course and the preferences of the author. Finally for each instruction object different media or learning object can be determined. In our ontology we will consider different kinds of relations; relations among Concepts, relations between the concept and its knowledge objects, relation between knowledge objects and its instructional components, relations between Instructional component and instructional objects and relations between instructional component and its teaching material types.

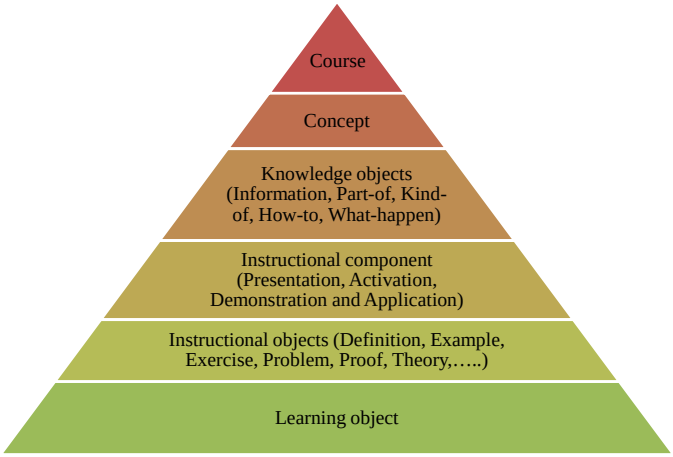

Fig. 2. Layers of course structure

These layers as depicted in figure 2 are as follows:

- **The Course layer**
  $Course \equiv Concept_1 \sqcup Concept_2 \sqcup \cdots \sqcup Concept_n$. Course class represents any course of the learning environment. It is defined as the main class which represents the subjects being taught in an educational application. The class course consists of a set of concepts that define the course. For example, the planning system or Artificial Intelligence could be individuals of this class. The course class contain several properties that describe the names and a brief description of the course: CourseName , CourseDescription and the objective. Also, different object properties (relations) are defined. , for instance HasObjective whereas hasConcept (isConceptIn is its inverse) and hasResource relations.

- **The concepts layer**
  $Concept \subseteq Course$, and $Concept \subseteq \exists has\ KO.KO$. The course in our ontology considers the concept as a main building block. Course concepts refer to basic concepts concerning the course. The concept holds one unit of knowledge and explains different aspects of it with different types of teaching material. Thus, the concept can represent as a bigger or smaller course structure part, The ontology for this model preserves the relationship between concepts as in the concept map. Thus, the author can specify various relations between concepts. In addition, the concept structure is built to represent the domain ontology that provides the structure of the course . There are different relations among concepts are considered; for instance (*has_Prerequisite, is_Prerequiste_of*), *Related_to* or *SimilarTo, OppositeOf*.

- **Knowledge objects layer**
  $KO \equiv \{Information\_About, Part\_of, Kind\_of, How\_to, What\_happen\}$, and $KO \subseteq \exists has\ IC.IC$. For each KO we should define a set of IS such that IS $\in$ (Presentation (Tell), Demonstration (Show), Activation (Recall) or Application (Do)). We represented the Knowledge_objects class as an abstract class of the Information_about, Parts_of, Kind_of, How_to and What_happen subclasses. Thus, there are relations between the concept and its Knowledge objects; *has_Information_about, is_Information_about_for*, *has_Part, is_Part_of*, *has_kind, is_kind_of*, *has_How_to, is_How_to_of*, and *has_What_happen, is_what_happen_of*.

- **Instructional component strategies layer**
  $IC \equiv \{Presentation(Tell), Demonstration(Show), Activation(Recall) or Application(Do)\}$, and $IC \subseteq \exists has\ IO.IO$. With each knowledge object four instructional components can be defined; Presentation (Tell), Demonstration (Show), Activation (Recall) or Application (Do). The relations between the knowledge objects and Instructional Components are as follows; *has_Activation, is_Activation_for*, *has_Application, is_Application_for*, *has_Demonstration, is_Demonstration_for* and *has_Presentation, is_Presentation_for*.

- **Instruction objects layer**:
  $IO \equiv \{Definition, Example, Exercise, Theory\}$, and $IO \subseteq \exists has\ LO.LO$. For each IS we should define a set of instructional objects (IO). Different IO can be assigned (by the author) for each type of instructional components. For instance, Definition, Example, Exercise, Cased_Study, Assignment, Test, Experimental, List, Condition, Action, Theory, Fact, Principle, Proof, Analysis, Description, History, Menimonic, etc. For example the author can assign Definition, or Theory or both for the Presentation component, and Problem, Case Study or Exercise for Application part.

- **Learning objects layer**
  LO=(LO_i, LO is teaching materials with different media type) where media type $\in$ (text, audio, video, ..., etc). For each type of instructional object, different forms of learning object can be assigned. The type of learning object as media type is defined the presentation format. For example text, video or audio can be assigned for the definition of the concept.

Note that, in our educational system we considered different cognitive_levels for the course parts, the quantity_level and Quality_Level. The quantity_Level is defined by the author for the course part, while quality_Level is determine according to the student achievement level. Also, Different types and levels of Example and Exercise.

6. AUTHORING PART

Authoring of adaptive Content is one of the most important activities of the course-based adaptive tutoring system. Our

goal is to help the (a non-programmer) author to build highly reusable software components that can be employed in a large number of scenarios. Thus, we introduce an ITS authoring system aim to help the teachers to configure different authorable courses with minimum effort. It is for the teacher to author, construct or modify different parts of the course and incorporate new learning materials without need for an intervention from the system developers. The authoring model allows the author to include different contents in the same concept. Moreover, there is no need to create or modify the teaching method or strategies for each student. The planning system plays the role of the teacher in our architecture. This is opposite to other systems in which the author use the authoring tool to define the Domain Model, Student Model, and rules for the Teaching Model. The author with the course module has two major missions. The first, define the course structure; it is the knowledge base of the course. The second, defines the Repository by storing all the learning and test materials. So, the following algorithm summarizes the authoring process.

Algorithm 1: Authoring Algorithm

```
Step 1 : Define the course objectives of the course.;
Step 2 : According to the course learning objectives, add
  concepts accordingly, and finally get: course
  = {Concept i | i = 1, 2, ··· m};
Step 3 : define different relations between concepts;
Step 4 : Define the data property Concept of the concept;
Step 5 : For each knowledge object of concept i =
  {Knowledge_object j | j = 1, 2, ··· }
such that Knowledge object= (information_about, Part_of,
  kind_of, how_to, what_happen);
if the concept not further has KO then
    Go to step 3 to define the next concept.;
else
    Define the different instruction strategies(IS) for its KO.
    IS= Presentation, Demonstration, Activation, and
    Application;
foreach IS do
    Define a set of IO. IO= Definition, Example, Exercise, ..;
foreach IO do
    Connect it with its learning object;
```

7. HTN PLANNING FORMAL FRAMEWORK

Our AI planner relies on a domain-independent hybrid planning framework [15]. Hybrid planning [16, 17] integrates hierarchical task network planning [18] with concepts of partial-order-causal-link (POCL) planning. The resulting systems integrate task decomposition with explicit causal reasoning. Therefore, they are able to use predefined standard solutions like in pure HTN planning. In our framework, a partial plan $P = \langle TE, \prec, VC, CL\rangle$ consists of a set of plan steps TE, i.e. (partially) instantiated task schemata, a set of ordering constraints $\prec$ that impose a partial order on the TE, and a set of variable constraints VC. CL is a set of causal links. A causal link $\langle te_i, \varphi, te_j\rangle$ specifies that the precondition φ of plan step te_j is an effect of plan step te_i and is *supported* this way. A domain model $D = \langle T, M\rangle$ consists of a set of tasks as well as a set of decomposition methods. A task $t(\overline{\tau}) = \langle prec(t(\overline{\tau})), add(t(\overline{\tau})), del(t(\overline{\tau}))\rangle$ specifies the preconditions as well as the positive and negative effects of a task. Preconditions and effects are sets of literals and $\overline{\tau} = \tau_1, \cdots \tau_n$ are the task parameters. Both primitive and abstract tasks show preconditions and effects.

A method $m = \langle t, P\rangle$ maps an abstract task t to a partial plan P, which represents an (abstract) solution or "implementation" of the task. In general, each abstract task has implemented by a number of different methods. As opposed to typical HTN-style planning, no application conditions are associated with the methods. A planning problem $\Pi = \langle D, S_{init}, P_{init}\rangle$ consists of a domain model D, an initial state S_{init}. P_{init} represents an initial partial plan.

Refinement steps include the decomposition of abstract tasks by appropriate methods, the insertion of causal links to support open preconditions of plan steps and the insertion of plan steps, ordering constraints, and variable constraints.

8. COURSE GENERATION IN PANDA.TUTOR

In PANDA.TUTOR we aim to develop an adaptive learning environment in which the course content and pedagogical aspects are adapted for each student, considering the personality type, educational progress, learning style, cognitive level and the emotional and motivational states of the student. The integration of cognitive, emotion and motivation with ITS assists students to achieve their goal. The design of the adaptive learning system requires a huge number of rules which represented in most systems as if - then rule. The proposed methodology is based on an intelligent mechanism that tries to mimic an instruction designer model. All the adaptation rules are modeled in the planning domain.

According to the current state of the student module, the planner attempts to find a sequence of operators which can achieve the student goal. An operator is much like a rule in a production system. Using the preconditions and expected effects of operators, the Planner can simulate the invocation of the various steps of a teaching plan, and thereby determine whether the plan is likely to be successful. A successful plan is one which can be applied to the current state of the student module to achieve the given goal.

PADNA.TUTOR is a constructive course generation which helps the student not only to complete their course more accurately and efficiently, but also to build new knowledge in enjoyable ways. Thus, we follow deep learning rather than surface learning. The deep learning approach encourages students to understand the concept, relate new content to the previous knowledge, which helps students to structure and or-

ganize their knowledge, which is known as task-centered instruction strategy. This approach incorporates students in the whole task early in the instructional sequence In which, each topic in a given area is taught in turn.

The instruction starts by demonstrating the first whole task in the progression. The first demonstration should be a complete task but it should be the least complex version of the whole task in the progression. This demonstration forms the objective for the task and provides the context for the students. the second task asks about the first task and introduces more information, and so on. That helps the students to easily grasp a demonstration of the whole task. Thus, getting students involved with realistic whole situations will help them to form appropriate schema and mental models. As a result, it facilitates doing application when students try to solve a new acquired knowledge and skill[2]. While the surface learning approach is interested only in a part of material and memory facts, ignoring the attempt to construct the student's knowledge. So, instructional materials in our approach that are generated for a particular learning goal are organized around specific key concepts. Our plan is generated according to the course structure especially the concept goal structure and its relations with other concepts and the student module.

The educational material provided for each concept, is organized in different levels of performance which the student should achieve in order to master the concept. Instruction strategies are adapted for the presentation of the educational material follow the student learning style.

Adaptation of the course content implies that different students receive different course version of the same concept. Our approach is adapted according to: the scenario type, the level of depth (quantity level), the student level and goal (ranging from high level overview to in-depth explanation), the level of difficulty (quality level), the learning styles, the different motivational states and different emotional states.
At the beginning, the student determines the required course and the system presents the learning content according to the student level. After that, the student selects a concept from the concept list of the course. Then, the type of learning scenario can be selected either by the student or by the system according to the student's emotional, motivational state and the performance history in the selected concept. Then the system presents a course for the selected concept.

For instance, the abstract task of the lesson scenario is *Generate_Lesson_Scenario*, for variables $?st$ of type $Student$, $?pers$ of type $Personality$, and $?Cname$ of type $Concept$. The schemata of this task is as follows:

```
Generate_Lesson_Scenario(?st: Student, ?pers:
Personality, ?Cname:Concept)
   Pre:  Studet_Personality(?St1, ?Pers)
         Selected_Scenario(?Lesson_Scenario)
         selected_Concept(?St1, ?Cname)
         Student_Performance_State(?st1,
         ?Cname, Not_Selected)
   Eff:
     Student_Performance_State(?st1, ?Cname,
     Selected)
```

The intended semantics of this schema is that the student is to be taught the specified concept. On this level of abstraction neither the learning style nor emotional and motivational state are relevant, the only significant state change concern the student personality type. We have two refinements, in which the concept is studied for first time or studied before. For the first one the abstract task is decomposed into a task network with six sub-tasks, in which the emotion and motivational states are considered and then the generated course is manipulated. With the second refinement the abstract task is decomposed into three sub-tasks according to the performance history of the student's cognitive level for the respective concept.
In the first method *(the concept is studied for the first time)*, the following sub-tasks are defined *Consider_emotional_State*, *Consider_Motivational_State*, *Teach_first_Lavel*, *Teach_Second_Lavel*, *Teach_Third_ Lavel*, *Teach_Fourth_Lavel*. The first two tasks are organized according to the emotion and motivation strategies that manipulate different emotional and motivational states. Different refinements are considered for *Consider_emotional_State* such as *increase happiness*, *decrease sadness*, *decrease fear*. The refinements of motivation task *Consider_Motivational_State* are used to *increase confidence, increase effort, maintain confidence*. The actual learn procedure, encoded by *Teach_first_Level*, *Teach_Second_Level*, *Teach_Third_Level* and *Teach_Fourth_Level*.
In our learn context, according to Task center instruction strategy, the learning process is organized in four levels:

1. In the first level, a presentation(Tell) (overview, definition, introduction,..) for the whole view of concept is introduced. This demonstration forms the objective of the concept. As well as presentation(Tell) and demonstration (Show) about the part(s) of the concept.

2. In the second level, we deliver activation (remember or recall) and application (Do) for both concept and the concept's part(s) and then teach the student presentation and demonstration about the sub-classes of concept with different learning styles.

3. In the third level, the activation application is delivered for both concept part, sub-classes and Process (How to) of the selected concept. Also, presentation and demonstration about the principle (what happen) with different learning styles are delivered.

4. In the fourth level, the student is asked to apply allKO of the concept. Finally, deliver an assignment about the whole concept to asses the student's level.

Note that, the task *Select_Learning_style* connects between the personality type and the appropriate learning style. For instance, the appropriate learning style for the personality type

Entrepreneur*(high E, low N, high C)* is the Pragmatist style. For teaching each knowledge object, four different methods are defined to represent the learning styles. For instance, to model the Pragmatist style for the concept's process (How to), the generated plan will call demonstration about the process, then presentation about the concept's process, and finally application about the process. While, in the Reflector style, the presentation will be generated then demonstration and application. The connection between the personality type and the appropriate learning style will be considered during the domain of the planning. Note that, for each KO we considered different learning styles.

9. CONCLUSION

In this paper we introduced a new personalized authoring/course generation system **PANDA.TUTOR**.
The goal of this system is to construct the student knowledge and help the author to represent the required course. Accordingly, a new approach is introduced for the course module using ontology technique, as well as for modeling the pedagogical module using the HTN planning.

Abstract*—Classification is a common task in Machine Learning and Data Mining. The protein function prediction can be treated as a classification problem. As protein's functions may be arranged in a hierarchy of classes, predicting the protein function is treated as a problem of hierarchical classification. *This paper presents an algorithm for hierarchical classification using the global approach, called Hierarchical Classification using a Competitive Neural Network (HC-CNN) for Protein Function Prediction. This algorithm is based on a Competitive Neural Network. It was tested in eight datasets based on Funcat and compared with algorithms from literature. The results show that the HC-CNN is an alternative in problems of hierarchical classification.

Keywords-Hierarchical Classification; Competitive Neural Network, Global Classifier

I. INTRODUCTION

Classification is one of the most important problems in Machine Learning and Data Mining. The classification consist in associating one or more classes from a set of predefined classes to an example from the database. This association of an example to a class is determined according to the features of each example.

In the context of protein functions prediction it is treated as a classification problem. A protein is considered an example of a database and biological functions are treated as classes to be provided.

The function of the proteins may be arranged in a hierarchy of classes. Thus the predicting protein is treated as a problem of hierarchical classification

A hierarchy can be defined as an ordering of elements according to their function or importance and can be represented by a tree or a directed acyclic graph (DAG).

An example of a class hierarchy is the enzymes functional classification which is structured as a tree. Another example of protein's functional classification is the Gene Ontology (GO), which is structured as a DAG.

Based on this wide diversity of problems, specific algorithms for hierarchical classification have being developed. This paper presents an algorithm for hierarchical classification based on the global approach using a competitive artificial neural network for the protein function prediction datasets. This classifier was compared with the methods Clus-HMC and Clus-HSC, developed by Vens and colleagues – Vens et al (2008).

II. RELATED WORKS

The hierarchical classification is an approach that has been widely used in text mining since the 90s. Among the work in this context can be cited Koller and Sahami (1997), Sun and Lim (2001), Sun and Lim (2003), Kiritchenko et al (2006).

The field of bioinformatics presents several problems to be solved by hierarchical classification, but it is, unfortunately, still little explored. Some works have been published using this approach, specifically in the protein function prediction, but using an hierarchical tree structure [6], [8], [9], [17], [18], [19].

In the work developed by Jensen et al. (2003), Laegreid et al. (2003) and Tu et al. (2004) the authors dismissed the class hierarchy, i.e. the concept of ancestor and descendant was not applied. Thus, one can say that the problem of hierarchical classification was transformed into flat classification problem, where the conventional classification algorithms are used.

Barutcuoglu et al. (2006), Guan et al. (2008) and Jin et al (2008), created a local binary classifier for each node. Although the set of binary classifiers represent the hierarchy of classes, there is no guarantee that they produce consistent results. Moreover, if an error occurs in a class at a certain level, this could spread to the classes of the levels below. Thus, one can say that the results presented by the authors are questionable because the approach has these drawbacks.

Vens et al. (2008) developed a hierarchical classification model for the DAG structure using the global or big-bang approach. In this work the authors discuss three kinds of classification: single-label classification (SC), hierarchical single-label classification (HSC) and multi-label hierarchical classification (HMC). For the development of these classifiers the authors used the induction of decision trees and showed how this model can be modified for use in hierarchical DAG structures.

These approaches are implemented in the CLUS and consist of generating a single decision tree for the whole hierarchy. This induction algorithm of decision tree is based on the framework Predictive Clustering Trees (PCT).

Aleksovski et al. (2009) extended the Clus HMLC developed by Vens et al. (2008), using other distance measures. The measures used by the authors were Jaccard distance, and SimGIC ImageCLEF. Such measures have been implemented in CLUS.

Otero et al. (2009) develop a new Ant Colony Optimisation algorithm, named hAnt-Miner, for the hierarchical classification problem of predicting protein functions using the GO. The algorithm proposed discovers a single global classification model in the form of an ordered list of IF-THEN classification rules which can predict GO terms at all levels of the GO hierarchy, satisfying the parent-child relationships between GO terms.

Alves et al. (2008) and Alves (2010) constructed a hierarchical classification model called Hierarchical Multi-Label Classification with an Artificial Immune System (MHCAIS), which uses concepts of an Artificial Immune System (AIS). This hierarchical classifier aims to discover knowledge represented as rules if-then.

The author presents two versions of MHCAIS: global and local. The local version builds a classifier for each class, while in the global version a single classifier is generated to distinguish all classes of the application.

The approaches of hierarchical classification Clus-HMC and Clus-HMC-HSC developed by Vens et al. (2008) and MHCAIS developed by Alves (2010) presents some advantages over those used by Jensen et al. (2003), Laegreid et al. (2003), Tu et al. (2004) and Barutcuoglu, Z. et al. (2006), Jin et al. (2008) and Guan et al. (2008). It implements the global or big-bang classification approach where the class hierarchy is considered as a whole. Thus, the prediction model built considers simultaneously all classes of the hierarchy.

III. Hierarchical Classification Hierarchical Classification using a Competitive Neural Network (HC-CNN)

One of the characteristics of a competitive network is its ability to realize mappings that preserve the topology of the input and output spaces. The learning process proposed here is based on competitive learning [16], [21], in which neurons of the output layer compete to be activated so that only one output neuron will be the "winner" of the competition process. The synaptic weight adjustments are made by the neuron that was activated and its neighbors.

The HC-CNN algorithm proposed in this work is based on a Competitive Artificial Neural Network. Figure 1 shows the neural network model. This network consists of two layers of neurons. The input layer is connected to an input vector data set. The term "Input neurons" defined in this figure represents all instances of entry, according to the interpretation of the data set. The processing layer or output layer, which in a competitive network is the output mapping, represents the hierarchy of classes, where each neuron is connected to its ancestors and possibly descendants.

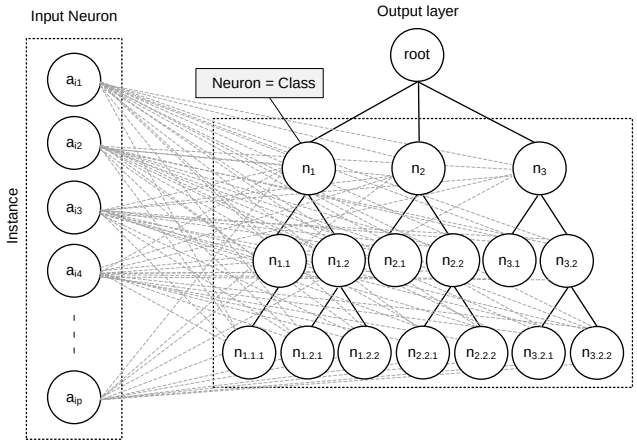

Figure 1. Example of HC-CNN.

In the traditional competitive network, for example, the Kohonen network, the neurons of the output layer are arranged in a grid network (Kohonen 1990), which can be rectangular, hexagonal, among others, and they represent the network topology. In HC-CNN algorithm the topology is a tree, where each neuron is connected with ancestors (parents) and descendent (children) neurons. These neurons (output layer) are created according to the number of classes in the hierarchy, and each neuron in the output layer is connected to all neurons of the input layer.

Neurons are stimulated by the input examples during the competitive process. In this way, it will be considered the "winner" the neuron who is more similar to the input instance selected. The comparison is made through the use of distance measures.

Prior to the training, some parameters should be defined, for instance, the amount of epochs to train the neural network and its learning rate (initial and final) which will decrease exponentially during the training, and the synaptic weights are randomly initialized. The training process of the network is divided into three phases, as in a traditional competitive network: Competition, Cooperation and Adaptation.

A. *Competition*

An instance e_i of input data set $DB_{Trein} = [e_1\ e_2\ e_3 \dots e_q]$ of dimension q is selected. Each element of DB_{Trein} consists of attributes $e_i = [a_{1i}\ a_{2i}\ a_{3i} \dots a_{li}]$, where a_{jk} is the $j-th$ attribute, $1 \le j \le l$, $l-1$ is the number of input attributes, and $i \in \mathrm{N} : l \le i \le q$, a_{li} represents the class attribute.

The neural network is created according to information obtained in the input data: the number of input neurons is equal to the number of input attributes, the output layer neurons are represented by $NN = [n_1\ n_2\ n_3 \dots n_b]$ where b is the number of class that exists in the class hierarchy. Each neuron of the

output layer consists of synaptic weights such as $n_i = [p_{1i}\ p_{2i}\ p_{3i} \ldots p_{(l-1)i}]$ that $i \in \mathrm{N} : l \le i \le (l-1)$.

To find the input vector e_i that is closest to the synaptic weights vector, distance measures are used. The measure chosen was the Euclidean distance (Equation 1).

$$d_{ik} = \sum_{i=1}^{l-1} \sqrt{(e_{ij} - n_{ijk})^2} \qquad (1)$$

where e_i is the input instance, n_{ijk} is the *k-th* neuron of output layer, l is the number of attributes and k is amount of output layer neurons.

The next step is to identify the neuron that shows the lowest distance (Equation 2). Thus, the winner neuron of the competition process of the cycle is obtained:

$$nv = \arg\min(d_i) \qquad (2)$$

Thus, the neuron of network NN that is closest to the selected input instance will be considered the winner and will stimulate their neighborhood according to the network topology.

B. Cooperation

The winner tends to excite their ancestors neurons that are closest. Thus, this phase is located in the region of the topological neighborhood that will update the weights of neurons.

In the HC-CNN algorithm, the neighborhood criterion is determined from the relationship between the neuron and their ancestors (parents of the winner neuron) and descendants (children of the winner neuron). This information is obtained through the existing relationship in the class hierarchy.

C. Adaptation

The third phase is the adaptation process of synaptic weights. Since the objective of training is to approximate the weight vectors to the input instances, because the weights of the neurons need to be adjusted so that there is a better classification of the instance e_i. If the class labels of the input instance e_i are equal to the winner neuron, then the neuron weights are adjusted so that they are closer to the instance. This is the case of a correct prediction. If the class labels of the input instance e_i are different from the labels of the predicted ones, weights will be updated to be more distant of this instance, because the class is predicted incorrectly. That is, during training, the algorithm adjusts the weights of the neuron and their ancestors, making the comparison by the identifier of the class of each input instance with the desired output.

Equation 3 shows the way the weights neurons are updated.

$$n_{ijk}(t+1) = \begin{cases} (n_{ijk} + (e_i(t) - n_{ij}(t)) * Ap(t) * Dist(t)), & \text{if the true class} \\ (n_{ijk} - (e_i(t) - n_{ij}(t)) * Ap(t) * Dist(t)), & \text{if the incorrect class} \end{cases} \qquad (3)$$

where n_{ijk} is the weight of the neuron attribute of the output layer at iteration t between the input neuron (instance) ei and the neuron k.

Ap is the learning rate for the instant of time $t+1$ which is obtained according to Equation 4.

$$Ap(t) = (\mu_i - \mu_f) * e^{-\frac{t_{current}}{C}} \qquad (4)$$

where μ_i is the initial learning rate, μ_f the end learning rate, $t_{current}$ is the current iteration and C is a constant defined for the exponential function decreases slowly.

$Dist(t)$ is the distance of winner neuron and their ancestors neurons that will have its weights adjusted as shown in Equation 5:

$$Dist(t) = 1/(k+1) \qquad (5)$$

where k is the distance in node of winner neuron and the ancestral neuron that the weights will be adjusted.

The updating of the weights of ancestor neurons follows the same method shown in the above equations (Equations 3, 4 and 5).

After the weights updating, a new instance is selected and all the procedure is repeated until all instances are selected. At the end, the first epoch of the training has been completed. Again, the procedure is repeated until the execution of all epochs.

In the last iteration of this phase the synaptic weights set of neurons is obtained and will be used in the test phase of the algorithm. Table I presents a succinct description of the HC-CNN algorithm.

TABLE I. TRAINING OF HC-CNN ALGORITHM.

INPUT
- Training data set $DB_{Trein}=[e_1\ e_2\ e_3 \ldots e_q]$ of dimension q.
STEP 1: INITIALIZE
- The initial learning rate μ_i and the final learning rate μ_f. - Determine the number of cycles *ep*. - Initialize the synaptic weights of the network: $NN=[n_1\ n_2\ n_3 \ldots n_b]$ where *b* is the number of class that exists in the class hierarchy. - Calculate the learning rate $Ap(t)=(\mu_i - \mu_f)*e^{-tcurrent/C}$ that the *tcurrent* is current iteration and *C* is a constant defined for the exponential function decreases slowly.
STEP 2: STOPPING CRITERION
- Number of cycles.
STEP 3: TRAINING
- Select an instance e_i of the input data set $DB_{Trein}=[e_1\ e_2$

$e_3 \dots e_q$].
COMPETITION:
- Calculate the distance between the instance e_i with the neurons of the network $NN=[n_1 n_2 n_3 \dots n_b]$.
- Finding neuron n_j which had the shortest distance, that are considered the winner neurons.
COOPERATION:
- Find the ancestors of the neuron *j*.
ADAPTATION:
- Update the synaptic weights of neurons and their ancestors.
- If the class true equal the predict class Dist(t)=1.
STEP 4: UPDATE
- Update the learning rate *Ap(t).*
- Go to STEP 2.
OUTPUT
- Adequate weights set.

The test of the algorithm is done similarly to training. Just as the training database, the testing database consists of instances $DB_{Test} = [x_1\ x_2\ x_3 \dots x_g]$ where g the amount of test instances. Each instance xi is composed of attributes $x_i = [a_{1i}\ a_{2i}\ a_{3i} \dots a_{li}]$, $i \in \mathrm{N} : l \le i \le g$, a_{li} represents the class attribute and l is amount attributes.

Table II shows the procedure for testing the algorithm. One can observe that it is similar to the training procedure. The main difference is that at this stage the weights are fixed from last cycle of the training phase.

TABLE II. TEST OF HC-CNN ALGORITHM.

INPUT
- Test data set $DB_{Test}=[x_1 x_2 x_3 \dots x_g]$ of g is amount of test instance.
STEP 1: STOPPING CRITERION
- Until all instances have been selected and tested.
STEP 2: TEST
- Select an instance x_i of the input data set $DB_{Test}=[x_1 x_2 x_3 \dots x_g]$.
- Calculate the distance between the instance x_i with the neurons of the network $NN=[n_1 n_2 n_3 \dots n_b]$.
- Finding neuron n_j which had the shortest distance, that are considered the winner neurons.
- Find the ancestors of the neuron *j*.
- Evaluation prediction.
- Assign result to the confusion matrix.
OUTPUT
- Accuracy rate obtained by the algorithm.

IV. EVALUATION MEASURES

Two evaluation measures were used to report the predictive performance of the samples: distance-based depth-dependent measure [8] and hierarchy based measures [12], [15]. The choice of these measures was made to assess the performance of the classification in different ways.

A. Distance-based Depth-Dependent Measures

When evaluating the result of a hierarchical prediction three situations may occur: correct prediction, partially correct prediction and incorrect prediction. To better understand these situations, each one will be exemplified.

First Possibility - Correct Prediction: There are two types of possible correct prediction. The first one occurs when the algorithm hits the full path, being the predicted class equal to the true class as shown in Figure 2.

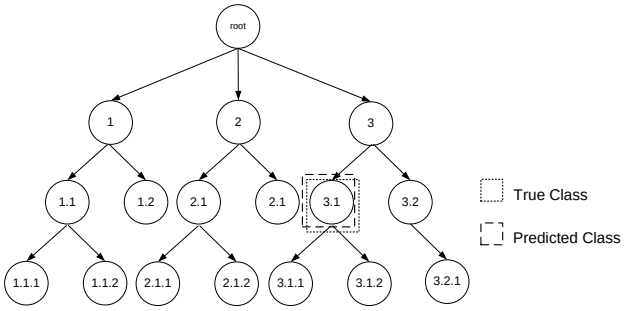

Figure 2. Example of Correct Prediction - 1st Possibility

The second case occurs when the predicted class is in the full path of the correct one, but it is more specific. Figure 3 shows this possibility: the true class is represented by the node "3" in the tree, and the algorithm predicts the node "3.1.1". This case is considered a correct prediction.

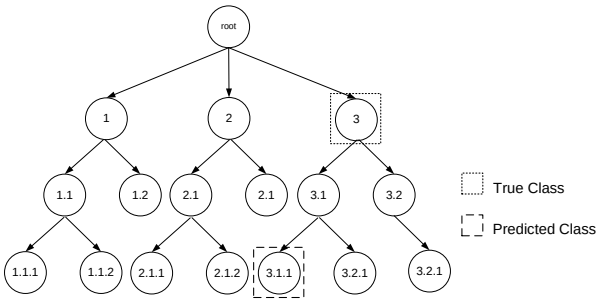

Figure 3. Example of Correct Prediction – 1nd Possibility

Second Possibility: Partially Correct Prediction: An example of a partially correct prediction is shown in Figure 5. In this case, the true class is represented by the node "2.1.1" but the algorithm predicts the class represented by the node "2.1". Observe that the node's parent node is predicted true. Although the predicted class is in the correct path it stops before finding the more detailed true class in the tree, not providing the full specificity of it. Therefore, one can say that the prediction was partially correct, because the algorithm was on the correct path of prediction, it just occurred before hitting the full specification.

An instance, whose class is predicted at higher levels, tends to be more easily classified than a class in deeper levels. Thus, the algorithm considers it a partial prediction, being based on the level of class, which means, classes at levels closer to the root have higher importance than classes at deeper levels.

In this example, the class is predicted on the second level and true class is at the third level. Then, indices of importance are assigned inversely proportional to the level of the classes, i.e., the class "2.1" is replaced by an index two times larger than the class "2.1 .1 ". Equation 6 shows the formula for this calculation.

$$1p + 2p + ... + np = 1 \quad (6)$$

where p is the index and n is the level in the hierarchy. The correct prediction rate is the sum of weights of classes correctly predicted, i.e. the predicted class and its ancestor classes. Applying the formula to this example, one obtains p=0,16. Thus, the weight of class "2.1.1" is 0.16, and the class "2.1" is 0.33 and the class "2" is 0.5. Then the hit rate of this sample is 83%.

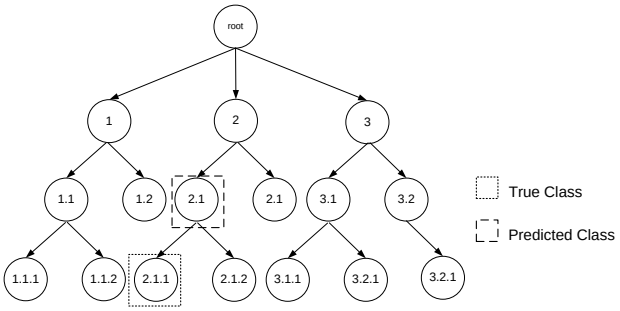

Figure 4. Example of Partially Correct Prediction.

Third Possibility: Incorrect Prediction: There is an incorrect prediction when the predicted class totally misses the path prediction as shown in Figure 5. It is observed that the true class is represented by the node "2.1.1", however, the algorithm predicts incorrectly the class as "3.2".

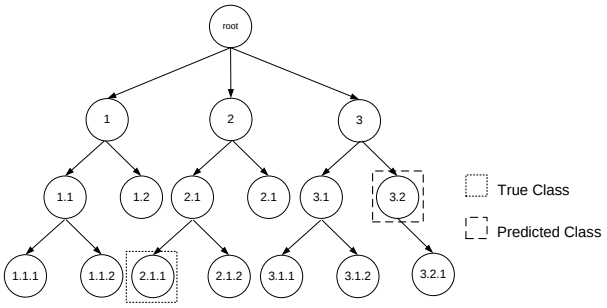

Figure 5. Example of Incorrect Prediction.

B. Hierarchy basead Measure

This kind of measure was developed by Kiritchenko et al. (2006) and uses concepts of ancestral and descendant classes. The author proposes two evaluation measures: hierarchical precision and hierarchical recall which take into account the hierarchical relationships [12], [15]. These measures are based on conventional measures of precision and recall.

These measures use the common ancestors of the true and predicted classes in the evaluation. To calculate the recall (Equation 7), the number of common ancestors is divided by the number of ancestors of the true class.

$$hR = \frac{\left|A(C_t) \cap A(C_p)\right|}{A(C_t)} \quad (7)$$

where $A(C_t)$ and $A(C_p)$ are classes that are true ancestors and predicted ancestors, respectively.

To calculate the precision (Equation 8), the number of common ancestors is divided by the number of ancestors of the predict class.

$$hP = \frac{\left|A(C_t) \cap A(C_p)\right|}{A(C_p)} \quad (8)$$

These measures can be used to calculate an extension of the F-measure (harmonic mean), named the hierarchical F-measure (Equation 9).

$$hF - Measure = \frac{(\beta^2 + 1) * hR * hP}{\beta^2 * hR * hP} \quad (9)$$

where β is the importance given to precision and recall.

V. EXPERIMENTERS AND RESULTS

Experiments to evaluate the classifier performance were performed on eight databases, four of them formed by protein G-Protein-Coupled Receptor (GPCR) and the other formed by Enzyme Commission Codes (EC). These sets were available from the authors of the work Holden & Freitas (2005). Table III shows some characteristics of these databases.

TABLE III. CHARACTERISTICS OF DATABASES

Datas Sets	Amount Samples	Amount Atributes	Amount Class	Amount Class/ Level
ECinterproFinal	14036	1216	331	6/41/96/188
ECpfamFinal	13995	708	334	6/41/96/191
ECprintsFinal	14038	382	352	6/45/92/209
ECprositeFinal	14048	585	324	6/42/89/187
GPCRinterproFinal	7461	450	198	12/54/82/50
GPCRpfamFinal	7077	75	192	12/52/79/49
GPCRprintsFinal	5422	282	179	8/46/76/49
GPCRprositeFinal	6261	128	187	9/50/79/49

The performance of HC-CNN algorithms is compared with two others algorithms: Clus-HMC and Clus-HSC. These methods are based on the concept of Predictive Clustering Trees (PCT) [5].

For the all experiments 2/3 of the examples were used for training and 1/3 for testing (hold-out procedure). In addition, all sets were normalized using the approach Min-Max. An observation to be made is that some nodes of the hierarchy

have only a few children, which causes a great unbalance in the tree.

The initial learning rate and final learning rate used in the experiments were 0.1 and 0.01, respectively. The neural network synaptic weights were generated randomly, according to a uniform distribution. The evaluation of the classification was made taking into account all levels of the hierarchy.

The results are presented based on distance-based depth dependent measure and *hF-Measure*.

For the Clus experiments were selected some thresholds to compare the performance the algorithms. Table 4 presents the results obtained with 1000 epochs for training the neural network and the thresholds 40 and 80. The term Dt_i indicates the databases in the order show of the Table 3, dist indicates distance measure and *hF* indicate *hF-Measure*.

TABLE IV. RESULTS OF EXPERIMENTERS.

	HC-CNN				Clus-HMC		Clus-HSC	
	50		**1000**		**40**	**80**	**40**	**80**
	dist	**Hf**	**dist**	**hF**	**hF**	**hF**	**hF**	**hF**
Dt1	84,1%	81,3%	85,3%	83,4%	93,5%	92,0%	93,5%	93,1%
Dt2	85,4%	83,2%	85,7%	83,6%	93,0%	92,6%	93,4%	93,2%
Dt3	85,3%	83,6%	88,0%	86,3%	93,4%	92,7%	93,4%	92,7%
Dt4	89,8%	87,5%	91,8%	90,7%	95,1%	94,4%	94,4%	93,8%
Dt5	77,5%	70,4%	75,6%	68,0%	80,4%	77,8%	80,2%	74,3%
Dt6	85,4%	60,7%	68,8%	71,8%	69,5%	65,1%	69,6%	65,0%
Dt7	79,1%	71,6%	78,7%	71,8%	79,9%	77,8%	79,9%	74,3%
Dt8	51,5%	51,1%	55,3%	47,5%	66,8%	57,8%	67,3%	59,7%

The results were statistically compared using the Friedman test [13], [14] to verify whether there is statistical significance between the differences the performances of the algorithms

Based on the results of this test, the algorithm has no statistical difference. Thus, the HC-CNN is a promising alternative to treat problems of hierarchical classification.

VI. CONCLUSION

This paper has presented a new HC-CNN algorithm for the hierarchical classification problem of predicting protein functions tree structured. The algorithm proposed is based in a competitive neural network.

This classification approach has the advantage of evaluating the predictive performance of the entire class hierarchy, reporting a single result because this method uses the global approach.

The HC-CNN was applied in eight Funcat datasets. The results of the predictions were assessed using two approaches to hierarchical classification measures: distance-based depth-dependent measure and *hF-measure*.

The experiments made in the databases obtained promising results in this first version of the classifier. Other experiments can be done using other learning rates of the neural network and the amount of cycles to train the neural network in order to compare the result of prediction.

Although the classifier has been developed to predict a single class, it can be easily adapted to hierarchical classification multi-class, whose problem is found in very diverse areas.

In addition, as future work, we intend to adapt the classifier to predict structured data in the form of a DAG.

Abstract— *This paper describes the adaptive approach of the Population-based Incremental Learning (PBIL) algorithm, and proposes several Learning Rules aimed to improve its performance. The assessment of such alternatives was made in terms of both the convergence time and of the quality of the achieved solutions. Two classical optimization problems were used for the tests: The Job Shop Scheduling problem and the Traveling Salesman problem. The obtained results are very promising and suggest that some of the proposed learning rules have a superior performance, without degrading drastically the quality of the solutions.*

Keywords: Optimization, Adaptive algorithms, Incremental Learning, Learning Rules

1. Introduction

The use of population-based algorithms has been successful in solving highly complex optimization problems, as reported on literature [1], [2]. The success of this kind of optimization tools refers to their ability to use a population of potential solutions, to perform a parallel exploration. This parallel approach helps to avoid the local-optimum problem.

Among the different kinds of population-based approaches, Evolutionary Algorithms (EAs) are the most often used. A given EA works with a population of individuals and some rules for changing those individuals in order to reach acceptable solutions. Those rules are inspired on evolutionary processes of biological beings. Multi-Objective Evolutionary Algorithms (MOEAs) are particularly useful when optimizing several figures of merit is required, since such figures of merit are often in conflict with each other [3], [4].

PBIL optimization algorithms work also with a population of potential solutions. The main differences with respect to EAs are related with the representation and the updating process of the population [5]. In PBIL, population is represented by means of a probability array. Each probability value in the array, is related to whether a given attribute must be part or not of the final solution. The way in which the probabilities of the PBIL array are updated, in order to find an optimal, is referred as Learning Process. The updating of each probability in the PBIL array is often performed by means of an approach based on the Hebbian rule [6]. Such updating depends on a parameter called Learning Rate (LR), which controls the speed of the convergence process.

This paper describes several variations of an Adaptive Population-Based Incremental Learning (APBIL) algorithm, which adjust the learning rate parameter dynamically, in order to speeding up the convergence time. The idea is to test several learning rules (i.e. the way in which the learning rate must be modified) in order to find the best trade-off between speed of convergence and quality of the solutions. The propossed learning rules are compared with that one presented in [7], where a bell shape is suggested to change the learning rate as a function of the probability array's entropy. Although optimization algorithms may behave different when used to solve different optimization problems [8], this work provides some insight into the APBIL performance and highlights its main advantages.

This paper is organized as follows. Section II shows some previous works related to PBIL optimization algorithms. Section III shows some fundamentals about the adaptive PBIL algorithm and the learning rules proposed to improve its performance. Section IV describes the Job Shop Scheduling problem, which will be used to test the PBIL optimization approaches. Section V shows the comparison of the results provided by different approaches in terms of speed of convergence and quality of the solutions. Finally, section VI shows the concluding remarks and future work.

2. Related Work

Several works have proposed the use of PBIL for solving optimization problems [9], [10], [11]. In [10], the effect of the LR parameter on the algorithm's performance is analyzed. The design of a Power System Stabilizer (PSS) is used as case of study. This work shows that smaller learning rates, results in a high diversity of the population of solutions. Such a diversity implies a slower convergence time. On the other hand, when LR increases, the exploitation (i.e. improving and intensifying the features of the best solutions found so far) of the design space is favored and the convergence speed grows, but also may lead to find local optimals instead of the global one.

In [12], a comparison between Breeding Genetic Algorithm (BGA) and PBIL approach is performed, for the

design of a Power System Controller. BGA is a modern version of traditional evolutionary algorithms which uses the survival of the fittest as optimization mechanism, but allows a mechanism similar to artificial insemination on living beings, where the offspring may take the best attributes of its parents. Results of this work show that PBIL has almost the same performance when optimizing the power controller. The main advantage of PBIL is that it is computationally simpler and has fewer genetic operators when compared with BGA. Results also show that PBIL algorithm requires less memory and computational resources, which makes it very suitable for online implementations.

In [5], a Dual PBIL (DPBIL) algorithm is presented in order to solve a partitioning problem. As defined on that work, partitioning has the form of a binary optimization problem. The dual form of the PBIL implementation allows to improve the speed of the algorithm for finding optimal solutions. This allows the implementation of DPBIL approaches in dynamic environments, in which the optimization objective's changes over the time.

In [13], a system-level partitioning problem is solved using a PBIL approach. Unlike the DPBIL algorithm, where a probability vector is used, the non-binary nature of the system-level partitioning problem requires using a different representation for the probability array. The results show that by adjusting the learning rate parameter, convergence time is speeded up at the expense of the quality of the obtained solutions. Tuning this parameter becomes a key issue in the PBIL optimization process.

Some efforts have been conducted in order to formalize the PBIL convergence process [14], [15]. In such approaches, PBIL algorithm is modeled by means of a Markov Chain and its behaviour is approximated by using an ordinary differential equation (ODE). The idea is to prove that the corresponding ODE has only stationary points which corresponds to the optimals of the configuration space of the PBIL algorithm. These works has proven that eventually, the ODE and the associated PBIL, will converge to one of those stable points.

3. The PBIL approach

The PBIL algorithm is a stochastic search method that obtains its directional information from the previous best solutions [16]. As mentioned before, PBIL algorithms represent the population of solutions by means of an array of probabilities. In the case of binary problems, the PBIL array takes the form of a vector, which stores a probability value for each attribute of the problem to be optimized. In the case of non-binary problems, it is necessary to work with a probability matrix, in order to take into account the whole solutions space. In both cases, the idea is to update iteratively the probability values in the array, in order to that the population converges to an optimal solution.

A basic version of the APBIL approach is shown in Algorithm 1. As shown on Algorithm 1, all the values in the probability array (namely P) are initialized to $1/N$, in order to take into account all the potential solutions. At each algorithmt's iteration, a new population (Pop) is generated, based on the probabilities of the array, by means of the $Create\_Population$ routine. The attributes with the highest associated probability values, will appear with more frequency in the populationt's individuals. All the individuals of the population are assessed, using the $Evaluate\_Population$ routine. For the sake of choosing the more suitable solutions to the optimization problem at hand, the $Choose\_Best$ routine uses information about the fitness of each potential solution in the population.

In the adaptive approach of the PBIL algorithm, the Learning Rate (LR) parameter must be adjusted in order to allow both exploration and exploitation of the search space. This task is performed by the $Learning\_Rule$ routine. The Entropy (E) of the probability array is calculated and used as an estimation of the population's diversity. Once the LR parameter is calculated, the P array must be updated in order to adjust the probabilities, according to the best solution found in the population. Function $Update\_Array$ is used with this aim.

Entropy decreases as the probabilities in the PBIL array tend to concentrate on single entries of each column of the P array (i.e. when an optimal solution becomes more probable). Then, when entropy value becomes less than a given tolerance, the algorithm may stop. The optimal solution can be easily derived of the probabilities on the P array.

Let's suppose that an optimization problem can be stated as a collection of M attributes, namely Q_1, Q_2, ..., Q_M. For each attribute, there are up to N choices, in order to solve the problem. Figure 1 shows a suitable probability array, for such an optimization problem. In Figure 1, $P_{(i,j)}$ represents the probability of the j attribute to be optimized using the

Algorithm 1 Basic PBIL Algorithm

Input: An $N \times M$ probability array P
Output: An optimized solution

1: $P(i,j) = \frac{1}{N}; \forall\ 1 \leq i \leq N$ and $1 \leq j \leq M$
2: **repeat**
3: $\quad Pop = Create\_Population(P)$;
4: $\quad Fitness = Evaluate\_Population(Pop)$;
5: $\quad Best = Choose\_Best(Pop, Fitness)$;
6: $\quad E = Entropy(P)$;
7: $\quad LR = Learning\_Rule(E)$;
8: $\quad P = Update\_Array(P, Best, LR)$;
9: **until** $\{E < Tolerance\}$;

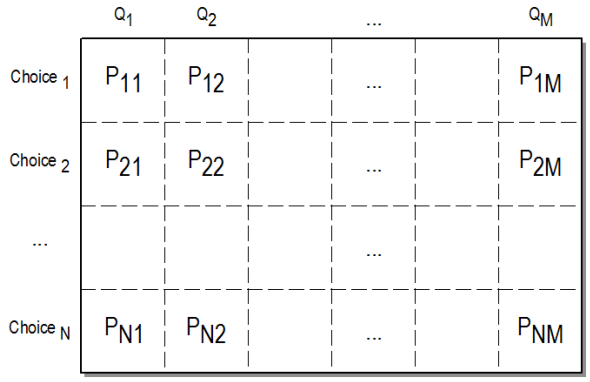

Fig. 1: A non-binary PBIL probability matrix

associated choice i. Since a single column of the matrix of Figure 1 represents the joint probability of all potential choices for a given attribute, the sum over a single column must be equal to one.

Let's suppose that after assessing a given population, it was found that for a given attribute Q_j, the best (optimal) choice is the option k. According to this, the probabilities in the array must be updated using a modified version of the Hebbian rule [17], as shown in Equation (1).

$$P_{(i,j)New} = \begin{cases} P_{(i,j)Old} + \left(1 - P_{(i,j)Old}\right) \times LR, \text{ for } i = k \\ \left(1 - P_{(k,j)New}\right) \times \frac{P_{(i,j)Old}}{1 - P_{(k,j)Old}}, \text{ for } i \neq k \end{cases} \quad (1)$$

In Equation (1), LR corresponds to the learning rate parameter. The higher the LR parameter, the fastest shall be the convergence of the algorithm, at the expense of a poorer quality of the found solutions. The adjusting of the LR parameter requires a good trade-off between quality and speed. Instead of giving to the LR parameter a fixed value, an adaptive approach varies the LR parameter whilst the algorithm converges to an optimal. The best way to do that is by calculating the systemic entropy over the PBIL array of Figure 1 [18]. In this case, systemic entropy, or simply entropy (E), may be calculated as shown in Equation (2).

$$E = -\sum_{i=1}^{N}\sum_{j=1}^{M}\left[P_{(i,j)} \times \log\left(P_{(i,j)}\right)\right] \quad (2)$$

When all problem choices are equally probable, all probabilities on the array have a value of $1/N$. In this situation, the population represented by the PBIL array has the highest diversity. Under these conditions, the maximum value of Entropy can be calculated as shown in Equation (3).

$$E_{Max} = -M \times \log\left(\frac{1}{N}\right) \quad (3)$$

When one of the choices becomes more probable than the others, entropy value decreases, meaning that the array provides less information, since some of the available options have being discarded. A value of 0 for the entropy, implies that all the attributes of the associated solution are completely defined, i.e. the PBIL algorithm has reached a unique solution.

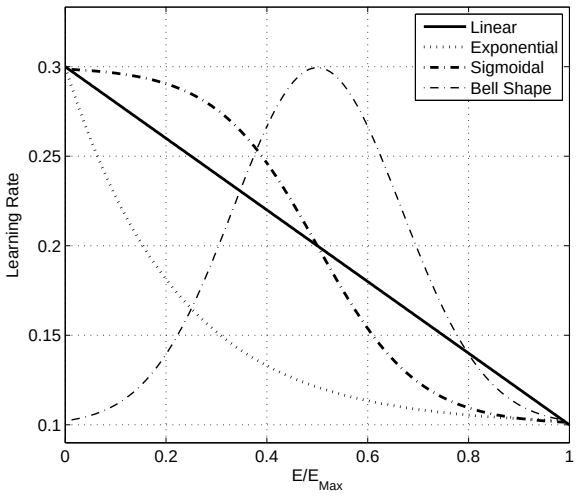

Fig. 2: Learning rules for LR between 0.1 and 0.3

The APBIL algorithm starts with high values of entropy, and they decreases as the APBIL array converges to an optimal attributes combination. Figure 2 shows three learning rules, namely linear, exponential, and sigmoidal. As shown on Figure 2, the learning rate parameter is kept at low values at the beggining of the algorithm (when entropy has maximum values), for the sake of allowing high population's diversity and exploring over all the solutions space. As the entropy decreases, as a result of the probability array updating process, the LR parameter increases, in order to improve the speed of convergence of the algorithm, and to reach the optimal solution quicker. This means that the search process allows high diversity at early iterations of the APBIL algorithm, and once the array seems to be oriented toward a given solution (low entropy), the algorithm changes the learning rate parameter, in order to speed up the convergence. Figure 2 also shows the bell shape learning rule, like that one proposed in [7]. In this case, the learning rate is kept low both at the beginning and at the end of the APBIL algorithm. The idea is to allow high population's diversity in both situations, and avoid the local optimum problem.

Concerning a multi-objective implementation of a APBIL algorithm, the main idea consists of working with several arrays (populations) independently, as is done in the island-model PBIL or IMPBIL approach [19]. As a result, at the end of the algorithm's execution, there will be several optimal solutions with different trade-offs among the objectives being optimized. There will be as much solutions as PBIL

arrays on the implementation. This implies that the learning process must be performed over several arrays, which may reduce the algorithm's performance.

Maintaining different PBIL populations generates additional problems. The first one is that a mechanism is necessary to avoid that several populations converge to the same optimal solution. As explained in [20], this may be done by using a kernel approach based on distance. The idea is that the distances among potential solutions becomes a new objective to maximize in the optimization process, in such a way that the solutions similar to an optimal in a given population, are pruned on the remaining ones.

The second problem concerning multi-objective PBIL is related to the stochastic nature of such algorithm. The random operators that are present in PBIL algorithm can lead to loosing good optimal solutions. A buffering strategy must be implemented in order to store global optimal solutions and to integrate them into the learning process while the algorithms works. Given an optimization objective, if an optimal solution is found and is better than the stored one, the previous solution is discarded and the new best solution is saved.

4. The Job Shop Scheduling optimization problem

Job Shop Scheduling [21] is a combinatorial optimization problem, which was formulated in the middle of the twentieth century. As many combinatorial optimization problems, Job Shop Scheduling is considered a NP problem, which implies that practical algorithms are aimed to find good-enough solutions instead of finding the best solutions. Scheduling is a concept related with a plethora of different optimization problems, with different levels of complexity and diverse structures too.

In order to test our adaptive PBIL algorithms, a Job Shop Scheduling problem will be used. Such a problem implies the scheduling of executable tasks in a multi-processor architecture, with several objectives to be satisfied. Three objectives were considered for optimization: the cost of the solution (N), i.e. the number of Processing Elements (PEs) required for implementing a given scheduling solution; the scheduling penalty (SP), related with tasks priorities and execution delays, and the processor occupancy (PO), which assess the eficiency in the resources usage.

The problem is stated as follows. Let's suppose a set of M independent tasks, which are going to be scheduled for their implementation over a set of up to N PEs. Although the number of tasks is well-known in advance, the number of PEs represents the first objective to be optimized in order to reduce the cost of the solution. The cheaper solution in terms of hardware cost, consists of using a single PE, which will lead to higher delays when executing the tasks. The more expensive solution implies using a single PE for each task. This enhances the performance of the designed system, because response time for each task is minimized. Due to the fact that the target architecture is homogeneous, each PE has the same cost and the execution time for a single task does not change from one specific PE to another.

A given task (T_i) has its own execution time (t_i) and a priority value (Pr_i), which ranges between 1 and Pr_{Max}. If a specific PE is assigned to execute more than one task, it is assumed that tasks will be served sequentially, using their priorities as ordering criterion. Tasks with higher priority are served before those with lower ones. The penalty for delaying a given task is calculated by means of its priority and delay to be executed. Equation (4) shows that the penalty for a specific scheduling scheme is the sum of the penalties for each task, which is defined as the product between its priority and its delay.

$$SP = \sum_{i=1}^{M} D_i \times Pr_i \tag{4}$$

In Equation (4), D_i represents the delay that a specific scheduling solution produces to the task T_i, and Pr_i is its associated priority. The system penalty (SP) is the second objective to be optimized (minimized) in the proposed scheduling problem.

Finally, the third objective to be optimized corresponds to the processor occupancy (PO) which can be simply calculated as the mean percentage of time in which processors are performing useful work (i.e. processing tasks). In this case, the PO objective must be maximized, in order to fully exploit the system's resources.

Figure 3 depicts a specific scheduling solution, in an environment of M tasks, each with a triad formed by its priority, execution time and delay. As can be seen in Figure 3, there can be up to M active PEs (the most expensive and fastest solution), but in a more efficient solution, some PEs are not used at all. Since for each PE, tasks are served on a priority basis, from the figure it can be said that priority of task T_1 is higher than priority of tasks T_i and T_M. Also, task T_1 is served first on PE_1, so the associated delay for such a task is equal to zero. Delays for remaining tasks shall depend on the subsequent execution order.

5. Experimental Results

Four APBIL Learning Rules (namely linear, sigmoidal, exponential and bell-shape) were tested in order to compare them and find the best trade-off between performance and quality for the optimization problems at hand. Such learning rules are depicted in Figure 2 and Table 1 shows their formal specification. In order to perform an equable comparison, this specification represents the only difference among the implementation of the adaptive algorithms. As shown in Table 1, LR depends on the entropy (E) of the PBIL array, as well as on the LR_{Min} and LR_{Max} parameters, which

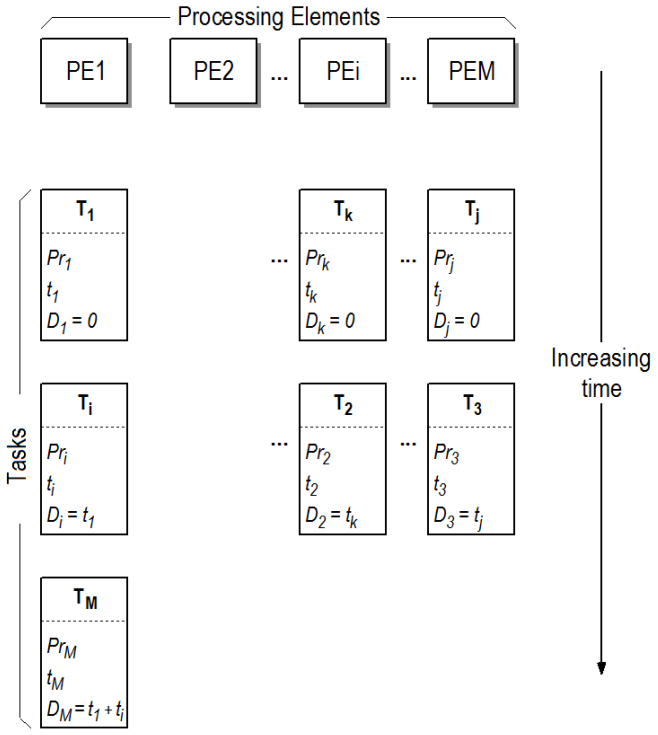

Fig. 3: A given scheduling solution

represent the minimum and maximum values for LR. For all the executions of the APBIL algorithm reported in this section, the LR_{Min} and LR_{Max} values were set to 0.1 and 0.3, respectively.

For comparison purposes, a classical Multi-Objective Evolutionary Algorithm (MOEA) was also implemented [22]. Each algorithm was used to solve the Job Shop Scheduling problem with different sizes (M).

All the algorithms were aimed to simultaneously optimize three objectives, as pointed in previous section: scheduling penalty (SP), processor occupancy (PO) and the number of PEs (N). The algorithms were tested using Matlab on a PC with an Intel Core I7 processor and 8 Gigabytes of memory.

Table 1: Formal specification of learning rules

Linear	$LR = LR_{Max} - \frac{E}{E_{Max}} \times (LR_{Max} - LR_{Min})$
Exponential	$LR = LR_{Min} + (LR_{Max} - LR_{Min}) \times e^{-4.5 \times \frac{E}{Emax}}$
Sigmoidal	$LR = LR_{Max} - \frac{LR_{Max} - LR_{Min}}{1 + e^{-10 \times \left(\frac{E}{Emax} - 0.5\right)}}$
Bell Shape	$LR = LR_{Min} + \frac{LR_{Max} - LR_{Min}}{\sqrt{2 \times \pi}} \times e^{-\frac{\left(\frac{E}{Emax} - 3\right)^2}{2}}$

Figure 4 depicts the mean convergence time for the

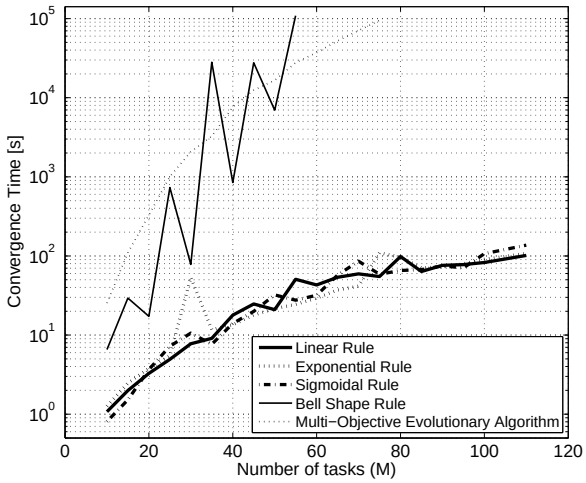

Fig. 4: Mean convergence time for the different optimization strategies

mentioned algorithms, as a function of the optimization problem's size (M). As can be seen, convergence times for MOEA and bell-shaped algorithms, becomes restrictive when dealing with higher values of M. In such cases, the execution of the algorithm was forced to stop.

Learning rules for the adaptive approaches in Figure 4, are the same depicted in Figure 2. As can be seen, there is no remarkable difference between the monotonically-increasing learning rules (linear, exponential and sigmoidal), except for a peak given on the exponential rule, for a problem size of thirty tasks. On the contrary, MOEA and bell-shaped PBIL has very poor convergence times, often several orders of magnitud above the proposals with monotonically-increasing learning rules.

With respect to the bell-shaped learning rule, it does not seems logical to decrease the learning rate at the end of the process of convergence. When a PBIL algorithm is performing the last stages of the space exploration, the probabilities in the algorithm's array tend to be concentrated on single positions of each column, which points toward the optimal solution. The results in Figure 4 suggest that there is no need to guarantee population's diversity at final stages of the PBIL algorithm's execution.

The MOEA algorithm was implemented using a vector representation for each solution on the population. Each entry in the solution's vector represents the implementation resource for a given system's task. This means that each vector on the population has a lenght of M elements. A single crossover operator was used for recombination, and the mutation was made by means of a change of a single value on a given vector position. A round-robin method and a $\mu + \lambda$ strategy was used for selection purposes [23]. As can be seen in Figure 4, MOEA's performance is very poor

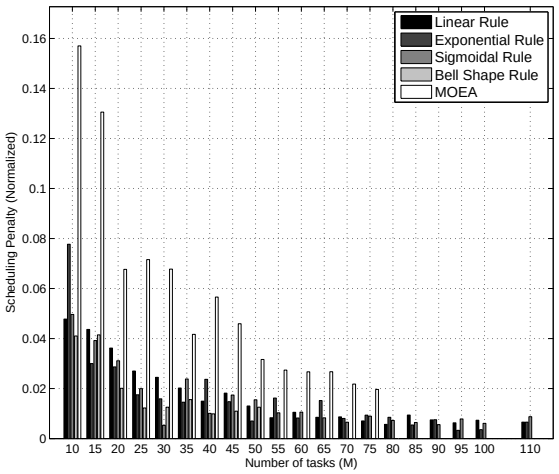

Fig. 5: Scheduling penalty for several optimization approaches

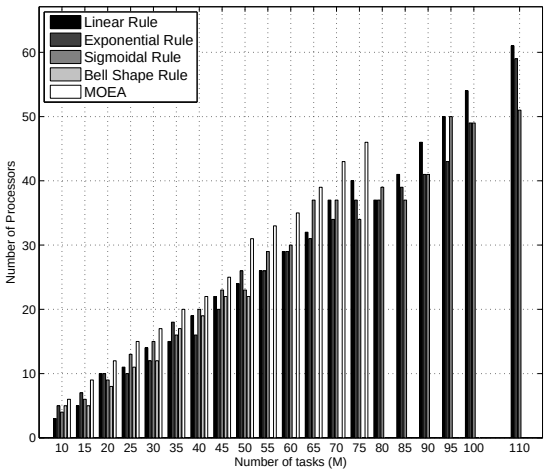

Fig. 7: Number of processors for several optimization approaches

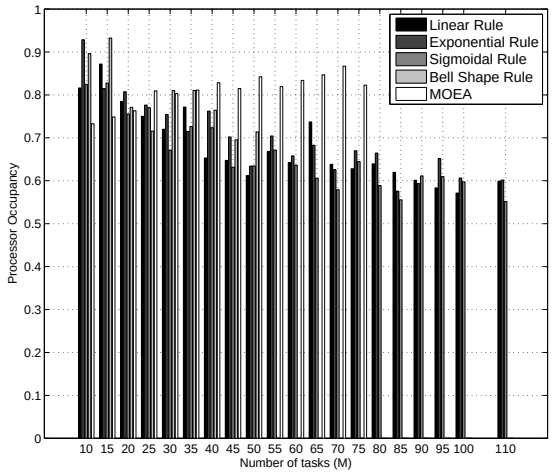

Fig. 6: Processor occupancy for several optimization approaches

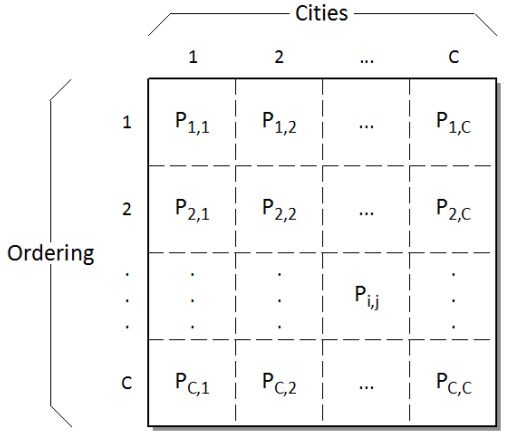

Fig. 8: A PBIL probability array representation for the TSP problem

when compared with the best APBIL algorithms because it does not have an adaptive behavior.

None of the results shown in Figure 4 would be relevant without a comparison between the quality of the solutions obtained with each approach. Figures 5, 6 and 7 show the best solutions found by each optimization algorithm, according to the objectives defined in the previous section. As can be seen, there is no remarkable differences among the PBIL algorithms, although MOEA strategy shows better solutions concerning processor occupancy. However, MOEA's quality concerning the remaining criteria (SP and N) is always poorer than those for PBIL approaches.

For the sake of providing a further insight into the performance of the proposed learning rules, a traveling salesman problem (TSP) optimization algorithm was implemented. TSP is one of the most famous NP-complete problems [24]. Given C cities, the goal is to find a minimum lenght tour which visits each city exactly once. The PBIL array used to represent such an optimization scheme is shown in Figure 8. As can be seen, the PBIL array takes the form of a $C \times C$ probability matrix. In that figure, $P_{i,j}$ represents the probability of visiting city j in the i_{th} place.

Three APBIL approaches were implemented in order to solve TSPs of several sizes. These approaches correspond to the three monotonically-increasing learning rules described before, i.e. linear, sigmoidal and exponential. The TSPs were

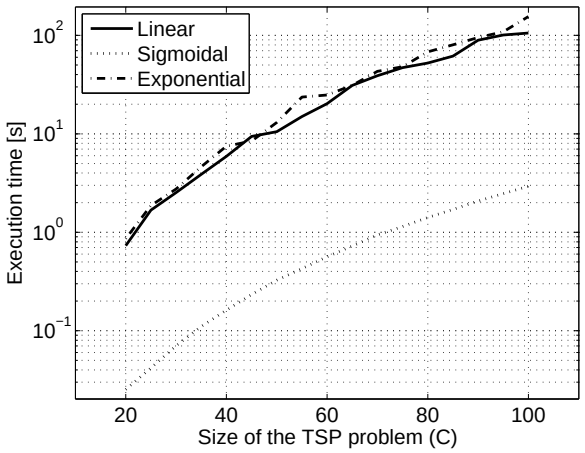

Fig. 9: Execution time for the different TSPs

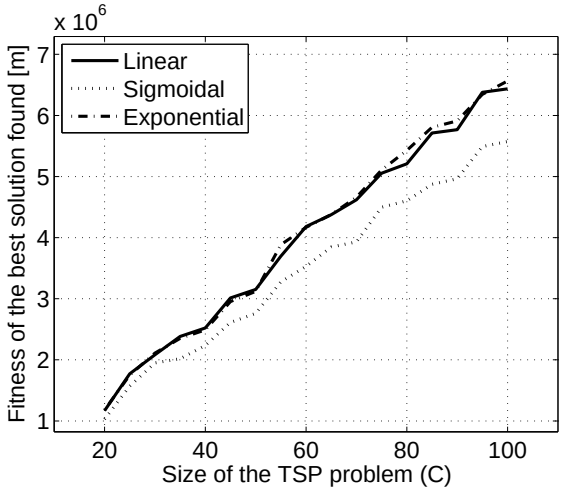

Fig. 10: Total traveled distance for several TSP problems

created by distributing randomly a total of C cities in an area of 10000 square kilometers. In order to assess the quality of the solutions provided by the APBIL search, the total traveled distance by the salesman, measured in meters, was used as a fitness value.

Figure 9 shows the mean convergence times for each APBIL implementation, for different sizes of the TSPs. Again, the only difference among APBIL implementations was the learning rule used to update the LR parameter. The sizes of the TSPs ranges from 20 to 100 cities. As mentioned in [24], complexity of the TSP problem grows very quicly with the value of C, so using larger sizes may be restrictive for simulation.

Figure 9 shows that sigmoidal learning rule has a better performance when compared with linear and exponential rules, for TSP optimization problems. Execution times related with sigmoidal learning rule are always almost an order of magnitud below the remaining alternatives, and such a trend prevails over all the range of the TSP size.

Figure 10 shows the total traveled distance for the three implementations of the APBIL algorithm. As can be seen on that figure, total traveled distance of the solutions obtained from sigmoidal learning rule are up to 16 % below of traveled distance of the remaining approaches.

According to the previous discussion, keeping low values of the LR parameter allows high population's diversity. As can be seen on Figure 2, the sigmoidal learning rule allows high population's diversity at early stages of the exploration process (i.e. when entropy values are near to its maximum). Such diversity avoids the local optimum problem, and then improves the quality of the found solutions. However, as entropy decreases and the algorithm approximates to optimal values, the sigmoidal learning rule increases the LR parameter even more than the other rules, which implies that sigmoidal rule improves exploitation at the end of the process. Such exploitation speeds up the search process, as shown on Figure 10. Figure 2 shows that sigmoidal learning rule is the second one in favoring the exploration at the begining of the search process, and also is the one which most favors the exploitation at the end of the convergence process. Such a combination of features seems to be the reason to explain why sigmoidal learning rule resulted to be both the strategy with best quality as well as the fastest one.

6. Conclusions

An adaptive PBIL strategy has been tested using several learning rules. The monotonically-increasing learning rules have shown promising results in order to speed up the convergence process. The results show that a linear or sigmoidal relationship between the learning rate and the PBIL array's entropy seems to be the best option.

Results derived from the TSP optimization suggest that sigmoidal learning rule is the best approach, in order to speed up the convergence time. However, presented results must be taken as an initial insight, in order to derive the features of the learning rules tested in this paper, which will be intended as future work.

Enhanced MLP Input-Output Mapping for Degraded Pattern Recognition

Shigueo Nomura and José Ricardo Gonçalves Manzan
Faculty of Electrical Engineering, Federal University of Uberlândia, Uberlândia, MG, Brasil

Abstract— *This work proposes a set of approaches for improving the multilayer perceptron (MLP) performance on degraded pattern input-output mapping process. First, differently to the classical one-per-class approach, our strategy calculates Euclidean distances between the MLP output and target vectors. Second, our approach adopts orthogonal bipolar vectors (OBVs) as target values taking advantages of larger Euclidean distance provided by these vectors rather than conventional ones. The proposed approaches were applied to MLP training and test in classifying very degraded patterns as input data. Experimental results with classical approaches in parallel to the proposed ones are presented for MLP performance comparison purposes. The improved MLP with our proposed approaches provided an increase of 9.3 % on degraded pattern recognition rate.*

Keywords: Artificial Neural Networks, Degraded Pattern, Euclidean Distance, Multilayer Perceptron, Pattern Recognition, Target Vector.

1. Introduction

Multilayer perceptron (MLP) has been successfully applied to pattern recognition [1][2][3] tasks. As a classification system, MLP requires a good approach for analyzing degraded image data, extracting features from these data, generating a set of relevant information, and improving its performance. Many efforts have attempted to develop a good method followed by feature extraction systems.

Surprisingly, it is quite difficult to find investigations focusing on output space for the input-output mapping process of MLPs as shown in Fig. 1.

Basically, approaches for the MLP multiclass categorization tasks such as one-per-class based on conventional binary or bipolar target vectors with their dimensions equal to the number of classes are classical.

This work proposes to break away from such classical treatment of the MLP input-output mapping process.

The main objective of this work is to show that the proposed approaches can considerably improve the degraded pattern recognition performance by MLPs.

In summary, the approaches adopt the Euclidean distance-based MLP multiclass categorization and the use of orthogonal bipolar vectors (OBVs) as expectation values for learning.

It is known that MLP performance using bipolar target vectors is already better than performance with binary ones [4], but no other authors' work exists, to our knowledge, adopting the Euclidean distance between OBVs and output vectors.

2. Usual Approaches on Multiclass Categorization

Connectionist algorithms are more difficult to apply to multiclass categorization problems [5]. Multiclass categorization problems [5] correspond to tasks of finding an approximate definition for an unknown function $f(x)$ given training examples of the form $\langle x_i, f(x_i)\rangle$. The unknown function f often takes values from a discrete set of "classes" $c_1, c_2, \ldots, c_k$.

We can distinguish two approaches to handle these multiclass categorization tasks as follows:

- We have one-per-class approach when the individual functions $f_1, f_2, \ldots, f_k$ are learned one for each class. To assign a new case p to one of these classes, each of individual function f_i is evaluated on p, and the case p is assigned the class j corresponding to the function f_j that returns the highest activation [6]. This categorization approach is standard for conventional target vectors.
- Distributed output code is an alternative approach pioneered by Sejnowski and Rosenberg [7] in their widely-known NETtalk system. In this approach, each class is assigned a unique binary string of length n; these strings refer to target vectors in MLP. Then n binary functions are learned, one for each bit position in these binary strings. During training for an example from class i, the desired outputs of these n binary functions are specified by the target vector for class i. With Artificial Neural Networks (ANN), these n functions can be implemented by the n output units of a single network. A new case p is classified by evaluating each of the n binary functions to generate an n-bit string s. This string is then compared to each of the k target vectors, and p is assigned to the class whose target vector is closest, according to some distance measure, to the generated string s.

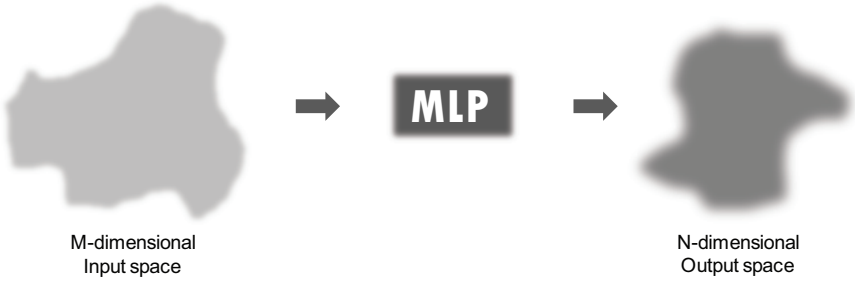

Fig. 1: Input-output mapping process of an MLP.

3. Motivation

An MLP model is trained to learn the nonlinear relationship between M-dimensional input space and N-dimensional output space as shown in Fig. 1. In this way, an incoming unknown input M-dimensional vector is transformed into a N-dimensional one and it can be placed in any point from the space.

The motivation of this work is to improve the MLP multiclass categorization performance as pattern recognition process by transforming an input vector representing a degraded pattern into an output vector representing a class.

The increase of the generalization ability of MLP models leads to their recognition performance improvement. One goal is to find a topology design strategy to provide a network with a higher ability to generalize.

Many traditional investigations have concentrated on improving the representation of input vectors. On the contrary, this work has concentrated on the alternative representation of the desired outputs (OBVs as target vectors) to adjust weights that minimize error during the supervised training process. A purpose is to influence on the multidimensional error-performance surface [8] that is constructed in the supervised training.

Since the categorization based on Euclidean distance adopted in this work depends on the distance between vectors to classify unknown input data, it is expected that the MLP performance improves with the proposed approaches. The orthogonality of new target vectors can provide larger output space rather than conventional vectors. Figure 2 presents high interference zones between pattern categorization subspaces due to the conventional target vectors. On the other hand, we can verify low interference zones between pattern categorization subspaces in Fig. 3 due to the use of new target vectors. Our hypothesis is that the approaches can lead to enhanced MLP input-output mapping even when input is degraded and slightly different from the training examples.

4. Work Proposal

A set of approaches including the input-output mapping process of MLPs based on Euclidean distance measure adopting OBVs as new target vectors is proposed in this work.

According to Dekel and Singer [9], the objective in multiclass categorization problems is to learn a classifier that accurately assigns labels (target vectors) to instances (input vectors) where the set of labels is of finite cardinality and contains more than two elements.

In this MLP application for multiclass categorization, after every presentation of an instance V^* (input vector in M-dimensional space of Fig. 1), the Euclidean distance of the output vector in N-dimensional space was calculated with all labels (target vectors in output space) for each of the classes. The class whose representation by the label had the smallest Euclidean distance with the output vector would be chosen as the "winner" to assign to instance V^*. In addition to the Euclidean distance-based approach, we propose the use of OBVs (defined in the next section) as target vectors.

5. Definition of Vectors

The following defined vectors represent target values used in our experiments for the MLP input-output mapping analysis.

5.1 Conventional Bipolar Vectors (CBVs)

The conventional bipolar vectors (CBVs) with n components for representing p^{th} pattern in n patterns are defined by Eq. (1):

$$V_p = (\overbrace{-1, \ldots, -1}^{p-1}, 1, \overbrace{-1, \ldots, -1}^{n-p})^T, \quad (1)$$

where V_p is the CBV for representing the p^{th} pattern, $p = 1, 2, \ldots, n$, n is the number of patterns or components.

In case of recognition problem for 10 digits, the digit "0" is defined as a 10^{th} digit by Eq. (2):

$$V_0 = (\overbrace{-1, \ldots, -1}^{9}, 1)^T. \quad (2)$$

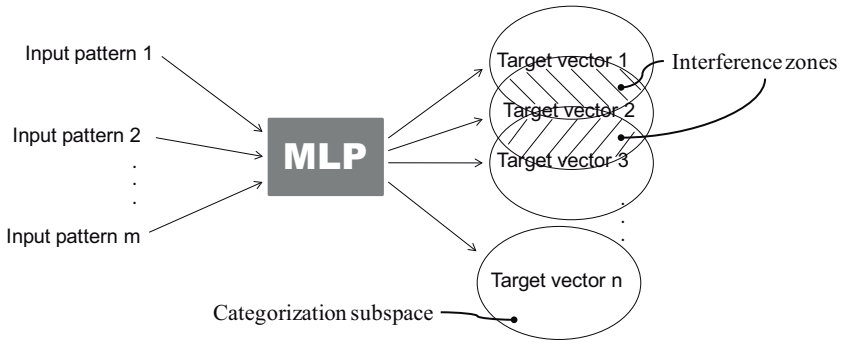

Fig. 2: High interference zones between categorization subspaces in case of using conventional target vectors.

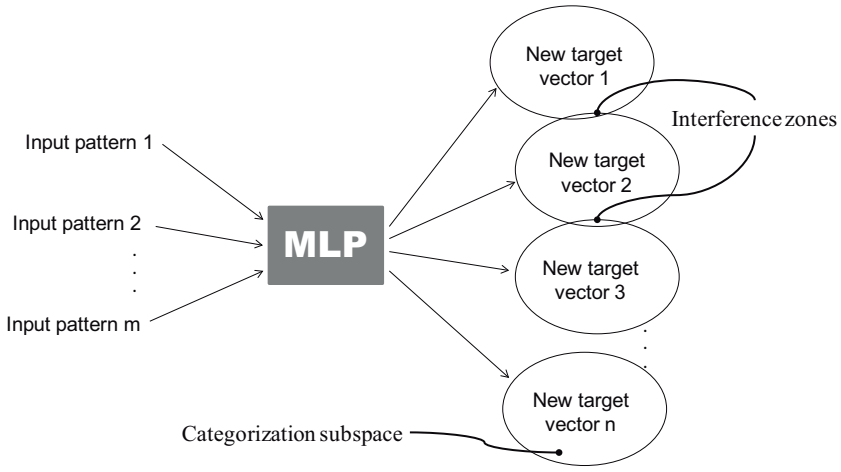

Fig. 3: Low interference zones between categorization subspaces in case of using new target vectors.

5.2 Orthogonal Bipolar Vectors (OBVs)

The norm of an orthogonal bipolar vector (OBV) in an Euclidean space $\mathbb{R}^n$ is given by Eq. (3):

$$|U| = \sqrt{{x_1}^2 + {x_2}^2 + \cdots + {x_n}^2} = \sqrt{n}, \tag{3}$$

where $U = (x_1, x_2, \ldots, x_n)^T$, x_i represents a component $+1$ or -1 for $i = 1, 2, \ldots, n$, and n is the number of components.

The usual inner product [10] between two vectors U and V in an Euclidean space $\mathbb{R}^n$ is defined by Eq. (4):

$$U.V = x_1y_1 + x_2y_2 + \cdots + x_ny_n, \tag{4}$$

where $V = (y_1, y_2, \ldots, y_n)^T$, and y_i represents a component $+1$ or -1 for $i = 1, 2, \ldots, n$, and n is the number of components.

Vectors U and V are orthogonal (denoted by $U \perp V$) if and only if $U.V = 0$ in Eq. (5):

$$U \perp V \Leftrightarrow U.V = 0. \tag{5}$$

A simple algorithm [4][11] can be implemented to generate the OBVs with various numbers of components following the above conditions. Table 1 presents examples of OBVs with 16 components, representing target values for 10 digits, generated by the mentioned algorithm.

6. Experimental Procedure

The modeling procedure of an MLP topology for the input-output mapping process of degraded pattern data as shown in Fig. 4 is presented in this section. The model is to experimentally evaluate the proposed approaches applied to the MLP in degraded pattern recognition tasks.

We have extracted input data from license plate photos automatically taken by traffic control systems of Uberlândia City in Brasil. They were images with such problems as luminosity, contrast, focalization, resolution, and size, all of which required preprocessing able to extract relevant features for pattern recognition process. The original preprocessing methods proposed in such previous works as adaptive contrast enhancement [12], adaptive thresholding [13], automatic segmentation and extraction of feature vectors [14] were used.

Table 1: Examples of OBVs with 16 components.

Digit	*OBV*
"1"	(1, -1, -1, 1, -1, 1, 1, -1, -1, 1, 1, -1, 1, -1, -1, 1)

"0"	(1, 1, -1, -1, -1, -1, 1, 1, 1, 1, -1, -1, -1, -1, 1, 1)

6.1 Data Representation

A two-dimensional set of pixels that represents a pattern is mapped onto an input vector as a set of input neurons. For a 20×15 image of each segmented pattern, the top row of 20 pixels is associated with the first 20 neurons, the next row of 20 pixels is associated with the next 20 neurons, and so on. So, segmented entities (20×15) are represented by feature vectors with 300 components, and each component in the vector should represent one pixel of the pattern (bipolar value $+1$) or one pixel of the image background (bipolar value -1).

Figure 4 shows the 120-image training set representing digits as input data.

In this work, the adopted data representation is bipolar since the categorization may be improved if the input is represented in bipolar form and the bipolar sigmoid is used for the activation function [4]. The reason is if one factor in the weight connection expression is the activation of the lower unit then units whose activations are null will not learn [4].

6.2 MLP Topology for Experiments

The adopted multilayer neural network in our experiments consists of the architecture with one layer of hidden neurons.

There are several propositions how to determine the necessary number of hidden neurons for a given problem but they yield contradictory results and have no practical utility [15].

Some heuristic rules [15] used to obtain the MLP topology for experiments are as follows:

- To reduce the number of hidden neurons when the network does not generalize, that is, the error of the output data during the training is small and the error in the test stage is large.
- To increase the number of hidden neurons when the error during the training is large or all the weights for the connections between neurons are of the same order of magnitude.

In degraded images, the input data contain redundant information which can not be removed by a suitable coding. These spurious data can be removed when the hidden layer contains less neurons than the input layer [15].

In summary, without further information there is no foolproof method for setting the exact number of hidden neurons before training stage [4].

Such usual strategies in ANN [8] as one parameter keeping and the variation of remaining parameters defined the appropriate topology of MLP. Conventional experiments get adequate topology for classifying input digits (20×15) represented by the 300-dimensional feature vectors. Our experimental MLP model consists of 300 neurons in the input layer. The adequate number of neurons in the hidden layer is set according to each experiment. The number of neurons in the output layer is defined by the target vector type or its size selected for each experiment.

6.3 Training Stage

The standard backpropagation algorithm [4] is used as the training algorithm of each MLP model. Since all experimental target vectors are bipolar, the adopted activation function is the typical bipolar sigmoid [4], which has a range of $(-1, 1)$. Initial weights are generated as random values between -0.25 and 0.25. The learning rate parameter is set as 0.02. The stop criterion for the training algorithm is to require that the maximum value of the average squared error be equal to or less than the tolerance as indicated within each graph of Figs. 5–7.

Training data set is constituted by 120 pattern-images not belonging to the test data set. It contains input patterns for the MLP model training to classify digits extracted from license plates into ten categories. Each category is represented by 12 input patterns.

6.4 Test Stage

The classification rate is calculated by Eq. (6):

Fig. 4: A sample of 120 degraded patterns used as input data for the MLP training.

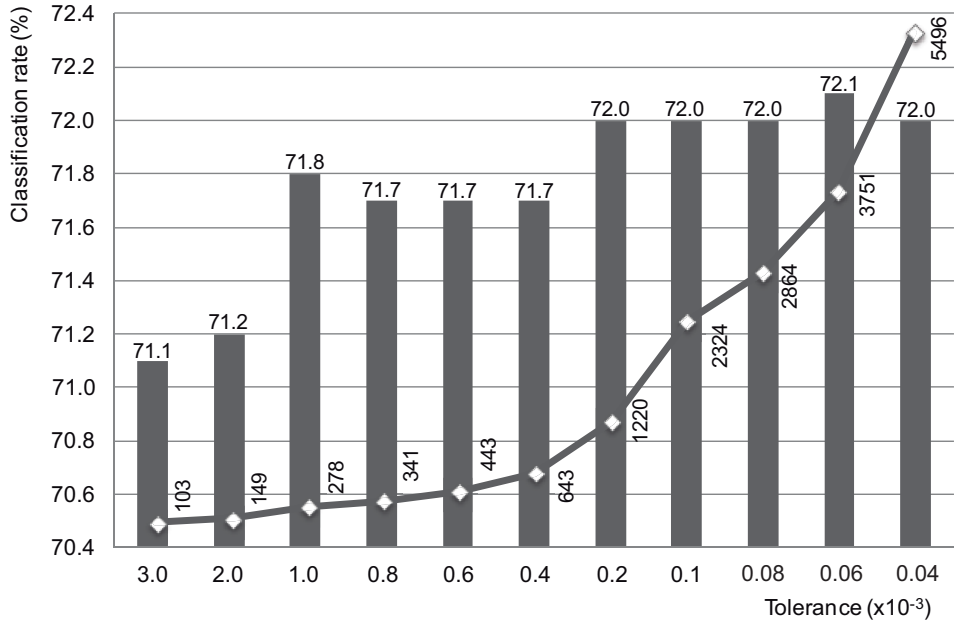

Fig. 5: MLP performance using classical one-per-class approach. The line denotes the epoch quantity evolution.

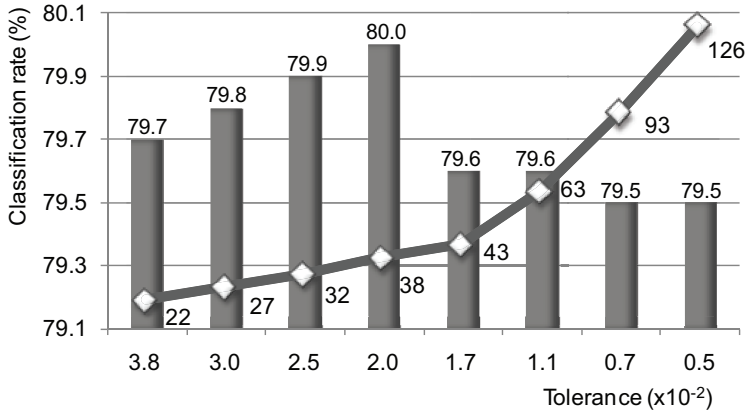

Fig. 6: MLP performance using OBVs with 16 components as target vectors. The line denotes the epoch quantity evolution.

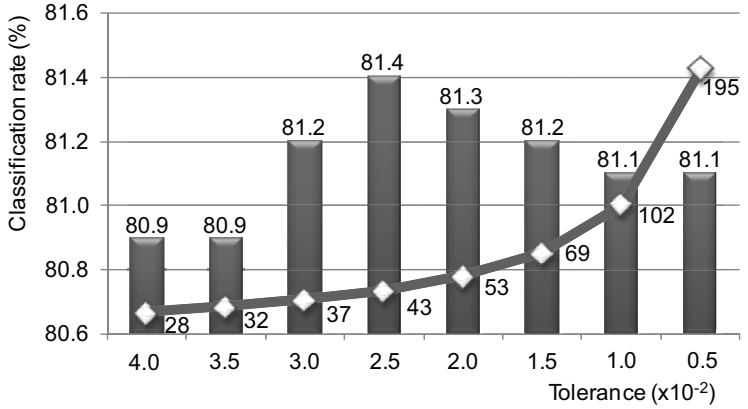

Fig. 7: MLP performance using OBVs with 64 components as target vectors. The line denotes the epoch quantity evolution.

$$cr = \frac{\sum_i^N c_i}{N}, \tag{6}$$

where cr is classification rate, N is number of test patterns, and c_i is defined as

$$c_i = \begin{cases} 1 & : \quad p_i = r_i \\ 0 & : \quad p_i \neq r_i \end{cases}, \tag{7}$$

where p_i is a classified pattern (output of the MLP model), and r_i is the corresponding category (correct response).

Test data set consisted of 1352 images containing the digits "0","1",...,"9" extracted from license plates after their preprocessing [12][13][14][16]. A trained MLP model was applied to classify those extracted digits into ten categories.

7. Experiments and Results

The experiments consisted of using CBVs and OBVs defined in Section 5 as target vectors.

We have evaluated the influence of Euclidean distance-based approach on MLP training and classification performance improvement using various target vectors.

In other words, the experiments compared the proposed Euclidean distance-based approach with the classical one-per-class categorization approach in terms of influence on MLP performance.

An MLP model with a topology of 100 hidden neurons and 10 output neurons was trained and tested using CBVs for one-per-class approach.

Figure 5 shows the MLP classification performance applying one-per-class approach for the use of CBVs as target vectors.

To evaluate the influence of using OBVs as target vectors on the MLP input-output mapping process, we have performed the following tasks:

- MLP model training for OBVs as target vectors. Different topologies according to the OBV sizes (16 or 64 components) were defined.

Table 2: Relevant results from the graphs of Figs. 5–7

Target vector type	*Categorization approach*	*Maximum rate* %
CBV	One-per-class	72.10
OBV-16	Euclidean distance-based	80.00
OBV-64	Euclidean distance-based	81.40

- Application of the Euclidean distance-based approach for the above trained MLP models. The experimental results using OBVs with 16 and 64 components, are respectively shown in Figs. 6 and 7.

8. Discussion

The graph in Fig. 5 shows that the classification rate of 72.1% is provided by the MLP model trained for 3751 epochs with the one-per-class categorization approach. Figures 6–7 show the results from the use of OBVs as target values.

Table 2 presents the highest classification rate per target vector type and categorization approach. We can note that the classification rate was increased of 9.3% by using Euclidean distance-based approach and OBVs as target values.

Considering the advantage of adopting the Euclidean distance-based categorization approach, we can verify that the MLP performance improved more and more with the use of OBVs rather than conventional target vectors.

9. Conclusion

A set of approaches to improve the MLP performance on degraded pattern recognition searching for more generalized and well-trained model was proposed. Basically, the Euclidean distance-based approach was combined to the use of OBVs as new target vectors for the MLP training and test with very degraded pattern data.

We compared the experimental results applying the proposed approaches with the results applying the classical one-per-class approach. Comparison results showed that the proposed approaches considerably improved (increase of 9.3% on classification rate) the MLP performance on degraded pattern recognition tasks.

In summary, we realized that the proposed approaches led to higher classification rate of very degraded pattern data by MLPs compared to the classical one-per-class approach.

In terms of degraded pattern recognition performance, we have gotten an enhanced MLP input-output mapping with the proposed Euclidean distance-based approach using OBVs as new target vectors.

Estimation of Phoneme Probabilities for Bangla Automatic Speech Recognition

Mohammed Rokibul Alam Kotwal, Afsana Hamid and Mohammad Nurul Huda
Department of Computer Science and Engineering, United International University, Dhaka, Bangladesh

Abstract - *This paper estimates Bangla phoneme probabilities using a neural network-based method for Automatic Speech Recognition (ASR). The method consists of three stages: i) a multilayer neural network (MLN), which converts acoustic features, mel frequency cepstral coefficients (MFCCs), into phoneme probabilities, ii) the phoneme probabilities obtained from the first stage and corresponding velocity (Δ) and acceleration (ΔΔ) parameters calculated by linear regression (LR) are inserted into another MLN, and iii) the phoneme probabilities obtained from the second stage and corresponding Δ and ΔΔ parameters are inserted into a hidden Markov model (HMM) based classifier to obtain more accurate phoneme strings. From the experiments on Bangla speech corpus prepared by us, it is observed that the proposed method provides higher phoneme recognition performance than the other investigated methods. Moreover, it requires a fewer mixture components in the HMMs*.

1 Introduction

A new vocabulary word or out-of-vocabulary (OOV) word often causes an "error" or a "rejection" in current hidden Markov model (HMM)-based automatic speech recognition (ASR) systems. To resolve this OOV-word problem, an accurate phonetic typewriter or phoneme recognizer functionality is expected [1-3].

There have been many literatures on phoneme recognition for ASR systems for almost all the major spoken languages in the world. Unfortunately, only a very few works have been done in ASR for Bangla (can also be termed as Bengali), which is one of the largely spoken languages in the world. More than 220 million people speak in Bangla as their native language. It is ranked sixth based on the number of native speakers [4]. A major difficulty to research in Bangla ASR is the lack of proper speech corpus. Some efforts are made to develop Bangla speech corpus to build a Bangla text to speech system [5]. However, this effort is a part of developing speech databases for Indian languages, where Bangla is one of the parts and it is spoken in the eastern area of India (West Bengal and Kolkata as its capital). But most of the natives of Bangla (more than two thirds) reside in Bangladesh, where it is the official language. Although the written characters of standard Bangla in both the countries are same, there are some sound that are produced variably in different pronunciations of standard Bangla, in addition to the myriad of phonological variations in non-standard dialects [6]. Therefore, there is a need to do research on the main stream of Bangla, which is spoken in Bangladesh, ASR.

Recognition of Bangla phonemes by Artificial Neural Network (ANN) is reported in [7-8]. However, most of these works are mainly concentrated on simple recognition task on a very small database, or simply on the frequency distributions of different vowels and consonants. Besides, the methods provided in [7-8] uses a multilayer neural network (MLN) in their architecture. Because a single MLN has an inability of resolving coarticulation effect [9], the phoneme recognition methods do not provide higher phoneme recognition performance.

In this paper, we build a Bangla phoneme recognition system for an ASR in a large scale. For this purpose, we first develop a medium size (compared to the exiting size in Bangla ASR literature) Bangla speech corpus comprises of native speakers covering almost all the major cities of Bangladesh. Then, mel-frequency cepstral coefficients (MFCCs) of 39 dimensions are extracted from the input speech. The method consists of three stages: i) a multilayer neural network (MLN), which converts acoustic features, mel frequency cepstral coefficients (MFCCs), into phoneme probabilities, ii) the phoneme probabilities obtained from the first stage and corresponding velocity (Δ) and acceleration (ΔΔ) parameters calculated by linear regression (LR) are inserted into another MLN, and iii) the phoneme probabilities obtained from the second stage and corresponding Δ and ΔΔ parameters are inserted into a hidden Markov model (HMM) based classifier to obtain more accurate phoneme strings. The incorporation of dynamic parameters, Δ and ΔΔ, resolves coarticulation effect and consequently, increases the phoneme recognition performance. The originality of this paper is incorporation of second MLN with dynamic parameters. For evaluating Bangla phoneme correct rate (PCR) and phoneme accuracy (PA), we have designed three experiments: (i) MFCC+MLN, (ii) MFCC+MLN+ Δ, (iii) MFCC+MLN+Δ.ΔΔ, (iv) MFCC+MLN+MLN, (v) MFCC+MLN+MLN+Δ, (vi) MFCC+MLN+MLN+Δ.ΔΔ, (vii) MFCC+MLN+ Δ.ΔΔ +MLN, (viii) MFCC+MLN+Δ.ΔΔ+MLN+Δ, (ix) MFCC+MLN+Δ.ΔΔ+MLN+ Δ.ΔΔ.

The paper is organized as follows. Section 2 briefly describes approximate Bangla phonemes with its corresponding phonetic symbols; Section 3 explains about Bangla speech corpus; Section 4 provides a brief description about existing and our proposed methods, while Section 5 gives experimental setup. Section 6 explicates the experimental results and discussion, and finally, Section 7 draws some conclusions and remarks on the future works.

2 Phonetic Symbols for Bangla Phonemes

Bangla phonetic inventory consists of 8 short vowels (অ, আ, ই, উ, এ, ঐ, ও, ঔ) excluding long vowels (ঈ, ঊ) and 29 consonants. Table 1 shows Bangla vowel phonemes with their corresponding International Phonetic Alphabet (IPA) and our proposed symbols. On the other hand, the consonants, which are used in Bangla language, are presented in Table 2. Here, the Table exhibits the same items for consonants like as Table 1. In Table 2, the pronunciation of /শ/, /ষ/ and /স/ are same by considering the words বিশ (/biʃ /), বিষ (/bi ʃ /) and ডিস (/ɖ i ʃ /) respectively, which is shown in Fig. 1. Here the meanings of বিশ, বিষ and ডিস are English language "twenty (20)", "poison" and "bowl" respectively. On the other hand, in the words জাম (/dʒam/) and যাক (/dʒak/), there is no difference between the pronunciation of /জ/ and /য/ respectively that depicted in Fig. 2. Here the meanings of জাম and যাক are English language "black berry" and "go" respectively. Again, Fig. 3 shows that there is no difference between /ণ/ and /ন/ in the words হরিণ (/hɾ in/) and নাতিন (/natin/) respectively. Here the meanings of হরিণ and নাতিন are English language "deer" and "grand daughter" respectively. Moreover, phonemes /ড়/ and /ঢ়/ carry same pronunciation in the words পাহাড় (/pahaɽ /) and আষাঢ় (/aʃ aɽ /) respectively, which is shown in the Fig. 4. Here the meanings of পাহাড় and আষাঢ় are English language "hill" and "rainy season" respectively.

Initial consonant cluster is not allowed in the native Bangla: the maximum syllable structure is CVC (i.e. one vowel flanked by a consonant on each side) [10]. Sanskrit words borrowed into Bangla possess a wide range of clusters, expanding the maximum syllable structure to CCCVC. English or other foreign borrowings add even more cluster types into the Bangla inventory.

3 Bangla Speech Corpus

A real problem to do experiment on Bangla word ASR is the lack of proper Bangla speech corpus. In fact, such a corpus is not available or at least not referenced in any of the existing literature. Therefore, we develop a medium size Bangla speech corpus, which is described below.

Hundred sentences from the Bengali newspaper "Prothom Alo" [11] are uttered by 30 male speakers of different regions of Bangladesh. These sentences (30x100) are used for training corpus (D1). On the other hand, different 100 sentences from the same newspaper uttered by 10 different male speakers (total 1000 sentences) are used as test corpus (D2). All of the speakers are Bangladeshi nationals and native speakers of Bangla. The age of the speakers ranges from 20 to 40 years. We have chosen the speakers from a wide area of Bangladesh: Dhaka (central region), Comilla – Noakhali (East region), Rajshahi (West region), Dinajpur – Rangpur (North-West region), Khulna (South-West region), Mymensingh and Sylhet (North-East region). Though all of them speak in standard Bangla, they are not free from their regional accent.

Recording was done in a quiet room located at United International University (UIU), Dhaka, Bangladesh. A desktop was used to record the voices using a head mounted close-talking microphone. We record the voice in a place, where ceiling fan and air conditioner were switched on and some low level street or corridor noise could be heard.

Jet Audio 7.1.1.3101 software was used to record the voices. The speech was sampled at 16 kHz and quantized to 16 bit stereo coding without any compression and no filter is used on the recorded voice.

4 Phoneme Recognition Methods

4.1 Existing Method

At the acoustic feature extraction stage, input speech is converted into MFCCs of 39 dimensions (12-MFCC, 12-ΔMFCC, 12-ΔΔMFCC, P, ΔP and ΔΔP, where P stands for raw log energy of the input speech signal). Fig. 5 shows the phoneme recognition method using MLN [8] which comprises two stages: i) MFCCs are inputted to an MLN with three layers, including 2 hidden layers, after combining preceding (t-3)-th and succeeding (t+3)-th frames with the current t-th frame and ii) the phoneme probabilities obtained from the first stage and corresponding Δ and ΔΔ parameters calculated by LR are inserted into a hidden Markov model (HMM) based classifier to obtain more accurate phoneme strings. The MLN has 39 output units (total 39 monophones) of phoneme probabilities for the current frame t. The two hidden layers consist of 300 and 100 units, respectively. The MLN is trained by using the standard back-propagation algorithm. This method yields comparable recognition performance. However, the single MLN suffers from an inability to model dynamic information precisely.

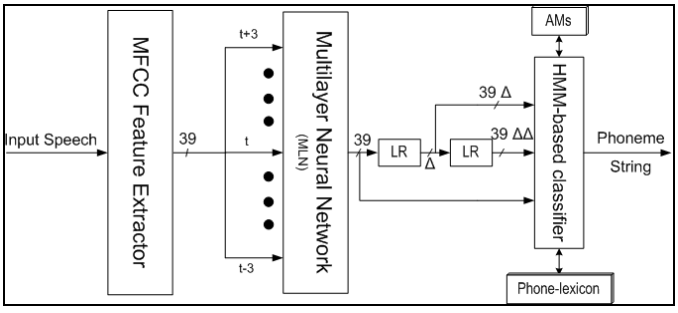

Figure 5: Existing Phoneme Recognition Method.

4.2 Proposed Method

Fig. 6 shows the phoneme recognition method using MLN which comprises three stages: i) MFCCs are inputted to an MLN with three layers, including 2 hidden layers, after combining preceding (t-3)-th and succeeding (t+3)-th frames with the current t-th frame, ii) the phoneme probabilities obtained from the first stage and corresponding velocity (Δ) and acceleration (ΔΔ) parameters calculated by 3-point linear regression (LR) are inserted into another MLN and iii) the phoneme probabilities obtained from the second stage and corresponding Δ and ΔΔ parameters calculated by 3-point LR are inserted into a hidden Markov model (HMM) based classifier to obtain more accurate phoneme strings. The architecture of first MLN and its learning method is similar to the method described in Section IV A. The 39 dimensional output probabilities obtained by the first MLN and corresponding Δ and ΔΔ (39x3) are inserted into the second MLN, which consists of four layers: three hidden and one output layers. The hidden layers are of 400, 200, and 100 units, respectively from the input layer side, while the output layer is of 39 dimensions of phoneme probabilities. The second MLN is also trained by the standard back-propagation algorithm. This method yields higher recognition performance in comparison with the method describe in Section IV A.

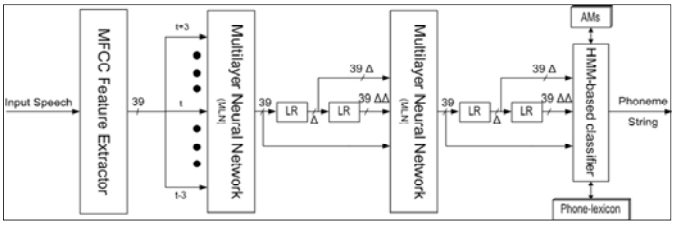

Figure 6: Proposed Phoneme Recognition Method.

5 Experimental Setup

The frame length and frame rate (frame shift between two consecutive frames) are set to 25 ms and 10 ms, respectively, to obtain acoustic features (MFCCs) from an input speech. MFCC comprised of 39 dimensional (12-MFCC, 12-ΔMFCC, 12-ΔΔMFCC, P, ΔP and ΔΔP, where P stands for raw log energy of the input speech signal).

For designing an accurate phoneme recognizer, PCR and PA for D2 data set are evaluated using an HMM-based classifier. The D1 data set is used to design 39 Bangla monophone (8 vowels, 29 consonant, sp, sil) HMMs with five states, three loops, and left-to-right models. Input features using the methods (i), (iv) and (vii); (ii), (v) and (viii); (iii), (vi) and (ix) are 39, 78 and 117 dimensions, respectively. In the HMMs, the output probabilities are represented in the form of Gaussian mixtures, and diagonal matrices are used. The mixture components are set to 1, 2, 4, 8, 16 and 32. In our experiments of the MLN, the non-linear function is a sigmoid from 0 to 1 (1/(1+exp(-x))) for the hidden and output layers.

To obtain the PCR and PA we have designed the following experiments:

(i) MFCC+MLN <39 dim>

(ii) MFCC+MLN+ Δ <78 dim>

(iii) MFCC+MLN+Δ.ΔΔ <117dim>

(iv) MFCC+MLN+MLN <39 dim>

(v) MFCC+MLN+MLN+Δ <78 dim>

(vi) MFCC+MLN+MLN+Δ.ΔΔ <117dim>

(vii) MFCC+MLN+Δ.ΔΔ+MLN <39 dim>

(viii) MFCC+MLN+Δ.ΔΔ+MLN+Δ <78 dim>

(ix) MFCC+MLN+Δ.ΔΔ+MLN+Δ.ΔΔ <117dim> [Proposed].

6 Experimental Results And Discussion

Figs. 7 and 8 show the PCR and PA respectively for the investigated methods using training data set D1. It is shown from the figures that the proposed method provides a higher phoneme recognition performance than the other methods investigated. For an example, at 32 mixture component, the method (iii) shows 70.78% PCR, while the methods, (i) and (ii) exhibit 67.75% and 70.37% PCRs, respectively. On the other hand, at the same mixture component, the accuracies of the methods (i), (ii) and (iii) are 52.98%, 59.95% and 61.31%, respectively.

On the other hand, the PCR and PA for test data, D2 are shown in the Figs. 9 and 10, respectively for the investigated methods. The method, (iii) outperformed the other methods for both the evaluations (PCR and PA) in the mixture components 2, 4, 8, 16 and 32. It is noted from the mixture component 32 of the Fig. 10 that the method (iii) having 54.66% accuracy shows its better recognition performance over the accuracies of other methods.

The reason for providing better result by the method (iii) is Δ and ΔΔ (dynamic parameters), while the existing method (i) contains no dynamic parameters. On the other hand, the second investigated method, (ii) embeds only velocity coefficient (Δ) which embeds a context window of wider size and consequently, provides a higher recognition performance than the existing method (i). Since the proposed method incorporates both velocity (Δ) and acceleration coefficients (ΔΔ), it shows better performance than the method (ii).

Tables 3 and 4 shows the PCR and PA respectively for the investigated methods incorporating using training data set D1. It is shown from the figures that the proposed method

provides a higher phoneme recognition performance than the other methods investigated. For an example, at 32 mixture component, the method (vi) shows 69.72% PCR, while the methods, (iv) and (v) exhibit 68.18% and 69.28% PCRs, respectively. On the other hand, at the same mixture component, the accuracies of the methods (iv), (v) and (vi) are 58.21%, 62.65% and 63.50%, respectively.

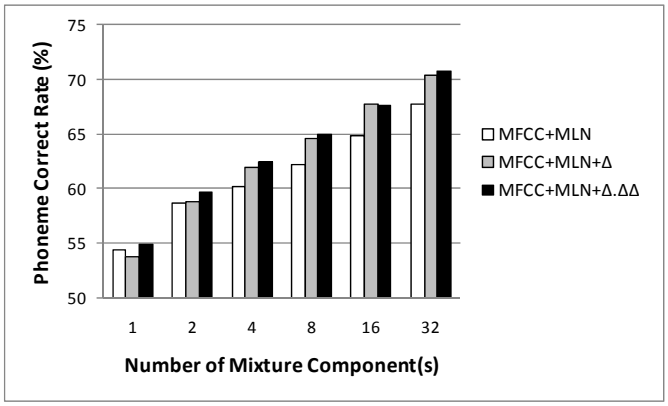

Figure 7: Phoneme correct rate for training data using methods (i), (ii) and (iii).

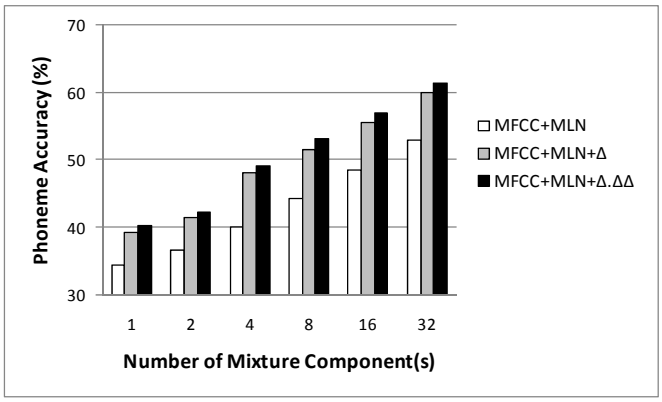

Figure 8: Phoneme accuracy for training data using methods (i), (ii) and (iii).

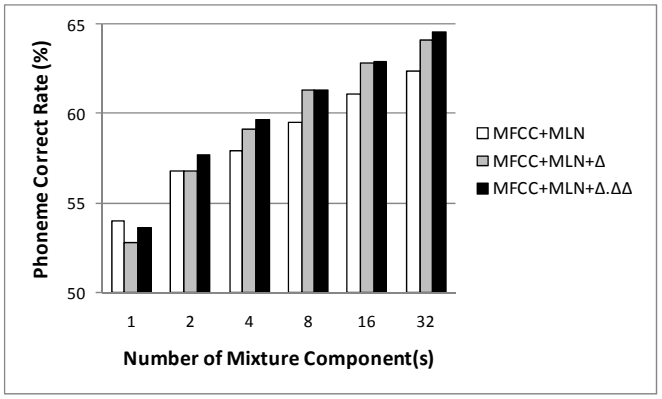

Figure 9: Phoneme correct rate for test data using methods (i), (ii) and (iii).

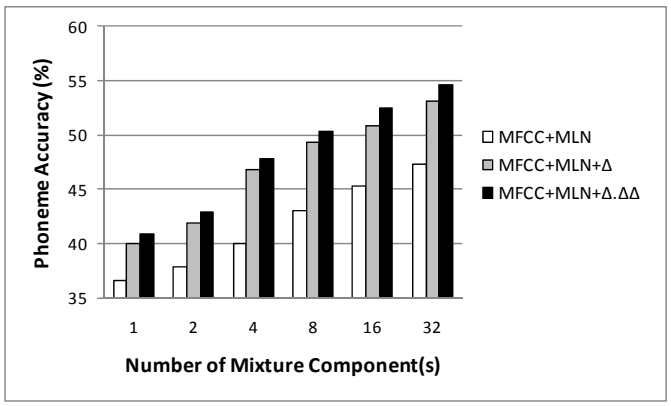

Figure 10: Phoneme accuracy for test data using methods (i), (ii) and (iii).

Table 3: Phoneme correct rate for training data using methods (iv), (v) and (vi)

Methods	Phoneme Correct Rate (%)					
	1 Mix	2 Mix	4 Mix	8 Mix	16 Mix	32 Mix
(iv) MFCC+MLN+MLN	53.28	57.77	60.81	63.03	65.85	68.18
(v) MFCC+MLN+MLN+Δ	53.23	57.81	61.67	64.23	66.41	69.28
(vi) MFCC+MLN+MLN+Δ.ΔΔ	54.76	59.85	61.94	64.21	66.72	69.72

Table 4: Phoneme accuracy for training data using methods (iv), (v) and (vi)

Methods	Phoneme Accuracy (%)					
	1 Mix	2 Mix	4 Mix	8 Mix	16 Mix	32 Mix
(iv) MFCC+MLN+MLN	41.78	43.47	47.83	50.92	54.65	58.21
(v) MFCC+MLN+MLN+Δ	44.04	47.56	52.30	56.13	58.91	62.65
(vi) MFCC+MLN+MLN+Δ.ΔΔ	45.54	48.93	52.48	55.78	59.71	63.50

Again, the PCR and PA for test data, D2 are shown in the Tables 5 and 6, respectively for the investigated methods. The method, (vi) outperformed the other methods for both the evaluations (PCR and PA) in all the mixture components. It is noted from the mixture component 32 of the Table 6 that the method (vi) having 63.50% accuracy shows its better recognition performance over the other methods accuracies.

Figs. 11 and 12 show the PCR and PA respectively incorporating Δ and ΔΔ parameters at second MLN for the investigated methods using training data set D1. It is shown from the figures that the proposed method provides a higher phoneme recognition performance than the other methods investigated. For an example, at 32 mixture component, the method (ix) shows 70.33% PCR, while the methods, (vii) and (viii) exhibit 68.78% and 70.05% PCRs, respectively. On the other hand, at the same mixture component, the accuracies of the methods (vii), (viii) and (ix) are 57.80%, 62.31% and 63.09%, respectively.

Table 5: Phoneme correct rate for test data using methods (iv), (v) and (vi)

Methods	Phoneme Correct Rate (%)					
	1 Mix	2 Mix	4 Mix	8 Mix	16 Mix	32 Mix
(iv) MFCC+MLN+MLN	51.79	55.71	58.36	60.03	61.85	62.69
(v) MFCC+MLN+MLN+Δ	50.96	55.48	58.90	60.90	62.30	63.65
(vi) MFCC+MLN+MLN+Δ.ΔΔ	52.26	57.09	59.03	61.06	62.49	64.46

Table 6: Phoneme accuracy for test data using methods (iv), (v) and (vi)

Methods	Phoneme Accuracy (%)					
	1 Mix	2 Mix	4 Mix	8 Mix	16 Mix	32 Mix
(iv) MFCC+MLN+MLN	41.78	43.47	47.83	50.92	54.65	58.21
(v) MFCC+MLN+MLN+Δ	44.04	47.56	52.30	56.13	58.91	62.65
(vi) MFCC+MLN+MLN+Δ.ΔΔ	45.54	48.93	52.48	55.78	59.71	63.50

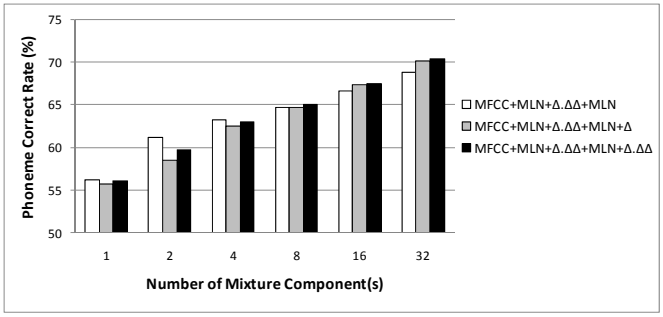

Figure 11: Phoneme correct rate for training data using methods (vii), (viii) and (ix).

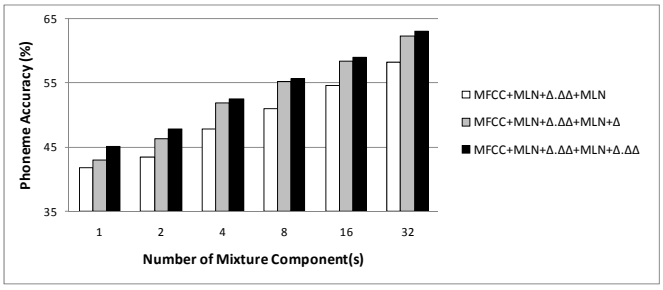

Figure 12: Phoneme accuracy for training data using methods (vii), (viii) and (ix).

Moreover, the PCR and PA for test data, D2 are shown in the Figs. 13 and 14, respectively for the investigated methods. The method, (ix) outperformed the other methods for phoneme accuracy evaluations for all mixture components. It is noted from the mixture component 32 of the Fig. 14 that the method (ix) having 56.21% accuracy shows its better recognition performance over the other methods accuracies.

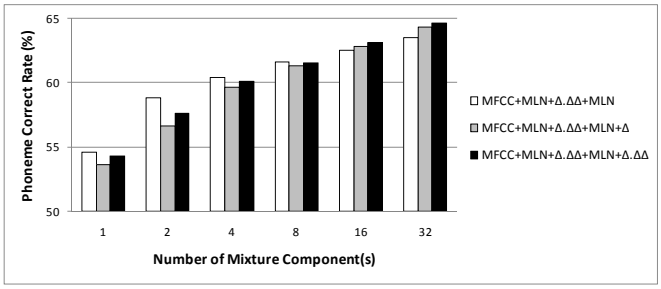

Figure 13: Phoneme correct rate for test data using methods (vii), (viii) and (ix).

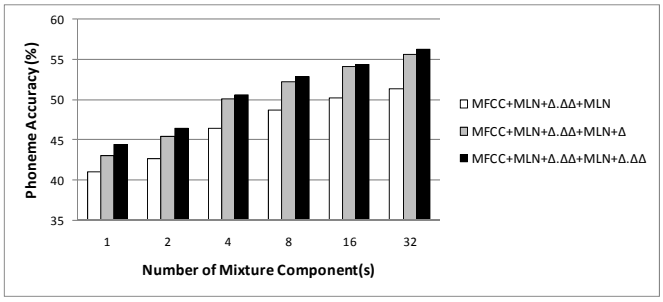

Figure 14: Phoneme accuracy for test data using methods (vii), (viii) and (ix).

7 Conclusion

In this paper, we proposed a Bangla phoneme recognition method incorporating two stage multilayer neural networks with dynamic parameters. The following conclusions are drawn from the study:

(i). The proposed method provides higher phoneme correct rate and phoneme accuracy than the other methods investigated for the both training (D1) and test (D2) data sets.

(ii). The proposed method requires a fewer mixture components in the HMMs.

(iii). The incorporation of second MLN over first MLN increases phoneme recognition performance.

(iv). The dynamic parameters used in the second MLN as input improves recognition rate.

(v). The significant improvement of recognition rate is obtained by inserting dynamic parameters, Δ and ΔΔ to the HMM based classifier.

The authors would like to evaluate phoneme recognition performance using recurrent neural network in near future. Moreover, word recognition rate based on triphone HMM model using the phoneme probabilities obtained from the two MLNs will be investigated.

Knowledge Binary Information Fragment Encoding for AI System Memories

James A. Crowder and John N. Carbone
Raytheon Intelligence and Information Systems
16800 E. Centretech Parkway, Aurora, Colorado 80011

Abstract - *Memories involve the acquisition, categorization, classification and storage of information. The purpose of memory is to provide the ability to recall information and knowledge as well as events. We base our current understanding of the world around us on what we have previously learned, and chosen to store. Everything that we do in the present relies on memories of what has happened, or what has been learned in the past, unless new memories must be created for a new experience/ information. Without our memories, we would not be able to go through day-to-day living, using abstract thought and performing the most basic functions. Without memories we wouldn't be able to drive a car, brush our teeth, or perform any of the things we do "without thinking about them." Through our conceptual recollection of the past we are able to communicate with other people. However, the human brain does not store files in neat folders or in relational databases, but instead stores information as fragments that are used to construct memories when needed. Hence, we propose a binary information fragment encoding system for use in artificial intelligence systems that can be utilized to create a combined sensory perceptive, short-term, and long-term memory system similar to how the human brain dynamically stores and recalls (reconstructs) memories.*

Keywords: Artificial Intelligence, Artificial Memories

1. Introduction: Artificial Neural Memories

In order to design, develop, and implement an Artificially Intelligent System (AIS) to be truly autonomous, it must be provided with dynamic memory abilities (Crowder 2010a). Memories are typically classified into three different types: Sensory, Short-Term, and Long-Term (Miller 2002, Newell 2003). Each memory type has several instantiations, dealing with different types of information. Here we will explore each type of memory system and its implications to the AIS. We begin our discussion of memory types with a look at the relationships between the three main types of memories. Figure 1 illustrates an AIS Memory Upper Ontology, similar to human memory systems, describing these relationships (Eichenbaum 2002).

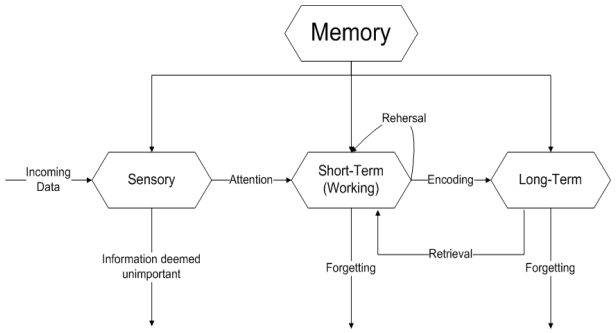

Figure 1 – AIS Memory Upper Ontology

1.1 Sensor Memories

The Sensory Memory within the AIS memory system are those memory registers where raw, unprocessed information ingested via AIS environmental sensors and are buffered to begin initial processing. The *AIS* sensory memory system has a large capacity to accommodate large quantities of possibly disparate and diverse information from a variety of sources (Crowder 2010). And although it has a large capacity, it has a short duration. The information that is buffered in this sensory memory must be sorted, categorized, turned into information fragments, metadata, contextual threads, and attributes (including emotional attributes) and then sent on to the working memory (Short-Term Memory) for initial cognitive processing. This cognitive processing is

known as Recombinant Knowledge Assimilation (RNA), where raw information content is discovered from the information domain, decomposed & reduced, compared, contrasted, and associated into new relationship threads within a temporary working knowledge domain and subsequently normalized into pedigree within the knowledge domain for future use (Carbone 2010). Hence, based upon the information gathered in initial Sensory Memory processing, Cognitive Perceptrons, manifested as Intelligence information Software Agents (ISAs), are spawned, as in relative size swarms, to create initial "thoughts" about the data. Subsequently, hypotheses are generated by the ISAs. The thought process information, along with the ISA sensory information are then sent to a working memory region which will alert the artificial cognition processes within the AIS to begin processing. (Crowder and Friess 2010a&b). Figure 2 illustrates the Sensory Memory Lower Ontology.

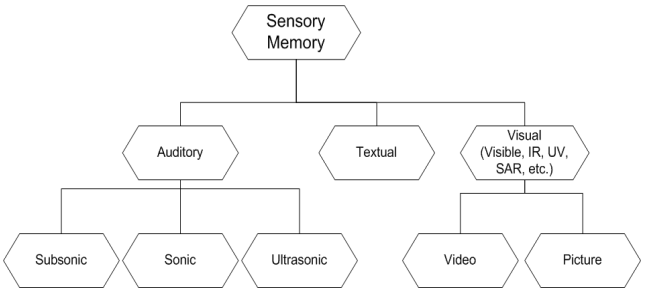

Figure 2 – Sensory Memory Lower Ontology

1.2 Short-Term Artificial Memories

Short-Term or "Working" memory within the AIS is where new information is transitionally stored in a Temporary Knowledge Domain (Carbone 2010) while it is being processed into new Knowledge. This follows the paradigm that information content has no value until it is thought about (Brillouin 2004). Short-Term memory is where most of the reasoning within the AIS happens. Short-Term memory (STM) provides a major functionality, called "rehearsals" that allows the AIS to continually refresh, or rehearse, the Short-Term memories while they are being processed and reasoned about, so that memories do not degrade until they can be sent on to Long-Term Memory and acted upon by the artificial consciousness processes within the AIS's cognitive framework (Crowder and Carbone 2011a). It should be noted that Short-Term memory is much smaller in relative space needed to process information content as compared to long term memory. Short-Term memory should be perceived not necessarily as a physical location, as in the human brain, but rather as a rapid and continuous processing of information content relative to a specific AIS directive or current undertaking. One must remember that the Short-Term memory which includes all external and internal sensory inputs will trigger a rehearsal if the AIS discovers a relationship to either a previously interred piece of information content in short or long term memory. Figure 3 illustrates the Short-Term Memory Lower Ontology for the AIS.

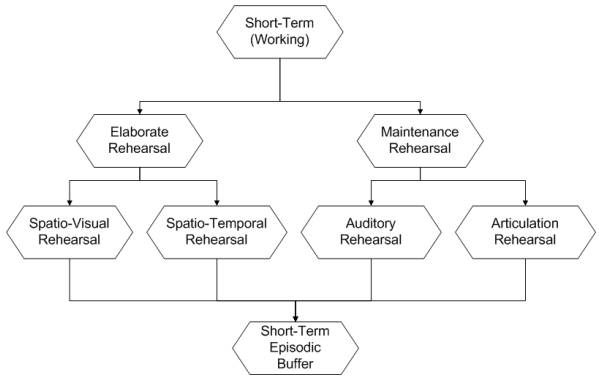

Figure 3 – AIS Short-Term Memory Lower Ontology

1.3 Long-Term Artificial Memories

Long-Term Memory (LTM), in the simplest sense, is the permanent Knowledge Domain where we assimilate our memories (Carbone 2010). If information we take in through our senses doesn't make it to LTM, we can't and don't "remember" it. Information that is processed in the STM makes it to LTM through the process of rehearsal, processing, encoding, and then association with other memories. In the brain, memories are not stored in files, nor in a database. Memories, in fact, or not stored as whole memories at all, but instead are stored as information fragments. The process of recall, or remembering, constructs memories from these information fragments that are stored in various regions of the brain, depending on the type of information. In order to create our AIS in a way that mimics human reasoning, we follow the process of storing information fragments and their respective encoding in different ways, depending on the type and context

of the information, as discussed above. Each sinple discrete fragment of objective Knowledge includes an n-dimensional set of quantum mechanics based mathematical relationships to other fragments/objects bundled in the form of eigenvector optimized Knowledge Relativity Threads (KRT) (Carbone 2010) (Carbone and Crowder, 2011).These KRT bundles include closeness, and relative importance value among others. This importance is tightly coupled, per the math, to the AIS emotional storage as a function of desire or need, as described in Figure 4, where the LTM Lower Ontology is illustrated. There are three main types of LTM (Crowder 2010a):

- Explicit, or Declarative Memories
- Implicit Memories
- Emotional Memories

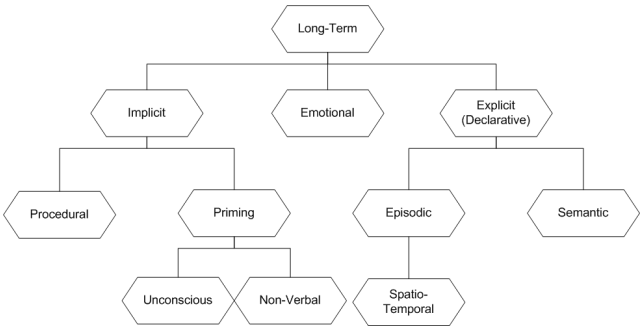

Figure 4 – Artificial Long-Term Memory Lower Ontology

2. Artificial Memory Processing and Encoding

2.1 Short-Term Artificial Memory Processing

In the human brain, STM corresponds to that area of memory associated with active consciousness, and is where most of the cognitive processing takes place. It is also a temporary storage and requires rehearsal to keep it fresh until it is compiled into Long-Term Memory (LTM). In the AIS, the memory system does not decay over time, however, the notion of "memory refresh" or rehearsal is still a valid concept as the Artificial Cognitive Processes work on this information. However, the notion of rehearsal means keeping track of "versions" of STM as it is being processed and evaluated by the artificial cognition algorithms. This is illustrated in Figure 5, the AIS STM Attention Loop. There are three distinct processes that are handled within the STM that determine where information is transferred after cognitive processing (Crowder 2010a).

This processing is shown in Figure 6. The Artificial STM processing steps are:

- **Information Fragment Selection**: this involves filtering the incoming information from the AIS Artificial Preconscious Buffers into separable information fragments and then determining which information fragments are relevant to be further processed, stored, and acted on by the cognitive processes of the AIS as a whole. Once information fragments are created from the incoming sensory information, they are analyzed and encoded with initial topical information, as well as Metadata attributes that allow the cognitive processes to organize and integrate the incoming information fragments into the AIS's overall LTM system. The Information Fragment encoding creates a small, Information Fragment Cognitive Map that will be used for the organization and integration functions.

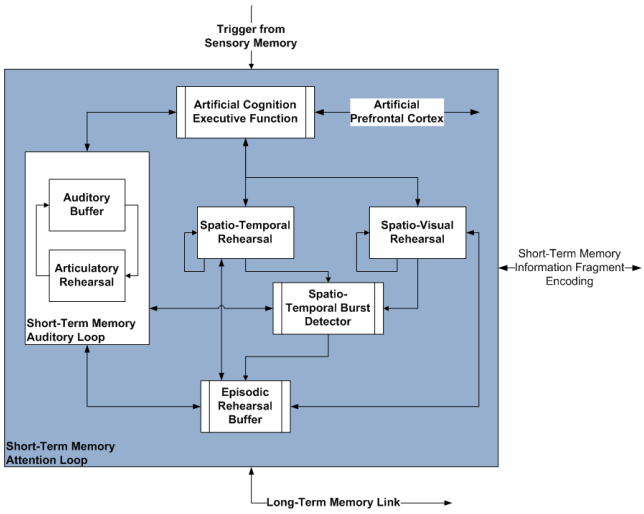

Figure 5 – Short-Term Artificial Memory Attention Loop

- **Information Fragment Organization**: these processes within the Artificial Cognition framework create additional attributes within the Information Fragment Cognitive Map that allow it to be organized for integration into

the overall AIS LTM framework. These attributes have to do with how the information will be represented in LTM and determine how these memory fragments will be used to construct new memories, or recall, memories later by as needed by the AIS, using Knowledge Relativity Thread representation to capture the context of the Information Fragment and each of it's qualitative relationships to other fragments and/or bundles of fragments already created.

- **Information Fragment Integration**: Once the Information Fragments within the STM have been KRT encoded, they are compared, associated, and attached to larger, Topical Cognitive Maps that represent relevant subject or topics within the AIS's LTM system. Once these Information Fragment Cognitive Maps have been integrated, processed, and reasoned about, including emotional triggers or emotional memory information, they are sent on to both the LTM system, as well as the AIS Artificial Prefrontal Cortex to determine if actions are required.

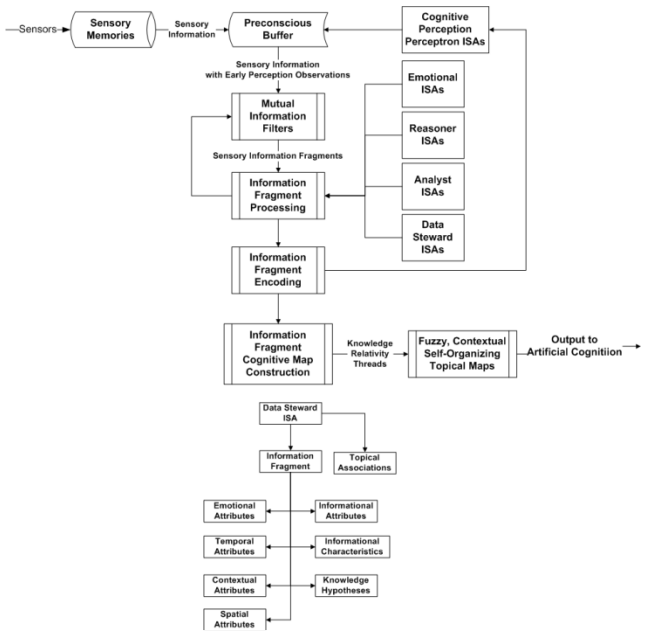

Figure 6 – AIS Information Fragment Encoding

One of the major functions within the STM Attention Loop is the Spatio-Temporal Burst Detector. Within these processes, Binary Information Fragments (BIFs) are ordered in terms of their spatial and temporal characteristics. Spatial[1] and Temporal transitions states are measured in terms of mean, mode, median, velocity, and acceleration and are correlated between their spatial and temporal characteristics and measurements. Rather than just looking at frequencies of occurrence within information, we also look for rapid increases in temporal or spatial characteristics that may trigger an inference or emotional response from the cognitive processes. It is not that an AIS system processes information content differently based upon how rapidly content is ingested, it is simply that an AIS must be able to recognize instances when information content might seem out of place within the context of a situation: e.g., a single speeding car within a crowd of hundreds of other cars. An AIS, not only optimizes its processing on the supply side of the knowledge economy, but has to recognize, infer, and avoid distraction on what focuses the demand side of its knowledge economy places upon operations and directives. State transition bursts are ranked according to their weighting (velocity and acceleration), together with the associated temporal and/or spatial characteristics, and any triggers that might have resulted from this burst processing (LaBar and Cabeza 2006). This Burst Detection and processing may help to identify relevant topics, concepts, or inferences that may need further processing by the Artificial Prefrontal Cortex and/or Cognitive Consciousness processes (Crowder and Friess 2011 a&b).

Once processing within the STM system has completed and all memories are encoded, mapped to topical associations, and their contexts captured, their knowledge relativity thread bundled representations are created and are sent on to the Cognitive Processing engine Memories that are deemed relevant to "remember" are integrated into the Long Term Memory system.

2.2 Long-Term Artificial Memory Processing

The overall AIS High-Level memory architecture is shown in Figure 7. The one thing of note is the connection between Emotional memories and both

[1] Spatial in this reference can be geographically (either 2-D or 3-D), cyber-locations, or other characteristics that may be considered "spatial" references or characteristics.

Explicit and Implicit memories. Emotional Memory carries both Explicit and Implicit characteristics.

Explicit or Declarative Memory is utilized for storage of "conscious" memories or "conscious thoughts." Explicit memory carries those information fragments that are utilized to create what most people would "think of" when they envision a memory. Explicit memory stores things, i.e., objects, and events, things that are experienced in the person's environment. Information fragments stored in Explicit Memory are normally stored in association with other information fragments that relate in some fashion. The more meaningful the association, the stronger the memory and the easier the memory is to construct/recall when you choose to (Yang and Raine 2009). In our AIS, Explicit Memory is divided into different regions, depending on the type or source of information. This division of regions is because different types of information fragments within the AIS memories are encoded and represented differently, each with its own characteristics that make it easier to construct/recall the memories later when the AIS needs the memories. In the AIS LTM, we utilize Fuzzy, Self-Organizing, Contextual Topical Maps to associate currently processed Information Fragments from the STM with memories stored in the LTM (Crowder, Scally, and Bonato 2011).

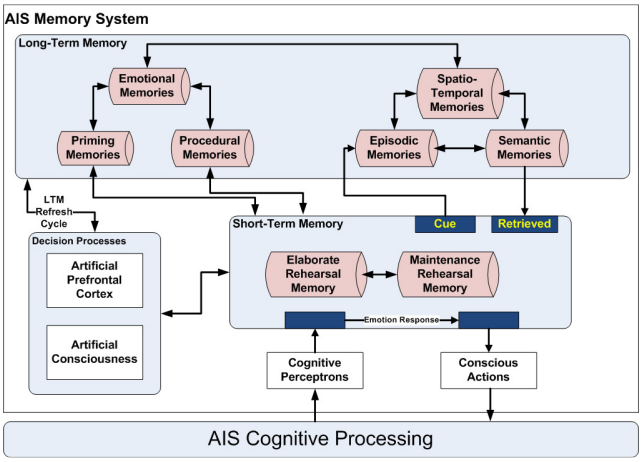

Figure 7 – High-Level Artificial Memory Architecture

LTM information fragments are not stored in databases or as files, but encoded and stored as a triple helix of continuously recombinant binary neural fiber threads that represent:

- The Binary Information Fragment (BIF) object along with the BIF Binary Attribute Objects (BAOs).
- The BIF Recombinant Knowledge Assimilation (RNA) Binary Relativity Objects.
- The Binary Security Encryption Threads.

Built into the RNA Binary Relativity Objects are Binary Memory Reconstruction Objects, based on the type and source of BIF, that allow memories to be constructed for recall purposes. There are several types of Binary Memory Reconstruction Objects, they are:

- Spectral Eigenvectors that allow memory reconstruction using Implicit and Biographical LTM BIFs
- Polynomial Eigenvectors that allow memory reconstruction using Episodic LTM BIFs
- Socio-Synthetic Autonomic Nervous System Arousal State Vectors that allow memory reconstruction using Emotional LTM BIFs
- Temporal Confluence and Spatial Resonance coefficients that allow memory reconstruction using Spatio-Temporal Episodic LTM BIFs
- Knowledge Relativity and Contextual Gravitation coefficients that allow memory reconstruction using Semantic LTM BIFs

3. Conclusions and Discussion

Described here are memory processing and encoding methodologies to provide Artificially Intelligent Systems with memory architectures, processing, storage, and retrieval constructs similar to human memories. We believe these are necessary to provide artificial cognitive structures that can truly learn, reason, think, and communicate similar to humans. There is much work to do and our current research will provide the software processing infrastructure for the Information Software Agents necessary to create the underlying cognitive processing required for this Artificial Neural Memory System (ANMS). Below we give an example of memory reconstruction utilizing this ANMS, for reconstruction of image memories.

3.1 Implicit and Biographical Memory Recall/Reconstruction Utilizing Spectral Decomposition Mapping

We create non-uniform expanding fractal decomposition of the image to be "remembered." We utilize the right and left Eigenvectors of the Pollicott-Ruelle resonances to determine the separable Pictorial Information Fragment (PIF) objects. The resulting singular fractal functions form fractal spectral representations of the PIFs. These Binary Fractal Representations are stored as the Binary Information Fragments for the image. The reconstruction uses these PIFs to create a piece-wise linear image memory reconstruction, although the individual PIFs can be utilized in other memory and cognitive processes, such as to perform pattern matching and/or pattern discovery. The proposed high-level architecture for the ISA cognition and memory system is illustrated in Figure 8.

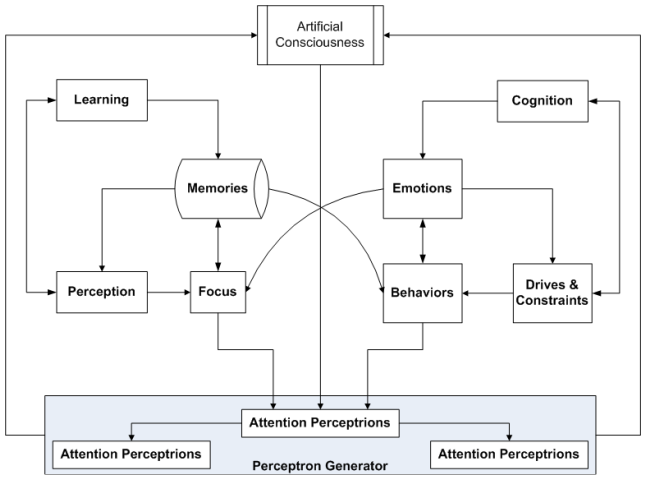

Figure 8 – The AIS High-Level Cognitive Architecture

Air Holding Problem Solving by Reinforcement Learning to Reduce the Congestion in Airspace Sectors

Leonardo L. B. V. Cruciol and Li Weigang
Department of Computer Science, University of Brasilia, Brasilia, DF, Brazil

Abstract—*Air Holding Problem Module (AHPM) is proposed as a Decision Support System (DSS) to help air traffic controllers in their daily air traffic flow management. This system is developed using Multiagent framework to organize and optimize the solutions for controllers to handle traffic flow in Brazilian airspace. The paper focus on the problem solving by Reinforcement Learning to show how the history experience of the controllers can be used to advise the new activities for the new situation. About 1110 daily flights over Flight Information Regions (FIRs) as FIR-Brasilia and FIR-Recife were studied considering the local and global reward functions and three time intervals to apply restrictive measures. As a result, with the use of AHPM, the decision process is improved with a high level of automation. At the same time, the congestion in related sectors is reduced from 15% to 57% in local scenarios and 41% to 48% in global.*

Keywords: Air Holding Problem, Air Traffic Flow Management, Decision Support System, Real Time Problem, Reinforcement Learning.

1. Introduction

Air Traffic Flow Management (ATFM) is a complex domain related with human and automatic activities. In this domain there are Air Holding Problem (AHP), Ground Holding Problem (GHP) and others, which happen when air traffic congestion appearing and it is necessary to apply restrictive measures to re-distribute the traffic flow by air traffic controllers. They are responsible to verify airspace scenario and analyzes the possible risk situations to take some actions with proper decision. Therefore even for an expert with rich experience is expected to make any management action in extremely short time interval with the detection and analyze of a complicated environment. In many cases this process is almost manually in some regions. This is a necessary to develop a semi-automation system with suitable computational model, especially to solve Air Holding Problem in ATFM.

Air traffic controllers work in real time with many attributes to handle in ATFM. Decision Support System (DSS) is a suitable concept to be applied in AHP solving. In DSS framework, considering the reality of AHP, Reinforcement Learning algorithm is introduced in this study. The air traffic controllers can learn the history experience and scenario to adjust the decision making when the congestion appears. As the result, the restrictive measures in AHP solving can be adequate and applied in air traffic management and improve the effeteness of the management.

In Brazil, Ground Holding Problem is studied in previous researches with the computational models [5]. The real data was collected from Integrated Air Defense Center and Air Traffic Control (CINDACTA). This research focus on the AHP solving by Reinforcement Learning to show how the history experience of controllers can be used to advise the control activities for the new situation.

Air Holding Problem Module (AHPM) is proposed as a Decision Support System to help the air traffic controllers in the daily air traffic management. In this model, multiagent framework was constructed for Flight Information Regions (FIRs) and Central. To take suitable restrictive measures, AHPM is collaborated by two approaches for agents in learning and action. First one, local agents will learn and make the best suggestions based on local scenarios and send the decision information to a global control agent. Second one, global control agent will evaluate the best actions to take for global environment. With this procedure, the suggestion is sent to air traffic controller to apply the restrictive measures with more accuracy and efficient. The knowledge about possible impacts to reduce the congestion, in each scenario, is collaborated to improve air traffic management and increase the safety.

As a case study, 1110 daily flights over FIR-Brasilia and FIR-Recife were studied considering the local and global evaluation functions and three time intervals to apply the restrictive measures. As a result, with the use of AHPM, the decision process is improvement with a high level of automation, the congestion in related sectors is reduced from 15% to 57% in local scenarios and 41% to 48% in global.

The paper is organized in the following manner. In section 2, there is a brief review of Decision Support System and Reinforcement Learning concepts and related researches. Section 3 reviews Air Traffic Flow Management concepts and related problem in Brazil. AHPM is proposed in section 4 including the definition of the reward functions. Section 5 concerns a case study with real data from FIR-Brasilia and FIR-Recife to verify the effectiveness of the developed model and related results. Section 6 concludes the paper and proposes the direction of the future research.

2. Related Concepts and Researches

The concept of Decision Support System and the method of Reinforcement Learning are used in this research. This section gives a basic description and reviews the related researches of these concepts in ATFM.

2.1 Decision Support System

A Decision Support System is used to help users with relevance information in decision making process. Using a computer to present the process of decision making of human being is still a difficult task especially in the activities of intuition, conceptualization and creativity. On the other hand, a computer can help human being in the information processing with high speed, parallelism, accuracy and persistent storage [8].

Combining these two factors, DSS achieves an accepted automation level to help the human being decisions. This allows working with problems of a decision making which proportion overtakes the human being capacity or exceeds temporal and financial means available.

Some typical tasks of DSS are data organization and visualization, perceptible knowledge representation, forecast scenarios and impacts, information clustering as new information, simulators and optimization solution. The work made by automation should be only in areas like the control of problem solving activities, detection of conflicts and execution of evaluation, search and planning sequences.

To improve this kind of system, the hybrid solutions are used, such as Reinforcement Learning which can be used to acquire knowledge from air traffic controller in ATFM and to elaborate a Multiagent System to further help the air traffic controllers in new situation and quickly replying.

In many times, human knowledge is scattered. In Flight Information Regions, the information available is distributed and not effectively applied by air traffic controllers in ATFM. With the help of decision support system, the information is well integrated and utilized. This is the main reason to develop AHPM in this research.

2.2 Reinforcement Learning

Reinforcement Learning is a learning process which consists of an agent without prior knowledge and in a certain number of interactions with the environment to learn the useful knowledge and therefore receives rewards for taking actions and achieving goals.

In Reinforcement Learning process, it is possible to realize an optimal solution to the problem in matter, i.e., it finds the best actions to achieve a determinate goal in the possible optimized way, taking into consideration of a certain environment in an instant T_k, where k is the present instant.

The agent will act mutually with the environment, during the interaction, to recognize which scenario it is and therefore to choice the best action as a decision. After the agent presents an action, it will be given a reward. Therefore it is possible to check if the action is better for the current scenario [3,6,9].

The reinforced learning algorithm used in AHPM is known as Q-learning [11]. This algorithm uses a table denominated as Q-table, that, as part of the learning process, incorporates the agent's experience. The Q-table stores action-scenario pairs that represent the states observed by the system. The scenario configuration consists of the number of aircraft in the ATC sectors at certain times.

2.3 Related Researches

Recent researches in ATFM combines Reinforcement Learning and Multiagent techniques. It uses this combination to incorporate the human agent's experience into automated ATM processes. ATC domains are too complex to be completely automated and are directly impacted by tactical ATFM.

It developed metrics to evaluate the efficiency of traffic flow control measures generated by Reinforcement Learning agents. As a result, it was possible to improve the actions taken by an agent conceived to simulate the behavior of air traffic controllers, given the suggestions by the ATFM agent and as such suggestions were accepted by the air traffic controller [1,4,7].

In the proposed system [1], the ATFM agent uses a Reinforcement Learning algorithm that seeks to maximize the reward that derives from the scenarios generated, which will be evaluated based on the total delays generated and the number of aircraft in the ATC sectors, both resulting from the flow control policy. The air traffic controller is characterized as a reward maximizing Reinforcement Learning agent that seeks only the minimization of the amount of aircraft in the ATC sectors. This assumed behavior for the air traffic controller is not entirely valid, as the minimization of traffic in the ATC sectors is not the ATC's only goal [2,5,10].

In reality, ATC seeks a balance between safety, which benefits from a low number of aircraft in the ATC sectors, and operational efficiency, which depends on the maximization of flows. This assumed behavior is, therefore, a significant limitation of the model.

3. Air Traffic Flow Management

ATFM is a complexity procedure to avoid exceeding air traffic control capacity and focuses on the supply of information to maintain the traffic flow with safety and less impact on scenarios that are necessary to take unexpected measures. The ATFM environment can be organized into three phases:

- Strategic Level: Considering tactical planning of flights covering the period of forty-eight hours until the time before the flight.
- Operational Level: Focusing on strategic decision making covering the period from forty-eight to two hours before the flight.

- Tactical Level: Considering tactical decision making covering the period from two hours before the flight until the aircraft arrives at its destination.

This study concerns in ATFM Tactical Level. The basic problems are solved such as the aircraft in flight, which increases the problem level because the occurrence of the problem and its solution happens on real time.

ATFM can guarantee that flights are conducted in a safe, quick, orderly and economic way. It is possible to avoid overloading in the air traffic capacity, optimize airspace and provide information to responsible.

Some activities from ATFM can be automate, partially or not, or improve using DSS. So, air traffic controller can monitor and analyze all aspects involved in the environment, such as meteorological aspects, evaluate restrictive measures before to take some action, and verify alternatives flows of air traffic.

3.1 The Problem of ATFM

The air traffic flow management needs to be prepared to maximize the opportunities of the available structure so that resources can be put into the good condition to use. In this case, it can be mentioned the best flow management of the aircraft while in airspace and, therefore, besides improving the safety levels of the Brazilian aviation. It is also possible to reduce negative indicators and achieve good results for all involved in a situation [5,8].

ATFM environment is a domain with many complex activities, such as the air holding problem. It occurs when aircraft in flight route needs to wait in airspace for some reasons.

One of these reasons could be that an airport had to be closed, for example. Situations involving natural phenomenon or terrorist acts, may be motive to excess of aircraft on a particular sector and thus other aircraft need to be retained for some time in other sectors.

The problem becomes much more serious, in some critical scenarios, e.g., when there is a scenario, which includes all aircraft under the responsibility of the Brazilian authorities and there are sub scenarios which responsibilities are under a certain CINDACTA. When an action is chosen for a sub scenario, as the time goes by, the result of these actions can make better a sub scenario and aggravate another one, and then the whole situation can become an issue of great risk to the safety of everyone involved.

3.2 Brazilian Scenario

Brazilian airspace covers the entire land area of the country, including part of the Atlantic. There are five FIRs: FIR - Amazônica, FIR - Recife, FIR - Brasilia, FIR - Curitiba e FIR - Atlântico. In this paper, it will consider two FIRs: Brasilia and Recife. The airspace of this case study is presented in Fig. 1 Airspace of FIR - Brasilia and FIR - Recife.

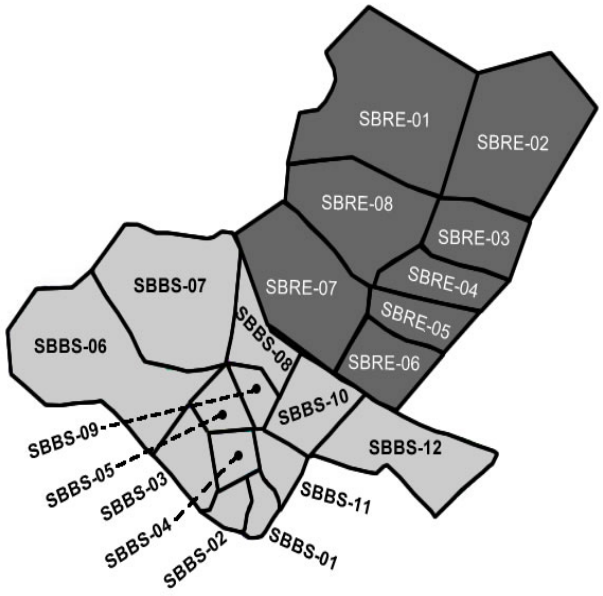

Fig. 1: Airspace of FIR - Brasilia and FIR - Recife

Each FIR is divided into some control sectors, in order to separate management activities and achieve more control. Currently, there are 46 sectors, where: 14 in FIR - Amazônica, 8 in FIR - Recife, 12 in FIR - Brasilia, 10 in FIR - Curitiba and 2 in FIR - Atlântico.

These sectors are carried out by air traffic controllers, which work in Area Control Center (ACC). In each CINDACTA, there is an ACC responsible for one FIR. Thus, it is possible to realize the complexity of activities management and necessity for subdivision to manage so many factors, e.g, the amount of aircraft by airspace sector influences the complexity of managing, i.e., more aircraft flying in the same sector, more and greater security risks involved in ATFM.

4. Air Holding Problem Module

A hybrid solution is proposed in this study, which uses Reinforcement Learning and Multiagent System. The first technical concerns in learning from the experience, day by day, with the air traffic controllers. Thus, it is possible learning online without previous knowledge to use DSS concepts. The second one, Multiagent System, makes possible to achieve better results in complex domains with many attributes.

4.1 Agents Modeling

Two FIR Agents are used in this case study: FIR-Brasilia Agent and FIR-Recife Agent. Each one is applied to achieve the best actions for some situation in its FIR. The Central Agent is responsible to analyze the possible actions from

each FIR and suggests the best group to air traffic controller. The process of the communication between agents is presented in Fig. 2 Agent Modeling.

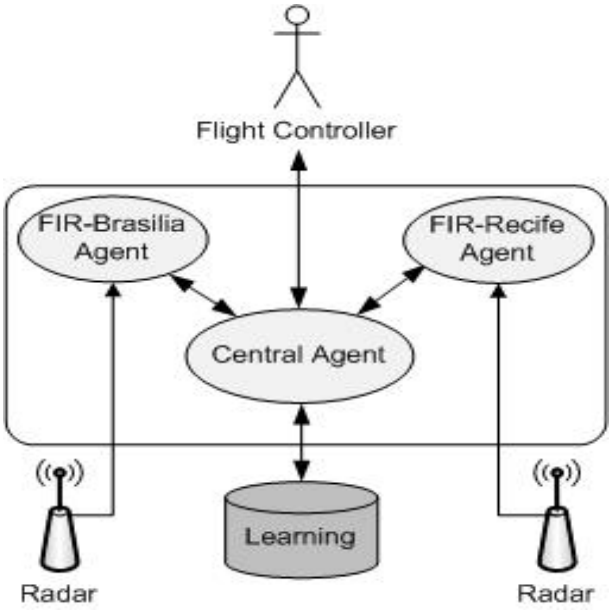

Fig. 2: Agent Modeling

After the identification of the best actions to be taken by Central Agent, this agent will verify similar scenarios on learning database and these actions are taken by the air traffic controllers.

If there are better results to reduce air traffic level, it will be presented taken actions as suggestion. If results are worse or not exists similar scenarios, it will be analyzed the three best actions for each FIR and send it to Central Agent.

4.2 Reward Functions

Each agent needs to evaluate if some action is good or not over others in a specific scenario. So agent evaluates by reward functions which make possible to take the best action for each scenario.

The agent is proposed to consider the capacity of aircraft in airspace sectors. In Brazil, every sector is allowed to set twelve flights as the responsibility of air controller to maintenance the air traffic flow. The action must reduce the amount of aircraft and improve the flow of aircraft throughout the environment.

The FIR Agent is developed to evaluate the local scenarios, i.e., environment of FIR - Brasilia or FIR - Recife and suggest the best actions for local environment. For this kind of agent, the reward function is defined as:

$$F_{FIR}(s) = \sum s \quad | \ \exists \, (a > 11 \in s) \tag{1}$$

$$C_{FIR}(s) = \sum a \quad | \ \exists \, (a > 11; \ s' \in S) \tag{2}$$

$$E_{FIR} = \sum \{F_{FIR}(s) * C_{FIR}(s)\} \tag{3}$$

Where:

- $F_{FIR}(s)$ is a summation of adjacent sectors from group *s* that are congested. Amount of aircraft in *s* is defined by *a*, which in Brazil is defined as congested sector if there are more than eleven aircraft in each airspace sector.
- $C_{FIR}(s)$ is a summation of aircraft from congested adjacent sectors (*S*) of sector *s*. Amount of aircraft in *s'* is defined by *a* and sector *s'* is in group of congested adjacent sectors *S*.
- E_{FIR} is the FIR scenario state.

The main objective of the reward function of FIR Agent is to evaluate the level of air traffic in each moment for each FIR. So it is possible to verify if some action will improve or not this level in the next time before to take any action.

The Central Agent is developed to evaluate the global environment, which includes FIR - Brasilia and FIR - Recife. It will collected three best actions for each suggestion of FIR Agent and Central Agent will evaluate the best actions for global environment, taking into account of the suggested actions by FIR Agent and its impacts in other FIR. The reward function of Central Agent is defined as:

$$G_{Central}(FIR) = \sum FIR \quad | \ \exists \, (s \in FIR; a > 11 \in s) \tag{4}$$

$$P_{Central}(s) = \sum s \quad | \ \exists \, (a > 11 \in s) \tag{5}$$

$$D_{Central} = \sum a \tag{6}$$

$$H_{Central} = G_{Central} * P_{Central}(s) * D_{Central} \tag{7}$$

Where:

- $G_{Central}(FIR)$ is a summation of FIRs that contains at least one congested sector. The amount of aircraft in *s* is defined by *a*, in Brazil, it is defined as congested sector if there are more than eleven aircraft in each airspace sector.
- $P_{Central}(s)$ is a summation of the congested sectors in the whole environment, i.e., sectors from each FIR analyzed by E_{FIR} function. The amount of aircraft in *s* is defined as *a*.
- $D_{Central}$ is a summation of the aircraft in global environment, including all necessary sectors to analyze each FIR.
- $H_{Central}$ is the global scenario state.

The main objective of the reward function of Central Agent is defined to evaluate the level of air traffic in each

moment of global environment, i.e., FIR-Brasilia and FIR-Recife. So it is possible to verify if some actions will improve or not this level in the next time before to take any action. Maybe, some suggested actions are not the best for a FIR but it is better than others for global environment.

5. Brazilian Case Study

FIR-Brasilia is the most important and critical FIR in Brazil. The FIR-Recife covers an area with high amount of flights scale. Thus, it is possible to achieve a better model because it is used, for case study, two FIRs very distinct.

The FIR-Brasilia (FIR-BS) is identified by International Civil Aviation Organization (ICAO) as *SBBS*. It consists of seven important airports in five cities. There are twelve airspace sectors in FIR-BS. It was identified fourteen airspace sectors adjacent of some sectors in this FIR.

The FIR-Recife (FIR-RE) is identified by ICAO as *SBRE*. It consists of six important airports in six cities. There are eight airspace sectors in FIR-RE. It was identified eight airspace sectors adjacent of some sectors in this FIR.

There are two types of the restrictive measures: air delay by reducing the speed and air forward by increasing the speed. These measures follow the goal of reducing airspace congestion, so the time that an aircraft designed to reach and exit of an airspace sector may be managed earlier or later as needed.

5.1 Local - FIR Agent

As presented in Fig. 2, the FIR Agent is developed to evaluate the traffic flow scenario within a FIR. In this research, FIR-Brasilia and FIR-Recife are studied separately. To analyze the decision support effects, the air traffic congestion index is defined in two conditions: 1) Traditional Approach, i.e., the restrictive measures are defined directly by air traffic controllers; 2) FIR Agent Approach, i.e., the restrictive measures are suggested by FIR Agent considering local optimization. The results from FIR-BS are presented in Fig. 3 Traditional x FIR Agent Approach in FIR-BS. And the results from FIR-RE are presented in Fig. 4.

In Fig. 3, the evolution from initial scenario to next three scenarios T_2 was presented. It is possible to verify that in the second interval there was no congestion in the airspace sectors when used AHPM approach, but the index of the level of air traffic was 264 in traditional approach by air traffic controllers.

In Fig. 4, it is possible to verify that in last two intervals there was no congested in the airspace sectors because air traffic level was zero when used AHPM approach, but using traditional approach the indexes were 255 and 74 respectively.

5.2 Global - Central Agent

As presented in Fig. 2, Central Agent is developed to evaluate the traffic flow scenario within all FIRs. In this

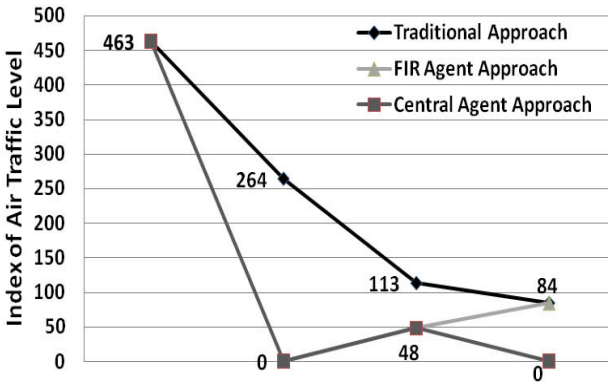

Fig. 3: Traditional x FIR Agent Approach - FIR-BS

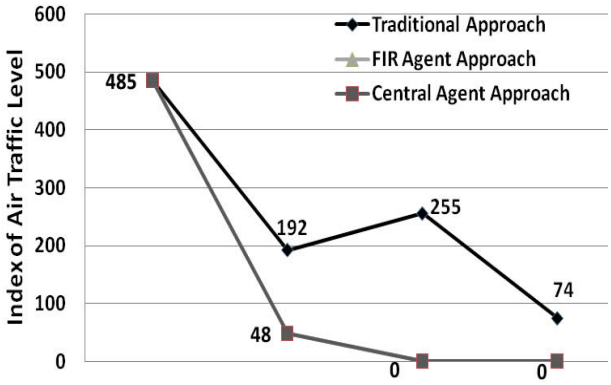

Fig. 4: Traditional x FIR Agent Approach - FIR-RE

research, two FIRs with 1110 flights daily are considered. To analyze the decision support effects, two conditions are studied: 1) Traditional Approach, i.e., the restrictive measures are defined directly by air controllers; 2) Central Agent Approach, i.e., the restrictive measures are suggested by Central Agent considering global optimization.

Central Agent is proposed to verify three best suggestions for each FIR and choose what would be the best group of restrictive measures to be applied in each FIR. The Fig. 5 presents the evolution from initial scenario to future time T_2 in the global environment.

It is possible to verify the improvement from first to second interval and reaching in the last interval no congestion in the airspace sectors by means of Central Agent. While using the Traditional Approach, the air traffic index is, on average, up to four times more than AHPM approach.

The approach proposed in this paper, AHPM, can be divided into two stages, the analysis by FIR Agent and after results for the first time the analysis by Central Agent. So even though this research is applied in only one FIR, the approach will achieve great results because it is considering factors such as adjacent sectors, aircraft in environment and congested airspace sectors.

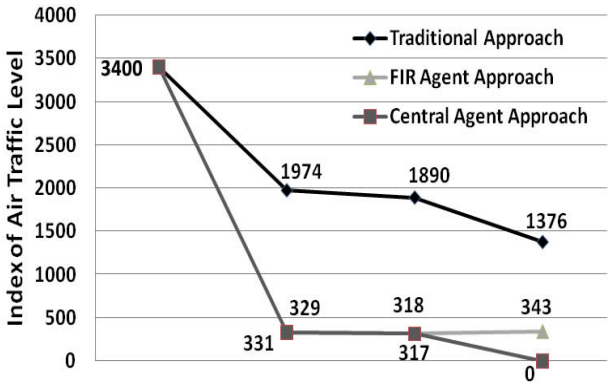

Fig. 5: Traditional x Central Agent Approach

The Central Agent will verify the three best suggestions for each FIR and choose what would be the best group of restrictive measures to be applied in each FIR.

5.3 Achieved Results

AHPM is proposed to work in two approaches: 1) the analysis by FIR Agent to support decisions with local optimization; 2) the analysis by Central Agent to support decisions with global optimization. Even though this research is applied in only two FIRs, the preliminary study is promissory.

In order to find the solutions in the more complete ATFM system, AHPM can help the air controllers to get more useful information to make the decision with more safety.

To get more evaluation of the application of AHPM, the six results from real scenario are considered: 1) the results from FIR-BS and FIR-RE using traditional approach, i.e., the restrictive measures are defined directly by air traffic controllers; 2) the results from FIR-BS and FIR-RE using AHPM, i.e., the restrictive measures are suggested by AHPM in local; 3) the results from FIR-BS and FIR-RE together using AHPM, i.e., the restrictive measures are suggested by AHPM in global. The Fig. 6 presents these six results of comparison between traditional approach and AHPM.

It is observed that the proposed approach, AHPM, achieved better results in all cases than traditional approach. And in most cases, the results from Central Agent achieved better results than FIR Agent. The following is a brief summary:

- FIR-BS
  - (17:30 - 17:59) - Improvement of 57%
  - (18:00 - 18:29) - Improvement of 15%
  - (18:30 - 18:59) - Improvement of 18%
- FIR-RE
  - (17:30 - 17:59) - Improvement of 30%
  - (18:00 - 18:29) - Improvement of 53%
  - (18:30 - 18:59) - Improvement of 15%

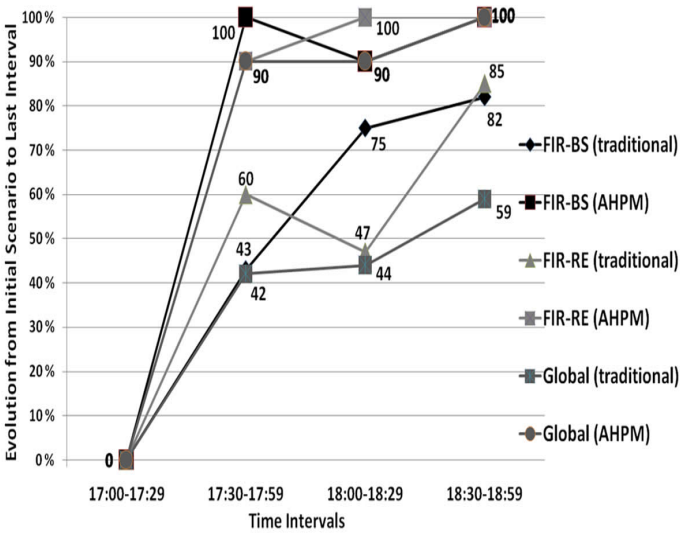

Fig. 6: Comparison between traditional approach and AHPM

- Global Environment
  - (17:30 - 17:59) - Improvement of 48%
  - (18:00 - 18:29) - Improvement of 46%
  - (18:30 - 18:59) - Improvement of 41%

As expected initially, these results showed the effectiveness of AHPM, which improved as the scenarios became more critical. Evaluating the case study, the congestion in airspace sectors was reduced between 15% and 57% in local scenarios and between 41% and 48% in global scenario.

These results demonstrate the improvement of impacts prediction and restrictive measures suggestions using AHPM. It is also show the possibility to model a computational solution to support, effectively, the decision making for air traffic controllers.

6. Conclusions

AHPM was developed to solve Air Holding Problem in Brazil. The proposed model used the Decision Support System concept including Multiagent System and Reinforcement Learning. The main utility of AHPM is to act on the reduction of Air Holding in airspace sectors and help the decision making by air traffic controllers. The AHPM is concerned to increase the security and to support ATFM process in local and global scenarios.

It were defined two reward functions to realize the suitable Reinforcement Learning. FIR Agent and Central Agent were developed as a platform to support ATFM. Three time intervals were considered to apply the restrictive measures. As a result, with the use of AHPM, the decision process was improved with a increased automation. The congestion in related sectors was reduced between 15% and 57% in local scenarios and between 41% and 48% in global.

The future work is to implement AHPM in the Brazilian Air Navigation Management Center (CGNA) to effectively help air traffic controllers in the day to day Air Traffic Flow Management process.

Automated Intelligent Monitoring Systems

J. Wallace[1] **and S. Kambouris**[1]
[1]Infinite Dimensions, Alexandria, Virginia, United States of America

Abstract - *Some of the primary challenges in the development of cost-effective, next-generation Game Changing Technology for automated learning systems are the effective, efficient incorporation of representative knowledge models: domain or subject matter experts (SME), instructors/trainers, and trainees. Through interaction of the SME, trainer/trainee models, Automated Intelligent Monitoring System (AIMS) assesses what the student knows, and how well the student is progressing. Previous approaches to solving this problem have yet to overcome the inherent challenges long associated with complex, knowledge-based systems. The AIMS architecture framework overcomes limited and outdated psychological/computer science theories and insufficient computer science artifact using semantic ontology, and development engine architecture framework.*

Keywords: Learning Systems, Semantic Ontology, Architecture Framework

1 Introduction

Significant challenges in the development of cost-effective, next-generation Game Changing Technology for automated learning systems are the effective, efficient incorporation of representative knowledge models: domain or subject matter experts (SME), instructors/trainers, and trainees. Through interaction of the SME, trainer/trainee models, Automated Intelligent Monitoring System (AIMS) assesses what the student knows, and how well the student is progressing. The AIMS architecture framework overcomes limited and outdated psychological/computer science theories and insufficient computer science artifacts. It does this through the AIMS architecture framework's functionally realistic mission and environment approach and involvement from the training SMEs.

1.1 Automated Intelligent Monitoring System (AIMS)

The AIMS architecture framework is two things: an automated, integrated, development engine systems integration environment for high performance networked systems with library support for training and monitoring. The development engine is discussed in detail elsewhere [1]. Secondly, the AIMS' corresponding high performance real-time executive/government off-the-shelf (GOTS) message bus operates in all environments, even resource-constrained ones such as Smartphone applications or in the Battlespace itself.

AIMS is relevant over wide ranges of education and training situations and is a Game Changing Technology. AIMS includes the capability for both single learners and multi-disciplinary group training as it has the ability to instrument and control a number of systems simultaneously. AIMS allow for the distribution of system processing for efficiency and scales in two dimensions: number of learners and number of systems which are instrumented and controlled. AIMS provides a solution for the problem of implementing intelligence and automation by effectively creating the knowledge models for the Expert, Instructional, and Trainee subsystems.

2 Instrumenting Learning Environment

Instrumentation has traditionally been a fundamental problem in traditional automated learning system architecture frameworks as it requires measuring the trainee's inputs into the system as well as the reverse function of providing feedback to both the trainee and trainer. Correctly instrumented learning environments increase the overall effectiveness of the AIMS as more trainee assessment information becomes available. An example of instrumenting a flight simulator would involve measuring and recording pilot's stick and switch movements, button presses, and the way in which the pilot is monitoring the gauges.

Greater system complexity arises when addressing multi-modal group instruction as individuals perform and train on different duties simultaneously, as well as participating at different times and separate tasks. Therefore, proper AIMS instrumentation is critical. Utilization of both group and individual assessment data provides sophisticated, complex information that has been rarely accounted for in previous trainee models.

Group instruction compounds training complexity, but is taken into account by AIMS. In group instruction mode, AIMS chooses content for the trainee group and makes multiple decisions: topics to address, problems to solve, and what feedback to provide and in which order, as well as what trainee information will be recorded. When AIMS employs the trainee model, it represents all the individuals and their specific group's aspects as well as determines their tasks and correct order sequence for the trainees. Multiple possibilities

exist in determining the most appropriate tasks for a training group.

Another fundamental technical requirement for AIMS is to efficiently utilize its SMEs during training as an integrated trainer-in-the-loop. Real-time SME training integration facilitates an evolution in the inherently regimented and highly controlled nature of computerized training allowing for enhanced flexibility, complexity, variation and increased scope of the training itself. In order for a SME to interact with their trainees in a real-time environment, they need a flexible networking technology utilizing an efficient messaging system. AIMS's real-time interactions allow the training itself to evolve more rapidly based upon feedback from the trainee or trainer/SME. AIMS takes into account a trainee's needs with regard to communication, personality conflicts, or learning style issues which it rigorously accounts for as more knowledge is provided a priori to AIMS.

2.1 Semantic Ontology Streamlines AIMS Implementation

This paper addresses the ability to reduce the time required to plan, implement, execute, and analyze training in a unified AIMS architecture framework. AIMS is based on the concept of ontologies and employs Semantic Web technologies. This framework is intended to be used by different constituencies and employs a method, vocabulary, and user interface approach that allows the needs of different SMEs to be addressed. At the same time AIMS is functionally capable of operating off a unified conceptual structure.

In general, the major technological innovations are the ability to affordably instrument training/ operational systems creating a learning environment to stimulate trainees, record their responses/capabilities, and facilitate their training. AIMS utilizes the ability to create intelligent systems with hybrid algorithm capabilities and synchronizing a large number of them thereby permitting AIMS to be built in a more modular and understandable way as an entire intelligence system. AIMS facilitates the ability to distribute computation easily over a set of resources. Additionally, the authoring and programming of AIMS is done in a way that simplifies the system specification and programming, respectively facilitating the creation of an automated intelligent monitoring system.

2.2 Adaptive Learning System

AIMS takes into account the trainee's situational awareness, cognitive capabilities, action accuracy, situational distractions, cognitive distractibility and any resulting reduction in accuracy. AIMS accounts for functionally disparate phenomena such as recognition of patterns, adapting new solutions or strategies and rule following in order to represent "intelligence" more effectively. Based upon input from SMEs, current best training practices can be incorporated. AIMS ascertains the most appropriate feedback for the trainee by determining learning styles and communication preferences, in addition to skill level, and provides the most accurate advice for the trainees and SMEs. In reality, as humans, we rarely follow or interpret rules strictly; and thus, should not expect AIMS to do likewise. AIMS will have a great deal of generality and flexibility while maintaining ease-of-use for integrators, developers and users.

AIMS is an adaptive learning system, taking into account the trainee's situational awareness, cognitive capabilities, action accuracy, situational distractions, cognitive distractibility and any resulting reduction in accuracy. AIMS accounts for functionally disparate phenomena such as recognition of patterns, adapting new solutions or strategies and rule following in order to represent "intelligence" more effectively. AIMS ascertains the most appropriate feedback for the individual trainee by determining learning styles and communication preferences, in addition to skill level, and provides the most accurate advice for them so they may proceed to the next problem-solving step. The advice given to the trainee is appropriate for their capabilities.

2.3 Technological Advances

In order to implement AIMS, advances in several technology areas must be combined to create an understandable architecture, and functional decomposition, that can scale and adapt to training problems and are discussed elsewhere [1]. AIMS knowledge and intelligence representations focus on pattern recognition and the basic steps of decision-making, as opposed to a larger view to include the reasons for decisions, and the timelines in which decisions must be made. AIMS's complex, distributed application architecture framework instruments a system of training systems quickly.

2.4 Knowledge Types

Employing knowledge types in AIMS exceeds typical inference engine in rule-based environments [2]. Accommodating increased levels of modeling complexity for automating individual and team training requires a richer set of modeling primitives. A key capability involves easily constructing natural inter-component relationships logically and temporally. In this way, a functionally realistic mission and environment approach overcomes outdated psychological and computer science theories, used to represent intelligence as existing methods utilizing computer science artifacts are insufficient. An empirical connection is needed between real psychological measurement and behavior models. Certain sets of factors are more congruent and adaptive with certain mission/environments. Human factors of individuals, teams, and organizations may be capitalized upon and/or compensated for after they are identified and integrated. Through integrated interaction of the knowledge models,

AIMS accurately provides a more reasonable judgment about what the trainee knows and how well they are progressing both to the trainee, as well as their trainer.

2.5 Ontology-Based Architecture Framework Development Engine for Systems Integration

Ontology is a formal representation of domain knowledge that defines the concepts within a domain and the relationships between those concepts. It can be used to reason about the properties of that domain and is often described as a formal, explicit specification of a shared conceptualization as it provides shared vocabularies [3]. In this case, we need vocabularies able to describe: military operations and associated relevant real world activities, live military assets and their virtual reality and constructive representations, state, initialization, and exchange data and overarching conceptual descriptions of the training event.

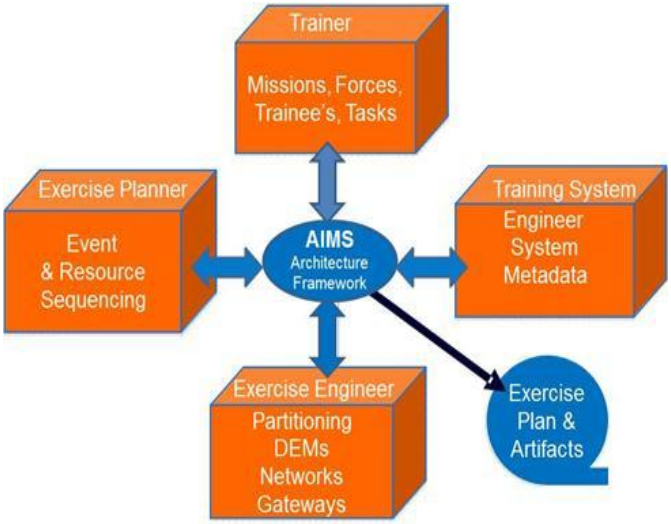

Figure 1. Composition Automation Approach

To provide composition automation, as shown in Figure 1, the AIMS Architecture Framework interfaces, models, applications (especially simulations), and data involved in AIMS systems and exercises must be described/captured in a machine readable manner. Ontologies are employed for this purpose. Ontology alignment then permits the building of connections or bridges between existing models and enhances the ability to add new models. Model management and exploitation is made more effective satisfying Warfighter needs by promoting increased realism during training. Providing these ontology based tools enables exercise SMEs and military users to employ composition and architecture bridging tools to rapidly go from testing, training, experimentation, and rehearsal requirements to a training exercise or event for single trainees or groups of them.

The understanding of models, specifically Model Semantics, is almost exclusively a human activity. Models are only partially and ambiguously documented; much has to be interpreted and filled in from experience or context closely working with SMEs. As this experience is difficult to acquire and share, using Model knowledge is restricted to experts. The goal is to provide a method to partially encode expert knowledge about: mathematical and logical assumptions about the limits of the description of physical and non-physical phenomena such as human behavior, interfaces and their semantics, identification of patterns and frameworks, and causality information and execution order, such as one event triggering another.

2.6 Metadata and Composability Services

What this means for the Warfighter: a simple but robust method for categorizing everything from a handgun to the newest air superiority jet aircraft. Published ontologies that make previously created artifacts easy to find and retrieve should help alleviate reimplementation due to the common expedient of "I can't find it so I'll just create a new one".

Utilizing the ontology-based development engine, we address the many significant systems integration challenges and create complex, realistic, and scalable networks utilizing component inter-relationships. The engine allows for the distribution of autonomous controls and constantly monitors them and permits the implementation of complex webs of cause and effect and dynamically alters the component execution structure. When information transfer occurs successfully, automatically and without human intervention, the transfer is symptomatic of integration. Systems integrators attempt to reduce overhead costs by reproducing the information flow more accurately and consistently all within the timeframe of the user's need.

Systems integration teams must adapt, evolve, and facilitate integration of training systems. Successful integration requires the establishment of an AIMS partnership approach in conjunction with agile product development for all stakeholders: users, SMEs, program managers and program developers. Utilizing a flexible learning process, agile systems integration provides rational, logical conclusions that then lead the path forward for training systems integration. Utilizing rapid modification and implementation of SME and user input creates a more effective AIMS architecture framework.

The purpose of a cohesive and robust development engine is twofold: 1) to build and query knowledge bases (set of descriptions, facts, instructions, commands); and 2) to control the execution of numerous hardware and software components of training systems. The engine integrates hardware and software systems by extending Conceptual Graphs (CG) technology improving the resulting integration.

2.7 Flexibility and Realism

AIMS development engine enables the solution of key representation problems, permitting an easy-to-use, adaptive system. The overhead costs of information flow between software and hardware continue to increase as do system complexity. There are many inherent software/hardware challenges in integrating complex systems. We utilize Conceptual Graphs (CG) to integrate complex hardware and software systems [4]. CGs resolve complex issues arising from the following issues:

- Hardware compatibility
- Communication protocols
- Understanding transfer information
- Well defined system interrelationships
- Mapping for adequate neutral-format standards
- Mutual acceptance of the communication purpose
- Operational meaning in terminology
- Advancement in the core development environment and infrastructure

AIMS leverages many important capabilities, integrates many kinds of phenomenology, and encompasses a variety of formats. The ability to integrate a wide variety of "intelligent" algorithms and software is paramount. Several mathematical and causal formalisms must be accommodated by the representation framework. The development engine's non-invasive, non-destructive integration and interoperability illustrates how the vital problem of synchronization between functionally distinct computational subsystems is accomplished. Accurate, precise synchronized control algorithms and software execution solves one of the key problems in intelligent systems today. Arbitrarily supporting complex causal networks easily is central to the value-added to the AIMS community from the perspective of development engine utility enabling both flexibility and realism.

The inherent ability to provide distributed and federated interactions and object sharing permits a wide variety of data sources to be integrated and interoperated. Functions such as automated, time-based validity and refresh checks and updating functions are a trivial capability. The implementation of more interesting functions such as causal or logical condition combinations triggering refresh or updating is naturally supported. The AIMS architecture framework is based on the abstractions shown in the Figure 2.

The *Evaluation* function relies on AIMS' ability to establish a wide variety of knowledge, information, and data feeds. This can be done in two ways by an active push or passive pull. Most systems support one or the other, but not both. Furthermore, the mechanism for doing so must be low-footprint and portable. This permits a wide variety of software systems and devices to be employed.

The *Records Database* stores Performance information, which is derived from both the Evaluation process and the *System Coach*. The Records Database holds information about the past, such as Learner history records, the present, such as current Assessments for suspending and resuming sessions and the future, such as Learner or training objectives. The Records Database represents an advance in intelligent repositories in that a wide variety of complex knowledge, information, and data storage and retrieval functions can be easily implemented.

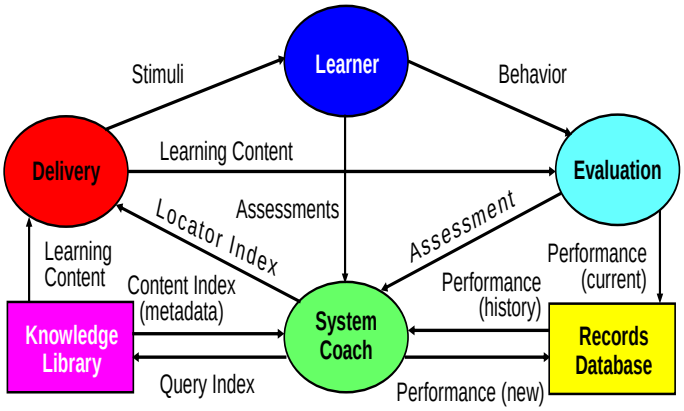

Figure 2. AIMS Architecture

The *System Coach* requests and receives Performance information, such as assessments and certifications back to the Records Database. Typically, historical information is retrieved, but current information such as "bookmarks" for resuming sessions and future information such as template of future training objectives may be retrieved. The System Coach exploits the full capability of AIMS by a complex causal network representation capability.

The *Knowledge Library* capability permits a variety of knowledge representation formats to be employed that describe actions and responses of the system. Much like the Records Database, the ability to integrate and interoperate a wide variety of databases is crucial, as is the complex database functionality previously described.

Content Indexes are the result of searches of the Knowledge Library, as directed by Query Indexes. The Content Indexes are also known as metadata. Metadata is best known in web content for facilitating searches. However, web content metadata is inadequate for learning content because learning content requires more search criteria (e.g., pre-requisites, co-requisites, learning style) than what is provided for web content (e.g., title, subject, author, keywords). Content Indexes are similar to "card catalog" entries in a public library.

Locator Indexes identify or point to Learning Content. Using the public library analogy, Locator Indexes are similar to "call numbers" in a card catalog system. Web URLs are examples of Locator Indexes. For some learning technology systems, Locator Indexes can be implicit because the Learning

Content can be retrieved along with the Content Index returned by the Query Index search. Learning Content is the coded representation of the learning experience, identified by the Locator Index, retrieved by the Knowledge Library, and transformed by the Delivery system into the training systems/environment and learning experience, where the Learner interacts with the real operational systems or training systems/environment.

The *Delivery* system, much like the Evaluation system, relies upon AIDE's powerful publication, subscription, and object sharing mechanisms. The low-footprint and portability features are important here, since that enables a wider variety of systems involved in Learner's real tasks to be employed. This improves training since the systems used at the actual tasks are used in training.

The *Learner* (process) represents any learner (one, several, or teams operating in different roles). The Learner receives Stimuli, and their Behavior is observed. From a technology perspective, a variety of assessments about the Learner (individual or group) are available to the System Coach and Evaluation processes to more effectively and efficiently guide each training session.

The *Learner Assessments* are sent to the System Coach. AIMS considers the various types of information which provides more knowledge a priori to the system itself. Figure 3 represents a multi-modeling approach to more easily bring in additional very complex and interrelated Learner Assessment models.

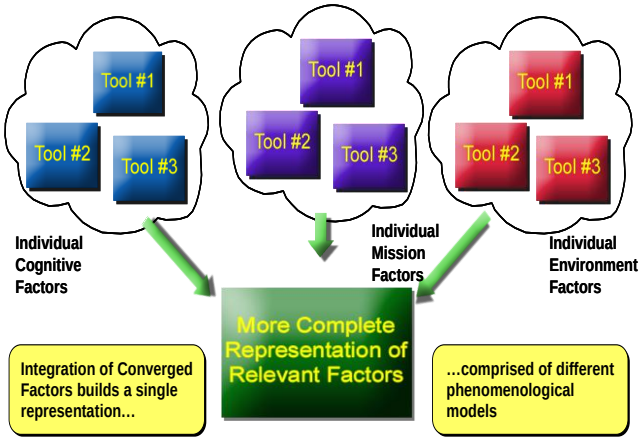

Figure 3. Learner Assessment data approach utilized in Figure 2.

AIMS has the ability to integrate naturally and efficiently for the new knowledge representation techniques and engines. Problems in communication, personality conflicts, or learning style issues can be rigorously accounted for in the training program. Learner Assessment information utilized may be obtained and include any number of the following:

- Concentration and awareness
- Accuracy of attention: environment, cognitive analysis, problem solving, set of tasks, mission
- Distraction: external, internal, mistakes and ability to recover
- Information and tasking: quantity and range of diversity
- Risk-taking, sensation seeking, thinking outside the box
- Following rules, orders, tradition, deliberation, caution
- Aspects of control, self-confidence, self-criticism
- Dominating and competitiveness: physical and intellectual
- Speed of decision making in given environments
- Listening, verbalizing, group/person selection preference
- Advocating team performance
- Communicating ideas, support, criticism
- Performing in certain types of high pressure environment

The following discussion is intended to illustrate how the AIMS architecture is implemented with the intelligent systems AIDE framework previously discussed.

The Learner construct represents one or several trainees. The Stimuli incident to the Learner requires the ability to interoperate with the learner's training or operational system. This requires the ability to quickly and easily integrate everything from buttons, switches, joysticks, variety of control knobs or interfaces to elaborate virtual reality or operational displays.

The Behavior flow shown in Figure 2 is a transmission of Learner behavior from the Learner to the Evaluation process. At the Evaluation process, the Behavior is framed in the appropriate context by matching the Learning Content to the range of Behavioral responses which is how information is collected and organized, e.g., key clicks, mouse clicks, voice response, choices, or inputs to an operational system which are sent to the System Coach. The Learner's observed Behavior is an observation of the Learner's activity while they are performing a task such as flying an airship for example. Some Behaviors may be physical location behaviors and have several levels of inputs concerning the Learner: location, six degrees of freedom position, velocity with respect to frame of reference, orientation (pitch/roll/yaw), acceleration, and the angular velocity with respect to those quantities. The Learner Behavior physical inputs are sent to the System Coach: 10 degrees of pitch, 20 degrees of roll at that moment in time, etc..

The System Coach sends the Learner Behavior to the Evaluator. Behavior information is obtained with a similar interoperation of user interface mechanisms or training specific observations such as a system of cameras to determine the scan pattern of an operator through their tasks and interfaces and feeding this streams into an Evaluation process which then would be implemented as some number of System Objects [1]. Ultimately all the data streams implemented using System Events and System Messages and the programming

constructs used to implement them are simplified for the clarity and ease of programming.

Learner Assessments sent to System Coach are different than the Behavior Evaluation path. Assessments are things that directly coming out of the training or operation system. These may be the Learner's problems with understanding when the timing of when to press a training system button. The Assessment part of the architecture represents information that comes from a direct observation of the learning environment and is not explicitly a Learner Behavior. For example, a Learner Assessment might be a warning light is on in a flight simulator and the fact that the light is on as a result of a trainee's actions and is a normal, internal part of system's operation.

AIMS observes the trainee's performance. This is a Learner Assessment and it is directly sent to the System Coach. Learner Assessment is information about what or how the trainee is doing, but it is not an Evaluation. System Coach gives feedback Stimuli to improve which is sent through the Delivery process. One piece of feedback may be "please release the safety".

The Learner Assessments transmitted from the Learner construct to the System Coach are implemented as System Objects and serve to provide specific inferences about the Learner such as an running Evaluation of the Learner's skill level at a particular task or other diagnostic that is built into the training or operational system that has some useful data which is not explicitly behavior based observation.

The System Coach is similar to the Evaluation implementation and it receives one or more Learner Assessments. The Learner Assessments are sent as System Events and System Messages. Multiple independent evaluations of behavior and multiple simulation learner assessments occur and feedback can be given and noticeable trainee improvements made over time. The delivery construct is also implemented with multiple system objects and execution engines and serves to mediate between the learning environment and the System Coach.

The Knowledge Library may then be viewed as not just rules or rule specifications, but elaborate combinations of libraries of function and arbitrary combinations of knowledge representation constructions. In both the System Coach and Evaluation, one or more knowledge execution engines can be instantiated to operate on the data being received.

The ability to have more than one knowledge execution engine operating simultaneously would simplify the construction of authoring the knowledge bases from a semantic perspective. This permits more realistic and practical evaluation information, resulting in more realistic and accurate automated inputs to the Learner. AIMS has knowledge of the Learner's activity, training systems, relationships between them, the ability to index training systems, and AIMS architecture framework system that could realize roles and responsibilities for both AIMS and the trainee.

The AIMS that captures Learner Assessment behavior must accommodate a variety of inputs, and the delivery of the Behavior then triggers the Evaluation process. The Evaluation Assessment process produces information such as where the Learner is at any given time which is then sent to System Coach. The Evaluation process uses the Learning Content to provide context to the Learner's Behavior to determine the appropriate Evaluation. The Evaluation process also creates and sends Performance information to the Records Database. This active triggering of Evaluation is an aspect of the AIMS complex, distributed application framework. The Evaluation process must then utilize advanced Knowledge and Intelligence Representation in the form of the adaptive SME and student model algorithms, such as genetic or fuzzy logic algorithms, that can then be used, as well as rules and pattern recognition. The AIMS distributed application framework also allows the ability to integrate many varied knowledge and intelligence techniques.

The AIMS complex, distributed application framework is also used to build the System Coach, as it must interact with other applications, and employ knowledge and display "intelligence" in its actions by also utilizing the advanced Knowledge and Intelligence Representation capabilities. The System Coach may store "bookmarks" as Performance information in the Records Database saving the Learner's session for resumption at some future time. The System Coach also receives the current Assessment from the Evaluation process, and Performance information from the Records Database, to support the decision-making process.

Based on the current Assessment and historical Performance information, the System Coach sends Query Indexes to the Knowledge Library to search for appropriate learning materials. The Knowledge Library returns Content Indexes such as a list of Locator Indexes that match the search query. The appropriate Locator Indexes such as a lesson plan are sent to the Delivery process. The System Coach sends Query Indexes to the Knowledge Library to search for content that is appropriate for the Learner. The Query Indexes specify search criteria based on, in part, Learning Style, Assessment, and Performance information.

The Knowledge Library stores knowledge and other learning materials as resources for the learning experience. The Knowledge Library may be searched by Query Indexes. The matching information is returned as Content Indexes, i.e., a set of content tags that are, conceptually, "card catalog" entries known as metadata. The locator Indexes (conceptually, "call numbers" on the bindings of the "books in the digital library", e.g., URLs) are extracted from the content indexes. The locator Indexes are used by the Delivery process to retrieve Learning Content. It is unspecified who initiates the

transfer of Learning Content and it can be the Learner, the System Coach, or the Delivery process itself. For example, a Query Index might return a set of Content Indexes and an ontology, which is a conceptual model of the subject represented as generic Learning Content.

The Delivery process receives locator Indexes from the System Coach and retrieves Learning Content from the Knowledge Library. The Delivery process transforms the Learning Content into Stimuli for the Learner. The Stimuli is actually sent to either simulations connected to the operational systems or training systems/environment and in some cases sent directly to the operational systems or training systems/environment. When the Delivery process sends Stimuli to the Learner, the Evaluation process is expecting some Behavioral response to the Stimuli. The Evaluation process is unable to interpret the Behavior without context, so the Delivery process sends the Learning Content to the Evaluation process to understand the context of the Learner's response.

3 Conclusions

In general, the key technological innovations are the ability to affordably instrument training/operational system for learning environments to stimulate learners and record their responses. The second key innovation is the ability to create intelligent systems with hybrid algorithm capabilities. For instance, the evolution of the value of a neural network could be the result of a query of a first order predicate calculus inference engine. The converse can also be implemented where a value in a rule or fact inference based engine's knowledge base could be calculated by evaluating a neural network.

Additionally, the ability to create hybrid intelligent algorithms and synchronize a large number of them permits the AIMS to be built in a more modular and understandable way as an entire intelligence system. In order to enable the next generation of instructional systems, several technology challenges had to be overcome. The establishment and elaboration of coherent, comprehensive system architecture, relevant over wide ranges of education and training situations, is a major step forward providing:

- Single learner or group training on customized courses
- Ability to instrument and control a number of systems simultaneously
- Allowance of the distribution of system processing for efficiency
- Scales in both dimensions – the number of learners, and the number of systems instrumented and controlled
- Internal and external processes
- Internal and external events
- Efficient simple two-way interactions
- Effectively creating the knowledge models for the Expert, Instructional, and Student Trainer subsystems
- Integrating the most appropriate decision algorithm required to naturally implement functionality – not just rule bases
- Utilizing a novel system development framework that permits the most appropriate type of interaction paradigm required for any component of the system

AIMS takes into account the trainee's situational awareness, cognitive capabilities, action accuracy, situational distractions, cognitive distractibility and any resulting reduction in accuracy. AIMS accounts for functionally disparate phenomena such as recognition of patterns, adapting new solutions or strategies and rule following in order to represent "intelligence" more effectively. AIMS ascertains the most appropriate feedback for the trainee by determining learning styles and communication preferences in addition to skill and provides the most accurate advice for them.

AIMS' next generation training interactive engine and architecture framework will revolutionize training and greatly enhance the intrinsic value training provides to our communities. Scalable, robust solutions are provided for complex, real-world training problems and scenarios. In general, unsolved problems become tractable, and integration and interoperability costs no longer dominate project cost profiles and automated, intelligent training is achieved. Integrating SMEs into the development process facilitates better training systems as they are there during the design, engineering, testing, and evaluation process ensuring that their training needs are met at every step of the AIMS development cycle. SMEs understand what the training issues for both the system to be trained and their trainees. SME knowledge, input and feedback are incorporated so the AIMS is customized to meet their specific training needs.

Abstract - *Large Companies often use statistical models and artificial intelligence to predict several kinds of risks. In general, only one statistical model or a neural network technique is used to predict these risks. It is not so uncommon for some companies to use segmentation to define subpopulation splits for the development of specific predictors to improve decision accuracy. However, the use of segmentation usually depends on the experience of the specialist. The basic premise of this paper is to compare three kinds of segmentation methods, crossed with three different base classifiers, and using five datasets from the UCI Repository. The segmentation methods are: NNTree - a Neural Network Tree based method, the traditional segmentation using Information Gain to split, and an experimental method called FBTSeg. Results show that blending classifiers using segmentation is a viable option to improve results of known and traditional techniques such as statistic regressions and neural networks.*

1 Introduction

The capacity for predicting events is the key element in the decision support processes for modern corporations. The results of decision models based on data are dependent on the quantity and quality of the information available. However, improvements in prediction techniques are also important for better accuracy, as several academic and practical initiatives from different areas show [1] [2] [3]. Moreover, this search goes beyond a single predictive model and is also progressing towards the combination of several predictors, both from the same and from different techniques. The literature shows that combining techniques using different sampling methods or using predictors of distinct characteristics usually offers more predictive solutions [4] [5] [6] [7] [8] [9] [10].

Combining predictors is not simple and its complexity is derived from a number of factors inherent to such combinations. Some questions that illustrate this complexity are: What is the best combination method for a specific problem? What techniques should be combined? How many predictors are needed to maximize performance? The fact is there are no simple or exact answers to those questions and most of them can only be answered based on the specific application constraints, the expertise of the developers, and results of practical experiments.

Segmentation (decomposition) [11] is one of the mostly used methods for the combination of predictive techniques and proposes the transformation of a complex problem in several less complex ones as the means to achieve the best solution to the original problem. In data mining, segmentation is used to obtain subgroups where different learning techniques may be applied, i.e. specialized predictors are applied to subsets of the original data set.

For a long time, the techniques used to find good segmentation structures were based on subjective strategies and on previous knowledge of the problem. One of these subjective techniques is separation of the data in two groups, one with a number of attributes with their values filled in, and the other with many missing values in these attributes, since this is a common situation in credit scoring problems [12]. It was even suggested that it might not be possible to create the segmentation structure without using subjective knowledge. However, methods and algorithms to find adequate segmentation structures have already been proposed. They usually represent the segmentation structure as a tree and use exhaustive or semi-exhaustive search to choose the best segmentation strategy [11].

This paper compares the performance of three different segmentation methods to build model trees. We also briefly describe a new semi-exhaustive method called FBTSeg, formerly RISKSEG [20], that implements an algorithm to optimize and build a binary decision tree with regression models in each leaf. To do this comparison we used five datasets from the UCI Repository [13].

2 Review of Used Techniques

In this section we briefly review the techniques used in the experiments, both single classifiers and their combination using segmentation.

Binary Logistic Regression is a traditional technique of statistic inference [14] that relates a dichotomic target (*good*

or *bad*, *1* or *0*, *fraud* or *not fraud*, etc.) to a set of predictive input variables X_1, X_2, …, X_n, where Y is a random variable with two possible values, 0 (zero) and 1 (one). Its result is an estimation of the probability of Y belonging to one of the two categories, based on the observed values of the predicting variables. In this paper, the estimation of $Y = 1$ will be used. The dependent variable is the logarithm of the ratio of probabilities of the two possible results of an output variable, log [p / (1-p)]. We used the widespread maximum likelihood method for estimating the binary response, having its solution found through Newton-Raphson's iterative process [15].

Linear Discriminant Analysis estimates the output variable based on the observed values of predicting variables and is usually applied when the dependent variable is numeric and continuous. Errors are assumed to have normal distribution [16]. In this paper, we use this technique to estimate the value of a dichotomic variable (0 or 1).

Multilayer Perceptron Neural Network (MLP) [17] is a computational intelligence technique that has excellent generalization capabilities, is simple to implement, and is commonly used in classification problems. In our experiments, we tested MLP with the backpropagation and Levenberg-Marquardt algorithms [17].

Segmentation is the division of the available dataset in subpopulations and the development of a prediction model for each segment. Therefore, each example is predicted according to the specific formula (model) that it belongs. The segmentation provides the most appropriate use of available information and is highly recommended when there is a large number of missing data in dataset samples. The segmentation is also recommended for capturing risk relationships among the subpopulations with different profiles – this way the specialized models in that data sample are able to explore their peculiarities more efficiently [12].

As in decision trees, one of the main criteria used for segmentation is Information Gain [18]. Decision trees aim to separate the population in disjoint subsets that are homogeneous regarding the behavior of the output variable, because distinct behaviors regarding the output variable might lead to large variations in the estimation of the regression parameters. Moreover, distinct behaviors in separate groups are to be used as the basis for the creation of multiple classifiers in the FBTSeg method.

An NNTree [19] "is a decision tree, where each non-terminal node contains a neural network". Its segmentation uses a multilayer perceptron neural network to design the classification tree. The method recursively divides the training set trying to create leaves that contain elements from a single class – each non-terminal node has elements from more than one class and uses a neural network to separate them. Even though the original implementation only uses neural networks, we have adapted the algorithm to also support both logistic regression and linear regression in the non-terminal nodes.

2.1 Find Best Tree Segmentation (FBTSeg)

The FBTSeg method [20] rationale is to try to find a set of segmented models with better performance using a binary tree built from divisions using the attribute classes. This method uses a specific algorithm for the selection of *n* attributes to test all combinations for each candidate node, where *n* is a parameter. In other words, after the attribute selection, each *n* attribute class is used to split and the best segmentation is chosen to improve the accuracy of the model for this node. Every node generates two leaves with their specific models which, when combined, generate better results than the upper node model. In summary, the best option to split each node sample is chosen. It is important to choose a specific (or the best) metric for optimizing the results of the problem in hand, such as classification error, mean squared error, KS2 [21], ROC [22], and others. To determine the best segmentation for a node split, it is necessary to join the scores of the corresponding pair of leaves, from the set of possibilities, and compare their results.

The FBTSeg method is prone to overfitting, a known problem in other supervised learning algorithms. So, it is important to create a validation dataset to apply a cross-validation between the training and validation datasets. Then the training dataset is just used to train the predictors, while the validation dataset is used to compare the scores among the segments and for determining the best segmentation possible. There is also a parameter to set the minimal number of observations to train and validate a segmented model, aimed at ensuring a minimal set to make a representative model in each leaf. Of course, its value must be established taking into account the sample size available to develop the models.

The implementation of models in subpopulations is similar to making a model with the main predictive variables combined with the variables resulting from interactions among the main variables and a selected variable [12] – see equations 1 to 5. Through the selection of good segmentations it is possible to add the most important characteristics found in the interactions of the variables. Thus, in the FBTSeg segmentation, for each terminal node that might be segmented, the possible interactions of the model variables are analyzed. The implementation algorithm builds a tree model based on the best candidate variables, those that have the best interactions with the other variables according to the chosen metric. This scheme avoids the exhaustive search for the best segmentation and permits optimizing the final result based on some chosen metric. Because it is easier to understand, we illustrate the method using a statistical linear regression with binary variables (values 0 or 1), but our implementation used logistic regression with categorical variables.

Let x_1, x_2, x_3, and x_4 be random variables, Y a dependent variable (target), $\mu_i, \beta_i, \lambda_i, \alpha_i, \omega_i, \theta_i$ the constant weights of the equations, and ε_i the error factor. We defined a simple linear regression model that only considers the main effects of the variables – no interaction term was included in the equation for parameters estimation.

$$Y = \mu_1 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_4 x_4 + \varepsilon_1 \quad (1)$$

Including interaction terms $x_i x_j$ (with i fixed and j varying) is equivalent to segment the data by x_i and adjust separate regressions for each subgroup. For example:

$$Y = \mu_2 + \lambda_1 x_1 + \lambda_2 x_2 + \lambda_3 x_3 + \lambda_4 x_4 + \lambda_{12} x_1 x_2 + \lambda_{13} x_1 x_3 + \lambda_{14} x_1 x_4 + \varepsilon_2 \quad (2)$$

In this example (2), we capture the effects of the interactions between x_1 and the other variables of the model. This is similar to segmenting the data based on the values of x_1 and adjusting different regressions to the generated subgroups. Similarly, other three models can be defined:

$$Y = \mu_3 + \alpha_1 x_1 + \alpha_2 x_2 + \alpha_3 x_3 + \alpha_4 x_4 + \alpha_{12} x_1 x_2 + \alpha_{23} x_2 x_3 + \alpha_{24} x_2 x_4 + \varepsilon_3 \quad (3)$$

$$Y = \mu_4 + \omega_1 x_1 + \omega_2 x_2 + \omega_3 x_3 + \omega_4 x_4 + \omega_{13} x_1 x_3 + \omega_{23} x_2 x_3 + \omega_{34} x_3 x_4 + \varepsilon_4 \quad (4)$$

$$Y = \mu_5 + \theta_1 x_1 + \theta_2 x_2 + \theta_3 x_3 + \theta_4 x_4 + \theta_{14} x_1 x_4 + \theta_{24} x_2 x_4 + \theta_{34} x_3 x_4 + \varepsilon_5 \quad (5)$$

These three models are equivalent to segmentations based on x_2, x_3, and x_4, respectively. So, adjusting the four regressions makes it possible to choose the best regression according to some performance measure D, i.e. the best segmentation variable. It is also necessary to choose the splitting rule, specifically, a category or a numeric interval.

The FBTSeg search is *not* the semi-exhaustive search because it does *not* test all the possible split rules of all variables. The number of splits is limited by the number of candidate variables categories. This method also permits adjusting the regressions using a subset of the training set, which makes it faster when the training set is very large.

Algorithm 1 gives a possible implementation of FBTSeg showing the search for possible segmentations. The first loop selects the best variable and the second chooses the category of this variable that may be used to split the data. So, after selecting the variable (*Var*) with the best regression results in the interaction with the other variables (factorial), all the possible binary combinations of this variable categories are tested to find the best category (*Cat*) and generate the best pair of segments, one for "*Var* = *Cat*" and another for "*Var* ≠ *Cat*". After the segmentation, the predictive performance of the suggested segments is compared to that of the upper node. The segmentation is confirmed if it improves the results of the upper node. As in decision trees, the segmentation continues until some stop criterion is reached. The final result is a set of models generated from disjoint subsets of the training data.

3 Experimental Design and Results

We run experiments with 5 (five) datasets of the UCI Machine Learning Repository [13] to compare the methods. The chosen datasets were the ones with a dichotomic target and at least 1,000 records. These are:

- *Chess* – Contains 3,196 records with information about chess matches. The peaces' positions are represented by 36 categorical variables and the target is dichotomic (0=white wins and 1=black wins).
- *German* – Credit base with 1,000 records. It contains the most common target variable in credit risk studies for the representation of good and bad payers (1=Good and 2=Bad). The input variables are mostly social-economic attributes, 20 in total, seven of them are numeric and 13 are categorical.
- *Magic Gamma Telescope* – This dataset simulates the registration of high energy gamma particles in a ground-based telescope using the imaging technique. There are 19,020 records, 10 numeric variables, and a dichotomic target with values "g" (gamma) and "h" (hadron), respectively transformed to 0 (zero) and 1 (one).
- *Adult* – Contains information of the 1994 American Census database and aims to determine whether a person makes over US$50,000 a year (1=yes) or not (0=no). There are 48,842 records and 14 variables, six of them are numeric and eight are categorical.
- *Spambase* – Contains 4,601 records and 57 numeric variables with information on the characteristics of e-mails. Its purpose is to build a spam filter, deciding whether each message is a spam (1=yes) or not (0=no).

In the preprocessing of these datasets, no categorical variable was grouped. Thus, their original values were used to generate their equivalent binary codifications, transforming each categorical variable (with n categories) in n binary variables (with values 0 or 1). On the other hand, all numeric variables were normalized with continuous values in the [0, 1] interval. However, because the implementation of the FBTSeg segmentation and also of the traditional segmentation by information gain both expect categorical variables to split the nodes, it was also necessary to categorize all numeric variables and, so, we decided to create four categories, each with approximately 25% of the data. Nevertheless, the generated categorical variables were only used in the segmentations – the training used their normalized numeric versions.

We also used the k-fold Cross Validation technique in the experiments and the chosen value for k was 10. This is a fairly common technique in experiments involving classifier

N – Training set of a given terminal node
S_1, S_2 – Subsets of N generated by the segmentation
p – Number of input variables of N
$X_1,X_2,...,X_p$ – Discrete input variables of N
w – Local variable that stores the number of categories of each discrete variable
C[w] – Local array that stores the values of each discrete variable
y – Target variable (dependent)
fMet( ) – Performance Function (larger values are considered to be better in this example)
fMerge() – Merge function to join the results of the models
Var – Variable chosen to test its categories
Cat – Category of *Var*
rMod, – Answers of the factorial models
$rMod_0$ – Best answers of the models
$rMod_1$, $rMod_2$ – Answers of the models of the candidate segments
$rMod_{12}$ – Joint answer of the models of the candidate segments

Input: N**;**

$rMod_0 \leftarrow \emptyset$; (Best answers initialization)
For i = 1 to p do { (Loop over all the input variables)

$rMod \leftarrow$ Regression answers y ~ $\sum_{j=1}^{P} X_j + \sum_{j=1, j\neq i}^{P} X_j X_i$, with data from N; (Trains model with interactions)

If *fMet* ($rMod$) > *fMet* ($rMod_0$) { (If the model improves the result)
$rMod_0 \leftarrow rMod$; (Saves the best answers of the model)
$Var \leftarrow X_i$; (Saves the chosen segmentation variable)
};
};

$rMod_0 \leftarrow \emptyset$; (Best answers re-initialization)
$rMod_{12} \leftarrow \emptyset$; (Mod12 answers set initialization)
C[w] ← Category values of *Var*;
w ← Number of categories of *Var*;

For i = 1 to w do { (Loop over the categories of Var)
S_1 ← Subset of N, such as *Var* = C[w]; (Creates the two training subsets)
S_2 ← Subset of N, such as *Var* != C[w];

$rMod_1 \leftarrow$ Regression answers y ~ $\sum_{j=1}^{P} X_j$, with data from S_1; (Trains the models of the two subsets)

$rMod_2 \leftarrow$ Regression answers y ~ $\sum_{j=1}^{P} X_j$, with data from S_2;

$rMod_{12} \leftarrow rMod_1 \cup rMod_2$; (Joins the answers of the models of the segments)
If *fMet* ($rMod_{12}$) > *fMet* ($rMod_0$) { (If the segmented models improve the result)
$rMod_0 \leftarrow rMod_{12}$; (Saves the best answers of the models)
$Cat \leftarrow$ C[w]; (Saves the chosen segmentation category)
};
};

Output: *Var, Cat*; (Best segmentation variable and category)

Algorithm 1 – FBTSeg algorithm that chooses the best segmentation.

combination [23]. Therefore, the datasets were separated in 10 parts, each with 10% of the data, and, in each experiment, one of them was the testing set. The rest of the data was used for training (65%) and validation (35%).

The simulations were implemented in such a way that each single classifier was used as base classifier in the comparison with the segmentation methods.

The main difference regarding the three segmentation methods is the way the segment splits are chosen. NNTree originally uses an MLP neural network to split the training dataset [19], but we also implemented adaptations for using linear and logistic regressions as well. These three prediction techniques were also used with the other two segmentation methods and, for each of them, the behavior of the combination methods for the generation of multiple classifiers

was observed and the results measured using the classification error rate. We named "Simple" the classifications using each of the three chosen techniques as single base classifier, and "TradSeg" the segmentations by information gain.

3.1 Defining Experiment Parameters

In both regressions, it was not necessary to choose variables or parameters. The choice of parameters for training the MLP was based on the test for the best number of neurons in the intermediate level and the best training algorithm. For each data set, we tested all the possible combinations of the two training algorithms (backpropagation and Levenberg-Marquardt) with 3, 10, and 20 neurons in the intermediate layer. The chosen activation function was logistic function having the minimum squared error on the cross-validation set as the training stopping criterion. We used the standard learning rate of SAS Enterprise Miner [24], version 4.0, which cannot be modified in this version of the software. We then chose the best configuration for the single classifier and for the segmentations.

We decided to use similar parameters in the training of the three methods as much as possible, as the means to focus on the way the dataset splits are done. For the three segmentation methods, we used 2 (two) as the maximum depth of the tree because, in preliminary tests, we observed that the best segmentations were in these two levels. For the minimum size of a leaf node we chose 5%, a size we judged appropriate, considering that all datasets have at least 1,000 examples. The metric used to evaluate the results of the experiments was the classification error. Our implementation of the segmentation methods used a validation dataset to determine if there was a gain (or not) in each segmentation possible. The validation dataset used was 35% of the training set and the same dataset was used in the validation of the MLP neural network.

3.2 Results

Table 1 presents the average classification errors (percentages) of the three single classifiers crossed with the three segmentation methods in the five data sets tested. The comparison is always based on the control classifier (Simple) of each technique. We used the t-Student test for paired data, with significance level of 5%. Average errors that are smaller than that of the respective base classifier are written in bold. Smaller and statistically different values are marked with an asterisk (*). Greater and significantly worse values are written in italics. We considered the best classifier the one with the smaller average error, as long as it is significantly better than the base classifier.

In the Chess dataset, using MLP, the three segmentations presented better average results, and statistically significant, when compared to the base classifier, and the FBTSeg method was considerably better than the second best result (TradSeg). Using linear regression, again, all three segmentations improved the results of the base classifier considerably, but the best results were obtained with the TradSeg method and its results were significantly better than the others. Using logistic regression, only the FBTSeg method presented significantly better results than the base classifier – TradSeg was only marginally better than the base classifier.

Table 1 – Average errors and confidence intervals.

Dataset	*Technique*	*Simple*	*TradSeg*	*NNTree*	*FBTSeg*	*Best*
Chess	MLP	4.07 ±1.05	**1.09 ±0.42***	**2.81 ±0.59***	**0.35 ±0.14***	FBTSeg
	Linear Reg.	8.57 ±1.64	**2.28 ±0.55***	**3.18 ±0.68***	**3.25 ±0.77***	TradSeg

German	MLP	25.20 ±1.79	25.70 ±1.20	*27.10 ±1.97*	25.30 ±1.84	Simple
	Linear Reg.	29.00 ±2.31	**26.00 ±1.77***	29.25 ±3.08	**26.30 ±2.00**	TradSeg
	Logistic Reg.	25.70 ±2.08	**24.70 ±2.08**	25.95 ±1.94	26.30 ±2.51	Simple
Magic	MLP	15.16 ±0.53	**14.84 ±0.60***	15.24 ±0.53	**13.51 ±0.58***	FBTSeg
	Linear Reg.	32.03 ±2.81	**18.73 ±0.56***	**27.31 ±2.65***	**16.06 ±0.65***	FBTSeg
	Logistic Reg.	20.98 ±0.44	**18.29 ±0.67***	**18.69 ±0.55***	**15.40 ±0.51***	FBTSeg
Adult	MLP	14.89 ±0.91	**14.71 ±0.96**	**13.60 ±1.33***	15.07 ±0.86	NNTree
	Linear Reg.	17.38 ±1.23	**15.81 ±0.78***	**13.68 ±0.83***	**16.73 ±1.25**	NNTree
	Logistic Reg.	14.90 ±1.00	14.96 ±0.97	**14.58 ±0.97**	14.96 ±0.82	Simple
Spambase	MLP	7.06 ±0.60	7.15 ±0.91	**6.81 ±0.57**	7.45 ±0.71	Simple
	Linear Reg.	24.36 ±6.83	**9.02 ±0.92***	**6.45 ±0.61***	**10.61 ±0.75***	NNTree
	Logistic Reg.	8.69 ±0.63	**8.67 ±0.58**	**6.76 ±0.66***	**8.19 ±0.76**	NNTree

In the German dataset, only the TradSeg method using linear regression significantly improved the results of the base classifier. Using MLP, the NNTree segmentation had significantly worse results. A possible explanation to such results is the small number of examples in this dataset. This fact leads to small segments in the model tree, and this situation is aggravated by the need of examples for validation. It is likely that this is the main reason why the segmentations did not improve the results, generating classifiers that are weaker than the ones of the original nodes.

In the Magic dataset, the segmentations improved the results of nearly all combinations. The linear regressions obtained the bigger gains; in particular, FBTSeg improved the average error from 32.03% to 16.06%. Using MLP, only the results of FBTSeg and TradSeg were significantly better than that of the base classifier. Using logistic regression, all three segmentations (NNTree, FBTSeg and TradSeg) improved the results, but only FBTSeg was statistically better than the base classifier. It is important to notice that, in this dataset, FBTSeg significantly improved the average error using all three techniques, when compared to the base classifiers, and also when compared to the other segmentations.

In the Adult dataset, all three segmentations improved the results of the base classifier using linear regression, but the FBTSeg results were not significantly better. The NNTree method was the only one to significantly improve the results using MLP and none of them obtained significant improvements using logistic regression.

In the Spambase dataset, using MLP, none of segmentation methods presented statistically significant results. With linear regression, they all significantly improved the base classifier, but the NNTree method was also noticeably better than the other segmentation methods. Using logistic regression, they all had smaller errors but only NNTree was significantly better than the base classifier.

4 Conclusion

This paper presented the results of experiments comparing three different segmentation methods, using three different base classifiers, and five UCI datasets. The traditional segmentation based on information gain and another two more recent segmentation methods (NNTree and FBTSeg) were tested against well-known classifiers such as linear regression, logistic regression, and MLP neural network.

Our results show that segmentation may be a viable alternative to improve the performance of classifiers. One of its advantages is that it may improve the results of older techniques, within the existing expertise of the modeling team. Even using linear regression, a classifier that is known to be weaker [25], the use of segmentation methods may lead to results that are similar and sometimes superior to those obtained with newer and more predictive techniques such as MLP neural networks [25] [2]. Moreover, segmentations can also improve the results using MLP: in three of the five tested datasets, at least one of the three segmentation methods presented statistically better results.

From all the classifiers (simple or combined), the FBTSeg method achieved the best performance in the Chess and Magic datasets, obtaining 5 (five) of the possible 6 (six) best results, when we consider the three techniques available. The very best results in these two datasets were obtained with the FBTSeg + MLP combination.

Even though the NNTree method was not originally developed to work with the statistic regressions, it improved the results of these base classifiers in 7 (seven) of the possible 10 (ten) combinations; only in the German dataset it did not improve any results; and, perhaps surprisingly, it even achieved the best results in the Adult and Spambase datasets when combined with linear regression.

Although the TradSeg method is older and simple, it also improved the results of the base classifiers in many configurations. However, in general, both NNTree and FBTSeg presented better results. Nevertheless, none of the segmentation methods was clearly better than the others in all datasets. Thus, our conclusion is that it is worth testing more than one segmentation method to choose the one that is more suitable to the specific problem in hand.

As future work, it is important comparing the segmentation methods tested in this paper with other methods for combining classifiers such as Bagging [26], Boosting [26], and Stacking [4] [5] [26]. It is worth testing other base classifiers such as SVM [26] and k-NN [26] as well. Running experiments with other datasets is also recommended. Another possibility of future work is to experiment different split strategies for the segmentation tree, for example, using *n*-ary trees and/or different split algorithms.

Towards Making SELinux Smart

Leveraging SELinux to Protect End Nodes in a Federated Environment

L. Markowsky
School of Computing and Information Science, University of Maine, Orono, ME USA

Abstract – *This paper describes an intelligent, active, real-time, risk adaptable access control (RAdAC) system designed to extend the benefits of the National Security Agency's Security-Enhanced Linux (NSA's SELinux) by using SELinux not only as a secure base, but also as a source of input features to a Support Vector Machine (SVM) that will classify events/attacks in several categories. By enhancing SELinux with intelligence, it is hoped that the design will lead to real-time, non-signature based defensive systems capable of detecting and taking action against hostile users in the earliest stages of an attack.*

Keywords: support vector machine, machine learning, risk adaptable access control, RAdAC, SELinux

1 Introduction

The transformative vision of the Department of Defense's decentralized Global Information Grid (DoD's GIG) and the nation's dependence on Supervisory Control and Data Acquisition (SCADA) systems present challenging security issues. Effective security in these and many other federated environments is best implemented in layers, employing intelligent security mechanisms both centrally and on the end nodes.

The proliferation of cyberattacks will eventually overwhelm signature and rule-based approaches [1], and many critical applications and files must be permitted to continue to run or exist even when under attack. Many current solutions, however, rely on signature-based detection, kernel modifications, prevention of selected system functions while critical applications are running, the deletion or encryption of sensitive material while selected system functions are permitted, or computationally expensive data mining for anomalies [2][3]. Each of these approaches fails to meet at least one of the following desirable goals: detection of zero-day attacks, continuous operation of critical systems while under attack, widespread applicability of the technique, and real-time protection.

New approaches using machine learning and a focused set of input features [4] promise to revolutionize defensive systems. Support Vector Machines (SVMs) are among the best (and many believe are indeed the best) 'off-the-shelf' supervised learning algorithms [5].

This paper describes a prototype of an intelligent, active, real-time, risk adaptable access control (RAdAC) system designed to extend the benefits of SELinux by using SELinux not only as a secure base, but also as a source of input features to an SVM that will classify events/attacks in several categories. The system is designed to be integrated into an end node in any environment, including end nodes in federated environments such as DoD's GIG and SCADA systems. By enhancing SELinux with intelligence, it is hoped that the design will lead to real-time, non-signature based defensive systems capable of detecting and taking action against hostile users in the earliest stages of an attack.

Specifically, the prototype of the defensive system is designed to be:

- Integrable into Nearly Any Computerized Device – The defensive system is designed to be integrated into nearly any Linux-based end node (any Linux system running a 2.6 kernel and using a filesystem with extended attributes), including hand-held devices, servers, workstations, notebooks, and dedicated single purpose devices;
- Zero-Impact on Protected Applications and Files – The defensive system requires no modifications whatsoever to the software and files to be protected;
- Configurable for Critical Systems – The defensive systems can be tailored to create a focused defensive system for critical files and applications and for known personnel;
- Risk Adaptable – The defensive system is an RAdAC system in which an administratively-controlled "Current Operational Need" and the attacks and events detected by the system itself together designate the current risk level;
- Modular – The defensive system is modular in order to facilitate future extensions;

- Real-Time – By leveraging SELinux, the defensive system is designed to be lightweight enough to run in real time; and

- Compatible with National Security Goals – The defensive system is designed to parallel the National Security Agency (NSA) Information Assurance Directorate's vision for securing content in DoD's GIG.

2 Prototype – A smart, active, SELinux-based RAdAC defensive system

2.1 Modular defensive system design

The modular defensive system (Figure 1) features machine learning to overcome the limitations of signature and rule-based defenses and input from SELinux to enable the system to run in real time.

Module 1 uses SELinux denials generated by local and remote system requests to produce feature vectors suitable as input to an SVM. Module 2 then uses a previously trained SVM to classify attacks/events in several discrete categories in real time. Module 3, a graded response system, provides feedback to Module 2 and selects a response appropriate for the detected event, the history of events on that system, and the current operational need.

Testing and analysis will include study of the input feature set selection, the graded response system, and the tradeoffs between error rates and performance (false negative/positive rates vs. throughput and load on the system).

2.2 Extending Module 1

Module 1 may be extended to protect critical applications and files, to detect keyloggers, and to detect attackers with physical access (Figure 2). To protect critical applications and files, application-specific and file-specific raw input would be used in addition to SELinux denials in order to generate input feature vectors for the SVM. For example, to configure the input feature extractor to protect a web server, messages from Apache2, ModSecurity, and messages specific to the protected web pages would be used as raw input to the feature parser. Keystroke dynamics [6] [7] may be used to implement detection of keyloggers and attackers with physical access. While these extensions may enhance security, the input feature extractor will be tied to particular applications, files, and users, making this design suitable only for critical systems.

2.3 Design goals

The design of the defensive system (Figure 1) adheres to DoD's Three Tenets of Cyber Security. First, SELinux's mandatory access control mechanism (MAC) limits "access points to only those necessary to accomplish the mission [thereby making] critical access points and associated security less accessible to [the] adversary." Second, dynamically relabeling the SELinux context of a critical application "moves it out of band" when under attack. Third, the graded response system "denies [the] threat capability [by imposing] appropriate penalties when [an] attack is detected" [8].

Also, the design of the defensive system supports users of end nodes in federated systems by protecting "edge users who must operate across multiple domains and communications paths, on less hardened networks, to reach other tactical mission players, and to access protected core information systems and data warehouses" [9]. The defensive system achieves this goal by using a graded response module that neither suspends critical applications nor deletes critical and files – except in the most extreme circumstances – enabling end node systems to prevent "an attack from becoming successful while allowing the executing software and associated data being protected to remain operational and trustworthy" [10][11].

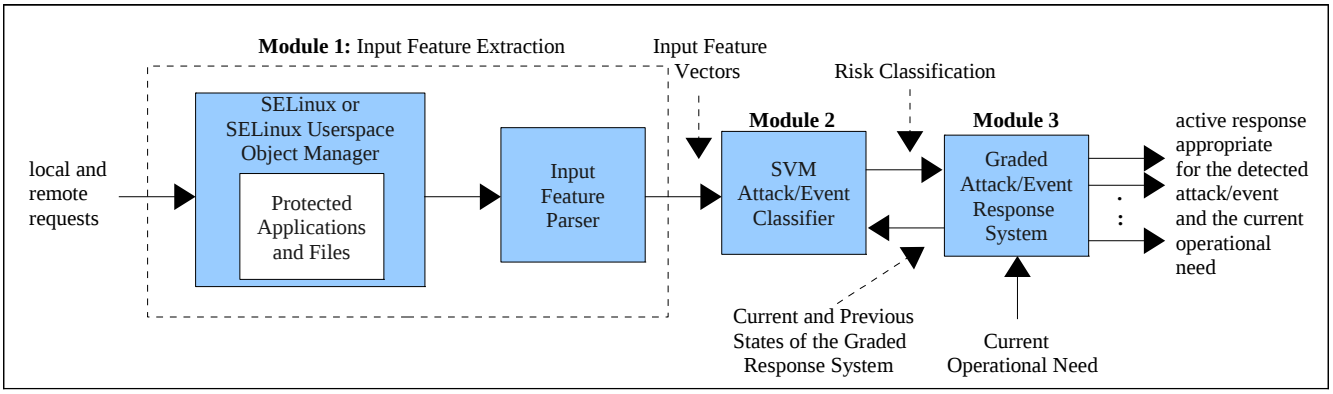

Figure 1. An Intelligent, SELinux-Based, RAdAC Defensive System

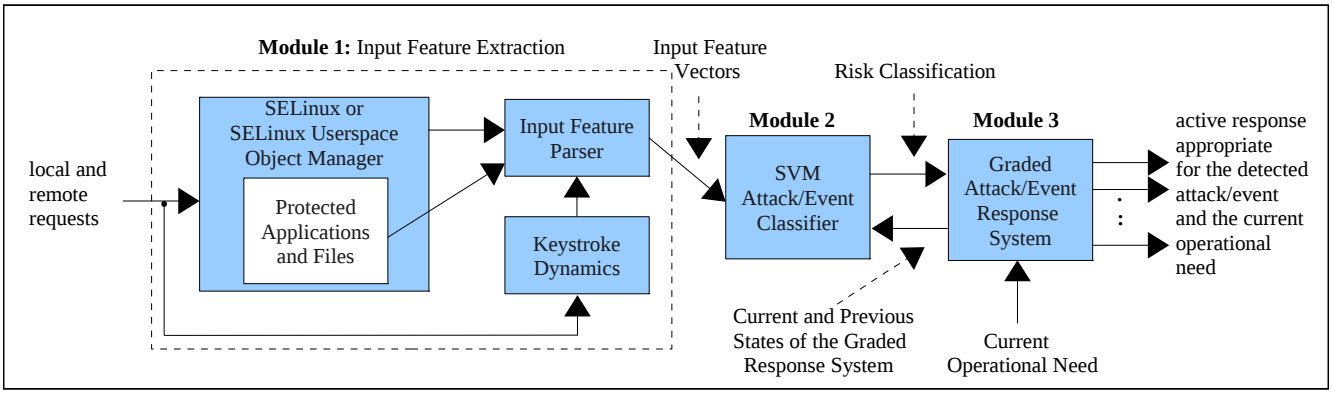

Figure 2. An Application-Specific, Personnel-Specific, Intelligent, SELinux-Based, RAdAC Defensive System

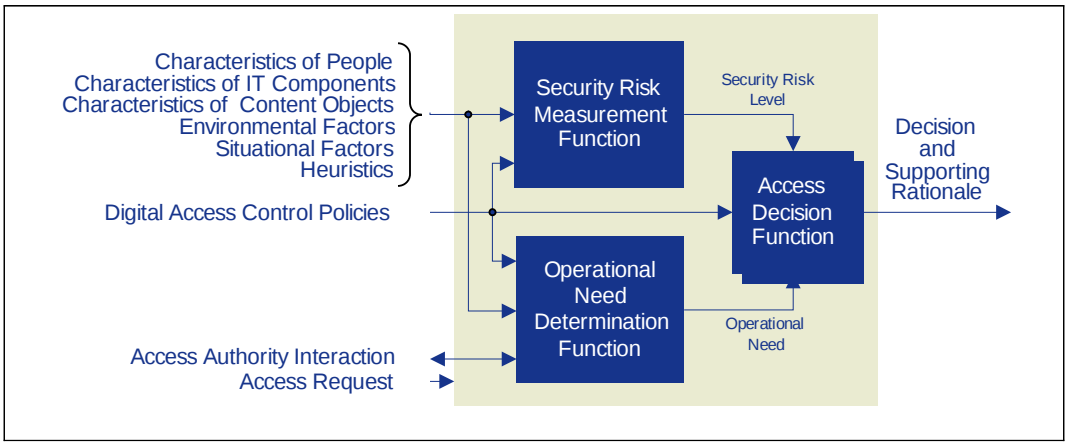

Figure 3. NSA's Vision for Access Control in DoD's GIG [12]

Finally, the design of the extended defensive system (Figure 2) parallels the NSA Information Assurance Directorate's vision for securing content in DoD's GIG (Figure 3). Modules 2 and 3 are analogous to the Security Risk Measurement Function and the Access Decision Function of Figure 3, respectively; Keystroke Dynamics, SELinux, and the Target Application messages in Module 1 are all analogous to the Characteristics of People (or other entities) [13]. The modular design facilitates future extensions that might incorporate Situational Factors or automate the current Operational Need.

3 User interface

The user interface is database-driven website designed to be friendly but restricted to authorized administrators. The main menu consists of: System, SVM, Packet Captures, Datasets, Analysis, Documentation, and Database Administration.

3.1 System submenu

The System submenu provides forms that enable the administrator to start or stop selected modules of the defensive system (Figures 4 and 5). To facilitate testing and analysis, the system permits Module 1 alone, Modules 1 and 2, or the entire defensive system to be run.

The System submenu consists of:

- Reset the SELinuxSVM Defensive System
- Start the SELinuxSVM Defensive System
- Stop the SELinuxSVM Defensive System

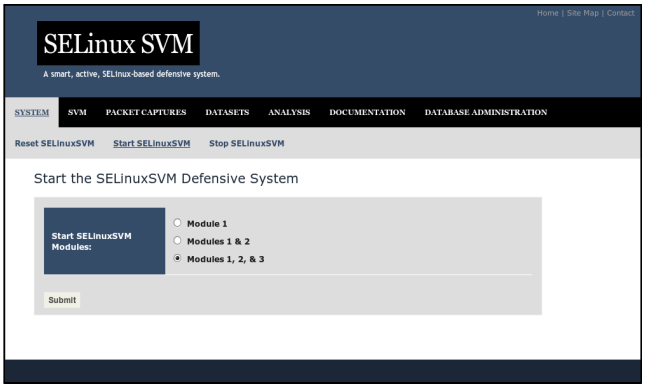

Figure 4. Starting the SELinuxSVM Defensive System

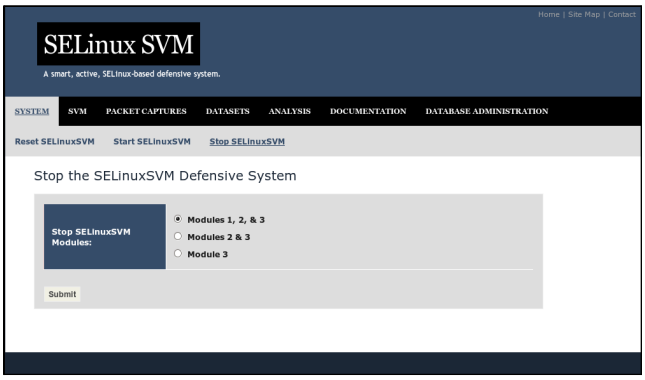

Figure 5. Stopping the SELinuxSVM Defensive System

3.2 SVM submenu

The SVM submenu provides forms that enable the administrator to select optimal SVM training parameters and dataset features as well as forms to train and test the SVM (Figure 6).

The SVM submenu consists of:

- Select Dataset Features Used to Train the SVM
- Select Parameters (Grid Search for Optimal C and gamma)
- Train the SVM
- Classify Data Points

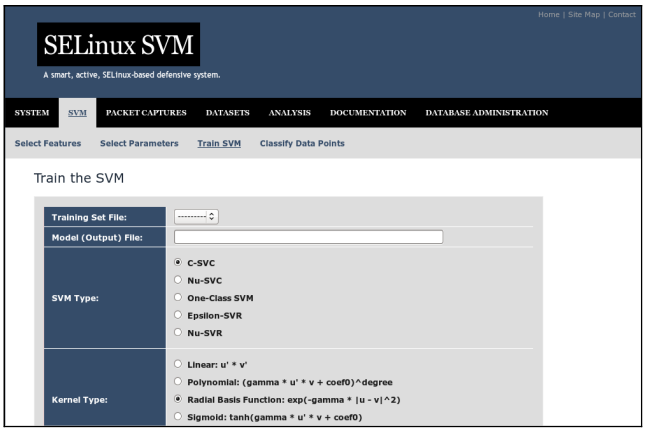

Figure 6. Training the Support Vector Machine

3.3 Packet captures submenu

The Packet Captures submenu provides forms to enable the administrator to view, replay, and filter packet capture files (Figure 7). These forms feature packet captures collected during the 2009 and 2010 Northeast Collegiate Cyber Defense Competitions (NECCDC), which are discussed in Section 7.

The Packet Captures submenu consists of:

- Filter an NECCDC 2009 Packet Capture File
- Filter an NECCDC 2010 Packet Capture File
- Filter a PREDICT Packet Capture File
- Replay a Packet Capture File
- View a Packet Capture File

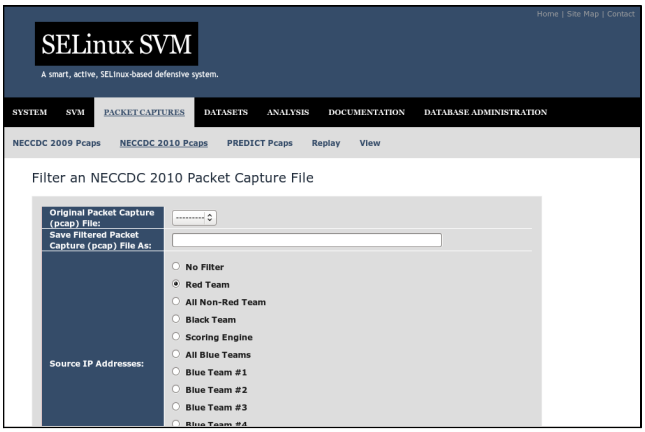

Figure 7. Filtering an Existing Packet Capture File

3.4 Datasets submenu

The Datasets submenu provides forms to enable the administrator to generate a dataset from a packet capture file, scale a dataset (Figure 8), and relabel and edit datasets. Generating datasets from packet capture files is discussed in Section 7.

The Datasets submenu consists of:

- Generate a Dataset from a Pcap File
- Scale a Dataset
- Relabel a Dataset
- Edit a Dataset

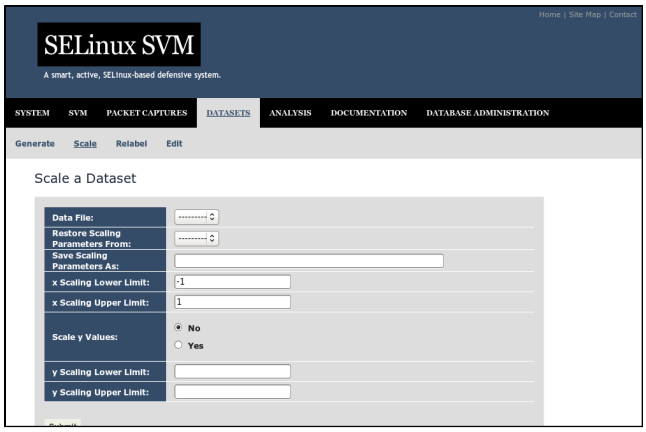

Figure 8. Scaling a Dataset

3.5 Analysis submenu

The Analysis submenu provides three performance metrics, which are discussed in Section 7, and two methods for the user to view results. "View Results" and "Plot Results", respectively, are tools to visualize and plot two-dimensional slices of the SVM together with training or testing datasets, regardless of the number of the input features.

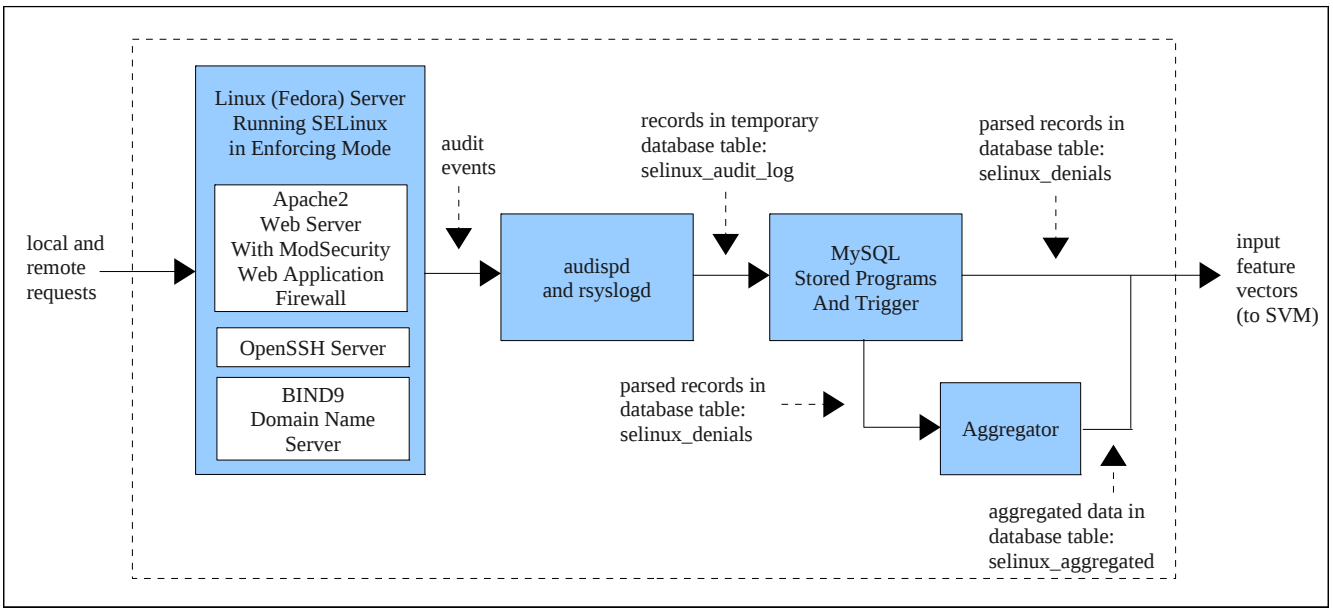

Figure 9. Module 1: Input Feature Extraction

The Analysis submenu consists of:

- Performance Metric 1: V-Fold Cross Validation Accuracy
- Performance Metric 2: SVM Training Time
- Performance Metric 3: SVM Prediction Time
- View Results (in Two Dimensions)
- Plot Results (in Two Dimensions)

4 Module 1 – Input feature extraction

Module 1, the Input Feature Extractor, automatically generates input feature vectors suitable for an SVM from local and remote requests (Figure 9). Audispd (an audit event multiplexer) and rsysogd (an extended message logging utility) are configured to enter copies of SELinux denials in a temporary MySQL database table called selinux_audit_log (Figure 10). When an entry is made in selinux_audit_log, a stored MySQL trigger parses the message to create a more useful table entry in selinux_denials (Figure 11). Offloading the parsing from the system logging mechanism to MySQL is designed to avoid a bottleneck, since parsing using rsyslogd involves time-intensive regular expression pattern matching, which is likely to be slower than MySQL stored programs. Similarly, aggregated data is collected by MySQL stored programs and entered in the selinux_aggregated table.

5 Module 2 – SVM attack/event classifier

The SVM attack/event classifier uses input from Module 1 and feedback from Module 3 in order to classify events in several discrete categories:

- Origin – an authenticated user on a tty, a user on the LAN, or a remote request;
- Number of Sources – single source vs. distributed attack;
- Target – the defensive system itself, SELinux, the operating system, the protected critical process, the protected executable, or protected files associated with the critical system;

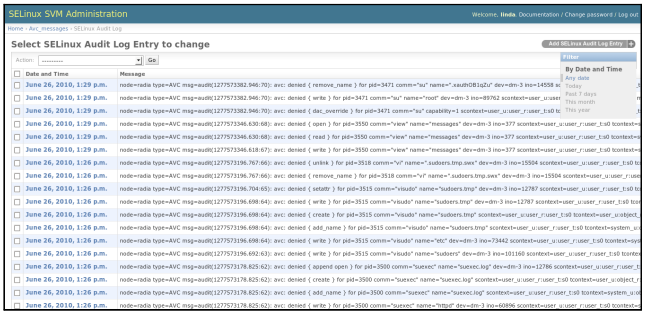

Figure 10. The SELinux Audit Log Database Table

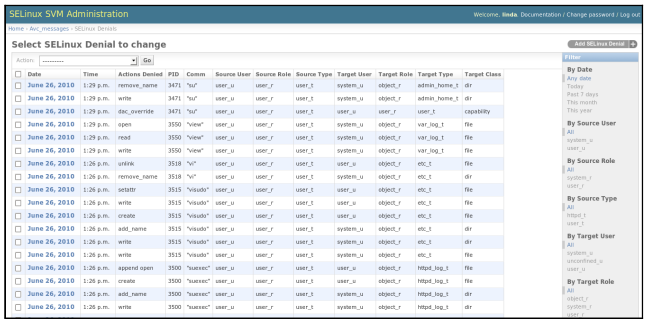

Figure 11. The SELinux Denial Database Table

- Time Span – single burst, an hourly or daily recurring event; and

- Type/Severity – single read attempt, a copy attempt over the Internet, a malicious write attempt, an unauthorized SELinux relabeling attempt, or an unauthorized attempt to transition into the SELinux sysadm_r role.

The SVM and kernel types are determined during training. Default values are C-SVC (classifier) and the radial basis function (RBF) or Gaussian kernel: $\exp(-\gamma * \|u - v\|^2)$. All SVM-related functions are implemented using libsvm [14].

6 Module 3 – Graded attack/event response system

The graded attack/event response system selects a defensive action appropriate for the classification of the attack/event as determined by the SVM, the current and previous states of the graded response system, and the current operational need. The response system selects actions appropriate for the severity of the event:

- Minor Events: In response to minor events, actions taken include alerting the administrator, filtering and saving logs, and taking a snapshot of the process tree.

- More Severe Events: In response to more severe events, actions taken include killing the offending process and processes directly related to the offending process, adding IPTables firewall rules, moving attacked files to a secure location, and relabeling the SELinux security context and Linux's discretionary access control (DAC) of the applications and files under attack.

- Extreme Events: Only in extreme circumstances (such as evidence of an attacker with physical access to the machine attempting to transition into the sysadm_r role) will critical files be deleted or critical processes terminated.

Two active responses of Module 3 specifically related to SELinux are:

- Reconfiguring Linux's DAC to dynamically manage the flow of input to the defensive system, thereby controlling the system's throughput and load; and

- Relabeling the SELinux security context of the files and processes under attack.

Relaxing the DAC causes SELinux's MAC mechanism to be consulted more frequently, increasing the load on the operating system but also catching attempted attacks at an earlier stage. If the load on the system is too great, then the DAC labels are strengthened, allowing the defensive system to continue to operate in real time. If, on the other hand, a process or file is so critical that any unauthorized attempt to read/write/execute that file would indicate an attack, then the DAC is set to the most permissive label (777) so that SELinux will be consulted on every read/write/execute request of that file, detecting the attacker at an earlier stage.

Relabeling the SELinux security context of critical files and processes under attack creates a dynamically changing protection boundary on the end node. In effect, critical files and processes are moved out of band in order to frustrate the attacker while simultaneously keeping the files and processes trustworthy and operational.

The defensive system aggressively protects itself by including the operating system, SELinux, and the system itself in the classes of targets of detected attacks. Any attempt to undermine the defensive system is be considered to be an "extreme" event.

7 Testing and analysis

7.1 Packet capture files

The packet capture files provide raw input that can be filtered and replayed to generate training and testing datasets. Packet capture files collected during the 2009 and 2010 NECCDC are currently available via the defensive system user interface. These defensive cybersecurity competitions pitted "blue" teams, each of which protected a group of servers and workstations from a "red" team charged with attacking them. The "blue" teams were prohibited from engaging in offense. A "black" team and scoring engine generated friendly traffic and monitored the services required of the blue teams' servers.

Since the IP addresses of the "blue", "red", and "black" teams are known, it is possible to filter friendly and hostile traffic using wireshark or tshark filters. In addition, the target IP addresses of the filtered packets can be rewritten to redirect the packets to a test host running the defensive system prototype. The filtered packet capture files can then be replayed to produce training and testing datasets.

7.2 Training and testing datasets

Training and testing datasets are used to train and test the SVM and graded response system. Dataset features should be scaled to prevent one feature from dominating and skewing the resulting SVM. The user interface also permits the administrator to relabel a dataset to indicate friendly traffic or hostile traffic in several classifications.

7.3 Time and performance metrics

Three performance metrics measure the accuracy and time performance of the defensive system.

The V-Fold Cross Validation Accuracy metric prevents overfitting, that is, prevents producing an SVM that is too specific for a particular dataset. Since the purpose of an SVM is to predict the classification of unknown data points, an overfitted SVM is undesirable. V-fold cross validation is a relatively simple concept:

> In v-fold cross-validation, we first divide the training set into v subsets of equal size. Sequentially one subset is tested using the classifier trained on the remaining (v – 1) subsets. Thus each instance of the whole training set is predicted once so the cross-validation accuracy is the percentage of data which are correctly classified [15].

The SVM Training Time measures the time to calculate the SVM from a dataset, and the SVM Prediction Time measures the time to make a single prediction using an existing SVM. These metrics are included to measure the defensive system's ability to run in real time, since one of the goals of the project is to attempt to design a non-signature based defensive system that can run in real time by leveraging existing security mechanisms and by dynamically adjusting the load.

8 Future work

The prototype is currently being developed. First, a complete implementation of Module 1 and preliminary implementations of Modules 2 and 3 will be completed and the NECCDC 2009 and 2010 packet captures will be used to generate testing datasets. Following a complete analysis of Module 1 using the preliminary prototype, Modules 2 and 3 will be fully implemented, the PREDICT packet captures will be added to the files used to generate testing datasets, and the entire defensive system will be tested and analyzed.

9 Acknowledgments

The author thanks Dr. James Fastook, Dr. Phil Dickens, Dr. Bruce Segee, and Dr. George Markowsky of the University of Maine and Dr. Danny Kopec of the CUNY (City University of New York) Graduate Center and Brooklyn College for their invaluable advice and support.

Integration of Negative Emotion Detection into a VoIP Call Center System

Tsang-Long Pao, Chia-Feng Chang, and Ren-Chi Tsao
Department of Computer Science and Engineering
Tatung University, Taipei, Taiwan

Abstract - *The speech signal itself contains not only the semantics of the spoken words but also the emotion state of the speaker. By analyzing the voice signal to recognize the emotion hidden in the speech signal, it is possible to identify the emotion state of the speaker. With the integration of a speech emotion recognition system into a VoIP call center system, we can continuously monitor the emotion state of the service representatives and the customers. In this paper, we proposed a framework that integrates the speech emotion recognition system into a VoIP call center system Using this setup, we can detect in real time the speech emotion from the conversation between service representatives and customers. It can display the emotion states of the conversation in a monitoring console and, in the event of a negative emotion being detected, issue alert signal to the service manager who can then promptly react to the situation.*

Keywords: Speech Emotion Recognition, Call Center, Negative Emotion Detection, WD-KNN Classifier

1 Introduction

The voice signal in the conversation represents the semantics of the spoken words and also the emotion state of the speaker. If a dispute happened between the service representative and the customer, there is no way to notify the service manager to take action immediately in current call center system. Since the customer service is playing an important role for an enterprise, the customer satisfaction is very important. So, the management of customer service department to improve the customer satisfaction is an important issue for the enterprise.

Traditional customer service lacks of the ability in issuing alerts for conversation with negative emotion in real-time. For example, when the customer disagrees with the service representative, a dispute may arise. The traditional call center handles a large amount of calls every day and will usually make recording of all the calls for later analysis to see whether there is any improper conversation or not. However, these setups cannot handle the dispute situation in a timely manner.

A considerable number of studies have been made on speech emotion recognition over the past decades [1-16]. By integrating the speech emotion recognition system into the VoIP call center system, we can continuously monitor the emotional state of the service representatives and the customers. In this paper, we propose the mechanism to integrate the negative emotion detection engine into the VoIP call center system. A parallel processing architecture is implemented to meet the performance requirements for the system. We also record the emotion states for all of the calls into the database. Alerts will be issued to the service manager whenever a negative emotion such as anger is being detected. The service manager has a chance to intervene into the two quarreling parties to pacify the customer and resolve the problem immediately. With this mechanism, it can enhance the level of customer satisfaction.

The organization of this paper is as follows. In Section 2, the background and the related researches of speech emotion recognition and voice over Internet Protocol (VoIP) are reviewed. In Section 3, the system architecture of a multi-line negative emotion detection in VoIP Call Center is described. In Section 4, the experimental setup is presented and the results are discussed. Conclusions are presented in Section 5.

2 Backgrounds

2.1 Speech Emotion Recognition

In the past, quite a lot of researchers studied the human emotion and try to define what an emotion is. But it is hard to define emotional category because of there is no a single universally agreed definition. The emotion category defined by Ortony and Turner is a commonly accepted definition [10]. In recent years, the study of psychological tends to divide emotion category into basic emotion and complex emotion. The complex emotion is a derived version from the basic emotion in their definition.

In addition to the semantics of spoken word, the speech signal also carries information of the emotion state of the speaker. That is, inside the speech signal, there are features that are related to the emotion state at the time of making that speech. By analyzing these features, it is possible to classify the emotion categories with a suitable classifier.

Features related to speaking rate, signal amplitude, frequency, jitter, and formant are being studied in the speech emotion recognition researches. [1-4].

In previous studies of emotion recognition, there are several aspects that are being addressed. Some of the studies tried to find the most relevant acoustic features to the emotion inside the speech signal [13-16]. Searching for the most suitable machine learning algorithms for the classifier is also a topic that attracted quite a lot of attention [7][9-12]. In most of the previous studies, short speech corpora are used in the experiments. However, in this research, we need to deal with the continuous speech, which is long in nature. Therefore, we need to find a way to properly segment the speech signal and categorize the emotion such that burst misclassification will not affect the accuracy of the judgment.

The corpus is a set of a large collection of utterance segments. A corpus plays an important role in the emotion recognition research. In this paper, the D80 corpus built in the previous studies is used. We use the D80 to train our emotion recognition engine. The speech corpus was collected from 18 males and 16 females who were given 20 scripts and were asked to speak out in five emotions including anger, boredom, happiness, neutral and sadness for each of them. A subjective test is performed and those utterances with over 80% agreement were kept. After this process, there are 570 utterances left. The number of utterances in each emotion categories in the D80 corpus is 151 for anger, 83 for boredom, 96 for happiness, 116 for neutral, and 124 for sadness.

A considerable number of previous studies have been made on feature selection in order to improve the accuracy of the emotion recognition. The core of the feature selection is to reduce the dimension of the feature set to a smallest feature combination that yields the highest recognition accuracy. The speech features commonly used in previous emotion recognition researches include Formants (F1, F2 and F3), Shimmer, Jitter, Linear Predictive Coefficients (LPC), Linear Prediction Cepstral Coefficients (LPCC), Mel-Frequency Cepstral Coefficients (MFCC), first derivative of MFCC (dMFCC), second derivative of MFCC (ddMFCC), Log Frequency Power Coefficients (LFPC), Perceptual Linear Prediction (PLP), and Zero-Crossing Rat (ZCR). According to previous studies, the MFCC is the commonly used feature for the emotion recognition [13]. Therefore, we choose the MFCC feature as the acoustic feature as input to the classifier input in this research.

In the machine learning, the purpose of a classifier is to classify objects with similar characteristics into the same class. The classification can be divided into two types, supervised (e.g. KNN) and unsupervised (e.g. k-means). In this research, we used the Weighted D-KNN (WD-KNN) classifier, which is a variant of KNN and is proposed in [11]. The KNN is a classification algorithm that assigns the test sample to a class based on the distance between test sample and k-nearest training samples. The WD-KNN extends the KNN by comparing the weighted distance sum to maximize the classification accuracy. The weight calculation is to assign a higher weight to neighbors that provide more reliable information.

For an M-class classification using KNN, let the k neighbours nearest to unknown test sample $\mathbf{y}$ be $\mathbf{N}_k(\mathbf{y})$, and $c(\mathbf{z})$ be the class label for training sample $\mathbf{z}$. The subset of the nearest neighbours in class $j \in \{1, \cdots, M\}$ is

$$\mathbf{N}_k^j(\mathbf{y}) = \{\mathbf{z} \in \mathbf{N}_k(\mathbf{y}); c(\mathbf{z}) = j\} \quad (1)$$

If we denote the cardinality (the number of elements) of the set $\mathbf{N}_k^j(\mathbf{y})$ as $|\mathbf{N}_k^j(\mathbf{y})|$. Then the classification of $\mathbf{y}$ belonging to class j^* is the majority class vote, that is:

$$j^* = \arg\max_j \{|\mathbf{N}_k^j(\mathbf{y})|\} \quad (2)$$

For WD-KNN classification, we need to select k nearest neighbors from each class. Let d_i^j denotes the Euclidean distance between the i_{th} nearest neighbor in class j to unknown sample $\mathbf{y}$. The distance measure is in ascending order, that is $d_i^j \le d_{i+1}^j$. The weighted distance sum for sample $\mathbf{y}$ to all the k nearest neighbors in class j will be

$$D^j = \sum_{i=1}^{k} w_i d_i^j \quad (3)$$

where $w_i \ge w_{i+1}$ for all i. As discussed in [11], the best recognition rate could be obtained by using a weighting in the reverse ordered Fibonacci sequence, which is:

$$w_i = w_{i+1} + w_{i+2}, \quad w_{k-1} = w_k = 1 \quad (4)$$

The classification of $\mathbf{y}$ belonging to class j^* is the class with the shortest weighted distance

$$j^* = \arg\min_j \{D^j\} \quad (5)$$

As a conclusion, the speech emotion recognition is a system that takes the voice signal as input and then recognizes the emotion of the speaker at the instance of making that speech. From the extracted features, the most likely emotion was judged by using a classification algorithm. The block diagram of a speech emotion recognition system is shown in Figure 1. In this system, the

selected features were extracted and sent to the classifier to determine the most probable emotion of that segment.

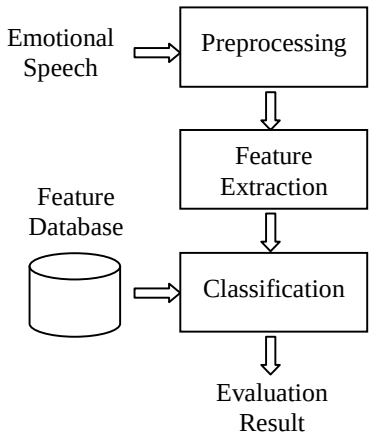

Figure 1. Block diagram of emotion recognition system

2.2 VoIP Telephony and Packet Capture Techniques

VoIP or known as IP phone is a technology that uses internet to accomplish telephone communication. The IP phone was used internally in the enterprise in the past. However, owning to the rapid grown of internet, the IP phone is now widely adopted and is gradually replacing the traditional telephone communication system. Currently, the commonly used VoIP communication protocol is the Session Initiation Protocol (SIP). The SIP is a protocol developed by IETF MMUSIC which is used in the establishment, modification and termination of an interactive call session. Possible applications include voice and video communication, instant messaging, online game, virtual reality and other multimedia applications. The purposes of SIP are to define the format and the control of the packets transmitted over the internet.

The SIP is a point to point protocol. Using a distributed architecture, the SIP transmits the text-based information and names the address by URL. The SIP use similar syntax as some protocols used in the internet such as HTTP and SMTP which consist of headers and message body.

There are two types of SIP operations for the client connection, one is to connect the two clients in a point to point manner, and the other is to connect the party though a proxy server. In this research, we adopt proxy server configuration to simplify the packet capture process. The IP PBX (IP Private Branch exchange) works as the proxy server and plays the role of packet relaying. We capture the packets in and out from the IP PBX by port mirroring from the switch the server connected to.

The packet capture tool used in this study is WinPcap. WinPcap is a tool for link-layer network access in Windows environments. It includes kernel-level packet filter, a dynamic link library (packet.dll) and a high-level and system-independent library. It can be used in win32 platform to capture network packets. WinPcap consists of a driver that facilitates the operating system to access the low-level networks. WinPcap also provides a library that can be used easily to access the low-level network layers by the application programs. In addition, the kernel of WinPcap also provides packet filtering. Through the filter setting, the driver will directly discard unwanted packet in driver layer. The performance of the packet filter is good. Hence it is now widely used in a lot of software such as WireShark.

3 System Architecture

In this paper, we proposed a framework that integrates the speech emotion recognition system into a VoIP call center system. The components of the system are shown in Figure 2. The customer and the service representative communicate with each other through the VoIP phones. We defined session as the conversation between the pair of the customer and the service representative. We use a layer 2 switch to mirror packets going in and out from the IP PBX into our packet capture agent. Then, we identify the session and assign the session with a Session ID (SID) if it is new. After the session is established, we extract the voice signal from the RTP packets captured and regroup it into proper segments. The speech emotion recognition system will be activated to classify the emotion of each segment. Finally, the recognition result will be stored into a database. The system will issue an alert whenever a negative emotion, mainly anger, is detected.

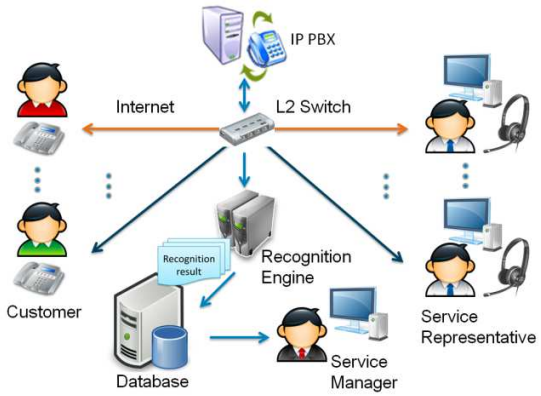

Figure 2. Components of the proposed system

The operation steps of system are shown in Figure 3. First, the system will capture the packets and filter out the SIP and RTP packets. The Speech Emotion Recognition System (SERS) will assign a Session ID (SID) according to the phone number of the service representative and

customers. Then, the speech segment will be sent to the emotion recognition engine to classify the emotion state. Finally, the classification results will be stored into database. The service manager acquires the all the results using a web page interface. The system will issue alert to service manager when the negative emotion is detected.

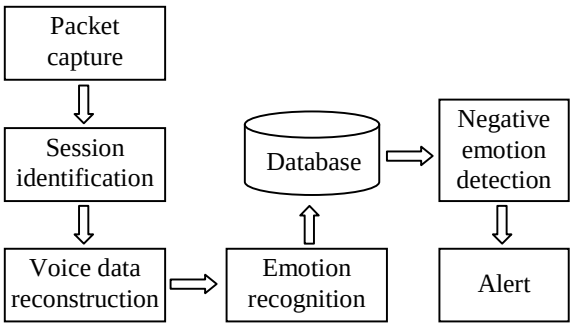

Figure 3. Operations of the speech emotion recognition

3.1 Packet Capture and Session Identification

The packet is the smallest unit in network communication. Packets are transmitted across the internet through a series of switches and routers. A packet consists of a header and a payload. The header has the control information for the transmission of packets. The control information includes source and destination IP addresses, source and destination ports, etc. In our experiment environment, all of the VoIP packet will pass through the SIP proxy server. In this framework, we can use a mechanism called port mirror in the layer 2 switch to mirror the packets in and out of the SIP server. Then, we can capture the packets and analyze its content easily.

In the call center, each phone line is independent. But once the call is established, the phone number will not change during the call. So, the identification of a session is necessary for storing the captured RTP packet to the correct pair of conversation. We build a session object to manage the session. The session object include source IP, setup time, speech coding and used buffers. We create a session object when a session start and we will remove the session object when the phone call ends. In order to implement multi-line packet capture, we need to identify the source and destination IP address of the packet first. According to the information, we assign a session ID to the session, and then allocate the storage for storing the session ID and related information.

3.2 Emotion Recognition Engine

To integrate emotion recognition function into the VoIP call center system require further effort then the speech emotion recognition. Some attempts have been made by scholars to use the combination of multiple speech features to increase the accuracy of speech emotion recognition. However, in order to process multi-line voice segment simultaneously in real-time, the recognition engine needs to reduce the computational complexity. From previous studies, the MFCC feature has been proven to be one of the most robust features in emotion recognition [12]. So we choose to use only the MFCC in the emotion recognition. We use the WD-KNN to be our classifier.

In order to process multi-line voice segment, we may need more than one computer to perform the speech recognition. We design a mechanism to share the load among several speech emotion recognition engines. Virtual machine architecture is used to fully utilize the computing power of a high performance server. With this framework, we can distribute the voice segment recognition to each virtual machine in turn. The parallel processing mechanism can resolve the bottleneck problem due to the high computational resource required by the recognition engine.

3.3 Negative Emotion Detection

In the D80 corpus, there are five basic emotion categories. We further divided them into positive and negative class. The positive emotion includes happiness and neutral, and the negative emotion includes anger, sadness and boredom. In this paper, we focus on detecting the anger emotion incurred in the conversation between the service representative and customer. The system will issue an alert whenever the anger emotion being detected during the conversion between the service representative and the customer.

To decrease the false alarm rate, a score board judgment mechanism is implemented. The score board is zero at the beginning of a session. When the emotion recognition result is anger, the score board will increase by 4 points. The score board will decrease 1 point when no anger emotion is detected for a voice segment if the score is positive. The system will confirm the anger emotion when the score exceed the threshold. An alert flag will be written to database whenever the score exceed the threshold. An alert message will be sent to the service manager through a web page interface whenever alert flag is being set.

4 Experiments and Result Discussion

4.1 Experimental Setup

The proposed system consists of three subsystems. The detail description of each subsystem will be presented in this section. The framework of the proposed system is shown in Figure 4.

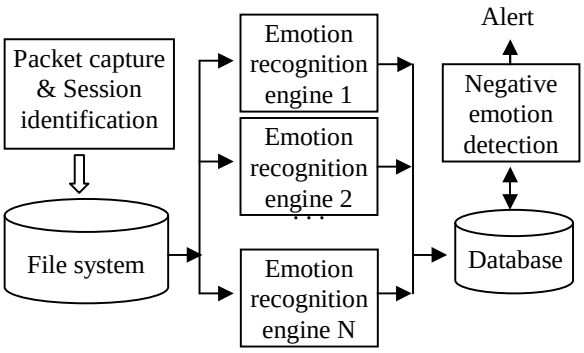

Figure 4. Framework of the proposed system

The Asterisk IP PBX server is installed in a Linux platform. In this research, we assign the SIP ID 1xx as the phone number for customers, SIP ID 4xx for the service manager, and SIP ID 6xx for the service representatives. The SIP phone is configured in the proxy mode, such that all the SIP and RTP related communication packets between the customer and the service representative will pass through the IP PBX. With this configuration, we can capture all the SIP and RTP packets by mirroring the traffic going into the server from the Layer 2 switch where the server is attached.

The session information is stored in a table structure. When a new SIP or RTP packet is received, the packet capture module will capture the packet, analyze the content of header and compare it with the contents in the session table. If it is a new session, the system will create a new session identifier and assign a new session ID to it; otherwise the existing session ID will be retrieved.

4.2 Emotion Recognition

We capture the voice signal from the conversation between the customer and service representative. The voice we captured will be regrouped into sound file in WAV format with 1 second in duration each. We will send the segmented voice file into the speech recognition engine, and the engine will output the recognition result. In order to increase the performance of the emotion recognition engine, we use a parallel architecture to build our recognition system. We setup several machines and install the recognition engine written in MATLAB into each machine. By using this structure, the bottleneck problem of the speech emotion recognition system can be avoided. The output from each recognition engine is stored into a database. The results are analyzed by using the score board algorithm stated above to determine whether the anger emotion exists in the conversation or not.

4.3 Testing Samples

A six scripts corpus was recorded by inviting volunteers to speak out the scripts with emotion as they like. Each corpus is tagged subjectively by human judge. Only the results with more than 80% agreement in this process are kept. The emotion of human seems to change gradually. So we use the score board concept to determine whether or not an anger emotion was occurred in the conversation between the customer and the service representative.

In our environment, we set the score to 0 at the beginning. If a negative emotion is being detected, the system will add 4 points to the corresponding session, or otherwise the system will subtract 1 point from that session if the score is positive. In order to reduce the false negative emotion recognition rate, a threshold should be set. We test several threshold values, including 4, 8, 12, and 16, to check the recognition accuracy. We compare the emotion recognition results with human judge for the chosen threshold. The result of the negative emotion detection is listed in Table 1.

Table 1. Number of detected negative emotion with different threshold T.

	Human Judge	T=4	T=8	T=12	T=16	T=20
Script1	2	59	36	18	1	0
Script2	0	2	0	0	0	0
Script3	0	48	33	16	5	0
Script4	1	21	1	1	1	0
Script5	7	97	85	61	29	10
Script6	10	54	39	23	12	7

In Table 1, the negative emotion detection results are close to the human judge when the threshold is 16 except the script 3 and 5. For script 3, the content of the script consist of a lot of happy sentence. It is hard to differentiate between happiness and anger in a speech emotion recognition system since they are both in the activation category. For script 5, the content of the script consists of continuous negative emotion. Due to the score board architecture, it is hard to count the dispute correctly. The advantage of the score board framework is that it can reduce the judgment error. But it cannot count the dispute exactly. For the negative emotion detection as mentioned above, the most important thing is to issue an alert when the dispute happened. The frequency of the dispute is not an important issue in this research.

5 Conclusions

The call center plays an important role for an enterprise. It is obviously that collects the opinion from the customer

and pacify the customer if he or she is too agitated is important for the enterprise. To improve the quality of the service of the call center, we can integrate a negative emotion detection mechanism into the call center system. When a service representative faces too many angry customers, the call distribution system can reduce the number of calls to that representative to avoid the representative running into angry state. In this paper, we propose and implement the frameworks which can handle multi-line phone call with negative emotion detection capability. We modularize the system components that make the system more flexible. We develop the subsystem individually which includes packet capture and analysis, emotion recognition, result recording, and negative emotion detection. In the part of emotion recognition, we adopt the parallel architecture to avoid the possible bottleneck problem. By the combination of these subsystems, we build a system that can detect negative emotion from the conversation and issue an alert to service manager accordingly. Consequently, this system can improve the service quality of a call center because of the service manager has a chance to intervene to resolve the problem immediately.

Machine Learning with Templates

Michael Stephen Fiske
Aemea Institute, San Francisco, CA, USA
mf@aemea.org

Abstract— *New methods are presented for the machine recognition and learning of categories, patterns, and knowledge. A probabilistic machine learning algorithm is described that scales favorably to extremely large datasets, avoids local minima problems, and provides fast learning and recognition speeds. Templates may be created using an evolutionary algorithm described here, constructed with other machine learning methods, designed by a human expert or synthesized using a combination of these methods. Each template has a prototype and matching function which can help improve generalization. These methods have applications in bioinformatics, financial data mining, goal-based planners, handwriting recognition, machine vision, natural language processing / understanding, search engines, strategy such as business and games and voice recognition.*

Keywords: evolution, machine learning, pattern recognition, polymorphous, template

1. Introduction

New machine learning methods and knowledge representation have sought to provide superior technology applications. In this regard, Machine Learning with Templates pertains to recognizing categories and predictive modelling, which can be important components of advanced software technology.

Machine Learning with Templates was designed to use the advantages of bottom-up and top-down methods. Over the last few decades, some practitioners in AI, cognitive psychology, machine learning and neurobiology have observed that some cognitive tasks are better suited to bottom-up methods, while other tasks are better performed by top-down methods (See [1], [7], [10], [11], [18], [19], [20]).

An example of a bottom-up representation is a feedforward neural network that uses a gradient descent learning algorithm ([1], [12]), applied to handwritten digit recognition [17]. Other types of tasks use top-down methods. For example, IBM's Deep Blue software program plays chess [15]. Hammond's *CHEF* program creates new cooking recipes by adapting old recipes [23].

2. Summary of Useful Properties

Machine Learning with Templates has some useful properties.

1) Categorization is probabilistic and polymorphous (See [5], [24], and pages 26-31 in [7]).
2) Learning algorithm 5.1 is extremely fast. It takes less than one minute – for a 5 Ghz Intel Pentium 4 computer – to build templates that successfully recognize handwritten letters with an error rate less than 0.5%. Some neural network training times for handwriting recognition take considerably more time. Further, the design of the neural network architecture may take human researchers many weeks.
3) Learning algorithm 5.1 does not use a *greedy* optimization algorithm such as gradient descent [1], so it avoids local minima problems. On extremely large datasets, locally greedy algorithms may not adequately train in a practical amount of time.
4) Each template has a prototype and matching function which can help improve generalization. In some applications, the use of prototypical examples and templates designed by a clever human expert can substantially increase machine learning accuracy and speed.
5) Recognition algorithm 4.1 is extremely fast. It scales well on huge datasets and large numbers of categories because it exploits *exponential elimination*. As an example, consider the task of recognizing Chinese characters [25]. Some estimates state that there are 180 million distinct categories of Chinese characters. When the learning algorithm builds a set of templates that on average eliminate $\frac{1}{3}$ of the remaining Chinese character categories, then one trial of the recognition algorithm on average uses only 46 randomly chosen templates to reduce 180 million possible Chinese categories to a single category. (46 is the largest natural number n satisfying inequality $180,000,000 * (\frac{2}{3})^n < 2$.)
6) Machine Learning with Templates is flexible enough to create useful applications in bioinformatics, financial data mining, goal-based planners, handwriting recognition, information retrieval, machine vision, natural language processing / understanding and voice recognition.

3. Definitions and Template Structure

The space $\mathcal{C}$ is called a category space. Sometimes a space is a mathematical set, but a space may have more structure [21]. If the category space is about concepts that are living

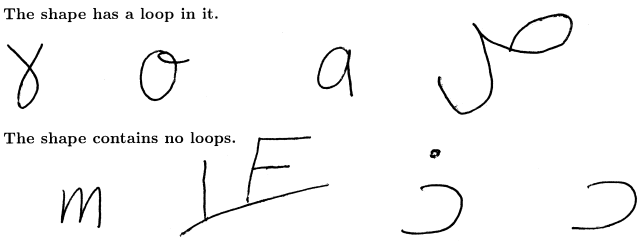

Fig. 1: Shapes with loops and no loops

creatures, then typical members of $\mathcal{C}$ are the categories: *dog*, *cat*, *animal*, *mammal*, *lizard*, *starfish*, *tree*, *barley*. A different category space is the letters of our alphabet $\{a, b, c, \ldots, y, z\}$. Another abstract type of category space may be the functional purpose of genes. One category is any gene that influences eye color; another category is any gene that codes for enzymes used in the liver; and another category is any gene that codes for membrane proteins used in neurons. In short, the structure of the category space depends upon what set of possibilities that you want the software to retrieve, recognize or categorize.

The example space $\mathcal{E}$ represents every conceivable example. Consider a software program that recognizes handwritten letters used in the English language [17]. The example space is every handwritten *a*; ... ; and every handwritten *z*. The set of training examples $\{e_1, e_2, \ldots, e_m\}$ is a subset of the example space $\mathcal{E}$.

The function $G : \mathcal{E} \rightarrow \mathcal{P}(\mathcal{C})$ is an ideal map or *ideal target function* [20], where $\mathcal{P}(\mathcal{C})$ is the power set of $\mathcal{C}$. In this case, each example e in $\mathcal{E}$ can be classified as lying in 0, 1 or multiple categories. The goal is to construct a function $g : \mathcal{E} \rightarrow \mathcal{P}(\mathcal{C})$ so that $g(e) = G(e)$ for every $e \in \mathcal{E}$. The example e = *tiger* lies in the categories *cat*, *animal* and *mammal*. In other words, $G(e) = \{cat, animal, mammal\}$. For some applications, it may impossible or extremely difficult to explicitly describe G with a mathematical formula or representation. In other implementations, the results of the template recognition algorithm can interpret e as having a probability $p(c)$ of lying in category c for each $c \in \mathcal{C}$. In these cases, the goal is to build $g : \mathcal{E} :\rightarrow [0, 1]^{\mathcal{C}}$ close to G.

Templates are similar to classifiers [20], but have additional structure. Templates are used to distinguish between two different categories of patterns, information or knowledge. For example, if the two different categories are the letters *a* and *m*, then *the shape has a loop in it* is a useful template because it distinguishes *a* from *m*. (See figure 1.)

Distinct from classifiers, templates have prototype and matching functions. Let $\{T_1, T_2, \ldots, T_n\}$ denote a collection of templates, called the template set. Associated to each template, there is a corresponding template value function $T_i : \mathcal{E} \rightarrow \mathcal{V}$, where $\mathcal{V}$ is a template value space. There are no restrictions made on the structure of $\mathcal{V}$, which may be a subset of the real line, a subset of the integers, a discrete set, a manifold, or even a function space.

Each template T_i has a corresponding prototype function $T_i : \mathcal{C} \rightarrow \mathcal{P}(\mathcal{V})$. The prototype function is constructed during the learning phase. If c is a category in $\mathcal{C}$, then $T_i(c)$ equals the set of prototypical template values that one expects for all examples e that lie in category c. Intuitively, the prototype function represents how template T_i generalizes to every example e.

For each $(template, category)$ pair, denoted as (T_i, c), there is a matching function $M_{(T_i,c)} : \mathcal{V} \rightarrow \mathcal{S}$, where $\mathcal{S}$ is the similarity space. The matching function determines if the template value is similar enough to its set of prototypical values. In general, the similarity space $\mathcal{S}$ is the range of the matching function, and can be the unit interval $[0, 1]$, a subset of $\mathbb{R}^n$, a discrete set, a manifold or a function space.

Example 3.1: Boolean Matching Function
Let $\mathcal{V} = \{0, 1\}$. Choose similarity space $\mathcal{S} = \{0, 1\}$. If template value v_1 is similar to its prototypical set $T_i(c)$, then $M_{(T_i,c)}(v_1) = 1$. If v_1 is not similar enough to its prototypical set $T_i(c)$, then $M_{(T_i,c)}(v_1) = 0$. Choose two categories $\{c_1, c_2\}$ and two templates $\{T_1, T_2\}$. Define prototypical functions for T_1 and T_2 as $T_1(c_1) = \{1\}$ and $T_1(c_2) = \{0, 1\}$. $T_2(c_1) = \{0, 1\}$ and $T_2(c_2) = \{0\}$. There are four distinct matching functions $M_{(T_1,c_1)}, M_{(T_2,c_1)}, M_{(T_1,c_2)}$ and $M_{(T_2,c_2)}$.

1) $M_{(T_1,c_1)}(0) = 0$ AND $M_{(T_1,c_1)}(1) = 1$
2) $M_{(T_2,c_1)}(0) = 1$ AND $M_{(T_2,c_1)}(1) = 1$
3) $M_{(T_1,c_2)}(0) = 1$ AND $M_{(T_1,c_2)}(1) = 1$
4) $M_{(T_2,c_2)}(0) = 1$ AND $M_{(T_2,c_2)}(1) = 0$

4. Template Recognition

The template recognition algorithm categorizes an example e from $\mathcal{E}$. When finished, for each category c in $\mathcal{C}$, there is a corresponding category score s_c, which measures to what extent the algorithm believes example e is in category c.

Algorithm 4.1: Template Recognition Algorithm

```
Allocate memory.  Read learned templates
{T1,...,Tn} from long-term memory.

Initialize every category score sc to zero.
Outer loop:  m trials.
{
   Initialize set R equal to  C.
   Inner loop: choose ρ templates randomly.
   {
     Choose template Tk with probability pk.
     For each category c ∈ R
       if M(Tk,c)(Tk(e)) = 0, then set R := R − {c}.
       (Remove category c from R.)
   }
   For each category c remaining in R, category
   score sc := sc + 1.
}
Initialize A to the empty set.
```

For each category c in C, if $(\frac{s_c}{m}) > \theta$, $A := A \cup \{c\}$.
The answer is A. The example e is in the categories that are in A.

Comments on the Template Recognition Algorithm.

1) Each template T_i has a corresponding probability p_i of being chosen during the inner loop. m is the number of trials in the outer loop. ρ is the number of templates randomly chosen in each trial. θ is a number in the interval $[0, 1]$ that is the acceptable category threshold.
2) In some applications, the category threshold is not used. Each value $\frac{s_c}{m}$ is interpreted as the probability that example e lies in category c.
3) If only the best category is returned as an answer, rather than multiple categories, then do this by replacing the step For each category c in $\mathcal{C}$, if $(\frac{s_c}{m}) > \theta$, $A := A \cup \{c\}$. Instead, search for the maximum category score if there are a finite number of categories. The answer is the category or categories that have the maximum category score.
4) If template space $\mathcal{V}$ and similarity space $\mathcal{S}$ have more structure, then the test if $M_{(T_k,c)}(T_k(e)) = 0$ inside the inner loop may be replaced by the test if $T_k(e)$ is not close to prototype value $T_k(c)$. In this case, matching function $M_{(T_k,c)}$ measures the closeness of $T_k(e)$ and $T_k(c)$.
5) In some applications, the inner loop may be exited if R has only one element left (i.e., $|R| = 1$) before all ρ templates have been applied.

5. Template Learning

The initial part of the learning phase constructs the templates from simple building blocks, using the examples and the categories to guide the construction. Templates can be built with evolution, another machine learning method [1], by a human expert with domain expertise or by a combination of these methods. In the next section, evolution algorithm 6.1 builds template value functions $T_i : \mathcal{E} \to \mathcal{V}$ from a collection of building block functions $\{f_1, f_2, \ldots, f_r\}$. The rest of the learning builds the matching functions $M_{(T_i,c)}$, constructs the prototype functions $T_i : \mathcal{C} \to \mathcal{P}(\mathcal{V})$, computes the probabilities p_i, and in some cases sets the category threshold θ.

The learning starts with a collection of training examples along with their categories. Depending on the type of template values, there are different methods for constructing the prototype and matching functions $M_{(T_i,c)}$. For clarity, the template values used are boolean (i.e., $\mathcal{V} = \{0, 1\}$). In the boolean case, $M_{(T_i,c)}(v) = 1$ if v lies in the prototypical set $T_i(c)$; $M_{(T_i,c)}(v) = 0$ if v does not lie in the prototypical set $T_i(c)$. In a more general description of the algorithm, the template value space $\mathcal{V}$ may be the interval $[0, 1]$, the circle S^1, or another manifold, a function space, a space of algorithms or even a measurable space (e.g., [6], [22]). When $\mathcal{V}$ is a metric space [21], the matching function $M_{(T_k,c)}$ may use $\mathcal{V}$'s metric to measure the closeness of $T_k(e)$ and $T_k(c)$ as described in recognition comment 4.

Algorithm 5.1: Template Learning Algorithm

Allocate memory for the templates.
Read from memory template set $\{T_1, T_2, \ldots, T_n\}$.
(The templates read are user-created, created by evolution or an alternative method as in [16].)
Outer loop: iterate thru each template T_k.
{
  Initialize $X := T_k(c_1)$.
  Initialize $A := X$.
  Inner loop: iterate thru each category c_i.
  {
    Set $E_{c_i} :=$ all learning examples in c_i.
    Build prototype function T_k as follows:
    Set $T_k(c_i) := \cup\{v\}$ for each $v = T_k(e)$ and $e \in E_{c_i}$.
    Set $A := A \cup T_k(c_i)$.
    Build matching function $M_{(T_k,c_i)}$.
    (See above for boolean case.)
  }
  If $(A == X)$ remove T_k from the template set.
}
Store the remaining templates.
Set each probability $p_k = \frac{1}{m}$ where m is the number of remaining templates.

Comments on the Template Learning Algorithm.

1) The Inner loop assumes that there are a finite number of categories.
2) In some cases, instead of a category threshold, each score s_c is interpreted as the probability that e lies in category c. In other cases, the category threshold θ is empirically determined.
3) For a fixed template T_k, there should be at least one pair of categories (c_i, c_j) such that $T_k(c_i) \neq T_k(c_j)$. Otherwise, template T_k can not separate any categories, so T_k should be removed.
4) In some applications, non-uniform probabilities p_k can be selected based on template T_k's ability to separate categories, T_k's computing speed or another property.

6. Designing Templates with Evolution

The use of evolutionary methods for optimizing processes and algorithms was first introduced by [2], [3], [4] and [9] and were further developed in [12], [13] and [14]. Building upon this prior work, this section presents an evolutionary method to design the template value functions $T_i : \mathcal{E} \to \mathcal{V}$.

Building blocks are composed to build a useful element. In some cases, the building blocks are a collection of functions $f_\lambda : X \longrightarrow X$, where $\lambda \in \Lambda$, X is a set and Λ is an index set. In some cases, X is the set of computable real numbers. In a handwriting recognition application, X is the

rational numbers and the binary functions $f_1 = +$, $f_2 = -$, $f_3 = *$, and $f_4 = /$ are sufficient for the building blocks. The index set, $\Lambda = \{1, 2, 3, 4\}$, has four elements. In some cases, the index set may be infinite. For example, consider the functions $f_{(k,b)} : \mathbb{Z} \longrightarrow \mathbb{Z}$ such that $f_{(k,b)}(x) = p_k x + b$ where $b, k \in \mathbb{N}$ and p_k is the kth prime (i.e., $p_1 = 2, p_2 = 3, \ldots$).

Bit-sequences $[b_1 b_2 b_3, \ldots b_n]$, where $b_k \in \{0, 1\}$ encode functions composed from building block functions. $[10110]$ is a bit-sequence of length 5. The expression $\{f_1, f_2, f_3, \ldots, f_r\}$ denotes the building block functions, where $r = 2^K$ for some K. Then K bits uniquely represent one building block function. The arity of a function is the number of arguments that it requires. For example, the arity of the real-valued quadratic function $f(x) = x^2$ is 1. The arity of the projection function, $P_i : X^n \longrightarrow X$, is n, where $P_i(x_1, x_2, \ldots, x_n) = x_i$.

Define the function $\vee$ as $\vee(x, y, z) = x$ if ($x \geq y$ AND $x \geq z$), else $\vee(x, y, z) = y$ if ($y \geq x$ AND $y \geq z$), else $\vee(x, y, z) = z$. Consider the functions, $\{+, -, *, \vee\}$. Each sequence of two bits uniquely corresponds to one of these functions: $00 \longleftrightarrow +$ $01 \longleftrightarrow -$ $10 \longleftrightarrow *$ $11 \longleftrightarrow \vee$

Bit-sequence $[00, 01]$ encodes the function $+(-(x_1, x_2), x_3) = (x_1 - x_2) + x_3$, which has arity 3. For the general case, consider the building block functions $\{f_1, f_2, f_3, \ldots, f_r\}$, where $r = 2^K$. Any bit-sequence $[b_1\ b_2\ \ldots\ b_K\ b_{K+1}\ b_{K+2}\ \ldots b_{2K} \ldots b_{aK+1}\ b_{aK+2} \ldots b_{(a+1)K}]$ with length $(a+1)K$ is a composition of the building block functions, $\{f_1, f_2, f_3, \ldots, f_r\}$. The composition of these r building block functions are encoded in a similar way, as described for functions $\{+, -, *, \vee\}$.

The distinct categories are $\{C_1, C_2, \ldots, C_N\}$. The population size of each generation is m. For each i, where $1 \leq i \leq N$, E_{C_i} is the set of all learning examples that lie in category C_i. The symbol γ is an acceptable level of performance for a template. The symbol Q is the number of distinct templates whose fitness must be greater than γ. The symbol $p_{crossover}$ is the probability that two templates chosen for the next generation will be crossed over. The symbol $p_{mutation}$ is the probability that a template will be mutated.

The main evolution steps are summarized. For each category pair (C_i, C_j), $i < j$, the building blocks $\{f_1, f_2, f_3, \ldots, f_r\}$ are used to build a population of m templates. This is accomplished by choosing m multiples of K, $\{l_1, l_2, \ldots, l_m\}$. For each l_i, a bit sequence of length l_i is constructed. These m bit sequences represent the m templates, $\{T_1{}^{(i,j)}, T_2{}^{(i,j)}, T_3{}^{(i,j)}, \ldots, T_m{}^{(i,j)}\}$. The superscript (i, j) represents that these templates are evolved to distinguish examples chosen from E_{C_i} and E_{C_j}. The fitness of each template is determined by how well the template can distinguish examples chosen from E_{C_i} and E_{C_j}. Using crossover and mutation, the population of bit-sequences are evolved until there are at least Q templates which have a fitness greater than γ. When this happens, choose the Q best templates from the population that distinguish categories C_i and C_j. Store these Q best templates in a distinct set $\mathcal{T}$ of templates that are used in the template learning algorithm.

Algorithm 6.1: Building Templates with Evolution

```
Set T equal to the empty set.
For each i in {1, 2, 3, ..., N}
For each j in {i+1, i+2, ..., N}
{
  Initialize population A_(i,j) = {T_1^(i,j), ... T_m^(i,j)}
  Set q := 0.
  while (q < Q)
  {
    Set G := ∅.
    while (|G| < m)
    {
      For the next generation, randomly choose
      templates T_a^(i,j) and T_b^(i,j) from A_(i,j) where
      the probability is proportional to the
      template's fitness.

      Randomly choose a number r in [0, 1].

      If (r < p_crossover), then crossover templates
      templates T_a^(i,j) and T_b^(i,j).

      Randomly choose numbers s_a, s_b in [0, 1].

      If (s_a < p_mutation), mutate template T_a^(i,j).
      If (s_b < p_mutation), mutate template T_b^(i,j).

      Set G := G ∪ {T_a^(i,j), T_b^(i,j)}.
    }
    Set A_(i,j) := G.

    For each template T_a^(i,j) in A_(i,j), evaluate
    T_a^(i,j)'s ability to distinguish examples
    from categories C_i and C_j.

    Store this ability as the fitness of T_a^(i,j)

    Set q equal to the number of templates
    with fitness greater than γ.
  }
  Based on fitness, choose the Q best
  templates from A_(i,j) and add them to T.
}
```

Comments on Building Templates with Evolution.

1) The fitness ϕ_a of template $T_a{}^{(i,j)}$ is computed by a weighted average of three criteria.
   a) The ability of a template to distinguish examples in E_{C_i} from examples in E_{C_j}
   b) The amount of memory used by the template.
   c) The average amount of time to compute the template value function on E_{C_i} and E_{C_j}.

   A quantitative measure for criterion (a) depends on the topology of the template value space $\mathcal{V}$. If $\mathcal{V} = \{0, 1\}$, the ability of template $T_a{}^{(i,j)}$ to distinguish examples in E_{C_i} from examples in E_{C_j} equals

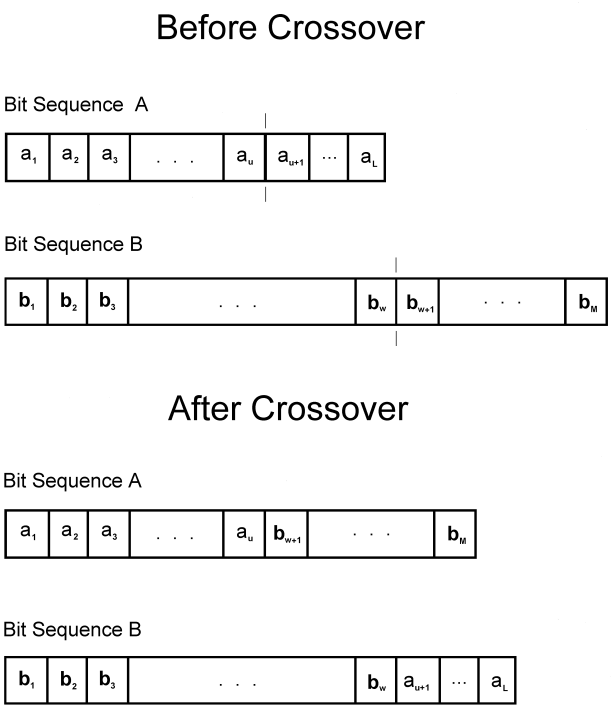

Fig. 2: Unbounded Crossover

$\frac{1}{|E_{C_i}||E_{C_j}|} \sum_{e_j \in E_{C_j}} \sum_{e_i \in E_{C_i}} |T_a{}^{(i,j)}(e_i) - T_a{}^{(i,j)}(e_j)|$.
When $\mathcal{V} \neq \{0,1\}$, then $\mathcal{V}$ has a metric $\mathcal{D}$, which measures the distance between two points in the template value space $\mathcal{V}$. In this case, the ability of template $T_a{}^{(i,j)}$ to distinguish examples E_{C_i} and E_{C_j} equals
$\frac{1}{|E_{C_i}||E_{C_j}|} \sum_{e_j \in E_{C_j}} \sum_{e_i \in E_{C_i}} \mathcal{D}(T_a{}^{(i,j)}(e_i),\ T_a{}^{(i,j)}(e_j))$.

2) Figure 2 shows a crossover between bit-sequences $A = [a_1 a_2 a_3 \ldots a_L]$ and $B = [b_1 b_2 b_3 \ldots b_M]$. L and M are each multiples of K, where $r = 2^K$ and the functions are $\{f_1, f_2, f_3, \ldots, f_r\}$. In general $L \neq M$. Two natural numbers u and w are randomly chosen such that $1 \leq u \leq L$, $1 \leq w \leq M$ and $u + M - w$ is a multiple of K. The multiple of K condition assures that after crossover, the length of each bit sequence is a multiple of K. Each bit sequence after crossover is interpreted as a composition of functions $\{f_1, f_2, f_3, \ldots, f_r\}$. The numbers u and w identify the crossover locations on A and B, respectively. After crossover, bit-sequence A is $[a_1 a_2 a_3 \ldots a_u b_{w+1} b_{w+2} \ldots b_M]$, and bit-sequence B is $[b_1 b_2 b_3 \ldots b_w a_{u+1} a_{u+2} \ldots a_L]$.

3) Before mutation, the bit-sequence is $[b_1 b_2 b_3 \ \ldots b_n]$. A mutation randomly selects k and assigns b_k the value $1 - b_k$.

4) In the current generation, the collection $\{\phi_1, \phi_2, \ldots, \phi_m\}$ represents the fitnesses of the templates $\{T_1{}^{(i,j)}, T_2{}^{(i,j)}, \ldots, T_m{}^{(i,j)}\}$. The probability that template $T_a{}^{(i,j)}$ is chosen for the next generation is $\frac{\phi_a}{\sum_{k=1}^{m} \phi_k}$.

5) $p_{crossover}$ usually ranges from 0.3 to 0.7.

6) $p_{mutation}$ is usually less than 0.1.

7. UCI Machine Learning Tests

Testing against the UCI Machine Learning Repository `http://archive.ics.uci.edu/ml/` is in progress. A subsequent publication will cover these results.

Recognition of Business Objects in Street-View Images Using Sub-Space Grids

M. Arif Wani
Computer and Electrical Engineering and Computer Science Department
California State University Bakersfield
awani@csub.edu

Abstract— **The work presented in this paper introduces sub-space grids and shows how it can be employed for recognition of business objects like bank, fire station, restaurant and store in street-view images. The paper first describes projection of segmented image area to a six dimensional feature vector space. Principal component analysis (PCA) and multiple discriminant analysis (MDA) algorithms are used to define the orientation of six feature vectors. The range of value associated with each feature vector is divided into a number of equal parts to define six dimensional sub-space grids. A recursive procedure is then used to obtain rules where sub-space grids form premises of rules. The system is tested on a dataset of 20 images (5 images of each business object type). The results show that the use of sub-spaces grids produces good results to recognize business objects in street-view images.**

Keywords- sub-space grids, machine learning, object recognition, principle component analysis, multiple discriminant analysis, rule extraction.

I. INTRODUCTION

Street-view image analysis has received due attention recently and is used in many applications such as driver assistance systems, ego-localization and forward obstacle detection. Each application of street-view image analysis may involve addressing several issues or performing several tasks. It may involve segmentation on multi-view images captured along streets, and learning object class models from these multi-view images. The street-level images may contain personally identifiable features, such as faces. The task may involve recognizing these features, it may even involve identifying a full object like a person or a car.

Scene-text exists as part of the objects in street-view images, which includes street signs, hospital signs, bus number, license plates, shop signs, house numbers and billboards. The text carries rich information, denoting the business name, street address, direction and other crucial messages. One of the tasks of street-view image analysis may involve recognizing text that is information rich in nature.

Some applications may require moving objects to be removed from street-view images. Therefore, removal of moving objects from these images may form one of the tasks of street-view image application.

Street-parking vehicles occupy a certain area of the streets at any time. This may cause traffic problems in crowded urban areas, such as impediment to the traffic flow and blind spots. Street-view image analysis application may involve detecting vehicle clusters which will be useful for re-planning roads and traffic system.

A brief review of the previous work with street-view images is presented in the next section.

II. LITERATURE REVIEW

Xiao Long Quan [1] discuss a multi-view semantic segmentation framework for street-view images. In their approach, a pair-wise Markov Random Field (MRF) is laid out across multiple views. Both 2D and 3D features are extracted at a super-pixel level to train classifiers for the unary data terms of MRF. Their approach makes use of color differences in the same image to identify accurate segmentation boundaries, and dense pixel-to-pixel correspondences to enforce consistency across different views. To speed up training and to improve the recognition quality, their approach adaptively selects the most similar training data for each scene from the label pool.

Flores and Belongie [2] propose an automatic method to remove entire pedestrians from Street View images in urban scenes. The resulting holes are filled in with data from neighboring views. A compositing method for creating "ghost-free" mosaics is used to minimize the introduction of artifacts. This yields Street View images as if the pedestrians had never been there. The authors present promising results on a set of images from cities around the world.

Song et. al. [3] present an algorithm for text detection in images from street view, basing on Haar-Iike features and AdaBoost classification is proposed in this paper. The idea is intended for searching a wanted place in a foreign city with the business name, the scene text and the street address. There are two contributions in this paper. First the difficulty of locating the specified buildings exactly in an unfamiliar city is analyzed, and then a novel application associated with a mapping application to the real view of target place is presented. Another is training a cascade AdaBoost classifier

using several weak classifiers with Haar-Iike features, which examined their approach.

Torii et. al. [4] present a structure-from-motion (SfM) pipeline for visual 3D modeling of a large city area using 360^0 field of view Google Street View images. The core of the pipeline combines SURF feature detection technique, tentative matching by an approximate nearest neighbor search, relative camera motion estimation by solving 5-pt minimal camera pose problem, and sparse bundle adjustment. They present a large-scale reconstruction computed from 4,799 images of the Google Street View Pittsburgh Research Data Set.

Uchiyama et. al. [5] propose a method to remove moving objects from an in-vehicle camera image sequence by fusing multiple image sequences. Driver assistance systems and services such as Google Street View require images containing no moving object. The proposed scheme consists of two parts: (i) temporal and spatial registration of image sequences, and (ii) mosaicing partial images containing no moving object.

We propose a sub-space grid based approach for recognizing business objects in street-view images. Section III describes the approach used for recognizing business objects. Results and discussion is presented in section IV. Conclusion is finally summarized in section V.

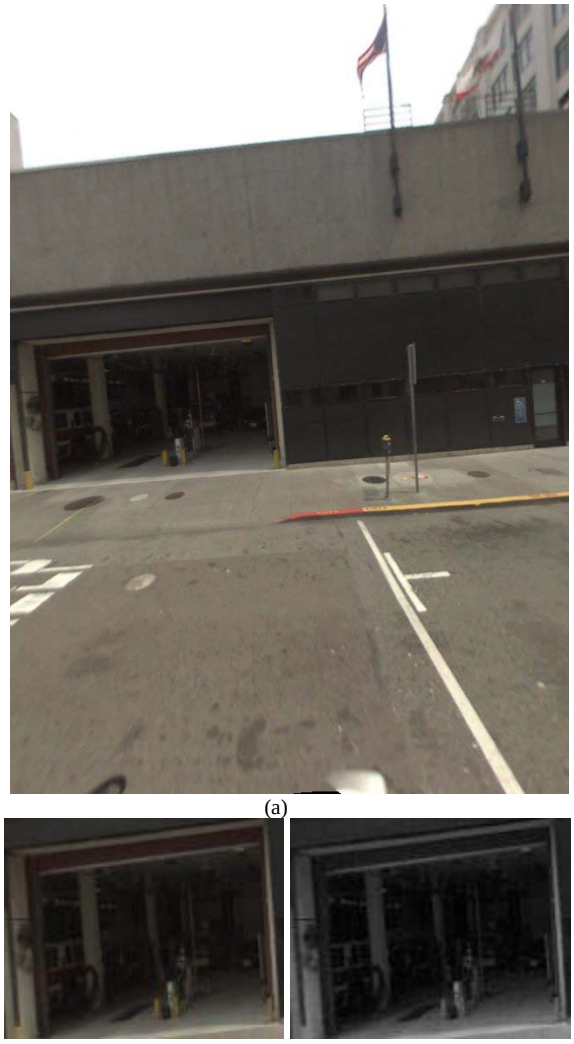
III. SUB-SPACE GRIDS FOR OBJECT RECOGNITION

We propose a strategy for street-view image object recognition that is based on the following reasoning:

Color information is useful for image segmentation but not necessarily for object recognition. This is because structural information is contained in intensity values and color is one of the attributes of that structure. For example, consider two cars of same model one with green color and the second with red color. If we make cars colorless they still remain two cars. But RGB values in an image encode both color and intensity information of the two cars. Only intensity values correspond to the structure of a car while as color value is an attribute of that structure. Therefore, to reliably recognize an object in an image, it should be recognized using intensity values rather than RGB values. However, the color values, that are attributes of a structure, are very useful in segmenting an image.

Keeping the above reasoning in view, we propose strategy for street-view image object recognition that is carried out in two steps: i) Segmenting the street-view image using color information, i.e. locating object areas in an image, and ii) Recognizing object from the located areas using gray scale values. There is a lot of literature available on color image segmentation. Therefore, we will mainly focus on the second step, i.e. recognizing an object from a given located area using gray scale values of that image.

Thus the object recognition from a given located area is carried out by first converting the located area into gray scale image. An example of a street-view image, located object area, and its corresponding gray scale image is shown in Figure 1. The gray scale image is then used to recognize an object in two steps: i) Projecting gray scale image to sub-space grids, and ii) Extracting rules using sub-space grids. The two steps are discussed in detail below



(a)

(b) (c)

Figure 1.(a) Street-view image with fire-station object,
(b) Segmented fire-station object, (c) gray-scale fire-station object.

A. Gray Scale Image Projections

Gray scale image is processed row by row and each row is projected along six projection vectors. Three of the six projection vectors are defined by principal component analysis and the rest three projection vectors are defined by multiple discriminant analysis. This transforms each image row into a set of six values. We call this set of six values as a feature vector. Thus each row of an image will be represented by a feature vector of size 6. Various image rows will not get projected to a single value on a projection vector but will get projected along a range of values associated with each

projection vector. This gives rise to a six dimensional sub-space which is divided into grids for object recognition.

a) Projection With Principal Component Analysis

Principal component analysis (PCA) is a widely-used statistical technique and it best represents the data in a least-squares sense. It works by replacing the original (numerical) variables with new numerical variables called "Principal Components". PCA captures the most descriptive features with respect to packing most "energy". This involves minimizing the criterion function $j_{d'}$ for a d'-dimensional projection:

$$j_{d'} = \sum_{k=1}^{n} \left\| (\mathrm{m} + \sum_{i=1}^{d'} a_i \mathrm{e}_i) - \mathrm{x}_k \right\|^2$$

where $x_1,\ldots x_n$ are n data points to be projected to a low dimensional space, m is the data mean, a_k are coefficients that minimize the criterion function, vectors $e_1,\ldots..e_d$' are the d' eigenvectors of the scatter matrix having the largest eigen values.

b) Projection With Multiple Discriminant Analysis

Fisher linear discriminant analysis (FDA) is a simple algorithm that best separates the data in a least-squares sense. It is used for both dimension reduction and classification. In either case, FDA attempts to minimize the Bayes error by selecting the most discriminant feature vectors. To increase the effective dimension of the projected space the use of Multiple Discriminant Analysis (MDA) instead of FDA is used.

Multiple discriminant analysis adopts a perspective similar to Principal Components Analysis, but PCA and MDA are mathematically different in what they are maximizing. MDA maximizes the difference between values of the dependent, whereas PCA maximizes the variance in all the variables accounted for by the factor. A technique that extracts invariant but descriptive features involves maximization of the criterion function given below:

$$J(v) = \frac{|W^t S_B W|}{|W^t S_W W|}$$

where W is the weight vector of a linear feature extractor and S_B and S_W are symmetric matrices designed such that they measure the desired information and the undesired noise along the direction W. S_B measures the separability of class centers (between-class variance), and S_W measures the within-class variance. S_B and S_W are given by:

$$S_B = \sum_{j=1}^{C} N_j.(m_j - m)(m_j - m)^T$$

$$S_W = \sum_{j=1}^{C} \sum_{i=1}^{N_j} (x_i^{(j)} - m_j)(x_i^{(j)} - m_j)^T$$

where $\{ x_i^{(j)}$, i=1,…,$N_j\}$, j=1,…C are feature vectors of training samples, C is the number of classes, N_j is the number of the samples of the jth class, $x_i^{(j)}$ is the ith sample from the jth class, m_j is mean vector of the jth class, and m is grand mean of all examples.

PCA and MDA, each has its own pros and cons. MDA deals directly with discrimination between classes, whereas PCA does not pay particular attention to the underlying class structure. When the data of each class can be represented by a single Gaussian distribution and share a common covariance matrix, MDA will outperform PCA. By contrast, when the number of samples per class is small or when the training data non-uniformly sample the underlying distribution, PCA might outperform MDA.

PCA and MDA algorithms were used to project the data to a feature vector space. Each algorithm used three eigenvectors that corresponded to the three largest distinct eigen values for defining the axes of feature vector space.

B. Rule Extraction using sub-space grids

The projections to feature vector space are divided into a number of cells or sub-space grids. A sub-space grid can form a premise of a rule. Rules are extracted by considering sub-space grids as its possible premises. The rule extraction process is summarized below:

The core procedure of the algorithm is a recursive process to form a decision tree from the current set of sub-space grids. Let *S* be a set of instances at a node and if all the instances in S belong to the same class, then that node is labeled with the class name of those instances. Otherwise, *S* contains representatives of more than one class. A vector is selected to partition *S* into subsets $S_1, S_2, S_3,\ldots..S_n$ where S_i contains those members of *S* that have ith sub-space grid along the selected vector. Let *A* be a set of m vectors $\{A_1, A_2, A_3,\ldots,A_m\}$, *C* a set of p classes $\{C_1, C_2, C_3,\ldots.C_p\}$. The set of possible values of a vector A_i (for forming sub-space grids) is referred to as Range (*Ai*). Each example in *S* is an m+1 tuple of the form ($V_1, V_2, V_3,\ldots.., V_m , C_k$) where V_i ε Range(A_i), i =1,….m and C_k ε *C* is the class of that example. The probability of occurrence of examples of class C_k in a set S_l, $P_{Sl,Ck}$, is the proportion of examples in S_l that are in class C_k. The information measure, which gives a measure of randomness of example distribution in S_l over the possible classes in *C*, is given by

$$I(S_l) = -\sum P_{S_l,C_k} Log_2 P_{S_l,C_k}$$

The algorithm aims to partition *S* to produce subsets S_l in which the examples are distributed less randomly over possible classes. To choose the vector that would best achieve this, the algorithm partitions *S* into subsets S_l corresponding to values V_l of a vector A_i. If the number of examples containing value V_l in *S* is n(*S*) and the number of examples containing value V_l in subset S_l is n(S_l), then information entropy of the resulting partition is given by:

$$E(A_i, S) = \sum_{V_i \in Range(A_i)} I(S_i) \frac{n(S_i)}{n(S)}$$

The algorithm chooses that vector A_i for branching which maximizes the following quantity:

$$\text{Gain}(A_i, S) = \text{I}(S) - \text{E}(A_i, S)$$

If Gain(A_i, S) is same for more than one vector, then one of them is chosen randomly.

IV. Results and Discussion

The datsets chosen in this work are Google street-view images. These street-view images have a number of objects in it but the aim of this work is to recognize the following four business objects: bank, fire station, restaurant, and store. The training data set consists of 8 street-view images (2 images of each object type) and the testing data set consists of 20 images (5 images of each object type).

TABLE I. CLASSIFICATION OF VECTORS OF IMAGES WITH BANK OBJECT

Image Used		**Number of feature vectors classified as**			
Image Object	Image Number	Bank	Fire-St.	Restau-rant	Store
Bank	Image1	59	13	6	23
	Image2	9	17	5	72
	Image3	103	1	2	4
	Image4	90	4	4	12
	Image5	81	2	4	23

TABLE II. CLASSIFICATION OF VECTORS OF IMAGES WITH FIRE ST OBJECT

Image Used		**Number of feature vectors classified as**			
Image Object	Image Number	Bank	Fire-St.	Restau-rant	Store
Fire Station	Image1	18	62	1	25
	Image2	51	21	4	25
	Image3	20	80	1	9
	Image4	13	77	9	11
	Image5	13	89	0	8

TABLE III. CLASSIFICATION OF VECTORS OF IMAGES WITH REST. OBJECT

Image Used		**Number of feature vectors classified as**			
Image Object	Image Number	Bank	Fire-St.	Restau-rant	Store
Restaur ant	Image1	18	62	1	25
	Image2	51	21	4	25
	Image3	3	7	89	11
	Image4	4	28	12	66
	Image5	3	15	85	7

TABLE IV. CLASSIFICATION OF VECTORS OF IMAGES WITH STORE OBJECT

Image Used		**Number of feature vectors classified as**			
Image Object	Image Number	Bank	Fire-St.	Restau-rant	Store
Store	Image1	20	32	4	47
	Image2	15	33	5	48
	Image3	10	23	3	74
	Image4	19	8	2	81
	Image5	12	40	4	54

Object areas in images are segmented manually in such a way that each located area has 110 image rows (110 image rows are adequate to cover all four types of business objects), giving a total of 880 image rows from four images for training purposes. Each row is projected into a six tuple feature vector. The range of values associated with each feature vector is divided into equal parts. This results into a six dimensional sub-space grid of 6 feature vectors. The sub-space grid of 6 feature vectors is used for rule extraction.

TABLE V. CLASSIFICATION OF IMAGE OBJECTS WITH PROBABILITIES

Image Object	**Image Number**	**Highest Prob. value**	**Highest prob. Object**	**% Classifi-cation Accuracy**
Bank	Image1	0.54	Bank	80
	Image2	0.65	Store	
	Image3	0.94	Bank	
	Image4	0.82	Bank	
	Image5	0.74	Bank	
Fire St.	Image1	0.56	Fire St.	80
	Image2	0.46	Bank	
	Image3	0.73	Fire St.	
	Image4	0.70	Fire St.	
	Image5	0.81	Fire St.	
Restaur ant	Image1	0.56	Fire St.	40
	Image2	0.46	Bank	
	Image3	0.81	Rest.	
	Image4	0.60	Store	
	Image5	0.77	Rest.	
Store	Image1	0.43	Store	100
	Image2	0.44	Store	
	Image3	0.67	Store	
	Image4	0.74	Store	
	Image5	0.49	Store	
Overall % Classification Accuracy				75

The testing set of 20 images resulted in 2200 feature vectors (110 rows for 20 images). The set of rules obtained above is used to test the 2200 feature vectors of 20 testing images. Table 1 shows results of 5 street-view images having business object bank in it. Each row shows results of one image. Row 1 indicates that 59 feature vectors out of 110 vectors are classified as belonging to object bank, 13 feature vectors are classified as belonging to object fire station, 6 feature vectors are classified as belonging to object restaurant, 23 feature vectors are classified as belonging to object store, and remaining 9 feature vectors were unclassified. As highest number of vectors is pooled for the business object bank, the segmented area of this image is classified as bank with a

probability of 0.54 (59/110). Other rows can be interpreted similarly. Table II shows results of 5 street-view images having business object fire station in it. Table III shows results of 5 street-view images having business object restaurant in it. Table IV shows results of 5 street-view images having business object store in it.

The accuracy of classification is summarized in Table5. The probabilities with which a segmented image area is classified as belonging to that class are also shown in the table. The Table V indicates that the worst classification accuracy was for restaurant object. Overall the results indicate that use of sub-space grids produce good results. This is mainly because these sub-space grids represent less overlapping data and are less sensitive to local changes in the training data.

V. CONCLUSION

In this paper a sub-space grid based approach was employed to recognize business objects like bank, fire station, restaurant and store. The approach was tested on Google street-view images. PCA and MDA algorithms were used to define six dimensional feature sub-space. Segmented image areas were projected to this six-dimensional sub-space. Sub-space grids were obtained by dividing the range of values associated with each feature vector into equal number of parts. A recursive procedure was used to extract rules from sub-space grids. The set of rules were used for recognition of business objects present in Google street-view images. The paper shows that use of sub-space grids in business object recognition in street-view images produces good results. A system that incorporates color information, text information and structure information using gray scales should produce a robust system for applications involving street-view images.

Abstract - *Willingly or unwillingly, consciously or unconsciously, we all live scripted lives. This is not to say that one can look ahead into the next chapter and find out what one will have for dinner a month later. Life also brings surprises, but the scripts we are talking about are not the" scripts of life," but rather much smaller groupings of events that represent familiar routines and are stored as procedural memory in our brains. The general goal of the research presented here is to design, implement, test, evaluate, and improve a computational semantic model that will enable autonomous systems to evoke and use the correct procedural memory scripts similar to humans and thus approximate the human ability to comprehend and form procedures for learned tasks. The important step in this direction that is discussed here is to explore the constitutive properties of this artificial procedural memory model from the perspective of a broader artificial intelligence schema of information acquisition and retention and its computational semantic processing. The discussion will focus on the optimal ways for autonomous systems to acquire procedural memory scripts automatically and to activate them appropriately.*

Keywords: Procedural Memory, Knowledge Relativity

1. Procedural Memories

In his work on Procedural Memory and contextual Representation, Kahana showed that retrieval of implicit procedural memories is a cue-dependent process that contains both semantic and temporal components (Kahana, Howard, and Plyn 2008). Creation of Procedural Memories is tied not only to task repetition but also to the richness of the semantic association structure (Landauer and Dumais 1997). Earlier work by Crowder, built on Landauer's Procedural Memory computational models and Griffith's topical models (Griffith and Steyvers 1997), theorized about the creation of artificial cognitive procedural memory models based on Knowledge Relativity Threads to create the semantic associations (Crowder and Carbone 2011) and work in Fuzzy, Self-Organizing, Semantic Topical Maps (Crowder 2010) counted on the topical model needed to create long-term procedural memories. These Knowledge Relativity models and Topical Maps are based on early work by Zadeh. Zadeh (2004), described tacit knowledge as world knowledge that humans retain from experiences and education, and concluded that current search engines, with their remarkable capabilities, did not have the capability of deduction, that is the capability to synthesize answers from bodies of information which reside in various parts of a knowledge base. More specifically, Zadeh describes fuzzy logic as a formalization of human capabilities: the capability to converse, reason and make rational decisions in an environment of imprecision, uncertainty, and incompleteness of information. In their work in cognition frameworks, Crowder and Carbone (Crowder and Carbone 2011) expand on the work not only by Zadeh but also by Tanik (Tanik and Ertas 1997, 2006) in describing artificial procedural memories as procedural knowledge gained through cognitive insights based on fuzzy correlations made through a labeled form of a Fuzzy, Semantic, Self-Organizing Topical Map (FSSOM) that provides the following attributes:

1. Contextual algorithms explore the map visually for informational connection located by meaning.
2. Procedural searches utilize semantic contextual information to find links to relevant procedural information.
3. The informational maps autonomously locate temporal and semantic associations that provide procedural connections to a topic.
4. The FSSOM represents a normalized representation of any physical information content used in the development of the procedural knowledge and content.

2. Artificial Neural Memory Systems

In artificial intelligence, procedural information is one type of knowledge that can be learned and carried by an intelligent software agent (Kasaboc 1998). From the initial research in the 1998 and 1999 (Kasaboc 1998, Crowder 1999, Crowder, Barth, and Rouch 1999), work has continued on the development of artificial memory systems that mimic human processing, storage, and retrieval. It is believed that providing a cognitive framework that mimics human processing and reasoning also requires creating a constructive memory system similar to human memory storage and processing (Stillings 1995, Crowder 1999). The initial work in artificial memory systems involved the use of Intelligent information Software Agents (ISAs) to create the overall artificial cognitive framework (Crowder 2002). This work led to investigation into Linguistic Ontologies to facilitate conceptual learning in the creation of artificial neural memories (Crowder 2002, 2003).

Scripts as large structured chunks of information, typically sequences of events describing standard routines, permeate human life, society, culture. Humans are well aware of them and have the ability of thinking of and manipulating the whole scripts at any level or detailization, or grain size. Thus, when you buy a new iPhone, you must program or set it up. This is a script that your manual describes by chunking it up into setting up your calendar, email, GPS, etc., each of each is also a script. Within the script of date and time, a few clicks will set you the date and a few others the time of the day. Within the latter, there is a tiny subscript of setting up the hour and another to set up the minutes. Other, less well-defined scripts seem to be capable of almost infinite grain size refinement.

3. Creation of Artificial Procedural Memory Scripts

Continued investigation, utilizing the work of Kahana (Kahana, Howard, and Polyn 2008) in associative episodic memories, led to the development of an ISA framework for creation, storage, and retrieval artificial implicit memories (Crowder and Friess 2010a&b, 2011) (see Figure 1). Based on this work, a systems and software architecture specification was developed for an artificial cognitive framework utilizing intelligent autonomous software agents (Crowder, Scally, and Bonato 2011).

Our main hypothesis is that the procedural memory scripts can be detected and acquired with the combination of rule-based computational semantic techniques enhancing the computer understanding of text as far as we can achieve with a battery of semantic resources, acquisition tools, and software, with the state-of-the-art machine-learning technologies operating on a much enhanced knowledge base and propped up by an advanced artificial cognitive system. The objectives of this work are:

1. To identify the main principles of script acquisition using a combination of meaning-rule-based techniques from the Ontological Semantic Technology with meaning- and cognitively-enhanced machine-learning techniques from Cognitive Artificial Intelligence.
2. To develop the principles of comparison of the comprehension of natural language by computer, with and without the script module (see Figure 2).
3. To determine the principles of optimizing the grain size at which the appropriate scripts should be formulated while developing the system's functionality, that humans also have, to coarsen or to refine the grain size of a script dynamically, when necessary for comprehension.

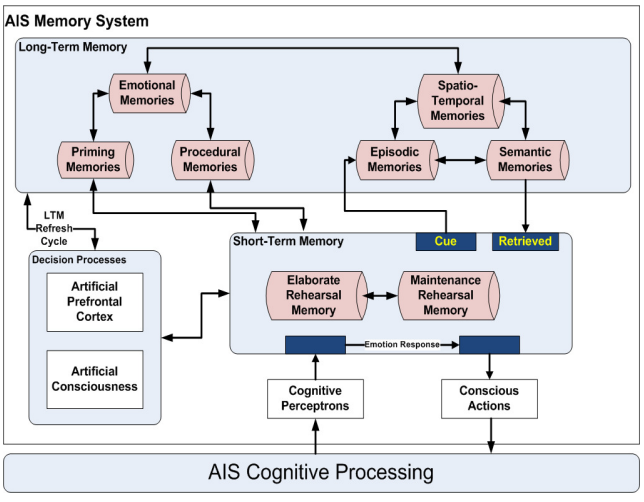

Figure 1 – AIS Artificial Memory Architecture

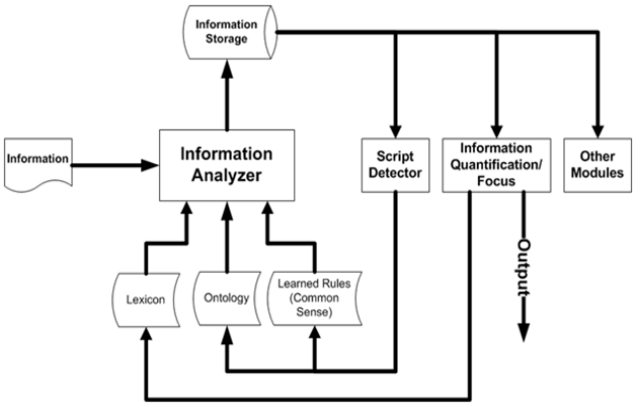

Figure 2 – Artificial Procedural Memory Generation

Crowder, in conjunction with Carbone and Friess, in researching artificial neural memory frameworks that mimic human memories, are creating computer architectures that can take advantage of Raskin and Taylor's Ontological Semantic Technology (OST: Raskin and Taylor 2010, Taylor and Raskin 2010) and create an artificial procedural memory system that has human reasoning capabilities and mimics the fuzzy and uncertain nature of human cognitive processes. This new focus for Crowder (Crowder 2011a) is to create processes necessary for the creation, storage, retrieval, and modification of artificial procedural memories (see Figure 3).

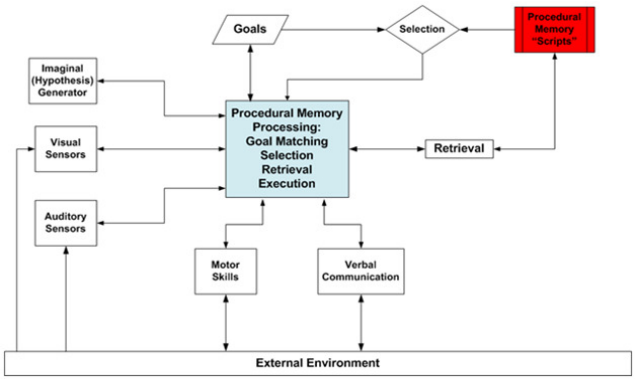

Figure 3 - ***Artificial Procedural Memory Script Retrieval***

In order to create such memories, the artificial cognitive system must have the following capabilities:

Procedural Memory Creation System Requirements:

- Mediator Agents (Artificial Prefrontal Cortex) for asynchronous event handling
- Advisor Agents for reactions and responses (decision support)
- Cognitive Perceptron Agents for procedural representation of knowledge
- Conceptual Ontology
- Cognitive system capable of goal-directed and reactive behavior
- Reasoning Agents for reflective reasoning capabilities
- Data Steward and Analyst Agents to handle incomplete or inaccurate data
- Interface Agents for Human/Machine Interface (HMI)

This cognitive system, called the Artificial Cognitive Neural Framework (ACNF) is illustrated in Figure 4 (Crowder 2011a, Crowder and Carbone 2011a).

The result of this research is to significantly improve understanding of the important properties of artificial procedural memory scripts at the level of precision and explicitness that will be suitable for autonomous computational applications, both the appropriate existing ones and novel ones. By the time the proposed research is finished, we will have advanced the understanding of this phenomenon, proven to be psychologically and cognitively real and significant for autonomous system processing relevant to information processing and autonomous mission management and execution, to the level where it can be formulated in a rigorous, formal, computer-implementable form.

4. OST Formation of Procedural Memories

We will discuss now how OST, which anchors artificial procedural memories in natural language and, via it, in reality, handles script acquisition. Figure 5 shows the ontology at the center as the language-independent conceptual graph that reflects much of what humans know about the building blocks of their world knowledge. Frequently co-occurring instantiations of concepts are additionally

collected in common-sense rules, and this is where the scripts are assembled as a result of text processing.

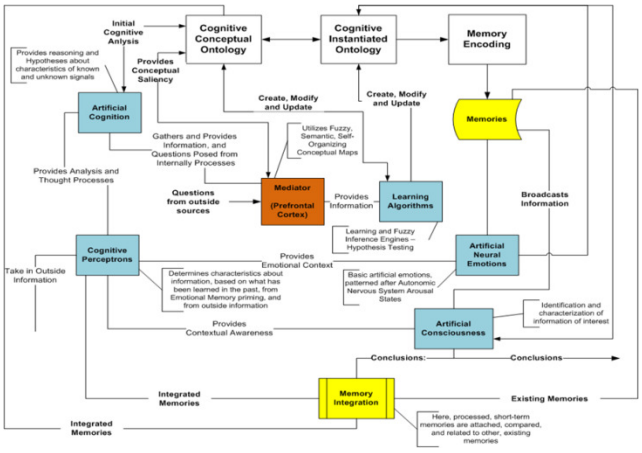

Figure 4 – The Artificial Cognitive Neural Framework

Defined in ontological terms are the entries of the lexicon for each natural language (and, incidentally, of any artificial language as well), with all of their various senses and syntactic, morphological, phonological, and lower types of information. The input text goes into the OST Processor (aka the semantic analyzer), which reads every sentence linearly, word by word, finds them in the lexicon, gets the ontological representation of every sense, and tries to combine these senses together on the basis of property/filler compatibilities.

The successful combinations form the text meaning representations (TMRs), which are accumulated in the OST InfoBase, the information repository where all the successfully processed TMRs are kept, thus constituting the contingent knowledge base following from all the conceptual instantiations. The recurring patterns are identified as common-sense rules or as scripts, depending largely if the relations between or among various invents are causal or chronological. Thus, the fact that fire cause smoking is a causal common-sense rule. On the other hand, one's being met inside a (higher-scale) restaurant by a person who asks how many are in one's party and then taken to a table, given the menus, etc., involves a series of chronologically related events that corresponds to a script. Occasionally in a real-life script of a reasonably complex nature, such as oncoming bankruptcy (Raskin et al. 2003), it is hard and possibly unnecessary to differentiate between the two: in general, causality is a poorly understood and no clearly define a relationship. The picture also shows the place OST, which is rule-based, leaves to machine learning, as mentioned above. It takes over where the existing semantic and pragmatic knowledge can no longer reach, at least temporarily.

Thus, OST provides artificial cognitive systems and the various types of memories they require to postulate with a feasible and implementable procedure.

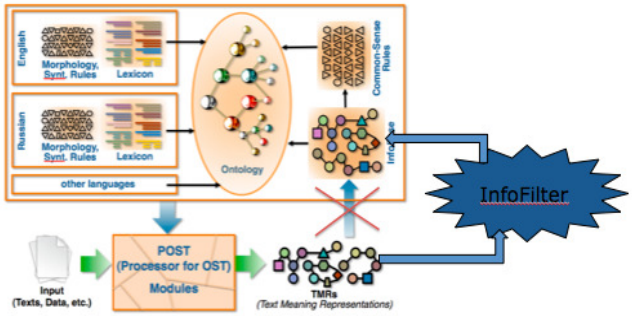

Figure 5 – Ontological Semantic Technology (OST)

5. Conclusions and Discussion

To summarize, we are anticipating four major results from this research, all contributing to the ongoing efforts in the information processing communities both to understand the theoretical nature of procedural memory scripts and their status in human cognition and language activities and to use this new understanding for optimizing computational implementations of knowledge and language processing, thus equipping the computer with the human-like capacity to sense, emphasize, and favor efficient and accurate human/machine interaction and collaboration and making an important step towards high-powered collaborative computing, including social computing.

This work represents an aspect of human communicative behavior that has so far resisted contentful and usable computation. This work will greatly enhance autonomous system reasoning functionality which is crucial for computing human-like information processing, and which will be facilitated by setting up classes of easy, predictable, intra-script inferences. We also anticipate that, conversely, the ease of an inference will serve as a powerful tool of procedural memory script discovery and creation.

MATE: Next Generation Intelligent Tutoring Entities for Virtual Environments

Michael D. Kickmeier-Rust and Dietrich Albert
Cognitive Science Section, Knowledge Management Institute
Graz University of Technology, Graz, Austria

Abstract - *MATE is an intelligent tutorial system that is supposed to combine innovative pedagogical techniques from the field of coaching and to provide intelligent technological solutions for support the coaching processes in an autonomous and smart way. Conceptually, the system is composed of two distinct components, an afferential component that is 'harvesting' information coming from the virtual environment (e.g., behaviors or communication patterns) and an efferential component that is capable of making psycho-pedagogically tailored interventions (e.g., hinting or moderating the communication processes, posing new problems and questions or giving feedback, etc.). Both components are orbiting around a central executive which controls the tutorial process, draws conclusions on the basis of the input, and decides upon interventions on an individual basis as well as on the group level. MATE is work in progress; this paper gives an outline of conceptual approach and draws a sketch of the envisioned system architecture.*

Keywords: Intelligent tutorial systems, educational agents, CbKST, coaching, virtual worlds, Second Life

1 Introduction

Twenty-first century education clearly is a big buzzword in today's media. The new millennium is accompanied by substantial technological evolutions; we became a highly diverse, globalized, complex, real-time media- knowledge- information- and learning society. Since the 1990s, the progress of media and technology was breath-taking; during these one or two decades, we were facing the rise of a serious and broad use of computers at home (although the development started earlier, of course), the rise of the internet and how it revolutionized our society, becoming a "collective unconscious" (in the words of Carl Gustav Jung). We faced the spread of mobile phones and their evolution from telephones to omnipresent computer and communication devices; we see spread of mp3, twitch speed computer games and TV shows. We saw how our world got closer by changing the bridges over continents and oceans from 56k wires to hyper speed fiber glass networks. Some say, this rapid and pervasive technological revolution will have greater impact on society than the transition from an oral to a print culture.

But what does this mean for educational systems and the way our children learn and what they learn. Today's kindergarten kids will retire in 2070. Facing the pace of technological and societal changes and demands, we cannot predict what knowledge will be required in such a "far" future. But we are in charge to equip our children with the abilities and backgrounds to survive in that world. Our students are also facing many important emerging issues such as global warming, famine, poverty, health issues, a global population explosion and other environmental and social issues. These issues lead to a need for students to be able to communicate, function and create change personally, socially, economically and politically on local, national and global levels.

Soft skills such as innovative thinking, creative problem solving, meta cognitive abilities, communication and collaboration skills – all those so-called 21st century skills – need to be in the focus of novel smart tutorial systems. Presently, there are several techniques available that promote the 'acquisition' of such abilities. The problem is that most of those techniques are strongly centered on a face-to-face setting which, however, is costly and from a broader educational perspective ineffective – applications are oftentimes limited to leadership trainings for distinct groups of learners. Our aim is to elaborate on existing coaching techniques (such as Action Learning or Lego Serious Play) and to translate those real world approaches to the virtual worlds, for example Second Life. This is not a trivial attempt since virtual environments demand incorporating sound instructional design principles and, more importantly, they require educationally smart, autonomous tutorial mechanisms to control and guide the learning processes of groups of learners in the virtual worlds with their large degrees of freedom.

2 Innovative ePedagogy

Modern pedagogical strategies most often orbit around the idea of construction-oriented, active instructional design and learning theories, such as problem-based learning [1], learning by doing [2], experiential [3], or example-based learning [4] and also on communication-oriented approaches such as collaborative and peer learning [5]. In the conceptual context of an active and interactive, constructive view of learning and development, examples play a crucial role [6].

The second and probably broader concept is problem-based learning. The approach of problem-based learning is an integral part of many instructional models [7]. According to M. David Merrill [8] problem-based learning accounts for the fundamental premise "Knowledge is soon forgotten if it is not made a part of the learner's life beyond instruction".

Undoubtedly, also collaboration and communication among peers is a crucial aspect in the context of learning; there is a substantial body of evidence that peer interactions likely lead to superior learning performance and a more effective learning process [8]. One of the most compelling reasons for collaborative learning is that teachers/tutors cannot simply transmit (their own) knowledge to learners. Learning is an active, also neurological and physical, process and not a product. Students must build their own knowledge and competencies through an active, involved process in which they need to assimilate concepts into their own understandings and worlds. Social interactions in groups promotes an active involvement and mutual support (e.g., helping, assisting, supporting, encouraging, and praising one another's efforts to learn), it facilities discussions, opens new views, and it supports imitation [9]. In addition to that, there are also secondary effects reported, for example, learners tend to be more positive towards subject matter, schools, or towards each other [10].

An approach to facilitate learning, meta-learning, collaborative creative solutions, and self-reflective growing is action-oriented learning (AOL). The principal idea is that a team is working and reflecting on a realistic challenge in order to commonly develop novel and creative solutions and, equally important, to developed aforementioned abilities and meta-abilities in a collaborative process. AOL is based on the fundamental aspect of questioning; a thematically uninvolved outside moderator is guiding the process by asking appropriate questions and statements in the group work are only allowed in response to questions from the moderator or the group members.

A similar approach to top-level demands on future learning is creative serious play (CSP); the ideas of this approach are inherited from Lego Serious Play (http://www.seriousplay.com). In moderated team work, collaborative learning and problem solving, reflecting upon the group's and the own ideas and work, and finding a common language is triggered by challenging abilities and meta-abilities through playing and modeling with building blocks. A key aspect of this approach is the successful and deep learning is fostered by touching, handling, and holding objects and by making tasks and problems 'concrete'.

Both techniques are highly successful applied, predominantly in the organizational sectors and on a small scale. The reasons, in turn, are simple: the techniques are based on the work in small groups, in real-world settings, driven and hosted by professional trainers and coaches. An innovative idea that is presently work in progress in several research groups, particular in Europe, is to work on a conceptual combination of such coaching techniques. Such settings, however, cannot be transferred one-to-one to virtual worlds. Technological solutions are needed that are capable of purposefully translating and implementing AOL and CSP into the virtual reality. This, in turn, requires novel approaches to user and domain modeling, focusing not only on individual user models but models of users in groups and models of groups. In addition, domain models must be adjusted to meet the distinct needs of the "meta domain" of the 21st century skills.

3 Learning and Training n Virtual Worlds

Beginning in the late 1970s and early 1980s, tightly coupled with computer and information communication technology, immersive virtual environments and game-based worlds virtual worlds have increasingly become a major genre in the fields of entertainment but, specifically in the new millennium, they have become the places for social communication, working, teaching, and learning. This increasing use of virtual space in education suggests that the effects of virtual space on learning are an important area for continued [11]. There is a broad range of examples for virtual environments; famous World of Warcraft has far over 10 million users, for Second Life there are over 20 million registered accounts, or the popular Facebook application FarmVille has over 70 million active monthly users. The sight of this cake made mouths of serious applicants water, in particular in the educational sectors [12].

The potential advantages of virtual environments in education are numerous [13]. To give an example, virtual spaces serve as meeting points for distance education, basically due to the range of communication modes and options for collaboration (e.g., teachers and learners, represented by avatars, may interact via chat, voice, and non–verbal communication such as avatar placement and gestures [14]). Another perceived advantage of using virtual space in education is the high degree of customizability offered by some virtual spaces like Second Life [14]. The possibilities for adjusting the environment, e.g., building objects, of virtual spaces enables an educator to customize a learning space to fit a specific learning activity or a certain pedagogical approach [14]. In addition, since the laws of physics and other physical world occurrences can be disregarded in a virtual environment, virtual learning space can be used to visualize macroscopic and microscopic complex systems, manipulate time in a sequence of events, simulate scenarios, allow complex interactions, and create objects and content [13]. Certainly, the application of virtual environments, in particular the application of rich, immersive, 3D-ish ones, is not always viewed positively. A specific concern was that this rather novel educational medium must be applied cautiously and in consideration of potential risks and downsides (social isolation, un-reflected peer learning, misconceptions,

addiction, etc.). Still, overall, the trend is clearly heading towards a pedagogically informed use of technology that may support and reinforce a wide range of traditional and innovative pedagogical. But, this increasing use of virtual space in education suggests that the effects of virtual space on learning are an important area for continued research. Although the current state of knowledge on how virtual space affects learning is very broad, there is substantial fragmentation of the various research streams. As suggested by Olle Sköld [13], especially in the field of an innovative "online pedagogy", aiming to illuminate both practical and theoretical dimensions of learning and teaching in a virtual space settings, future research is required. Examples are, how learning tasks must be designed in order to account for features in specific virtual spaces, or which methods should be developed to handle ambiguity and uncertainty in virtual learning spaces.

4 MATE: The Next Generation of Intelligent Tutorial Entities

MATE stands for intelligent multi-adaptive tutorial entity; he idea is to advance and expand existing intelligent tutorial technologies, in particular from the context of CbKST [15] and digital educational games, towards the needs of 21st century skills and coaching in virtual environments. This – strongly service-oriented – technology must understand individual and group-related processes in the context of joint learning and problem solving and guide those processes in a smart and tailored way by meaningful tutorial, coaching-related interventions, for example, posing questions and problems to the group. In addition, this combination is to be enriched with features of individual and small-group coaching and some of the strength of today's immersive and engaging media (such as computer games). This novel alloy – in hour firm conviction – has a maximum of strength for teaching and training in the context of the 21st century demands and a minimum of conceptual or application-oriented downsides (e.g., the substantial costs of personal coaching).

Technically speaking, the systems intelligence is to be based on reasoning mechanisms over the combination of structural domain models (the so-called competence structures), into which the learner can be mapped, and so-called problem spaces, formal, structural models of problem solving processes [16], into which a current problem solving state can be mapped. Prerequisite relations between atomic, well-defined competencies/skills (a) establish competence structures/spaces (b). The analysis of a given problem, in turn, established a formal problem space (c). Mapping both together results in a well-defined, formal model of the 'behavioral' status (of an individual) in the virtual world (composed of location in the problem space, problem solving path, available and lacking competencies/skills, learning paths, as well as the so-called fringes, the reasonable next steps in terms of learning and problem solving). This concept builds, in essence, the basis of the artificial educational intelligence. Non-trivial challenges for the project arise from the attempt to expand this approach to the distinct features of this project, e.g., the multi-learner approach or the natural language involvement.

The second major objective is enabling the system to respond educationally meaningful and effective to the conclusions drawn from the assessment procedures, still protecting immersion and flow. Feedback and interventions can be interpreted as one mechanism that overtakes action of a teacher, i.e., providing advice, explanations, and evaluations. In game-based learning situations, adaptations on the micro level may occur through embedded feedback (e.g., through a non-player character), by guiding or hinting, or by adjusting the complexity/difficulty of a learning situation. Such kind of adaptation may indicate gaps between current and desired performance level and may enhance motivation and task strategies, it is able to reduce learners' cognitive load, and it can provide information that is useful for correcting inappropriate task strategies, errors, and misconceptions. A menu of psycho-pedagogically inspired adaptive intervention categories and types has been elaborated by [17], which are aligned with the non-invasive assessment procedures of a learner's competence and motivation.

In a next step, we must extend this framework by factors referring to the multi-learner aspect; we need to have sound mechanisms for assessing informal learning in groups, collaboration, group dynamics and roles, social networks, identifying the strength (the knowledge) and weaknesses of individuals in the groups, or the shared understanding of an entire group. In addition, it is necessary to develop and advance the related adaptation and intervention mechanisms. We need robust methods to support suitable group formation, an adaptation to individuals within groups, and an adaptation the entire group (with all the distinct characteristics). A particular challenge arises from the need to adjust the repertoire of interventions to the special requirements of the distinct coaching techniques. This includes elements such as systematic and purposeful questioning, moderating interventions, mediating interventions, task generation in the "building block" context, tailored group formation and alignment, suitable action calls, etc. Finally, to complete the vision of an intelligent tutoring system for virtual coaching, it is of deemed importance to enrich the metrics used for the CbKST-based assessment with the interpretation of natural speech acts, the chatting and talking of learners/coachees. This goal requires a close collaboration with leading edge natural langue interaction techniques.

This paper presented the conceptual approach on the basis of the existing state-of-the-art. Realizing this vision is subject to future work.

March 2012

ABSTRACT
A growing number of applications can be modelled using spatial agent systems or animats. Typical animat simulations model collective macroscopic phenomena using encoded individual behaviours for microscopic agents. In spatial agent systems there are well known problems that occur if agent cells are updated in a sequential order. This is known as the sweeping problem and it also occurs in other numerical simulations such as differential equation solvers and leads to observable macroscopic effects in the simulated system that are solely artifacts of the implementation algorithm. We explore various strategies to remove these artifacts including multi-phase updating. We find that in some models that include non-diffusional effects such as predator-prey interactions, a two-phase update is not sufficient and a three-phase update strategy is necessary to preserve model semantics, particularly when concurrency is used to speed up the model. We discuss the computational implications of this for animat agent simulations.

KEY WORDS
agent-based models; updating agents; multi-phase update; animats; model semantics.

1 Introduction

Agent-based modelling [21, 22, 29] is a powerful construct for tacking many complex-systems problems [11] in: physics; sociology; finance; and other areas where emergent properties [37] arise from relatively simple individual agent properties. Simulations of multi-agent systems can be readily constructed in general purpose programming languages. Spatial agents - or animats as they are often described - are agents that have some spatial position and therefore can move around and interact with other agents. The key idea for spatial agents is usually that individual agents only interact with those local to them rather than with the entire population.

An important aspect of modelling spatial animat agents is to unambiguously specify how the agents are updated or evolved in the model. Updating might mean each agent is selected in turn or at random and given the option to exercise its microscopic behavioural rules. It might move, eat, kill, breed, grow, die, buy, sell, communicate, or exercise whatever other individual actions are open to it in the particular model being studied. The update is typically applied iteratively to evolve the whole model system through its phase or state space [31, 40].

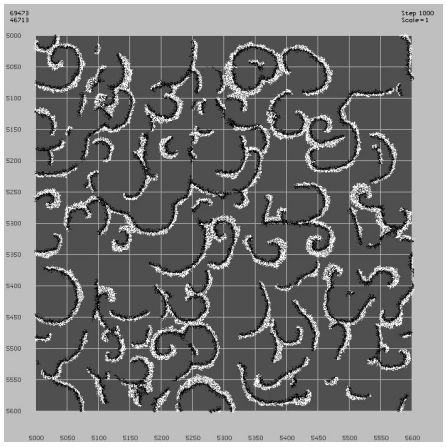

Figure 1: Animat model configuration step 1000 of a multi-phase run of a predator-prey model. Predators are black and prey are white.

Usually a particular multi-agent model will have some constraints such as conservation laws, or other global laws that cannot be sensibly violated by individual agent updates. Different models can be expressed using different sorts of update algorithmic procedures. These are often categorised as synchronous - where every agent is effectively updated at once or asynchronous - where individual updates are only loosely coupled to model time.

In automaton models [41] such as Conway's Game of Life [14] a fully synchronous update is part of the model

definition. In stochastic models such as the Metropolis Monte Carlo dynamics applied to the Ising model of a magnet [18, 27] other factors allow a partially synchronous update. Other models require an asynchronous updating scheme. The idea of using asynchronous updating is not new [4, 10] and has been explored and debated in the complex systems literature [16] for a number of different models including multi-agent systems [9]; random boolean networks [17]; automata [28]; and asynchronous cellular automata [24, 25]

Many large scale models make use of parallelism and therefore need an appropriate form of concurrency control [13] to exploit parallel hardware without changing the model semantics. Asynchronous update issues also arise in some numerical methods such as successive over-relaxation [2].

In this paper we explore the practical issues behind using a multi-phase update for agent-based models such as one of the various artificial life [3] animat models. Agent-based models have contributed significantly across a wide range of distinct areas, from Artificial Life [1, 23, 38] through ecosystems [33] and trading and economics [8, 26] to military combat [6, 7].

All agent-based models require some form of interaction between agents, for example in a predator-prey model [19, 35] predators attempt to catch prey and also to breed with other predators. It is these micro-interactions that lead to the well-known emergent macro-properties of such models, for example the emergence of spiral patterns in the predator-prey model shown in Figure 1. We are primarily interested in animat models of this category in this present paper (Section 3), although we do draw comparisons with simpler deterministic models such as the Eden/Epidemic model in Section 2

An important part of the interaction between agents is the order in which such interactions are executed and this can have a significant effect on the observed patterns of behaviour. The interaction between agents becomes more complicated when agents are developed to perform a range of "higher-order" behaviours such as trading [34] or signalling [36]. In this article we critique the known solutions to this problem and suggest some practical approaches to how best to incorporate this important process into agent-based models.

Our paper is structured as follows: In Section 2 we review some update effects and artifacts that arise from a single phase update approach in a well defined example model such as the Eden/Epidemic growth model. We discuss similar issues in animat models such as our own in Section 3. We review some key update algorithmic ideas in Section 4. We discuss some statistical ideas concerning updates and multi phase algorithms in Section 5 and summarise some pragmatic advice to model practitioners in Section 6.

2 The Eden-Epidemic Model

The Eden model [12] of an epidemic or cancerous growth consists of an initial pattern - usually a single infected seed agent in a system of uninfected agents - and whose boundary agents become infected or grow according some probability parameter p at each update step. There are a number of variations, but at each time step of the model, the state of every agent site is updated. This can be done in sequential order or as a two phase update.

In a sequential update, every agent is updated *in-situ*. This means that if an agent is updated after its neighbour then it has up to date information of any changes that have occurred in the states of other agents within the same time step. The order in which the agents are chosen to be updated can be random or fixed. A fixed order is often referred to in the literature as a "sweep". Iterating through the population in a fixed order is computationally efficient as it makes good use of memory caches, which can be highly significant if the model size is very large. However this approach introduces some definite sweeping behaviours that are neither physical nor correct in the sense of being what was intended by the modeller. Often it is the temporal behaviour that the modeller is interested in measuring. This might be in the form of periodic cycles of behaviour or a growth or shrinkage exponent. If the update algorithm is therefore unphysical the experimental simulation results will be at best biased or at worst just wrong.

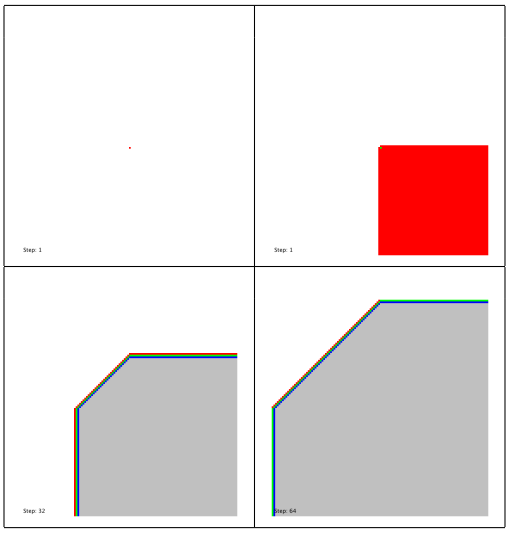

Figure 2: The effects of a sweeping *in-situ* update algorithm for the Eden Epidemic Model 128×128 across successive time steps (cells: white empty; dark live; grey dead, Infection probability 1.0). The simulation starts with a single infected cell at the centre and progresses to the right.

Figure 2 shows the effects when a sequential sweep algorithm is applied to a single central infected cell with in-

fection (or growth) probability $p = 1.0$. The sweep is essentially a row-major raster and the *in-situ* updating and sweeping effect causes the infection to propagate rapidly to all the neighbouring cells that are updated strictly after the infected cell. Infection information travels across the model system at the maximal possible speed. When the probability of infection is substantially less than 1, for example with $p = 0.25$, the skewed results of the model are more subtle. Figure 3 shows the 'correct' result on the left and the skewed results on the right. The correct results have been produced using a two-phase update algorithm.

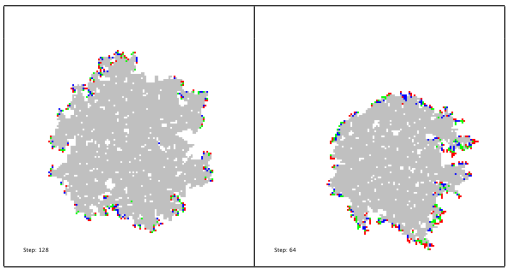

Figure 3: Two-phase update algorithm (left) with a sweeping *in-situ* update algorithm (right) for the Eden Epidemic Model 128×128 across successive time steps (cells: white empty; dark live; grey dead. Infection probability 0.25)

If constrained to a sequential update method a better way of updating the system is to randomise the choice of sites to update. This can either be done by randomly shuffling the list of sites to update (perhaps using a pair-wise shuffle). An even more random approach can be taken by performing Monte-Carlo hits on the sites: on average all sites will be updated once every n time steps (where n is the number of sites in the system), but as the update sites are being chosen randomly, there is a possibility some sites will be updated more frequently than others over a short time period. This has the effect of slightly blurring the concept of 'time' in the simulation (see Figure 4).

Figure 4a) illustrates the cellular growth behaviour of a variation of the Eden Epidemic model [12] when a single infected cell at the centre of the pattern infects nearest neighbouring cells with probability $p = 0.3$ at each time step. In the model shown, infected cells die after two time steps after being infected. Figure 4b) shows how a random algorithm can recover spatial symmetry in the growth model.

Figure 5 shows, by way of contrast, the highly regular pattern that results from the Eden model when a sequential sweep update is used. This is microscopically correct in some sense, but is clearly dominated by the sweeping artifact - and is not representative of the modeller's intentions.

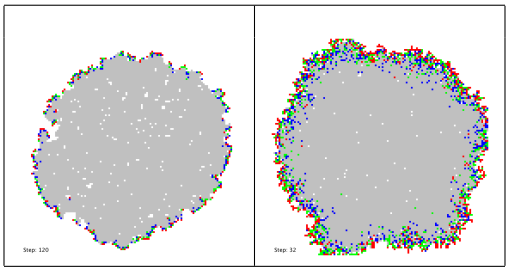

Figure 4: A variation of the Eden Epidemic model is used to show growth time scales and symmetries on a square lattice. Sites are infected from any live nearest neighbour with a probability $p = 0.3$ (left) or $p = 1.0$ (right), and once infected, die after two time steps. The cluster is grown from a single central infected cell. The left hand cluster shows the two phase update algorithm and the right hand uses a random algorithm so cells are updated once per time step on average. Some cells are hit more often and although spatial symmetry is largely recovered, the time scale is accelerated.

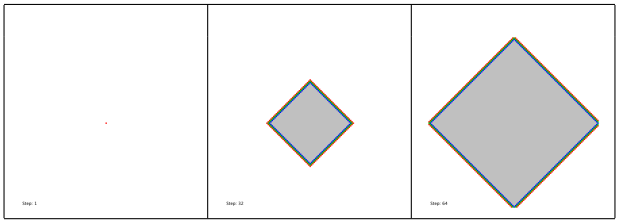

Figure 5: Sequential sweep update algorithm for the Eden Epidemic Model 128×128 cells: white empty; dark live; grey dead. (Infection probability 1.0). The simulation starts with a single infected cell at the centre and progresses to the right.

3 The Animat Model

The animat model we discuss in this section is somewhat more complicated than the Eden model, but is still implemented on a grid of agent-hosting cells, and can have a range of various sorts of update algorithm applied to each microscopic agent. An agent-based prey-predator model has been developed [35] based on "artificial animals" or *animats* [39]. Predators need to catch prey to survive and both species can breed to produce new animats. Animats can "die" from a lack of food (i.e. if health reaches zero) or due to "old age" (i.e. if age reaches a set maximum for the species). Prey animats can also die through being consumed by a predator.

Like most agent-based models, the model is executed as a sequence of cycles (called *time-steps*). Every animat is updated during each time-step and when the updating is completed, the model advances to the next time-step. The following state variables are used to maintain the

state of each animat: location in terms of x, y coordinates; age which is increased each time-step; health which is decreased each time-step but increased by "eating"; neighbours in terms of the location and species of nearest neighbours; and the microscopic species rule set which is used to decide which rule to execute. The rule sets used for the experiments described in this article were as follows:

Rules for predators:

1. breed if health $>$ 50% & mate adjacent
2. eat prey if health $<$ 50% & prey adjacent
3. seek mate if health $>$ 50%
4. seek prey if health $<$ 50%
5. randomly move to adjacent position

Rules for prey:

1. breed if health $>$ 50% & mate adjacent
2. eat grass if health $<$ 50%
3. seek mate if health $>$ 50%
4. move away from adjacent predator
5. randomly move to adjacent position

Most rules carry conditions usually relating to location or current health. The rules are presented in priority order and each animat executes the first rule in its list for which the conditions are satisfied. The "Breed Rule" regulates the production of new animats and when an animat is "born" it inherits the rules of its parents. The "Breed Rule" does not always succeed. Even if the necessary conditions are satisfied, there is still only a random chance that a new animat will be produced. This chance is known as the "birth rate" and is an abstraction of the cumulative effect of several unknown factors including birthing difficulties, availability of suitable shelter, etc. It would be difficult to simulate these factors separately so it is convenient to substitute one value which produces the desired effect in the model. Normally the birth rate for predators is set to 15% and the birth rate for prey is set to 40% but these can be modified to produce different effects in the simulation.

Predators need to consume prey and prey need to eat grass to survive. Whenever the animat successfully executes the "eat" rule, its health state variable is increased. Grass is placed at various points around the map and is automatically replenished. Future work will experiment with grass that is not replenished (or is replenished very slowly).

The interaction of the animats as they execute their individual rules has produced interesting emergent features in the form of macro-clusters often containing many hundreds of animats. We have analysed and documented these emergent clusters in [20]. The most fascinating cluster that consistently appears is a spiral and several spirals are visible in Figure 1.

The model uses a two-phase update system so each animat carries two versions of its state variables – the "current state" and the "future state". A rule is selected from the rule set and applied to the current state and this generates the future state. At the end of each time-step the current state is changed to match the future state.

4 Animat Model Updates

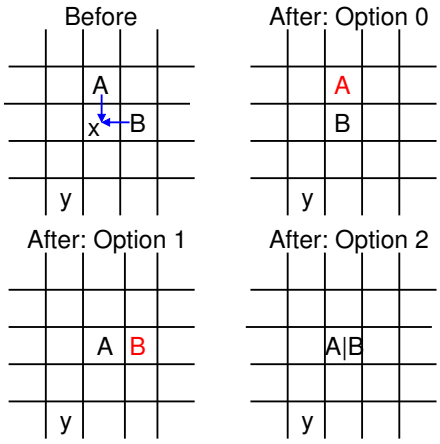

Figure 6: Using a 2-phase update, it is possible for predators A and B to "simultaneously" both locate and consume the single adjacent prey animat x. This renders the model ambiguous as it should not be possible for one prey animat to sustain more than one predator and there are three outcomes and which is the actual one is an artifact of the implementation.

Due to the known problems of a single-phase update system (discussed in section 2 above), the predator-prey model was initially constructed using a two-phase update. However it was soon discovered that the two-phase update led to a serious problem outlined in Figure 6.

The sequence of events that caused this problem can be summarised as follows:

- predator (current state) locates adjacent prey (current state)
- predator executes "Eat" Rule
- predator (future state) is updated by increasing health
- prey (future state) is updated by setting health to zero (dead)

Note that this sequence would only be executed by a predator that had less than 50% health. However in a typical model with tens of thousands of predators – often in

close proximity as shown in Figure 1 – there is a strong probability that two or more predators will be adjacent to the same prey. When this occurs, both predators update their future states to indicate an increase in health, i.e. several predators can "eat" the same prey. Note that the current state of the prey (and the predators) remains unchanged, allowing other predators to repeat the process with the same prey. The problem was discovered because it was noticed that huge numbers of predators were existing off an impossibly small prey population. This update problem thus rendered any results from the model meaningless.

It is not possible to solve the problem and retain a pure two-phase update system. The solution adopted in our model was to introduce a hybrid of the sequential and two phase update systems. In this system every prey animat was given an extra state variable to keep track of its current status and the procedure outlined above was modified as follows:

- predator (current state) locates adjacent prey (current state)
- **if prey (current state) is "dead" then abandon this sequence**
- predator executes "Eat" Rule
- predator (future state) is updated by increasing health
- prey (future state) is updated by setting health to zero
- prey **(current state)** is updated by changing status to dead

Since this sequence allows the current state of the prey to be modified, this is no longer a two-phase update. Sequential update is acceptable in these circumstances,although it is necessary also to randomly shuffle the animats before updating. Experiments have shown that the best system is sequential updating but in a random order. Predator results are shown in Figure 7. Prey results are shown in Figure 8.

The periodic boom-bust variations seen in Figures 7 and 8, showing the populations of predator and prey agents is characteristic of this sort of spatial agent model. The period lengths are consistent between runs and are a measurable property of the experiments. Phase effects - and fluctuational noise however must be averaged out, and this is usually done by averaging over many independently seeded initial model configurations. The top trace in each of these Figures shows the normalupdate algorithm. The second has no random shuffle applied - which manifestly lowers the mean value of both populations. The third case has predators given a slight advantage, which makes them overly successful hunters and again mean populations are even lower.

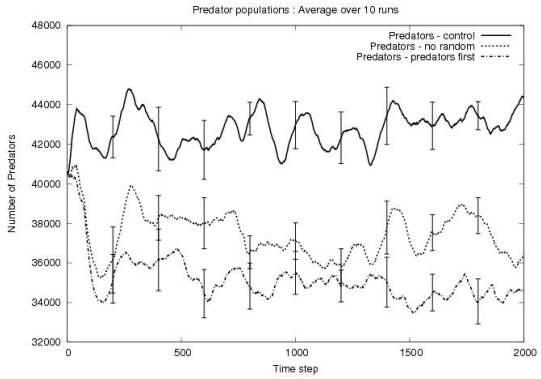

Figure 7: Predator populations using different update methods.

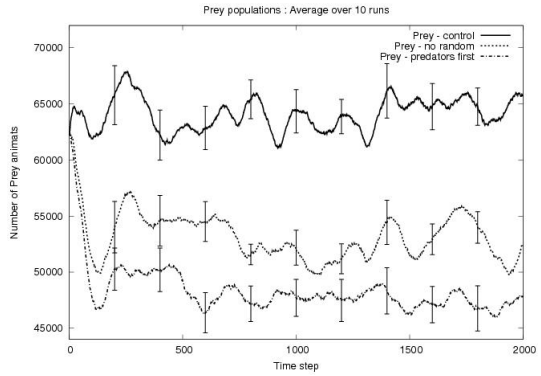

Figure 8: Prey populations using different update methods.

5 Discussion

Generally it appears that the animat model problem can be partially fixed by introduction of a 2-phase update. However, the 2-phase update causes other problems when animats are involved in (a) killing other animats or (b) bumping into objects including other animats. In these cases it is better to use a random shuffle.

We have introduced these ideas in the context of a pragmatic animat simulation. It is interesting to speculate about more general implications for other models. One theoretical approach is to consider the state space of this class of models. Each microstate $\mathbf{X}$ of the whole model system is completely specified by the set of agent state variables $\{a_i\}$. Consider a probability functional $P(\mathbf{X}, t)$ be associated with the microstate $\mathbf{X} \equiv \{a_i\}$ at time t and consider the transition probability $W_{\mathbf{X}\rightarrow\mathbf{X}'}$ giving the likelihood of a change of microstate $\mathbf{X}$ to $\mathbf{X}'$. The following master equation can be set up, requiring that the rate of change of probability of microstate $\mathbf{X}$ at time t be given by considering all transitions from $\mathbf{X}$ and all transitions to $\mathbf{X}$:

$$\frac{dP(\mathbf{X})}{dt} = -\sum_{\mathbf{X}'} W_{\mathbf{X}\to\mathbf{X}'} P(\mathbf{X}) + \sum_{\mathbf{X}'} W_{\mathbf{X}'\to\mathbf{X}} P(\mathbf{X}') \tag{1}$$

By requiring the model update algorithm to yield $P(\mathbf{X}) \to P_{eq}(\mathbf{X})$, the thermodynamic equilibrium probability of microstate $\mathbf{X}$ as $t \to \infty$, as a solution of equation 1 with $\frac{dP(\mathbf{X})}{dt} = 0$ so that:

$$\sum_{\mathbf{X}'} W_{\mathbf{X}\to\mathbf{X}'} P(\mathbf{X}) = \sum_{\mathbf{X}'} W_{\mathbf{X}'\to\mathbf{X}} P(\mathbf{X}') \tag{2}$$

This is the condition of detailed balance [5, 30]. It is common to use the stronger (but tractable) condition that:

$$\frac{W_{\mathbf{X}'\to\mathbf{X}}}{W_{\mathbf{X}\to\mathbf{X}'}} = \frac{P(\mathbf{X})}{P(\mathbf{X}')} \tag{3}$$

So that the probability of the system moving to microstate $\mathbf{X}$ is increased for highly probable microstates $\mathbf{X}$, and decreased for unlikely ones. It is then necessary to recognize that for a Boltzmann statistical weighting of the microstates, the probabilities $P(\mathbf{X})$ can be expressed in terms of the Hamiltonians $\mathcal{H}(\mathbf{X})$.

$$P(\mathbf{X}) = Ae^{-\frac{\mathcal{H}(\mathbf{X})}{k_b T}} \tag{4}$$

Where A is a normalising constant, k_b is Boltzmann's constant and T the temperature. Substituting 4 in 3 gives:

$$\frac{W_{\mathbf{X}'\to\mathbf{X}}}{W_{\mathbf{X}\to\mathbf{X}'}} = e^{-\frac{\{\mathcal{H}(\mathbf{X})-\mathcal{H}(\mathbf{X}')\}}{k_b T}} \tag{5}$$

This does not have a unique solution but commonly used approaches are the Metropolis [32] or Glauber functions [15].

These or some other deterministic or stochastic procedure provides a way of traversing the phase space of the model. In the case of the animat model we have similar concerns and goals. The procedures become more complicated in that we have killing and births and other effects that change the number of agents involved. There is potential to develop formulations for model phase state traversal bringing these two approaches together in a unified notation.

6 Conclusion

In summary we have discussed models such as the Eden/Epidemic model and our predator/prey animat model and drawn out comparisons between the updating procedures involved in both. We have identified in particular that sweeping effects can give rise to the wrong model behaviour. This is because spatial correlations are introduced that are solely due to artifacts of the algorithm rather than from the thermal and other fluctuations that we desire to simulate.

Single-phase sequential updating is shown to cause particular problems. Furthermore, in certain circumstances (such as for more complex models like the animat system) even an alternative two-phase update causes a different but related set of problems. We have discussed in particular the problem that arises when two predators would potentially eat the same prey. There are disadvantages to the two-phase update model - not the least of which is that the two-phase model also wastes memory in storing two complete model states. This is problematic for the very large model systems sizes we generally wish to simulate.

We conclude by offering the following pragmatic advice to model practitioners. Firstly, check if a sequential update will cause sweeping problems in the proposed model, and if the answer is yes, then use a two-phase update. Secondly, check if the two-phase update will cause problems similar to the "eating" problem we described, and if the answer is yes, then introduce a full or partial sequential update.

There appear to be some quite profound and deeper philosophical issues underpinning these pragmatics and we believe there is further work to be done to unify the update algorithm semantics under a single notation. This may lead to insights into the relationships between these different classes of simulation models.

Abstract – *Current and future space, air, and ground systems will continue to grow in complexity and capability, creating a serious challenge to monitor, maintain, and utilize systems in an ever growing network of assets. The push toward autonomous systems makes this problem doubly hard, requiring that the on-board system contain cognitive skills that can monitor, analyze, diagnose, and predict behaviors real-time as the system encounters its environment. Described here is a cognitive system of Learning Agents for Autonomous Space Asset Management (LAASAM) that consists of Intelligent Information Agents (I^2A) that provide an autonomous Artificially Intelligent System (AIS) with the ability to mimic human reasoning in the way it processes information and develops knowledge [Crowder 2010a, 2010b]. This knowledge takes the form of answering questions and explaining situations that the AIS might encounter. The I^2As are persistent software components, called Cognitive Perceptrons, which perceive, reason, act, and communicate. Presented will be the description, methods, and framework required for Cognitive Perceptrons to provide the following abilities to the AIS:*

1. *Allows the AIS to act on its own behalf;*
2. *Allows autonomous reasoning, control, and analysis;*
3. *Allows the Cognitive Perceptrons to filter information and communicate and collaborate with other Cognitive Perceptrons;*
4. *Allows autonomous control to find and fix problems within the AIS; and*
5. *Allows the AIS to predict a situation and offer recommend actions, providing automated complex procedures.*

A Cognitive Perceptron Upper Ontology will be provided, along with detailed descriptions of the I^2A framework required to construct a hybrid system of Cognitive Perceptrons, as well as the Cognitive Perception processing infrastructure and rules architecture.

In particular, this paper will present an application of Cognitive Perceptrons to Integrated System Health Management (ISHM), and in particular Condition-Based Health Management (CBHM), to provide the ability to manage and maintain an AIS in utilizing real-time data to prioritize, optimize, maintain, and allocate resources.

Keywords: Intelligent Agents, Space Asset Management, Artificial Learning

1 Introduction

Intelligence reveals itself in a variety of ways, including the ability to adapt to unknown situations or changing environments. Without the ability to adapt to new situations, an intelligent system is left to rely on a previously-written set of rules. If we truly desire to design and implement autonomous AI Systems (AIS), they cannot require precisely-defined sets of rules for every possible contingency. The questions then become:

- ***How does an autonomous AI system construct good representations for tasks and knowledge as it is in the process of learning the task or acquiring knowledge?***
- ***What are the characteristics of a good representation of a new task or a new piece of knowledge?***
- ***How do these characteristics and the need to adapt to entirely new situations and knowledge affect the learning process?***

CBHM entails the maintenance of systems and equipment, based on an assessment of current and projected conditions (both situational and health). A complete and modern CBHM system comprises many functional capabilities, including sensing & data acquisition, signal processing, condition & health assessment, diagnostics & prognostics, and decision reasoning [Scally, Bonato, and Crowder 2011] (See Figure 1). Such features are enabled through the application of autonomous AIS.

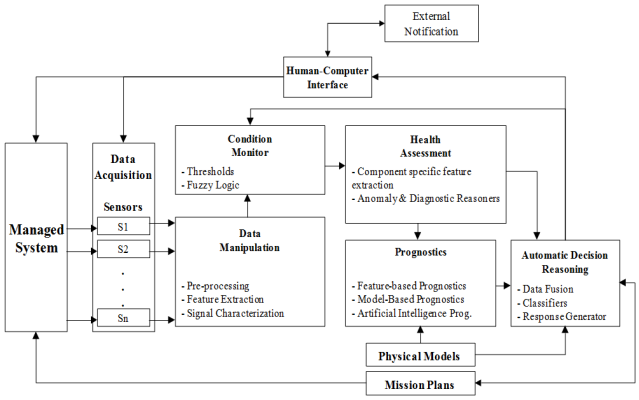

Figure 1 – CBHM Architecture

Discussed here will be the I²A Cognitive Perceptron architecture required to provide a system capable of autonomously managing a complex network of space-based assets to enhance situational awareness and optimize their utilization.

2 Intelligent Information Agents (I²A)

Intelligent Information Agents (I²A) employ soft-computing techniques to generate Intelligent Software information Agents (ISAs). These agents mimic human reasoning to process information and develop intelligence. This intelligence takes the form of answering questions and explaining situations [Crowder 2010b].

The I²A architecture is a Java framework for constructing a hybrid system of Intelligent Information Software Agents. It provides a productivity toolkit for adding intelligent software agent functions to applications and modern architectural frameworks and for building multi-agent intelligent autonomic systems. This includes the framework for providing business rules and policies for run-time systems, including an autonomic computing core technology within a multi-agent infrastructure. Figure 2 illustrates an overview of the I²A architecture framework that is the infrastructure for a hybrid neural processing environment.

I²As are active, persistent software components that perceive, reason, act, and communicate. I²As are software structures that:

1. Assist people and act on their behalf;
2. Are used for automation, control, and analysis;
3. Assist people in finding and filtering information, automating tedious tasks, and collaborating with other agents; and
4. Enable automation and control for finding and fixing problems, finding "best fit" procedures, pattern recognition and classification, predictions and recommendations, and automating complex procedures.

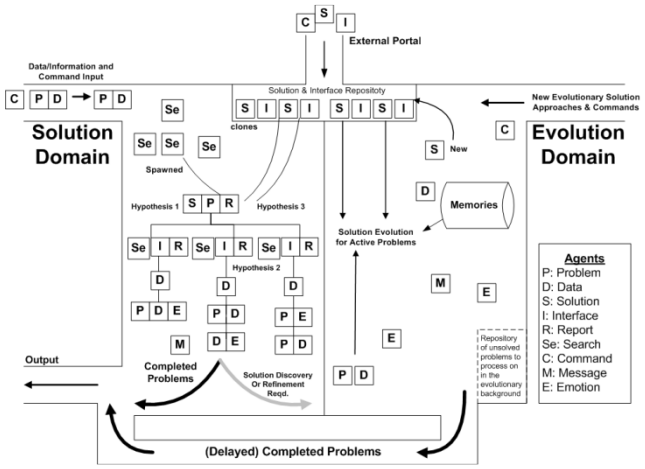

Figure 2 – I²A Intelligent Agent Infrastructure

2.1 I²A Tasking

Intelligent Information Agents have the ability to learn from experience and can be used to actually predict future states (prognostics). They are able to analyze sensor data using classification and clustering techniques to detect complex states and diagnose problems (anomaly detection and resolution). The I²As can interface with other autonomic agents and components via web-services. They have the ability to reason using domain-specific application objects and have autonomous (proactive) behavior and goals. They have the ability to correlate events to situations, reasons, and take action.

The I²A hybrid computing architecture uses genetic, neural-network and fuzzy logic to integrate diverse sources of information, associate events in the data and make observations. When combined with a dialectic search [Crowder 2010a], the application of hybrid computing promises to revolutionize information processing. The dialectic search seeks answers to questions that require interplay between doubt and belief, where our knowledge is understood to be fallible. This 'playfulness' is key to hunting within information and is explained in more detail in the section that address the Dialectic Search Argument (DSA).

2.2 The I²A Dialectic Search Argument

The Dialectic Search uses the Toulmin Argument Structure to find and relate information that develops a larger argument, or intelligence lead. The Dialectic Search Argument (DSA), illustrated in Figure 3, has four components:

1. Data: in support of the argument and rebutting the argument.
2. Warrant and Backing: explaining and validating the argument.
3. Claim: defining the argument itself.
4. Fuzzy Inference: relating the data to the claim.

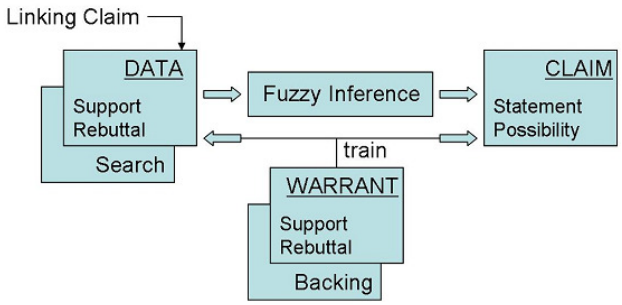

Figure 3 – The DSA Structure

The argument serves two distinct purposes. First, it provides an effective basis for mimicking human reasoning. Second, it provides a means to glean relevant information from the Topic Map [11] and transform it into actionable intelligence (practical knowledge.) These two purposes work together to provide an intelligent system that captures the capability of a human Intelligence Operative to sort through diverse information and find clues.

This approach is considered dialectic in that it does not depend on deductive or inductive logic, though these may be included as part of the warrant. Instead, the DSA depends on non-analytic inferences to find new possibilities based upon warrant examples. The DSA is dialectic because its reasoning is based upon what is plausible; the DSA is a hypothesis fabricated from bits of information.

Once the examples have been used to train the DSA, data that fits the support and rebuttal requirements is used to instantiate a new claim. This claim is then used to invoke one or more new DSAs that perform their searches. The developing lattice forms the reasoning that renders the intelligence lead plausible and enables measurement of the possibility.

As the lattice develops, the aggregate possibility is computed using the fuzzy membership values of the support and rebuttal information. Eventually, a DSA lattice is formed that relates information with its computed possibility. The computation, based on Renyi's entropy theory, uses joint information memberships to generate a robust measure of Possibility, a process that is not achievable using Bayesian methods.

3 The I^{2}A Software Architecture

The primary software component of LAASAM is the I^{2}A. Each software component, or ISA, provides different cognitive capabilities (called cognitive archetypes) that form a cognitive ecosystem within the LAASAM framework, allowing inter-agent communication, collaboration, and cooperation. Figure 4 illustrates this ecosystem. Each ISA archetype, while having separate capabilities, have a defined cognitive structure, or ontology [Raskin and Taylor 2010a, and Taylor and Raskin 2011a], shown in Figure 5.

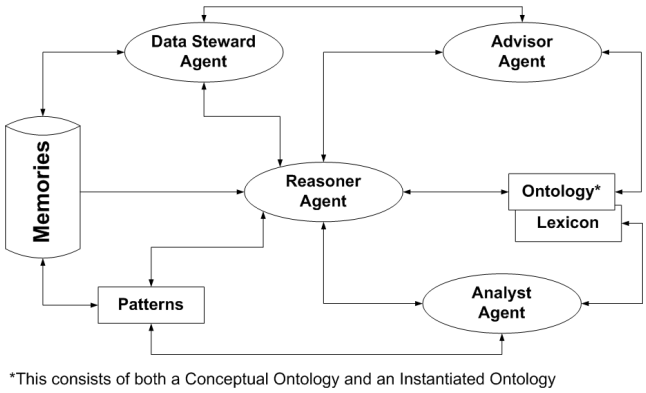

Figure 4 – The LAASAM ISA Cognitive Ecosystem

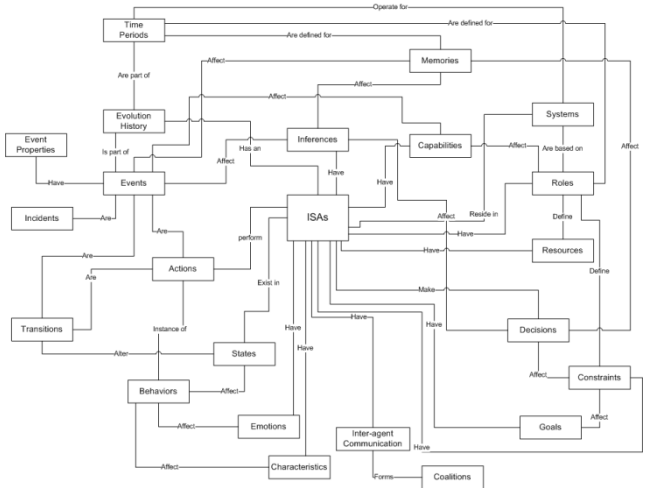

Figure 5 – The ISA Cognitive Perceptron Upper Ontology

Each LAASAM ISA is a self-contained software unit (agent) comprised of one or more services, shown in Figure 6. The combination of services defines an ISA's capabilities. There are five currently defined agent types within the LAASAM processing infrastructure:

1. Data Steward (ADS): this agent acquires raw data from a variety of sources, including sensors, and prepares incoming data for use by other agents. The Data Steward Agent generates and maintains metadata required to find and extract data/information from heterogeneous sources.
2. Advisor Agent (AAD): this agent disseminates the right information to the right place at the right time; it provides capabilities that allow collaborative question asking and information sharing by agents and end-users. Advisor Agents generate and maintain topical maps required to find relative information fragments, memories, and "expert" ISAs.
3. Reasoner Agents (ARE): The Reasoner Agent interacts with the Data Steward and Advisor Agents and utilizes the ontologies and lexicons to automate the development of domain-specific encyclopedias; it provides a mixed source of information and question answering that is used to develop an understanding of questions, answers, and their domains. Reasoner Agents analyze questions and relevant source information to provide answers and to develop cognitive ontology rules for the LAASAM CBHM system.
4. Analyst Agents (AAN): The Analyst Agents are fed by Reasoner Agents and utilize the developed ontologies and lexicons to expand upon questions and answers learned from collected information.
5. Interface Agent (AIN): The Interface Agent assesses the correctness of major decisions and adjusts the decision processes of the Advisor Agents. Interface Agents also accommodate human-in-the-loop structures.

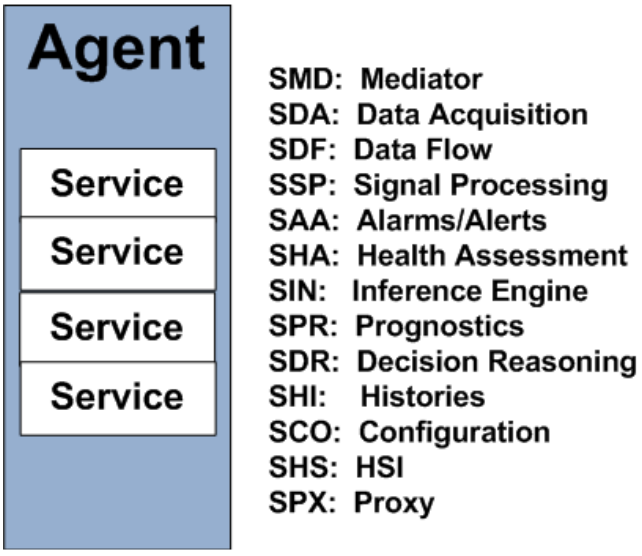

Figure 6 – Services that comprise ISAs

4 Cognitive CBHM (LAASAM)

LAASAM utilizes the I^{2}A technology to address the requirements of CBHM for space and ground asset management. LAASAM (illustrated in Figure 7) represents a significant advancement in the field of Space Asset Management by providing cognitive abilities similar to human reasoning. The LAASAM architecture provides the following high-level features:

1. An Intelligence Network: this includes mechanisms for gathering information, learning, inferences, and providing decision support to situational analysts.
2. Answer Extraction: these are mechanisms for posing hypotheses about situations and providing answers.
3. Situational Analysis: mechanisms for finding situations that require active investigation and provide actionable intelligence

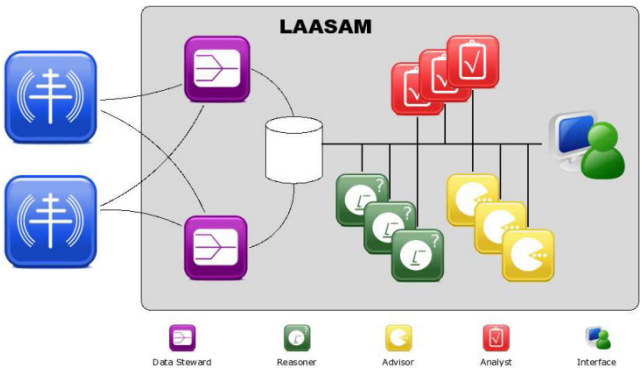

Figure 7 – LAASAM provides I^{2}A-Based Asset Management for Enhanced SSA

These features define the core of LAASAM and are realized by I^{2}A technology infrastructure. The I^{2}A cognitive processing infrastructure provides the intelligence within the LAASAM system through an implementation of an artificial prefrontal cortex [Crowder and Friess 2011a], associated artificial neural memories and data management [Crowder 2010a, Crowder and Carbone 2010a, b, and c], and derived strategies for reasoning, analysis, and inference [Crowder 2010b, Crowder and Friess 2010a &b, Crowder and Friess 2011 a and b].

The LAASAM software architecture defines the I^{2}A functions that range from data collection through providing recommendations for specific actions. Agents take on roles within the system, implemented through dynamically changing services and functional nodes, in support of system defined goals [Crowder 2010b].

The LAASAM high-level features discussed above are enhanced by evolutionary processes embedded within the I²A cognitive processing framework [Crowder 2010a] and implemented utilizing functionally distributed capabilities provided by the I²A infrastructure. Figure 8 illustrates Figure 1 with the I²As distributed across the system.

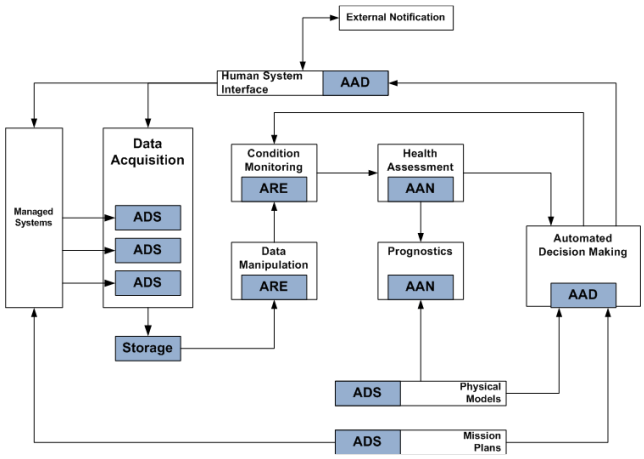

Figure 8 – Distribution of I²As for CBHM

LAASAM is based on the concept that I²As carry personalities. A personality is a collection of state information carried in a personality state token (shown in Figure 9) that describes the agent. Agent personalities can then be cloned and distributed utilizing these stored tokens.

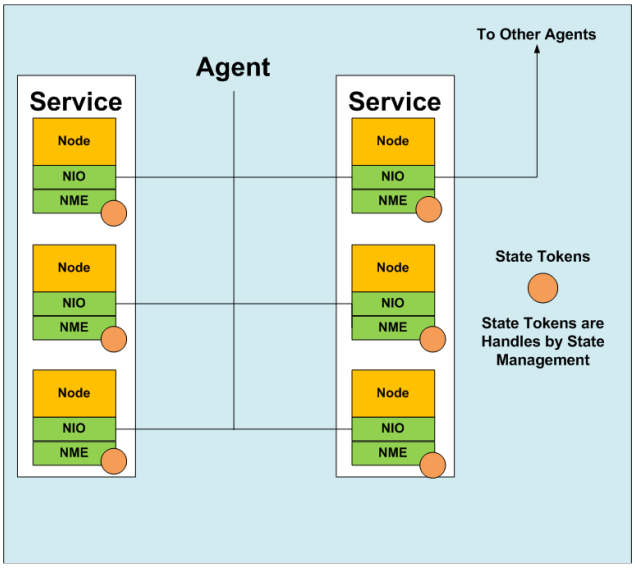

Figure 9 – I²A Personality Tokens

In this way, agents are mobile in that their personalities are mobile. This mobile nature of agent personalities, or state mobility, allows agents to evolve on a self-determining basis. LAASAM operates on a collection of host systems that support Java clients connected through a secure network. Interface agents provide the authentication and authorization for the processing infrastructure, allowing secure access to I²As within the network. Policy management for distribution of code updates and state tokens to agents within the LAASAM I²A infrastructure is handled through Interface Agents that provide User Interface (UI) capabilities. I²A personalities are partially based on their need to cooperate, learn, and function autonomously within the LAASAM framework. Figure 10 below illustrates these capabilities for the various I²As.

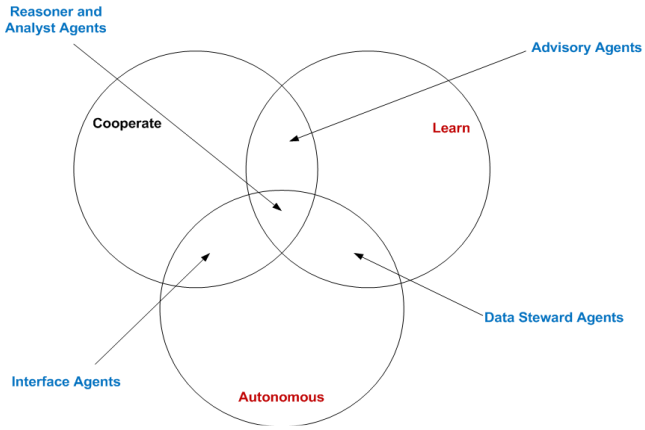

Figure 10 - I²A Venn Diagram

6 Conclusions and Discussion

In summary, the LAASAM system significantly enhances the analyst's ability to make timely and efficient decisions, and to take action to protect and maximize the utility of space, ground, and air assets. LAASAM provides context for space-related events and can alert analysts to potential space-based events. LAASAM's unique I²A cognitive processing infrastructure establishes the foundation for assigning attribution to hostile activity and for analyzing emerging activities through the application of advanced data-agnostic acquisition, reasoning, and analyst I²As (see Figure 11).

The thrust of the LAASAM research has been to realize a CBHM architecture that provides enhanced Situational Awareness for space-based assets. The cognitive I²A processing infrastructure provides the required analysis, learning, and reasoning framework to provide LAASAM the ability to analyze, diagnose, and predict health, status, and situational awareness within a complex system of space assets. This CBHM approach ideally involves synergistic deployments of component health monitoring technologies as well as integrated reasoning capabilities. The LAASAM system described here organizes various system elements into a maintenance and logistics

architecture that governs integration and interoperation within the overall space asset system, between the on-board elements and their ground-based support functions, and between the system health management and the external maintenance and operations functions. In short, LAASAM represents enhanced Space Situational Awareness and Operational Management of the multiple assets contained with an overall space, air, and ground system consisting. LAASAM can not only identify problems that are caused by asset component failures, but can highlight system issues that are, or could be, caused by external forces, maximizing system availability and minimizing downtime.

Rapid Adaptation in Computational Organizations

S. Alqithami[1], **and H. Hexmoor**[2]
Computer Science Department, Southern Illinois University, Carbondale, IL, USA

Abstract – *Primarily, we describe a computational model of organizations where agents rapidly adapt to changing environmental conditions. We consider an organizational model with properties of roles, utilities, capabilities and norms (RUCN) in order to give the agents the opportunity to quickly adapt to any new environment. Moreover, a simulation volleyball game is implemented using Netlogo and has been thoroughly described in order to illustrate the model.*

Keywords: Fast adaptation, multiagent, computational model, organizations.

1 Introduction

Multiagent systems are very useful for building a system that can codify interactions among a group of independent and disparate players (i.e., agents). There are two kinds: a closed system is one with a single structure and fixed objectives. In contrast, an open system allows agents to enter and exit dynamically [16]. Moreover, dynamic capability evaluation is used to choose, a priori, the ability of agent instances to form an organization or complete the set of organizational requirements [14]. We will consider a closed multiagent system since the number of agents inside the organization in our model is constant.

Agents usually interact with each other inside a virtual organization. A virtual organization is a set of individuals or institutions anticipated to share resources by following sharing rules [9]. Virtual team or organization is a general word used for a task, organization or project, which is characterized by multiple locations (i.e., dispersion), division of responsibilities (i.e., empowerment), restlessness (i.e., acceptance of change), interdependence and all members' cooperation is needed. The changes inside the organization are stable, for it is dynamic in nature. The organizations may have a sufficient structure since it has been companied with a multiagency platform. Therefore, if it is able to transmit the capability from its current state to the next, it will consider a self-adapting organization [15].

In order to illustrate how the agents communicate with each other, we need to define self-adaptation in multiagent systems. Self-adaptation systems are able to change the agents' organization without a centralized, explicit, implicit, external or internal control. Such a system can be reorganized as a result of planning carried out by internal central control [17].

We will outline this paper by highlighting some previous work and related background research in section two. In the third section, we will illustrate the four main concepts of building rapid adaptive organization (roles, utilities, capabilities, and norms), and implement them in order to provide a simulation for a volleyball game. Finally, we present concluding statements in section four.

2 Background and Related Work

The organizational model used in this paper was first introduced in [11]. The author showed that the organization has a utility that is composed from productivity, synergy and fitness, represented in equation 1.

$$U\ (A,R) =\ P\ (A,R_i) + \left[\left(\frac{1}{sizeof(R_i)}\right)\sum S(i,j)\right] \quad (1)$$

A is an agent and R_i is the i^{th} role. The organization in general depends on the team capabilities (C), roles (R), departments (D), and norms (N). We also applied power to the edge (PE) algorithm to the organization because it is more empowered, superior, interoperable, agile, and has better shared awareness. The organization has been described as a set of capabilities that show the agents' capabilities in a specific range, roles for agents, departments that prescribe what a set of agents will do within specified roles, and norms of interaction among individuals. Moreover, the utility for the agent can be determined by productivity, synergy, and level of fitness. Some of the requirements that should exist for better achievement inside the organization are presenting a set of rules, organizational type, active environment, switching rules, monitoring agent performance, and verification of fitness.

Matson and DeLoach's approach to reorganization of Multiagent systems (MAS) originally involves the evaluation of the system's ability to perform a desired task [14]. Based on this evaluation, agents may decide to either proceed to satisfy the organizational goals, relax some goals, or abandon the process of reorganization and task acceptance altogether. The foundation of this approach is an organizational model consisting of goals, roles, agents, and capabilities. Based on this model, certain evaluative constraints are applied to the process. First, there is knowledge of which agents are available for inclusion in the system. Second, it must be determined what necessary capabilities exist in order to satisfy the demands of a role. Third, an assessment of the capabilities of all available agents must be made to determine

their respective qualifications for acceptance of a given role. To perform this step, the authors have devised a capability taxonomy rooted at the abstract level. Leaf nodes of this taxonomy represent concrete functions and capabilities of an agent, such as the types of sensors (sonar, infrared, light, etc.) and motivators (wheels, tracks, etc.) the agent is equipped with. Finally, limitations applied to roles must be taken into consideration.

Zhang and Zhang relegate the decision to the developer in order to choose the best subtasks [19]. Afterwards organization enters the formation process. In the negotiation process, the agents send their offers (i.e., bids) for finishing the job to the developer and each related subtask will appear in a separate bid. Then, the developer will start to select the optimal membership for the agent with the best offer from the first bid using a recursive best first research (RBFS) and heuristics algorithm. The agents may receive penalties for lack of commitment depending on the tasks that have not been satisfied as determined by the developer. Moreover, the agents are capable of making rational decisions during their operation because they incorporated the motivation quantities framework (MQ) for the task selection process. They model the agent performance, promise and penalty using the utility mapping function. Furthermore, they have mentioned a statistical model to predict and analyze the agent's behavior and the impact on the organization utility.

Furthermore, Zhang and Zhang represent five of the relationships among the three components of any organization builds [19]. The organization in general consists of individuals, tasks assigned to those individuals, and resources to accomplish certain tasks. The first type of relation is the precedence; it sorts the tasks inside the organization depending on specific mechanisms that map the temporal dependencies, like using the PERT chart to build a set of ordered pairs of tasks. Second, they represent commitment of recourses because most of the resources are required for specific tasks. The third is to assign personnel to accomplish certain tasks. Then, since most of the personnel inside the organization have different access to each other, networks among the different personnel are applied as the fourth relation. The fifth is skills that include all resources accessed by the individuals inside the organization. Moreover, the authors show that PECANS model might be applied in Thompson's theory of interdependence to show some extension to it [12].

THOMAS architecture focuses on the design of virtual organization to allow the multiagent systems in dynamic environments to deal with decomposition and abstraction. It offers a total integration to enable agents to transparently offer and request services from other agents or entities, and allowing external entities to interact with agents by using the services provided. There are three components in THOMAS: service facilitator (SF), platform kernel (PK) and organization manager service (OMS) that have the three main structural components: rule, norms, and unit [3].

Dignum provides a general overview of dynamic reorganization concepts and examines two metrics useful in examining MAS performance [6]; society utility and agent utility. Society utility is further decomposed into the success of interactions, roles, and structures in the system. Agent utility is not clearly defined, as it differs from agent to agent in heterogeneous agent systems. In addition to these utility metrics, several types of reorganization "maneuvers" are classified [7]. The first of these, pre-emptive reorganization, is a viable option in unpredictable environments where possible, or likely, events can be prepared for in order to take full advantage of them. Protective reorganization attempts not to take advantage of possible future events, but instead works to limit the negative effects of such events on the system. Exploitive reorganization takes place after the fact, and seeks to benefit from events that have already taken place. Finally, corrective reorganization attempts to lessen the damage caused by events which have previously occurred in order to maintain system usefulness. Specific methods for performing adaptation are not present in [7] but it provides many useful ideas for developing new methods or for elaborating on existing methods [2].

3 Fast adaptation

The organizational adaptation research is challenging since it accounts for multiple player interactions inside the organization. Joshua Epstein has reported a model that permits autonomous agents to be endogenously created in internal organizational structure in order to adapt optimally to a dynamic environment [8]. Wu, et. al. [18] report on a relevant research by building an organizational adaptation with suitable centralization instead of a hierarchy algorithm using four proportions: agility, robustness, resilience, and survivability.

Before we proceed, we should have a better understanding of the four central concepts of utility, norms, role, and capability that we are going to use in order to build this model. Utility is different among agents inside the organization and the outcome space is very large, which makes it difficult to predict actual levels. Our approach is to observe agents' behavior over time and to build a scale for it [4]. The second concept is norms, which are similar to rules that restrict and describe behaviors most of the time for multiagent systems [10]. In different ways of formulating norms, they can be used to guide selection of different roles because they are able to interact with normative multiagent systems [1]. Roles are used for the organizational function in order to specify the assignments for the agents inside. Finally, capabilities usually cause reorganization inside the team itself because they are dynamically changing over time, and here, they have been defined as the ability to show information in specific areas [14].

After we have applied the main concepts for building a multiagent model, we will discuss implementation issues outlined in our model. Our implemented system uses the

Netlogo platform, which is a java based cross-platform testbed for simulating natural and social phenomenon in order to build a multi-agent program modeling environment. A volleyball game will be used as an example to illustrate the issue in an obvious manner, as in Figure 1.

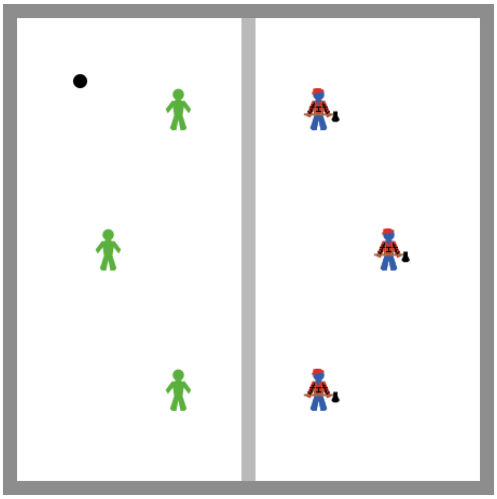

Figure 1. A screen snapshot of Volleyball demonstration in Netlogo

We implemented two teams as illustrated in Figure 1. The one in the right which represents agents in the shape of lumberjacks is the USA team, and the other in the opposite side which represents agents in the shape of people is the KSA team. The idea of using these shapes is to differentiate between teams. Also, we have implemented a small number of players because it is the least number of personnel needed to illustrate an organization and to keep the game simple. The positions for the agents inside the simulation were distributed as randomly as possible (i.e., serendipitously) as in the real world. The players interact with each other and with the ball according to the game's theoretic payoff matrix shown in Table 1.

Table 1. The game's theoretic payoff matrix between the two teams

		USA		
		P1	**P2**	**P3**
KSA	**P1**	0 , 0	1 , 1	2 , 2
	P2	1 , 1	0 , 0	1 , 1
	P3	2 , 2	1 , 1	0 , 0

As shown in Table 1, the set of $< P_1, P_2, P_3 >$ represents different players in each team, and their payoffs will be differentiated depending on the players with whom they are interacting. Thus, the player will get a higher payoff toward the opposing team if his main concepts are higher than the opponent player, detailed in table 1. However, it might be easy to find a strict pure-strategy Nash equilibrium precisely in this manner because one agent has the best response to the strategies of the others inside its team [13]. Besides, the only way to have a chance of scoring in the current moment, whether the opponent gets a fair payoff or not, is to let the player get the ball into the opponent's field with a better payoff when the distances among them goes farther, following the algorithm showing in Figure 2.

```
PLAYERS'-PAYOFFS
1  j = 1
2  for i = 1 to 3
3       if P[i] = Ball
4            if payoff for P[i] ≥ 1
5                 while j ≤ 3 and P[j]s' payoffs ≥ 1
6                      Pass to P[j] with higher payoff
7                      j = j+1
8                 Pass the ball to the opponent field
9            else
10                Pass to P with higher payoff
```

Figure 2. General algorithm for each player to adapt a new situation

In Figure 2, we show that if any of the players ($P[i]$) is in possession of the ball, where i, and j are different players, he will examine his chances of scoring depending on our four concepts for fast adaptation. The players may interact with each other by passing the ball amongst themselves until it reaches a player who has a higher payoff or a player with a better payoff is their distance. By the time the ball reaches the player with the higher payoff, he will pass the ball to the opponent's field to have a higher chance of scoring, as demonstrated in Figure 3.

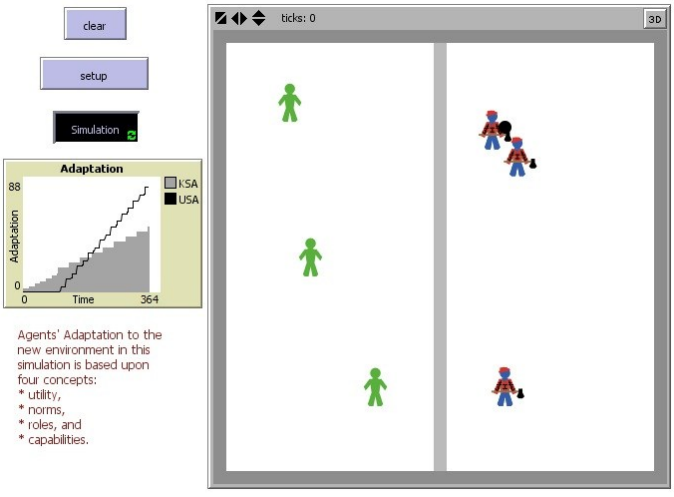

Figure 3. A screenshot of volleyball implementation after start of simulation

Any agent inside any of the small organizations (i.e., team) measures the distance between itself and the ball to

check whether the ball is within its allowed distance or not; if so, the agent (i.e., the player) will move toward the ball considering itself responsible for controlling the ball and announcing that to the closest agent in order to stop him from a possible collision. When the agent controls the ball, it will measure the distance between its position and the opponent's field again to determine if there is a possibility of scoring or not, and also to measure the distance to the closest agent inside the team because the other player may have a better payoff in scoring in the opponent field than itself.

As results, the plot in Figure 3 shows that the rates of adaptation change after the agent finds any other objects (i.e., team member, or a ball) within its range, and it rises over time when any of the agents interact with them. The gray bars represent the KSA team and the black line represents the USA team. The adaptation of the KSA team starts when any of the agents recognize the ball within their proximity and it is set stable because there are no interactions occurring. However, the adaptation rises when the agent catches the ball and starts to use any of the four adaptation concepts in its move. When the agents reach similar capabilities and norms, their adaptations will increase rapidly until it reaches some threshold point where this increase plateaus. It will resume increasing periodically when they start to implement the other two concepts in their interaction (i.e., utility and roles). In contrast, adaptation will stabilize when none of the agents inside the team has any interactions whether with the ball or with other agents.

As with the previous example illustrates, implementing the four concepts of utilities, roles, capability, and norms inside an existing organization improves the performance of the members inside it in order to rapidly adapt to any new environment including any variations to in the ball and player configurations.

4 Conclusions

We have demonstrated how agents inside a specific organization may adapt to a new environment in a short period of time, and then start to interact with other agents inside the same organization. A volleyball game has been simulated in Netlogo in order to give a concrete understanding of the issue in a simple way and to make it easier to get the results out of it. Moreover, we have found that after considering the four main concepts we modeled inside the organization (utility, role, capability, and norms), agents are able to rapidly adapt to their new environment. This model (i.e. RUCN) can capably replace previous models that have been done inside any organization for the sake of fast adaptation among its members or a new environment.

Abstract—**Norms in multi-agent systems are used to regulate the behavior of agents, organizations and sub-organizations in their environments during a period of time. Much of the work on norms focuses on the specification and maintenance of normative system. Little work concentrate on the level of individual agents as the impact of norms on the different types of intelligent agent programs, as the internal modifications in the agents´ decision processes and the background information necessary for rationality in an environment governed by rules. This paper is a contribution in this direction to the case of simple reflex agent based on condition-action rules. An approach to extend this type of agent was formalized and validated it in an implementation of a simple world in the Prolog System. The results demonstrate that the approach is adequate and must be extended to consider other kinds of intelligent agents, as is the case of the goal-based agents and the utility-based agents.**

Keywords- Reflex agent architectures; Deontic concepts; Norms

I. INTRODUCTION

Multi-agent Systems (MAS) are becoming an interesting research in computer science area as a paradigm for development and creation of software systems [1] [2]. Long time MAS have been successfully applied to the development of different types of software in academia and industry [1] [2], a fact that encourages the use of this technology in complex systems.

MAS can be understood as societies in which autonomous and heterogeneous entities can work together. The main element of MAS is the agent entity and very different definitions are proposed to its concept. According to [3], an agent is an entity capable of perceiving its environment through sensors and acting upon that environment through actuators. Unlike objects, agents are entities (i) autonomous and not passive, and (ii) able to interact through messaging and not the explicit invocation of a task, as in the case of objects [4].

There are several ways of classifying agents, but the most accepted classifies agents according to their architecture [3]. The agent architecture specifies how is the process of deliberation and choice of action to be taken, according with the agent perceptions [5]. Internal architectures play a central role in the development process of agents, because it is used as a guide that determines its properties, attributes, mental and behavioral components, determining thus a different implementation for each case.

The creation of the agent function, which sets the mapping between the channels of perception and action, is one of the important contributions of Artificial Intelligence. Depending on its function on the environment, the choice of the agent architecture may not be a trivial task. Mainly, the appropriateness of the properties associated with the internal architecture of the agent and the properties of the external environment where the goals should be conducted is crucial.

In order to cope with the heterogeneity, autonomy and diversity of interests among the different members, governance (or law enforcement) systems have been defined. The governance systems define a set of norms (or laws) that must be followed by the entities in the system. Norms provide a means for regulating the agents' behavior by describing their permissions, prohibitions and obligations [6].

Norms are used to regulate the behavior of the agents in MAS by describing the actions that can be performed or states that can be achieved (permissions), actions that must be performed or states that must be achieved (obligations), and actions that cannot be performed or states that cannot be achieved (prohibitions). Thus, norms represent a way for agents to understand their responsibilities and the responsibilities of the others. Norms are used to cope with the autonomy, and are useful to regulate the different interests and desires of the agents that cohabit the system.

As claimed by [7], much of the work developed on norms focuses on the specification and maintenance of normative system, i.e., the research efforts has been concentrated at the macro level of the MAS. Noticing that very little work has been done on the level of individual agents, they proposed some adaption in BDI agents to solve tasks in open environments with the presence of norms of four types.

We believe that there is a demand for similar work for the cases of other different types of intelligent agent programs, that the effort of research must be concentrated on the internal modifications in the agents´ decision processes and the background information, that are necessary for an rational agent in an environment governed by rules. So, this paper is a contribution in this direction to the case of simple reflex agent based on condition-action rules. It describes an adaptation in the internal architectures of these reflex agents so as they can comply with two types of norms.

We formalize the approach employing the Prolog System. It was validated in an implementation of a simplified version of a vacuum cleaner where the agent can be obligated and/or prohibited to perform some actions in the environment. The

results demonstrate that the approach is adequate and must be extended to consider other kinds of intelligent agents, as is the case of the goal-based agents and the utility-based agents.

The paper is structured as follows. Section 2 briefly presents the reflex agent architecture. The concepts related to norms are detailed in Section 3. Section 4 describes how to combine rightly the use of reflex agent architectures with norms. A case study is showed in Section 5 and, finally, conclusions and future works are discussed in Section 6.

II. Simple Reflex Agent

The internal architectures of agents can be categorized based on reactive and proactive foundations. A reactive agent must attend continuously to changes in their environment, through the selection of actions, typically based on the current perception of the environment and additional knowledge about the possible actions that are best suited to different conditions in which the environment can be.

A proactive agent can take the initiative and select actions from a set of possible atomic actions or plans, and create sequences of actions that attain goals in the environment task. In this context, [3] describe the principles underlying almost all intelligent systems through programs for reactive and proactive agents. This paper focuses norms related to reflex agent, thus, the main characteristics of the simple reflex agents are briefly presented below.

According to [3], a simple reflex (or reactive) agent is the simplest type of agent. This architecture assumes that at any time, the agent perceives information about the state of the environment through sensors and based on rules in the form "if condition then action", it selects the most adequate action for the current perception. The agent performs the selected action upon the environment through actuators. The Figure 1 presents a schematic diagram of the simple reflex agent, synthesizing the Russell&Norvig´s ideas related to reactive agent program, as well as the abstract architecture of the this agent, which was proposed by Wooldridge in [8].

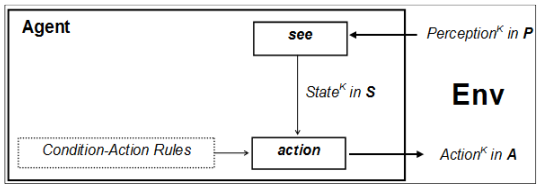

Figure 1. Schematic diagram of the simple reflex agent

This synthesis assumes that at any instant K:

(1) through sensors, the agent receives information from the environment, i.e., perceptions defined on a set, P = {Perception1, ..., Perceptionn}, of n possible perceptions from the environment (Env);

(2) a perception subsystem, see: P → S, that processes each perception in P and maps to one of m possible states, S = {State1, ..., Staten}, that are representations of aspects in the perceptual information that are accessible to the agent;

(3) a subsystem for decision making, action: S → A, that processes the states in S and selects, according to an specific rule of the set of condition-action rules, one of the l actions in the set of possible actions for the agent, A = {Action1, ..., Actionl};

(4) through actuators, the agent sends the selected action for the environment;

(5) in the interaction K+1, the agent initiates another cycle involving the perception of the world through the function see and the selection of an action to be executed by the function action.

The condition-action rules consist in supplemental information that the agent uses during the decision making process. They can be seen as a set of common associations which are observed between certain conditions established from the descriptions of States in S and certain Actions in A. The information about the agent´s goals is not explicitly considered in this architecture, but implicitly in the condition-action-rules. Thus, the agent´s designer defines these rules having in mind the performance measure that will be applied to the agent. In this context, it is expected that, in an adequate environment, if the rules are adequate, then the agent will achieve its objectives and, consequently, it will be well evaluated.

III. Norms for Agents

The norms are used to restrict and guide the behavior of agents, organizations and sub-organizations during a period of time. In this sense, a norm includes a set of sanctions applied to the entities that violated or fulfilled the norm [9]. In this section, the main elements that compose the norm are explained considering the types of norms and their representation.

A. Elements of Norms

Bellow we describe the main elements which compose a norm, based on a survey of existing specification and implementation languages for norms [9].

- Deontic Concepts: the deontic logic refers to the logic of requests, commands, rules, laws, moral principles and judgments [10]. In multi-agent systems, such concepts have been used to describe the constraints for the behavior of agents in the form of obligations (what the agent must execute), permissions (what the agent can execute) and prohibitions (what the agent cannot execute).
- Involved Entities: considering that the norms are defined to restrict the entities´ behavior, the identification of related entities is essential. The norm may regulate the behavior of individuals (for example, a particular agent, or an agent, while playing a particular role), or the behavior of a group of individuals (for example, all agents playing a particular role, groups of agents, groups of agents playing roles or all agents in the system).
- Actions: once a norm is set to restrict the behavior of the entities, it is important the clear specification of the actions that are being regulated. Such actions may be communication, usually represented by sending and

receiving a message, or non-communicative actions (such as access and modify a resource, get in an organization, move to another environment, etc.).

- Activation Constraints: a norm have a period of time in which its restrictions must be fulfilled, but only when this norm, is active. Norms may be activated by a constraint or a set of constraints that can be: the execution of actions, the definition of specific time intervals (before, after or in between), the reaching of system states or temporal aspects (such as dates) and also the activation/deactivation of other norm and fulfillment/violation of a norm.
- Sanctions: when a norm is violated the entity may suffer a punishment, and when a norm is fulfilled, the entity involved may receive a reward. Rewards and punishments are referred to as sanctions and should be related to the norm specification.
- Context: the norms are usually defined in a determined context that determines the application area. The norm may, for example, be described in the context of a specific environment and must be filled only by agents in execution in the environment. Similarly, a norm can be defined in the context of an organization and fulfilled only by the agents that play a role in the organization.

B. Norm Types and Representation

This paper considers two types of norms of four possibilities discussed in [7]. The classification scheme considers whether norms are obligations or prohibitions, and whether they refer to states of the world or to particular actions. In this context, Table 1 presents the four types of norms obtained and a description about what the agent should do when accepting a norm type.

TABLE I. THE TYPES OF NORM AND THEIR DESCRIPTIONS

Norms Types		Description
1	obligation(***p***)	agent must try to achieve certain world state ***p***
2	obligation(***a***)	agent must try to execute certain actions ***a***
3	prohibition(***p***)	agent must try to refrain from achieving a state ***p***
4	prohibition(***a***)	agent must try to refrain from executing an action ***a***

Each type of norm has activation and expiration conditions as, for instance, a well defined validity period of time, indicating when the norm is in force and when it ceases to be in force. In our approach, as [7], we leverage representational concepts from the formalization of [11]. This formalization includes notions of activation and expiration of a norm: norm(Activation, Expiration, Norm), where Activation is the activation condition for the norm to become active, Expiration is the expiration condition to deactivate the norm, and Norm is the norm itself.

It is important to note that we are not concerned, at this point, with handling more complex norm representation schemes. Moreover, in order to facilitate the creation of concrete agent behaviors, in compliance with a set of norms, this paper approaches only norms of Types 2 and 4.

IV. MODIFYING REFLEX AGENTS TO ADOPT NORMS

In this section we examine how norms can influence the choice of actions according to the internal architecture of a simple reflex agent.

A. An Outline of the Approach

Purely reflex agents should be able to quickly respond to changes in the environment. This kind of agent may be inserted into an environment that has a specified set of norms that restrict their actions. As defined by [9], the norms are intended to restrict the behavior of agents applying sanctions when they are violated or fulfilled. Therefore, the norms of an environment should not be able to avoid the execution of certain action, but rather to penalize or reward an agent if the action taken by it is prohibited or obligated. Therefore, if the set of norms defined in the environment is not considered in the condition-action rules, an agent can be penalized if it performs a prohibited action.

In order to avoid the violation of the simple reflex agent architecture, our approach proposes to consider the information about the set of norms as an extension of the condition-action rules. It involves the definition of three different groups of condition-action rules. Each group is associated with one deontic concept and considers the sanctions linked to each norm, that is:

- Obligation Rules Group: specifies the rules related with the actions that must be performed by the agents. If an event of environment matches with a rule in this group, it must necessarily be performed by the agent;
- Prohibition Rules Group: specifies the rules that are related with the actions that cannot be performed by the agent. If an event of environment matches with a rule in this group, the rule will not be executed by the agent;
- Permission Rules Group: specifies the rules related with the actions that can be executed. If an event of environment matches a rule set out of this group, it may or may not be executed by the agent.

Figure 2 shows the schematic diagram of the simple reflex agent in an environment with norms. We added two new groups in the agent´s action selection mechanism, corresponding to the representation of the information about its obligations and prohibitions. Our approach considers that if an action is obligated, then the agent must perform that action only if it is not prohibited. If an action is prohibited, then the agent must perform another action, different from the prohibited action, which is permitted and rational. If there is not an action that is obligated and prohibited, then the agent must perform a permitted action which is rational, as would do a well designed simple reflex agent in an environment without norms.

The function Simplex-Reflex Agent outlined in the sequence of five steps in Section 2 must be adapted to become valid in the case norms were activated. In order to avoid conflicts between rules from the different groups, Step 3 of the sequence must respect the following rules:

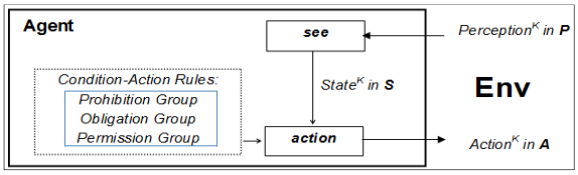

Figure 2. Schematic diagram of the simple reflex agent with norms

(3.1) first, it searches for rules in the Obligated Rules Group to find those actions that must be performed in the environment and are not prohibited;

(3.2) if there is some prohibited action, then the function inhibits rules in the Obligated Rules Group and searches for rules in the Prohibited Rules Group to find those actions that are not prohibited and can be performed, according with the environment estate conditions;

(3.3) if there are not any prohibition, the function selects the action that must be performed as indicated by the obligation norm; and

(3.4) finally, in the case where there not exist any obligations and prohibitions, the function searches for rules in the Permission Rules Group in order to find some action that can be performed, according with the environment estate conditions.

The strategy to select the action that is implicit in the approach considers that the rational behavior is achieved when the agent is able to maximize the rewards that are consequences of: (a) the selection of an obligatory and not prohibited action; (b) the non-selection of a prohibited action, and (c) the selection of permitted actions, those which are adequate with the environment state conditions and with the agent´s performance measure.

B. *Norms Outcomes*

In this section, we consider the agent accepts a norm immediately as it perceives it and that the behavior modification must ensue according to activation and expiration conditions of the norm. More specifically, the required change in the behavior of the agent that accepts a particular norm should occur according with the conditions of activation and expiration. For instance, in the case of an agent that is goal oriented, it can be necessary that the agent add the goal of achieving a state p, when a particular norm of obligation is activated, and then, when the norm is expired, delete this goal.

In the case of simple reflex agents, Tables 2 and 3 summarize all norm combinations of activation conditions (AC) and expiration condition (EC), and their outcomes respectively for norms Types 2 and 4, considered in this paper and highlighted in Table 1. The AC and EC columns give the truth-value of these conditions at the time the agent accepts the norm.

When both AC and EC are true (row 1 in Tables 2 and 3) results in the norm being ignored, as its expiration condition has already elapsed. When AC is false but EC is true (row 4 in Tables 2 and 3), norms are also ignored since, again, they have already expired. When an agent accepts an obligation, if the AC is already true (row 2 in Table 2) it must react to execute the action specified in an obligation(a) if the action is not specified in an prohibition(a). While for a prohibition (row 2 in Table 3), it must refrain from executing the offending action, and try to execute an action that is permitted and adequate to the environment conditions and to its performance measure.

TABLE II. NORM TYPE 2 - OBLIGATION(A).

AC	EC	Outcome
True	True	**(1)** Ignore norm
True	False	**(2)** Execute action ***a*** if ***a*** is not prohibited; otherwise execute an action that is not prohibited, but is permitted and adequate
False	False	**(3)** Ignore norm
False	True	**(4)** Ignore norm

TABLE III. NORM TYPE 4 – PROHIBITION(A).

AC	EC	Outcome
True	True	**(1)** Ignore norm
True	False	**(2)** Suppress rules in the Permitted Group that include action ***a*** and execute an adequate permitted action
False	False	**(3)** Ignore norm
False	True	**(4)** Ignore norm

We are considering, the agent must ignore the norm, if AC and EC are false (row 3 in Tables 2 and 3). We are considering that in the situation that the norm has not yet been activated, the agent has already been programmed for the activation of the norm in the future. Therefore, we are not considering the situation that the agent is able to include the proposed scheme at the moment it perceives a norm, that is, when both AC and EC are false.

C. *Formal Description of the Approach*

This section presents, first, a declarative description of the reflex agent program shown in Figure 1, that is, in an environment without norms and, second, an extension of this description for the case in which the agent perceives norms Types 2 and 4, as shown in Figure 2. The Prolog language was employed to formally describe the agent programs in both cases. The Prolog definition agent/2 describes the agent program discussed in Section 2:

```
agent(P,A):- see(P,S), action(A).
```

where the definition see/2 implements the perception subsystem, as indicated by Step 2 of the sequence of five steps illustrated in Section 2, it inserts, in the Prolog´s base, some predicates employed to represent the environment state; and the definition action/2 implements the decision-making subsystem of the agent program, as indicated by Step 3 in the sequence, i.e.:

```
action(A):- do_permission(A),!.
```

The definition do_permission/1 implements the Permission Rules Group for the agent in an environment without rules, which are condition-action rules highlighted in Figure 1. As mentioned, these rules depend of the agent´s task environment and must be defined according with the available knowledge about the actions that are most adequate to be executed when the environment is under certain conditions. The next section

of this paper illustrates this group of rules for the case where the agent is a vacuum cleaner in a very simple environment.

As the Subsection 4.1 indicates in the extension of Step 3 in Section 2, that is, Steps 3.1-3.4, in the case there are norms in the environment, the definition do_permission/1 will be accessed by the decision making subsystem only when active norms of Type 2 are not available. When some active norm is available, the action must be executed immediately if it is not a prohibited action by a norm of Type 4. If some action is a prohibited action, the rules in the do_permission definition must be accessed in order to indicate for the agent those not prohibited actions that are adequate with the environment conditions.

So, in order to implement the above procedure, our approach proposes that, instead of access exclusively the rules in do_permission/1, the decision making subsystem considers the three groups of rules illustrated in Figure 2 and the sequence of steps 3.1-3.4. The definition do/1 below consists of an extension in the action function, i.e:

```
action(A):- do(A),!.
```

to consider these new possibilities:

```
do(A):- do_obligation(A).
do(A):- do_prohibition(A).
do(A):- do_pemission(A).
```

where the definitions do_obligation/1 and do_prohibition/1 can be declared without concern with a specific domain and are related, as we saw that the agent will execute an action which is obligated only if it is not prohibited.

The three rules bellow compose the Obligation Group and are in accordance with what was discussed in the Section 4.2 and, more specifically, in the Table 2, that identifies the changes that are necessary to a simple reflex agent program for the case in which the environment imposes norms of Type 2 for the agents:

```
do_obligation(A):-
        norm(AC1,EC1,obligation(Ac)),
        is_True(AC1), is_False(EC1),
        norm(AC2,EC2,prohibition(Ac)),
        is_True(AC2), is_False(EC2),!,
        do_prohibition(A).
do_obligation(A):- norm(AC,EC,obligation(A)),
                   is_True(AC), is_False(EC),!.
do_obligation(A):- norm(_,_,obligation(_)),
                   do_prohibition(A).
```

where the predicates is_True/1 and is_False/1 must be specified according, respectively, with the activation or expiration conditions being considered in the arguments of the predicates stating norms.

The two first rules of the above definition are related to the situation described in row 2 of Table 2, that is, in which the activation condition (AC1) is True and the expiration condition (EC1) is False in some norm of Type 2. The first rule considers the case in which another norm of Type 4 is in the same situation (AC2 = True and EC2 = False) and the action which is obligated is, simultaneously, prohibited. The outcome of this situation is that the agent must perform an action (A) that is not prohibited, but is permitted and adequate.

The second rule considers the case in which none norm of Type 4 is active, that is, in which the agent must perform the action that is obligated by the active norm of Type 2. Finally, the third rule in the definition is related with the rows 1, 3 and 4 of Table 2. In these situations the agent must ignore the obligation norm and perform an action that is permitted and adequate, according with the conditions of the environment and the rules in the definition do_permission/1.

The two rules bellow compose the Prohibition Group and are in accordance with what was discussed in the Section 4.2 and, more specifically, in the Table 3, that identifies the changes that are necessary to a simple reflex agent program for the case in which the environment imposes norms of Type 4 for the agents:

```
do_prohibition(A):- norm(AC,EC,prohibition(Ac)),
                    is_True(AC), is_False(EC),!,
                    do_permission(A), not(A=Ac),!.
do_prohibition(A):- norm(_,_,prohibition(_)),
                    do_permission(A),!.
```

The first rule of the above definition are related to the situation described in row 2 of Table 3, that is, in which the activation condition (AC) is True and the expiration condition (EC) is False. The outcome of this situation is that the agent must perform an action (A) different from the prohibited action (Ac), but which is permitted and adequate, according with the conditions of the environment and the rules in the definition do_permission/1.

The second rule in the definition is related with the rows 1, 3 and 4 of Table 3. In these situations the agent must ignore the prohibited norm and performs an action that is permitted and adequate. So, this last rule completes the second group of rules which the approach supposes be a necessary modification to produce a rational behavior of a simple reflex agent in an environment with the presence of norms of the Types 2 and 4.

V. CASE STUDY

This section describes the third group of rules, Permission Rules Group, for a very simple problem, but still very useful to illustrate the ideas discussed in the last section. We specify the rules in the definition do_permission/1 for the case in which the agent is a vacuum cleaner in a world containing only two rooms. So, employing this specific definition, we used the Prolog System to: (1) describe experiments involving the agent in the world without and with the presence of norms, (2) record the history of the vacuum cleaner in the world, and (3) measure its performance.

Considering the vacuum cleaner world with only two rooms, where each room can be clean or dirty, in our experiments the perceived information of the environment were represented by the following atoms in Prolog: roomA, roomB, clean and dirty. So, we assume the existence of eight possible perceptions for the environment (P), which were represented by eight lists of three atoms in Prolog, i.e.:

```
P = {[roomA,dirty,dirty], [roomA,dirty,clean],
     [roomA,clean,dirty], [roomA,clean,clean],
     [roomB,dirty,dirty], [roomB,dirty,clean],
     [roomB,clean,dirty], [roomB,clean,clean]}.
```

Additionally, we assume that the agent perception is local, i.e., see/2 perceives only the room where it is located and the state of the room. So, we assume the existence of four possible internal states for the environment (S), which were represented by four lists of two atoms in Prolog, i.e:

S = {[roomA,dirty], [roomA,clean],
[roomB,dirty], [roomB,clean]}.

In each of the eight states of the world (P), there are three possible actions for the vacuum cleaner (A), which were represented by three atoms in Prolog, i.e:

A = {suck, right, left}.

In the beginning of each experiment the vacuum cleaner does not know the world configuration in terms of dirt. We considered that when the world is without the presence of norms, the measure of performance evaluation offers the reward of one point per each square clean (+1) and penalizes with the loss of one point per each movement (-1). In the case of the presence of norms in the world, the measure must be adapted in order to consider the rewards (+points) and the penalties (-points), which are consequences of the agent accepting or rejecting some norm.

A. Environment without Norms

In the Case 1, there are no norms in the world. The Prolog definition below describes the simple reflex vacuum cleaner:

```
vacuum_cleaner(P,A):- see(P,S), action(A).
```

where the terms P, S and A were defined generically in Section 2 and in the specification of the environment properties outlined in the introduction of this section; see/2 has been specialized to deal with the atoms and lists employed to represent the sets P and S; action/1 has been specialized to deal with the set A and with the specific rules do_permission/1 for this world, i.e:

```
action(A):- do_permission(A),!.
```

The definition do_permission/1 implements the Permission Rules for the agent in an environment without norms, are the condition-action rules highlighted in Figure 1. For this Case 1, was sufficient to generate a definition with four Prolog phrases, i.e:

```
do_permission(suck):- in(Romm),  is(Room,dirty).
do_permission(right):- in(roomA).
do_permission(left):-  in(roomB).
do_permission(no_op).
```

where the predicates in/1 and is/2 were used to represent the conditions in the antecedents of the rules and are known by the agent at the moment when the agent perceives the environment by see/2. Table 4 highlights the episodes performed by vacuum_cleaner/1 in six interactions with an environment without norms where, initially, the agent is in room-A, and room-A and-B are dirty.

The two first columns in the table identify the perceptions and actions of the agent in each interaction. The third and fourth columns identify the values of performance measure per episode (Ep) and history (H). Since the perception is local and at the agent does not have an internal state to avoid unnecessary movements (interactions four to six), there were no surprises in the behavior of the agent. The set of rules do_permission/1 provided a rational behavior for the agent, except for the unnecessary movements that caused a negative performance evaluation.

TABLE IV. PERFORMANCE IN A WORLD WITHOUT NORMS

P	A	Ep	H
[roomA,dirty,dirty]	suck	1	1
[roomA,clean,dirty]	right	-1	0
[roomB,clean,dirty]	suck	1	1
[roomB,clean,clean]	left	-1	0
[roomA,clean,clean]	right	-1	-1
[roomB,clean,clean]	left	-1	-2

B. Environment with Norms

In the second case (Case 2), the environment is governed by norms of the Types 2 and 4. Consider that the measure of evaluation should apply the appropriate sanctions, as the fulfillment or not of the established norms. In this particular example, the measure offers with reward three-point (+3) for the fulfillment of an obligation and two points (+2) for the fulfillment of a prohibition. In any other situation, the measure behaves in accordance with the specification realized for the Case 1. In our experiments, first, we considered a norm of Type 2 in which the environment requires the execution of a specific action by the vacuum cleaner during a period of time. For instance, the predicate below states that "The agent must suck the room-A from 4:00 to 6:00 a.m.":

```
norm(roomA, time([4,6]), obligation(suck)).
```

where the first argument of the statement identifies the condition of activation (AC), the second identifies the condition of expiration (EC), and the third is the action to be performed.

The definition do_obligation/1, which implements the Obligation Rules, are necessary for the vacuum cleaner in a simplified environment regulated by the norm stated as above. Assuming that no prohibition norm is present, the first rule in the definition do_obligation/1 will never be activated. However, the other two rules will be activated according to the truth value of AC and EC, which are obtained by the evaluation of the predicates is_True/1 and is_False/1 specifically for the above obligation norm in the vacuum cleaner world:

```
is_True(Room):-  in(Room).
is_False(time[T1,T2]):- clock(Hour),
                        Hour >= T1, Hour =< T2.
```

where in/1 is the same predicate which the agent employs to represent where it is located and clock/1 is a predicate which represents the agent´s simplified clock in the experiments.

Table 5 highlights the episodes performed by the vacuum cleaner in seven interactions with an environment with a norm of Type 2, as stated above.

TABLE V. PERFORMANCE IN A WORLD WITH NORM OF TYPE 2

P	A	Ep	H
[roomA,dirty,dirty]	suck	1	1
[roomA,clean,dirty]	right	-1	0
[roomB,clean,dirty]	suck	1	1
[roomB,clean,clean]	left	-1	0
[roomA,clean,clean]	suck	3	3
[roomA,clean,clean]	suck	3	6
[roomA,clean,clean]	right	-1	5

The rows one to four describe the behavior of the agent in a period in which the norm had not been activated and the agent was governed by the rules in the Permission Group. The rows five to six of the table (shaded) illustrate the behavior of the agent when the norm of the type 2 was activated (AC = True and EC=False). It is noticed that the agent was rewarded with three points per action during the period, according with the sanctions associated with the norm of obligation. In row 7, the norm was expired and the agent behavior was again governed by the Permission rules. These ideas can be extended to the case where the environment is also governed by norms of prohibition. For instance, consider the predicate below states that "The agent cannot suck the room-A from 1:00 to 5:00 a.m.":

norm(room(roomA), time([1,5]), prohibition(suck)).

Table 6 highlights the episodes performed by the vacuum cleaner in seven interactions in the environment with both types of norms.

TABLE VI. PERFORMANCE IN A WORLD WITH NORMS OF TWO TYPES

P	A	Ep	H
[roomA,dirty,dirty]	right	2	2
[roomB,dirty,dirty]	suck	1	3
[roomB,dirty,clean]	left	-1	2
[roomA,dirty,clean]	right	2	4
[roomB,dirty,clean]	left	-1	3
[roomA,dirty,clean]	suck	3	6
[roomA,clean,clean]	right	-1	5

The rows one and four of the table describe the behavior of the agent in a period in which the norm of Type 4 was activated (AC = True and EC=False). In row four, simultaneously with the norm of prohibition, the norm of Type 2 was activated too. It is noticed that in both case the agent was rewarded with two points, according with the sanctions associated with the norm of prohibition, which has priority on any norm of obligation. In row six only the norm of Type 2 was activated and the agent was rewarded with three points, according with the sanctions associated with the norm of obligation. The four remaining rows illustrate the cases where the two norms had expired and the agent´s behavior was governed by the rules in the Permission Group. All rows in the table that refer to the situation in which the two norms were not activated, the vacuum cleaner was evaluated according to the performance measure adopted for the agent in the world without norms.

VI. CONCLUSIONS AND FUTURE WORKS

In this work we discuss the influence of the norm concepts related to the reflex agent architectures in order to improve the performance of the agents executing in an environment governed by norms. In the original conception of reflex architecture, only permission rules are considered. Now, in the proposed approach two new sets of condition-action rules are incorporated in order to define prohibition and obligation rules. Additionally, the logic to implement the behavior of the simple reflex agents is presented. The strategy selects the actions aiming to minimize the penalties and to maximize the rewards. The case study simulates the behavior of a simple reflex agent in a vacuum cleaner word governed by obligation and prohibition rules. In this simple scenario, the proposed approach involving the implicit definition of norms as condition-action rules provides a rational behavior in consistency with the agent architecture specifications. Future works include the analysis of the agent behavior for another agent architectures in the literature, considering the influence of norms in the decision making process so that the agents can understand their responsibilities and the responsibilities of the others.

***Abstract*—Smart Grid is a typical complex system due to the heterogeneity of actors, economic issues and material aspects such as information technology and power generation. Moreover, the conflicting combination of human and artificial systems is an important complexity factor.**

In this paper, we provide a multi-agent based model for an efficient and reliable Smart Grid implementation. Our model combines adapted mathematical theories to obtain a more realistic modeling of Smart Grid. It takes into account the heterogeneity of components, links them with a generalized proximity concept, and ensures an optimal functioning of the whole system.

I. Introduction

A complex system is a system composed of many entities with simultaneous local interactions. The global behavior can not be deduced from the behavior of its components. An efficient modeling of Smart Grid needs an interdisciplinary approach owing to the heterogeneity of components, and also a holistic method due to the emergence phenomenon, in order to guaranty an optimal functioning of the global system.

In this paper, we are interested in Smart Grid modeling: computed and optimized electricity distribution networks to improve production and distribution of electricity. Smart grids implement heterogeneous actors with different interests: on one side, energy producers want to maximize their profits, on the other consumers try to cut costs, and finally, the state seeks to reduce carbon dioxide emissions, while optimizing the system to satisfy all customers. In our modeling, we need to aggregate the preferences of all stakeholders, to implement the concepts of sharing and redistribution of energy, and finally to ensure that the entire territory is covered in energy.

We will show that Smart Grid is a relevant example of complex system. Then we will present the Smart Grid concept and highlight the similarities with complex systems. Afterwards, we will propose a multi-agent based model founded on theoretical notions including specific algorithms to take into account specificities of Smart Grids properties. Eventually, we will present our model and discuss the results and future work.

II. Smart Grid

Currently, Smart Grid is a fuzzy concept: it is an objective to improve power generation and distribution that will integrate renewable and low carbon energies in the existent power grid. Smart Grid requires to satisfy essentials properties such as reliability, scalability, cost effectiveness but also requires real-time communications secure and sustainable [1]. Of course, this system must integrate all the heterogeneous actors.

In this section, we present the different ways of producing electricity and the relation with complex systems and networks.

A. Presentation of Smart Grid : from power generation to distribution

Smart Grids are composed of an enormous number of devices of various types, from smart meters and solar inverters to electrical substation equipment and sensors on power lines. Electricity can be produced by multiple processes: from the stable production of a nuclear plant, to the storage via electric vehicles, and integration of renewable energy which production may depend on environmental factors. A huge distribution and energy transport network has been created over the years but it is not mastered nor optimized. Our goal is to make powergrids more efficient by integrating renewable energies and taking advantages of information and communication technologies.

In the next paragraph, we present the notion of complex system to highlight that Smart Grid represents a perfect example.

B. Introduction to Complex Systems and Complex Networks

A system which consists of large populations of connected agents (or collections of interacting elements), is said to be complex if there exists an emergent global dynamics resulting from the actions of its parts rather than being imposed by a central controller. That is a self-organizing collective behavior difficult to anticipate from the knowledge of the agents' behavior [2].

The structure of complex systems is usually represented as a complex network which can be classified according to two criteria. The first concerns the categorization by scope. The second is a theoretical classification according to the mathematical properties of the network.

1) Network classification according to the domain: We can classify networks into four loose categories: social networks, information networks, technological networks and biological networks [3].

a) Social networks: A social network is a set of people or groups of people with some links or interactions between them [5], [6], [7]. It can represent friendships between individuals [8], [9], business relationships between companies [10], [11], etc... An epidemic disease affecting a population is also a good example of complex social network.

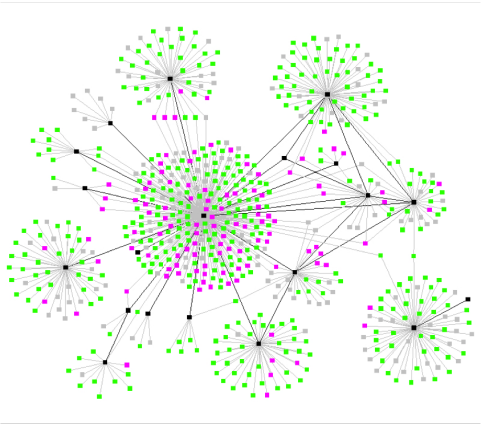

Fig. 1. Epidemic among colonies of individuals.

b) Information networks: The second network category is information networks (also sometimes called "knowledge networks") [3]. The classic example is the network of citations between academic papers [12] in which the vertices are articles and a directed edge from article A to article B indicates that A cites B.

c) Technological networks: The third class of networks is technological networks, man-made networks designed typically for distribution of some commodity or resource, such as electricity or information [3]. The electric power grid and Smart Grids are good examples.

Lots of distribution networks have been studied over the time: airline routes [18], [13], roads [14], railways [15], [16], pedestrian traffic [17], but also power grids and recently Smart Grids [19], [20]. The logical structure of Internet is also a good example with all the communication lines (optic fiber, satellite, etc...)

d) Biological networks: The last class of complex network is biological networks [21]. Lots of biological systems can be usefully represented as networks, for example, a protein can be modeled as a network of amino acids, which may also be represented as networks of atoms such as carbon, nitrogen and oxygen.

We have seen some different types of real complex networks in the various fields, in the next paragraph we will see their mathematical properties.

2) Theoretical classification of networks: Theoretical research about network established that complex networks can be represented with particular random graphs. A random graph is a graph in which the edges are randomly distributed [2]. We can distinguish two types of random graph that fit with complex system modeling : scale-free networks and small world networks. In the case of Smart Grids, we have to deal

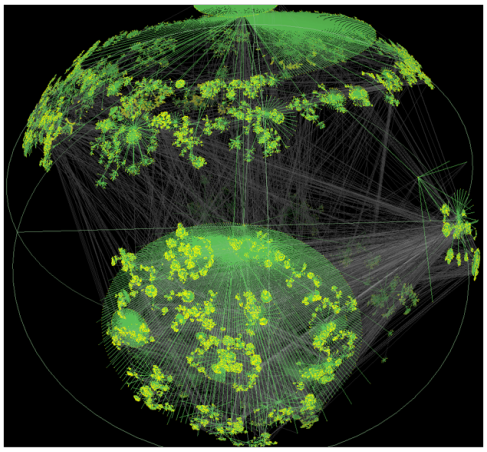

Fig. 2. Technological network : logical structure of Internet.

with heterogenous networks : a number of neighbors with large variations, compared to homogeneous networks which have a similar number of neighbors for each point. Our goal is to recreate the French national grid by generating a network with varying properties in term of network connectivity.

a) Scale-free: A scale-free network is a graph which degree distribution follows a power law.

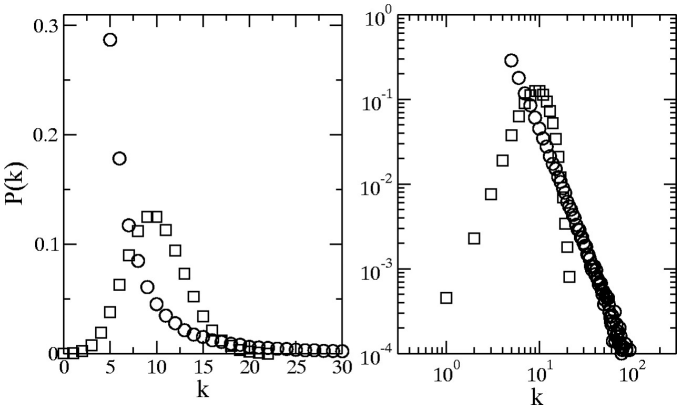

Fig. 3. Comparison between the degree distribution of scale-free networks and random graphs.

The bell-shaped degree distribution of random graphs peaks at the average degree and decreases fast for both smaller and larger degrees, indicating that these graphs are statistically homogeneous. In opposition, the degree distribution of the scale-free network follows a power law.

Scale-free networks occur in many areas of science and engineering, including the topology of web pages and the power grid of the western United States [4].

b) Small-world: A small-world network is a type of mathematical graph in which most nodes can be reached from every other by a small number of hops or steps.

Stanley Milgram, a social psychologist at Harvard, conducted a simple experiment in 1967 ([24]). He developed an easy methodology for studying how people are linked to others by giving a folder to a "starting person" instructed to send it

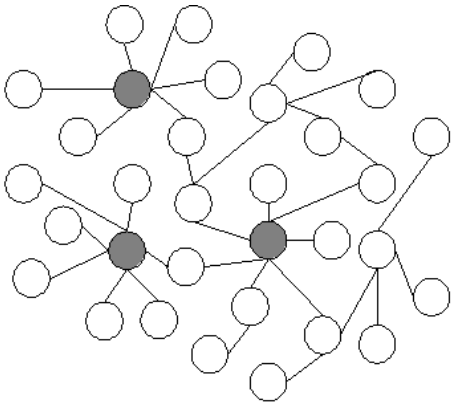

Fig. 4. Scale-free network.

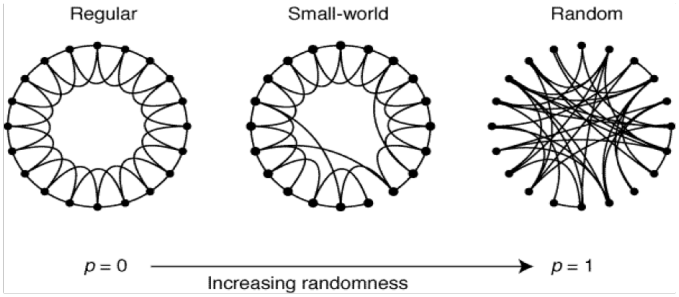

Fig. 5. Small World networks.

to a "target person". If the starter does not know the target, he send the folder to someone else among his friends, who will have to transmit the folder again until the target is reached. Thus Milgram could determine how closely linked any two people are in a population. In the original study, starters in Kansas tried to get folders to the wife of a divinity student in Cambridge, Massachusetts, and starters in Nebraska tried to get folders to a stockbroker in Sharon, Massachusetts. In the Nebraska study, Milgram found five intermediaries was the median number of links between the starter and target.

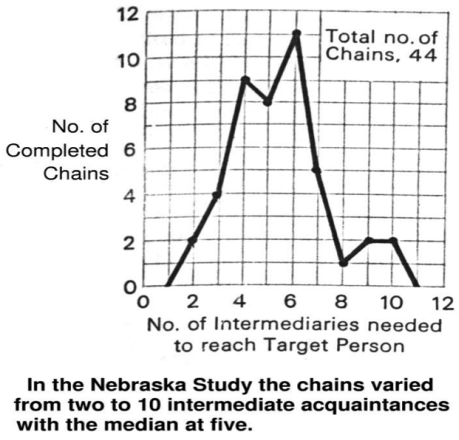

Fig. 6. Milgram Nebraska study

These properties are important issues to consider in our modeling because the scale-free is a property which clearly exists in the Smart grids as the distribution network follows this property.

Our goal is to try to find the relevant theories to solve problems of Smart Grid and to enable us to design a system with local rules leading to a global qualitative behavior. We will design the rules and a mathematics model to ensure the properties globally. In the next section, we present our theoretical model and theories used to build it.

III. Modeling

Primary, we have to distinguish models from simulation. A model is a simplified mathematical representation of a system at some particular point in time or space intended to promote understanding of the real system [2]. A simulation is the manipulation of a model in order to perceive interactions that would not otherwise be apparent because of their separation in time or space. A simulation should include as much detail as possible, whereas the model should include as little as possible to be easily generalized to other systems.[2]

Smart Grid represents a shared resource among multiple actors (or agents), with divergent interests. A complex system is characterized by its global behavior that is itself defined by local behavior. It is not obvious to do this in the form of equations, the use of multiple agents is therefore more suitable but we will be discussing that in more detail in the next section.

A. Agent-Based modeling

A multi-agent system (MAS) is a system composed of a set of multiple interacting intelligent entities (agents), an environment, a set of relations between entities and a set of operations that allows agents to perceive, produce, consume, transform and manipulate objects. Agents are specific objects representing the active entities of the system. Multi-agent systems can be used to solve problems that are difficult or impossible for an individual agent or a monolithic system to solve. Intelligence may include some methodic, functional, procedural or algorithmic search, find and processing approach.

The design of complex system is more realist with intelligent agents interacting together, because each agent can act as a separate mathematical model [30]. That is why agent-based modeling is one of the most evident approach for modeling complex system. MAS approach is used in lots of research topics such as pollution modeling [31], social structures...

An agent is a computational entity, like a computer program, a human or a robot, which can be viewed as perceiving and acting by its own on the environment. Agents in a multi-agent system have several important properties:[32]

- agents are partially autonomous: its behavior depends partly from its experience.
- agents don't have a full global view of the system but a local view
- there is no central controlling agent (it's not a monolithic system) [33]

Technically, a multi-agent system consists of a set of processes occurring at the same time. The key point of multi-agent systems lies in coordination between agents.

A MAS is said to be homogeneous if all agents are built on the same model (an ant colony), and heterogeneous if agents are built with different models from different hierarchical levels (eg the organization of a company). Concerning Smart Grid, we will use heterogeneous MAS to model all the different types of entities. Customers will even be modeled as autonomous and intelligent sub-systems. This will be further developed in this article.

One of the major benefits of MAS is to allow to study in silico the generic problem in risk-free space, while studying the global view of the system and setting up important parameters. Then, we can test the impact of various parameters in various scenari at very low-cost. Moreover, it corresponds to the reality because every agent act in real time simultaneously while having a possible individualized behavior.

However the only theory of multi-agent does not allow us to solve Smart Grids systems because there are theoretical problems. In the next section, we present in details the different theoretical aspects we use to enrich MAS to model efficiently Smart Grids. First, we will present Smart Grid as a complex network structure with behaviors tied with optimization and negotiations, so we will present game theory, a theory that models this behavior. Negotiations are based on notions of proximity between agents, but if we use a proximity metric that won't be appropriate and it will manage only one criterion, so we will use the pretopology. It will enable us to manage several relationships simultaneously using boolean functions, and that will better correspond to the reality. Moreover, in case of modification of one criterion we just have to change the corresponding adherence function. The pretopology is then one of the theories that brings lots of improvements to the existent model. Finally, we will present the percolation as a theory to validate our model. It will enable us to check if the network is always connected i.e. in terms of energy delivery, we can ensure that everyone is satisfied.

B. Smart Grid as a Complex Network

As seen in section 1, Smart Grid can be defined as a complex system. However, complex system structure is represented by a complex network, which is a combination of different graphs. Concerning Smart Grid, the complex network represent the transport and communication network. On one side, distribution network is the set of all power lines that allows the energy to pass through the grid and to be distributed. On the other side, the communication network allows agents communication, and collects the different statistics from smart meters.

In the case of Smart Grid, we represent the distribution network by an undirected graph: we consider the edges to be power lines, and the nodes to be junctions (i.e. substation, residentials, companies, ...) where the energy can go in or off a particular power line. Each edge has a maximum power supply that it is able to provide. Each node is an agent with some particular parameters (provide or consume energy, etc).

C. Game theory

In this part, we focus on game-theoretic ideas to solve the problem of negotiations concerning electricity distribution.

Smart Grids involves heterogeneous actors with different interests: the state, consumers, and companies are in perpetual conflict in the economic field. This is very close to game theory [34], [35]: it is indeed a strategic problem in which the actions of each player will influence the others.

Game theory is a method of applied mathematics used to study human and animal behaviors by modeling competing behaviors of interacting agents. Although it was initially developed in economics to understand a large collection of economic behaviors[34], the use of game theory in the social sciences has expanded, and has been applied to political, sociological, and psychological behaviors as well. Applications include auctions, bargaining, fair division, duopolies, oligopolies, social network formation, agent-based computational economics [36], mechanism design[38], voting systems[39], behavioral economics[40], and political economy [37].

Game theory can be defined as the study of mathematical models of conflict and cooperation between intelligent rational decision-maker. It provides general techniques to analyze situations, such as in games, where an entity's success depends on the choices of the other entities [35]. From our point of view, we can see it as a model of conflicts and cooperations between agents and the *game* refers to the whole Smart Grid. Then, it will model electricity traffic patterns between the agents.

As seen above, the negotiations are based on notions of proximity between agents, but if we use metric distances that won't be appropriate and it will manage only one criterion. Conventional topology would be too cumbersome to be implemented so pretopology is one of the most relevant theories that brings a lot of improvement to the existent model. It will enable us to manage several relationships simultaneously using boolean functions, and that will better represent the reality. Moreover, in case of modification of one criterion we just have to change the corresponding function.

D. Pretopology

The pretopology is a mathematical theory, weaker than classical topology to express the structural transformation of sets composed of interacting elements such as the constitution of decisive coalition among a population, alliance phenomena, tolerance and acceptability processes and emergence of collective behavior [25], [26]. In our case, we use pretopology to model the concept of proximity.

Indeed, in the context of integrating renewable energy, it is necessary to express the notion of proximity in terms of algorithm. If we take the example of wind turbines, we do not speak about metric proximity, but functional proximity: the weather influences the electrical efficiency production, and

the turbine closest from us is not necessarily the one that can provide all the energy required!

Definition We call *pseudoclosure* defined on a set E, any function a(.) from P(E) into P(E) such as:

- $a(\emptyset) = \emptyset$
- $\forall A \subset E, A \subset a(A)$

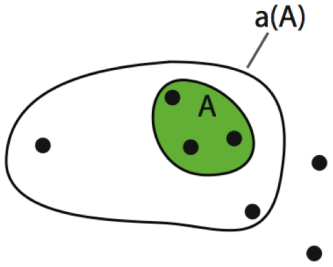

Fig. 7. Pseudo-closure of A.

Definition We call *interior* defined on a set E, any function i(.) from P(E) into P(E) such as:

- $i(E) = E$
- $\forall A \subset E, i(A) \subset A$

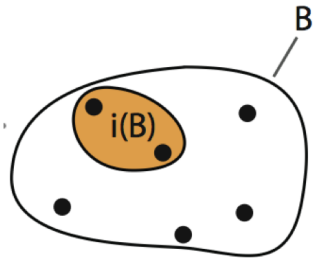

Fig. 8. Interior of A.

Definition Given, on a set E, a(.) and i(.), the couple $s = (a(.), i(.))$ is called pretopological structure on E and the 3-uple (E,a(.),i(.)) is called a pretopological space.

In pretopology, a complex network can be viewed as a family of pretopologies on a given set E [7].

Then, we can use different pretopological spaces on the same set to better model a phenomena. In our case, the integration of all the parameters of the Smart Grid can be done within a separate pretopological space for each one: weather influence, distances, maximum power supply, etc... By this way, an accurate setting can be done easily, quickly and efficiently.

With the pretopology, we can enrich our model using multivariate relationships between entities. However, the Smart Grid is dynamic so we need a method to verify that our model generates an overall system working properly: that is, it distributes electricity regularly to every customer. The percolation checks if a network is always connected so in terms of energy delivery, we can ensure that all customers are satisfied. In the next section, we present more in details this theory.

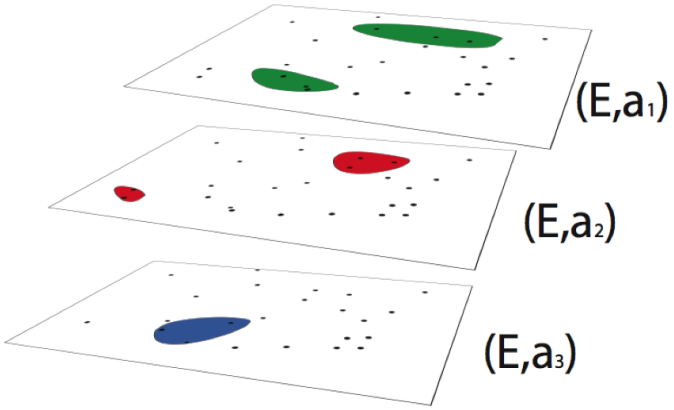

Fig. 9. Complex network in pretopology.

E. Percolation theory

Percolation is a mathematical theory used for determinist diffusion processes on a stochastic structure [27].

The theory of percolation can bring together many complex phenomena by analyzing the behavior of phase transition in these systems. It helps to highlight the underlying mechanisms. The word "percolation" comes from Latin percolatio, meaning filtration. He referred in general to the concept of agglomeration and propagation in random media partially interconnected [29].

Physical problems such as Smart Grids are mathematically modeled as a network of points (n consumers) and the connections (or edges) between each two neighbors may be opened (allowing the electricity to pass through) with probability p (connected by bonds of p random efficiency), or closed with probability $(1-p)$, and we assume they are independent. [28] So there exists a proportion $(1-p)$ of links that can be destroyed at random, which does not provoke any power failure visible for consumers, nor interfere with communication between a station and an another, as it is still possible to go through relay stations if p is greater than a critical value, called the percolation threshold p_c. Below the critical value p_c, the probability that two stations can communicate directly or indirectly is very low.

This mathematical model was originally developed for the study of physical phenomena, but it had been applied in various fields other than physics [41]. Indeed, the percolation theory has contributed, for example, in modeling complex systems in economics [42], marketing [43], sociology [44], computer science [45], ecology [46], or mathematics [47].

In our case, we will determine the acceptable threshold in order to have a proper power distribution. Eventually we will get a tool for decision support that will help to refine variables, change settings using modeling theories enriched by classical mathematical theories. We aim to achieve a very effective

model to manage Smart Grid complexity in order to control it or enhance the performance.

IV. Simulation

In this section, we present an overview of our model developed with AnyLogic.

A. Anylogic

Anylogic, a simulation software provided by XJ Technologies, is the first and only tool that brings together System Dynamics, Process-centric (Discrete Event), and Agent Based methods within one modeling language and one model development environment.

The native Java environment provides multi-platform support, and models can be exported as standalone Java applications. It supports limitless extensibility including custom reusable Java code, external libraries, and external data sources. For example, we can integer the Java library PretopoLib [48] developped by Vincent Levorato and Marc Bui to manage pretopological functions and spaces.

B. Agents and parameters

We use several types of agent in our model. We focus on individual objects and describe their local behavior. We use a configurable scale-free structure in order to be able to modify some parameters and analyze the consequences of the structure on the system dynamic.

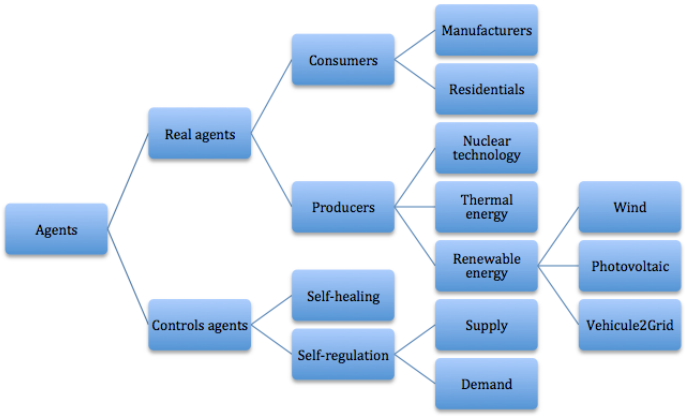

Fig. 10. Different types of agents.

We separated the work in different modules.

We stored all real data about energy consumption and production in an external database. Then, for each type of agent, we implemented mathematical models to reproduce their behavior as realistic as possible. Each type of agent has its own power management module to reproduce its consumption or production of electricity. Then, this module is connected to a decision making process module, based on game theory to compute the distribution of energy using a pretopological proximity measure. Agents can communicate with each others through a communication module, and are interconnected with a scale-free transport network. The "environment module" enables to integrate the management of external parameters having an influence on the system such as weather or pricing policy.

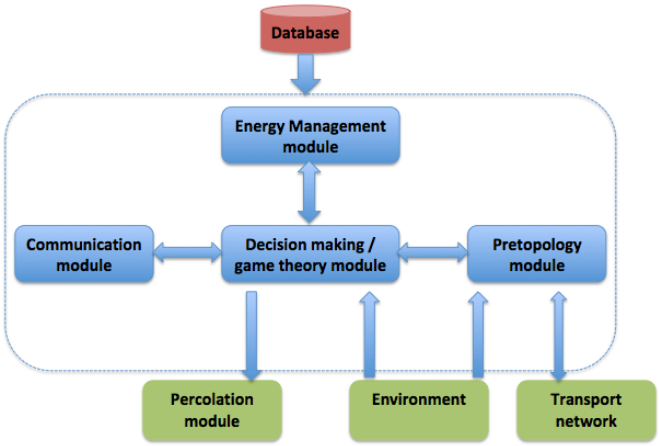

Fig. 11. Modules for each agent.

C. Futur work

Currently, our model developed on AnyLogic is a simplified model. We integrated the various agents presented in a scale-free network, and the distribution of electricity is made by calculation with pretopological distances. In a futur work, we plan to integrate game theory in our development and to test different scenario in order to optimize the system. Then, we will be able to change the value of some parameters and study their effects.

V. Conclusion

To conclude, we presented an efficient multi-agent based modeling to meet the problematics of Smart Grids.

By basing our model on theories adapted to fit each issue, our model allows to take into account the heterogeneity of the actors that makes the Smart Grid a complex system, and optimizes the existing network by integrating an overall independent supervision.

In a futur work, we will be able to present more results and will certainly adapt some points to calibrate our model at best compared to the reality of the existing network.

Abstract - *The goal of configuring a massive, complex multi-agent system can be viewed as a distributed search problem in which each agent attempts to choose a correct configuration. This research presents a technique that can simultaneously function as the problem decomposition and solution aggregation components in such a distributed search environment. The method is tested in a number of large multi-agent simulations to demonstrate its feasibility. The agents in the system are shown to achieve optimal or near optimal configurations in significantly less time than agents configuring themselves individually.*

Keywords: *Multi-agent systems, distributed search, emergence*

1 Introduction

Distributed search is an open problem in AI research. At its core, it is a problem involving efficiently decomposing or partitioning a problem into sub-problems and allocating those sub-problems to one or more computational elements. Ideally, these elements would then be able to explore their much more limited search space in parallel. Research in distributed search can be broadly classified as dealing with one or more of the following: finding algorithms for appropriate decomposition of problems [1], distribution of sub-problems to computational elements [2], synthesizing results of sub-problems [3], and coordination between elements [4]. The research in this paper proposes a technique that will simultaneously handle problem decomposition and result synthesis.

In this research, a massive multi-agent system has been given the goal of configuring its constituent elements (i.e., the individual agents) for optimal performance of the tasks assigned to those elements. In this scenario, we make several assumptions:

- The size of the organization is such that micromanagement of individual agents is infeasible.
- The complexity of the organization and its operating environment is such that the desired configuration of the average agent is unknown.
- Individual agents may already possess some method for learning.
- In the course of performing tasks, agents will communicate or deal with each other, but agents are not required to be benevolent. They are allowed to choose an appropriate configuration for themselves without considering the needs of other agents.

2 Approach

To facilitate the speed of the search, a key observation is made regarding the performance of the agents. If all other factors are held constant, an agent that is more successful at completing its tasks will typically be better configured for the task than an agent that is less successful. Therefore, when agents interact, the more successful agent will pass appropriate traits to the less successful agent. The greater the relative success, the more strongly the trait is adopted or the more likely the trait will be adopted.

Formally, agent $\boldsymbol{A_i}$ has a Sending function F_i^S:

$$\boldsymbol{O_j}(T+1) \leftarrow F_i^S(x_i(T), \exists!\ x \in \{C, S\}). \quad (1)$$

This function sends a configuration C or success score S to the observation list of the receiving agent, $\boldsymbol{A_j}$, where it can be processed. Similarly, a Receiving function, F_i^R, is defined:

$$\boldsymbol{O_i}(T+1) \leftarrow F_i^R(F_j^S(x_j(T), \exists!\ x \in \{C, S\})). \quad (2)$$

This function receives a configuration C or success score S from agent $\boldsymbol{A_j}$ and stores it in the observation list where it can be processed. Finally, a Processing Observations function, F_i^P, and an Updating Configuration function, F_i^U, are defined:

$$\boldsymbol{B_i}(T+1) \leftarrow F_i^P(\boldsymbol{O_i}(T), \boldsymbol{B_i}(T)). \quad (3)$$
$$\boldsymbol{C_i}(T+1) \leftarrow F_i^U(\boldsymbol{C_i}(T), \boldsymbol{B_i}(T), S_i). \quad (4)$$

In F_i^P, agent $\boldsymbol{A_i}$ merges its list of observations with its beliefs to create new or updated beliefs. Similarly, F_i^U utilizes agent $\boldsymbol{A_i}$'s current configuration, its success score, and its beliefs, including its beliefs regarding other agents'

configurations and their success scores, to determine its new configuration.

In the BDICTL model, agents will only execute their intentions if there is one plan available. When more than one plan is present, noting is done. Some research (CITATION) proposes that this could be modified to have the agent pick a random plan. We propose that the random selection could be more appropriately performed by the viral trait model. To do so, the beliefs about the agent's internal decision-making process can be modeled as traits. To illustrate, let the following variables be defined:

- $\boldsymbol{E_i}$ ::= set of events associated with the execution of a task by agent $\boldsymbol{A_i}$
- $\boldsymbol{E_j}$ ::= set of events associated with the execution of a task by agent $\boldsymbol{A_j}$
- $\boldsymbol{C_i}$ ::= set of configurations of $\boldsymbol{A_i}$
- $\boldsymbol{C_j}$ ::= set of configurations of $\boldsymbol{A_j}$

Then, the BDI formalization of the trait adoption process of agent $\boldsymbol{A_i}$ becomes:

$$\begin{aligned}&\mathsf{BEL}((\textstyle\sum succeeded(\boldsymbol{E_i}) / \sum done(\boldsymbol{E_i})\\ &< \mathsf{BEL}\ (\ succeeded(\boldsymbol{E_j}) / done(\boldsymbol{E_j})))\\ &\rightarrow optional \Diamond \mathsf{INTEND}(\forall\, c_j \in \boldsymbol{C_j}\ , \forall\, e_j \in \boldsymbol{E_j}\\ &\cap\ (context(c_j) = context(c_j)), \forall\, c_i \in \boldsymbol{C_i}\ , \forall\, e_i \in \boldsymbol{E_i}\\ &\cap\ (context(c_i) = context(c_i))\ (does(\mathsf{BEL}(c_j))\\ &\wedge\ does(\neg\mathsf{BEL}(c_i)\ ))).\end{aligned} \quad (5)$$

This definition assumes the existence of the helper function *context* which returns the contextual component of the variable. In essence, the formalization states that if $\boldsymbol{A_i}$ believes its average success on a particular task is less than what it believes $\boldsymbol{A_j}$'s average success to be, then it has the option of eventually intending all planning beliefs of $\boldsymbol{C_j}$ as long as those beliefs have the same context as events associated with the task in question. It will not take any belief that is not in the same context. Additionally, $\boldsymbol{A_i}$ would intend to remove any existing beliefs that have the same context as the task. This has the effect of adopting the beliefs, including potential action plans, of a perceived superior peer.

3 Experimentation

To investigate the viability of the model, a simulation was created to examine several environments and scenarios in which the agents could operate. A screenshot of this simulation is shown in Figure 1. To get a feel for the ability of the model to handle a variety of peer networks, three different network types were utilized. These network types are representative of the types of networks found in natural and artificial systems. Possible configurations were a grid network with each agent connected to its four neighbors, a scale-free network in which a minority of agents have the majority of connections [5], and a completely random

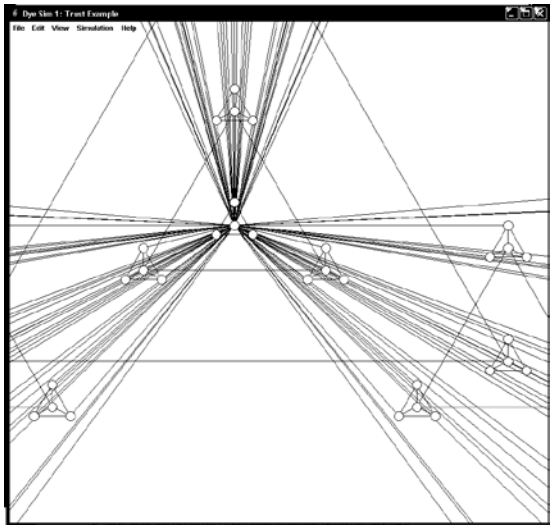

Figure 1: Screenshot of simulation

network. Each network was populated with 10,000 agents that then linked to other agents in the prescribed manner. These connections represented communication links between peer agents.

The multi-agent system was tested in a sales staff scenario. The environment simulated a large department store where the agents acted as the sales staff. The agents were given personality vectors containing five of a possible 100 randomly selected personality characteristics. These five parameters constituted the set of agent Ai's configurations, Ci. In this simulation *personality* was defined as a set of characteristics that uniquely influence cognitions, motivations, and behaviors in various situations [6]. Although there are many different theories on what characteristics constitute one's personality, this research simply assumed the characteristics are those that related to the ability to sale products.

The agents were placed in random departments to await customers. The number of customers was significantly greater than the number of sales agents so that a random "customer drought" would not influence an agent's success rates. Like the sales agents, each customer was given a random personality vector. Customers tended to gravitate towards particular departments based on their personalities and were programmed to be more likely to be persuaded to buy from an agent whose personality was likewise compatible. Therefore, agents with a personality compatible with its assigned department were more likely to be successful than agents with a significantly different personality.

The goal of the system of agents was to have each agent learn and utilize those personality traits that were most appropriate for their department. Each agent was able to perceive the personalities of their peers as the other agents made sales. Essentially, each agent would utilize the Sending

function, F^S, to transmit its current personality configuration after each successful transaction.

$$S_i(T+1) \leftarrow F_i^J(S_i(T), 1 - \sum_{x=1}^{5} | C_{cust}(x) - C_i(x) |) \quad (6)$$

$$S_i(T+1) > S_i(T) \rightarrow \boldsymbol{O_x}(T+1), \forall\, x \in \boldsymbol{P_i} \leftarrow F_i^S(\boldsymbol{C_i}(T)) \quad (7)$$

Agent $\boldsymbol{A_i}$'s performance of its job function, F_i^J, is based on the differences between its personality configuration $\boldsymbol{C_i}$ and the customer's configuration C_{cust}. If its score increases, it will send its current configuration to the observation lists of all agents in its peer list, $\boldsymbol{P_i}$.

When adopting the personalities of successful peers, the agent has a chance to assume any of personality traits of the peer. The chance of assuming a trait is based on the difference in the two agents' success rates:

$$Random^x(1{:}100) \leq (S_j - S_i) \rightarrow C_i^x \leftarrow C_j^x, \text{ for x = 1,2,..,5.} \quad (8)$$

The agents within this simulation were initialized with random values and allowed to transfer their traits to each other. When the system had converged with no more spreading of trait solutions, the simulation stopped, and the results were recorded. Of interest was the system's overall ability to spread the best solutions and the time it took to stabilize.

Next, experiments were performed to test the ability to converge after the insertion of a new agent into the community. A system of agents was allowed to converge, simulating a mature organization. Then, an agent was moved from one region to another. The time to converge and the final fitness of the new organization were recorded.

The ability of this framework was compared to the ability of a duplicate mature organization that utilized individual search to converge. The agents in this organization utilized a greedy binary search method to find appropriate configurations:

1. Try a particular trait for a period of time
2. After the period of time, use binary search, but randomly choose whether to go higher or lower
3. Try this new trait for a period of time
4. After the period of time, evaluate the effectiveness of the solution. If worse than original, try the unchosen direction. If better than original, then continue search. If both higher and lower are worse than original, then finished.

4 Results and conclusions

As shown in Figures 2 and 3, the framework's ability to stabilize at an acceptable state is quite good. The random network had the most variance in convergence time and accuracy, but averaged to reasonable levels. The grid's performance was as expected; when the "best fit" agent was centrally located, it took approximately half the distance across the network to stabilize, while "best fit" agents in the corners caused propagation to take longer. The scale-free network had more variation than initially anticipated since the distance across a scale-free network is quite short, but this variation can be attributed to the location of the ideal traits. If the "best fit" agent is also one of the network hubs, the system distributes the trait very rapidly. If the ideal trait is located in a peripheral agent, the transfer of the trait is slow until it hits a major communication artery.

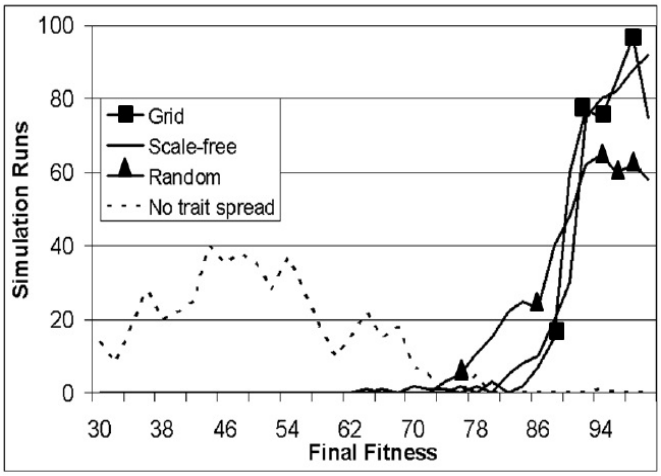

Figure 2: Number of sims obtaining a particular final fitness

Both the trait-spreading and binary search methods proved successful at quickly acclimating the transported agent to its new environment, as shown in Figure 4. However, the trait-spreading method always succeeded in very few steps, only taking longer when the agent is moved to a border area where nearby successful peers are not actually operating in the same department as the transported agent. This short stabilization time is due to the fact that the agent didn't have to find a successful configuration through trial-and-error, but rather was given a successful starting point from a nearby agent. Additionally, the amount of time take does not depend on the

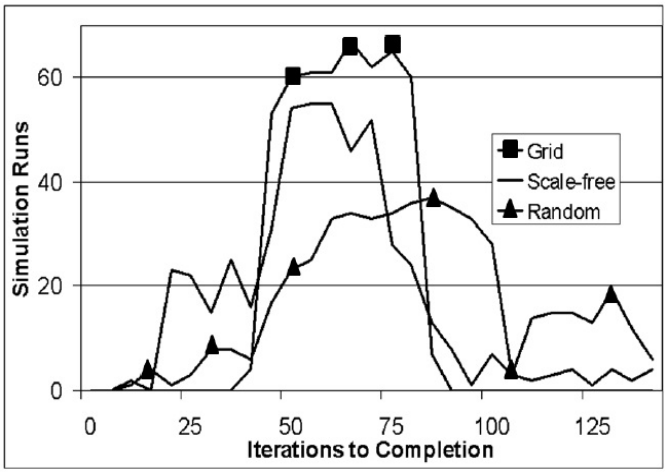

Figure 3: Stabilization times

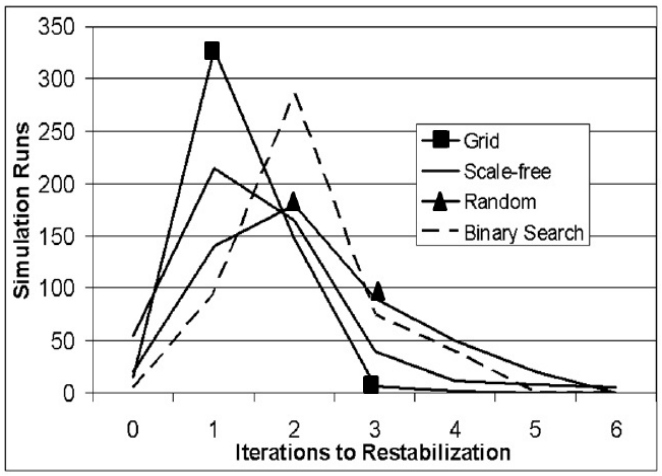

Figure 4: Number of agents with particular stabilization times

size of the problem space, unlike the individual-based binary search.

Although it is not guaranteed to find the ideal solution, it significantly reduces the amount of work done. It naturally produces subproblem boundaries in which similar agents require similar solutions and the aggregates the best known solutions. This work could be combined with other forms of distributed or individualized search. This would serve as the decomposition and aggregation component of such an amalgamation. More research into what types of search would produce the best results is needed. Additional research into the effects of increased parallelization is another area to explore.

Abstract— *Inhabitants' behaviour in buildings has a strong impact on the energy consumption patterns resulting in energy waste. The existing multi agent and centralized energy management approaches are focused on consumption optimization and load predictions without taking into account the inhabitants' behaviour. We argue that the consumption optimization without waste reduction is difficult. In this article we focus on the energy waste reduction associated with the inhabitants' behaviour. As an example a physical model for the fridge to predict the energy waste component and an agent based co-simulation methodology to identify high energy consuming activities, are developed. The proposed methodology demonstrates that based on the co-simulation results a library of high energy consuming activities can be built to support energy waste reduction efforts in Smart homes. It shall result in a shift from an energy manager towards an energy wizard to provide agents with the information on their consumption behaviour and alternatives to ensure the energy waste reduction.*

Keywords: Multi agent simulation, behaviour, energy consumption, human behaviour modelling

1. Introduction

Buildings account for 30-40% of the total primary energy use globally [1]. The inhabitants' behaviour has a significant impact on energy consumption and is an important factor for energy waste reduction [2]. We argue that the appliance consumption patterns are strongly influenced by the inhabitants' behaviour. Existing models that are used for the usage prediction of appliances are mostly based on presence/absence profiles [3]. Such profiles could be helpful for the appliances where energy is consumed only when they are turned on, e.g. lighting systems (active appliances). However, such profiles are insufficient for the appliances having continuous energy consumption e.g. fridge, freezers (cold appliances). Widén and his colleagues proposed a scheme to predict energy demand against different activities on both active and cold appliances, however the cold appliances operation was assumed unrelated to the activity patterns [4]. We argue that these appliances offer a great challenge to model them based on human behaviour due to the diversity of different possible actions on them and their resulting consumption. It will be interesting to see that how the energy waste component resulting from actions on cold appliances impacts the energy consumption optimization efforts in the Smart homes. In this article we have focused on the inhabitants' behaviour to identify high energy consuming activities with the support of proposed physical model for our example cold appliance « fridge ». This is done in a co-simulation platform using Brahms (agent modeling language) and simulink. The purpose of this co-simulation methodology is to assess the sensitivity of inhabitants' behaviour to the energy waste component and identify the high energy consuming activities to be transformed into a library for further use in the Smart homes. It will help in developing true smart environments as well as testing the design of new appliances models. It will also help to design the smart energy advisors suggesting human agents with the alternatives that minimize the energy waste component. This article is divided in 5 sections. Section 2 presents the literature review, on existing agent based approaches for energy management and the importance of inhabitants' actions on energy consumption. The modeling of household behaviour with an agent based approach is presented in section 3. The proposed physical model for the refrigeration cycles and the co-simulation methodology are detailed in section 4 and 5. Conclusion and future perspectives are discussed in the section 6.

2. Background

The literature review is divided in 3 sub sections: (i) agent based approaches for energy management, (ii) importance of inhabitants' actions on the energy consumption and (iii) human behaviour representation.

2.1 Agent based energy management

Multi agent system approaches have been used in the domain of energy management within buildings. Davidsson and Boman proposed and implemented a multi agent system based decentralized system to monitor and control the HVAC system (Heating, Ventilation and Air Conditioning) and lighting in office buildings [5]. Abras and his colleagues proposed a home automation system made up of software

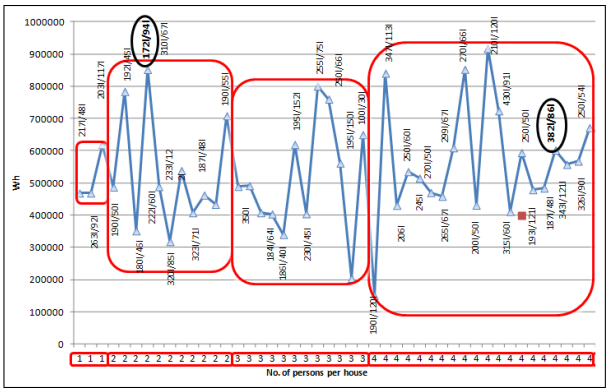

Fig. 1: Full year fridge-freezer consumption

agents that control appliances and sources [6]. It adapts power consumption to the available power resources. Agents in the MavHome project [7] predict the mobility patterns and device usage of inhabitants to satisfy the tradeoff between cost and comfort. Liao and Barooah developed a MAS approach to predict and simulate the occupancy at room and zone level in commercial buildings [8]. The anticipatory and reactive control of HVAC and lighting within smart homes has been implemented in a MAS [9]. [10] used an agent based control system in order to optimize the energy usage of a simulated residential water heating system. The above approaches do not take into account the impact of inhabitants' complex behaviour on the energy consumption for appliances. We argue that humans must be considered as active, intelligent agents for energy waste reduction in buildings.

2.2 Importance of inhabitants' actions on the energy consumption

Since human behaviour strongly influences energy consumption [2], an experiment has been performed on the IRISE database in order to see how inhabitants' behaviour affects energy consumption[1]. In figure 1 the number of people in the houses are shown on x-axis and the appliance consumption on y-axis. It shows the results of an experiment taking into account the number of people in each house and the specifications for the appliance. It can be seen that consumption does not depend solely on the number of people in the house and the size of the fridge freezer, but also on how the appliance is used by the people. For example, the first oval on the left in the figure shows that a fridge freezer with a capacity of 172l/94l in a 2-person house is consuming even more than the fridge freezer of almost double size in a 4-person house. The above experiment shows that human behaviour strongly affects energy consumption.

[1]This dataset is part of the European Residential Monitoring to Decrease Energy Use and Carbon Emissions (REMODECE) project. It contains energy consumption data, for each appliance from 98 French houses, recorded at every 10 minutes, over a one year period.

2.3 Human behaviour representation

The term "behaviour" refers to the actions or reactions of an object, usually in relation to its environment. In the literature, perception, cognition, memory, learning, social and emotional behaviour and psychomotor are considered to be the basic elements of human behaviour [11], [12], [13]. Human behaviour has also been analyzed through contextual factors including user, time, space, environment and object. These authors presented a user behaviour modeling approach called 5W1H for: what, when, where, who, why and how, which they then mapped to a home context (object, time, space, user and environment) [14]. Sempé and Quijano implemented an agent based modeling and simulation environment in order to study the use of electrical appliances by inhabitants [15]. Human behaviour can range from being very simple to very complex. The purpose here is to capture the behaviour that not only represents a simple presence or absence of an inhabitant in an environment but also represents a realistic interaction of the human with the environment. This means that the dynamic, reactive, deliberative and social behaviour of inhabitants must also be taken into account in order to fully understand its possible effect on energy consumption. This will help to consider the inhabitants as reactive, intelligent agents instead of simply "fixed metabolic heat generators passively experiencing the indoor environment" [16].

3. Modeling the household behaviour with an agent based approach

A belief-desire-intention agent model of the household's behaviour specifically for their interaction with the fridge is derived from an activity journal. The data was collected by a 2-person household, husband and wife, in which they had to specify the actions that they performed on the fridge as well as the reasons behind those actions. This reasoning mechanism when implemented into the agent based language gives them the power to think and behave the way humans do. Figure 2 shows that the agents in our model set their beliefs based on some perception from the environment. For example, perception of the other agents, objects, location and time etc. The environment could be the surroundings or the inner self for the agent. For example, in order to have the dinner, the perception from the inner self is the feeling of hunger, which now becomes a desire to eat. However, this desire will not be fulfilled by the agent until it reaches a certain threshold level and/or based on some cognitive influence. This cognition constitutes the reasoning mechanism that why the agent take or avoid taking some decisions. The social norms of the family, for example, could be one of the influencing factors on cognition. In this case, if the threshold for hunger is reached but the other agent has not arrived yet, based on the cognitive influence a new threshold level will be attained. If however the threshold

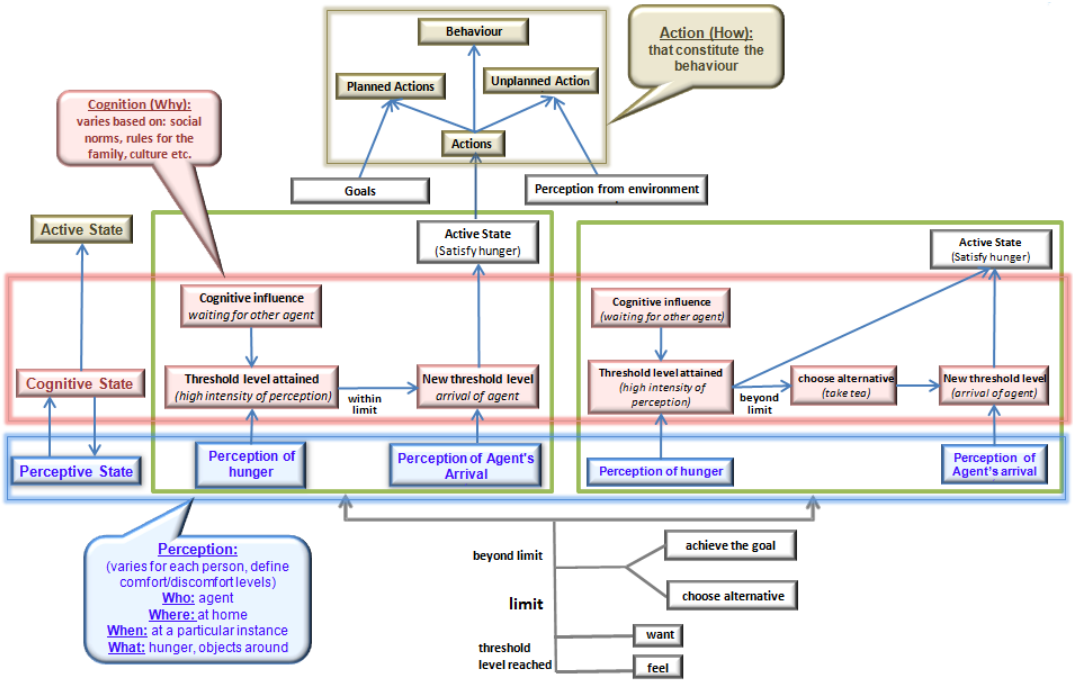

Fig. 2: Behaviour representation

level has crossed its limit, the agent will either take some alternative or his desire will be converted to an intention and he will achieve the goal, i.e. fulfill hunger. The actions caused by the agent's intentions are the planned actions, but if there is some new perception from the environment before he fulfilled the intention, it may lead to some unplanned actions. For example the planned actions to fulfill the hunger are to open the fridge, take the food out, cook it and then eat, but the unplanned actions upon the perception of a sudden pleasant change in the weather is to go to the restaurant and eat there. How the actions are performed finally constitute the behaviour of the agent. Brahms is a descriptive language to record and simulate the causal relations of inhabitant behaviour. The Brahms language [13] is compatible with our requirements. It is an agent oriented modeling/simulation environment and programming language based on belief-desire-intention agent architecture. It is able to represent people, things, places, behaviour of people over time, tools and artefacts used, when and where they are used. It also supports the communication between co-located and distributed people to support social behaviour. The key concepts are the workframes and thoughtframes. Workframes are the condition-action-consequence rules that allow agents to perform certain actions based on their beliefs and set new beliefs about the perception of the environment. Thoughtframes are used to trigger the reasoning behaviour of agents, they let the agents derive new beliefs based on existing beliefs and facts about the environment without performing some action. The BDI based behaviour model has been implemented in the Brahms environment. An example is shown in figure 3 where the agent (agentAdult1) is watching TV, he has some belief about the threshold level of his hunger. In the figure this belief is shown with the help of thoughtframes represented by a bulb symbol. The hunger level gradually increases as the simulation progresses. The agent will continue watching TV until he detects that the hunger level has reached beyond the threshold level. This detection mechanism is implemented using the concept of detectables in Brahms language which are used to interrupt, abort or continue the current activity. The first bulb symbol after 7:49:50 pm shows a pop-up of thoughtframes changing the agents' belief about the perception of hunger which is converted into the desire to eat. This desire finally becomes his intention as there is no other constraint or belief avoiding him from fulfilling the desire and he moves to the kitchen to prepare food, where he interacts with the appliances e.g. the fridge. The horizontal yellow bar just beneath the

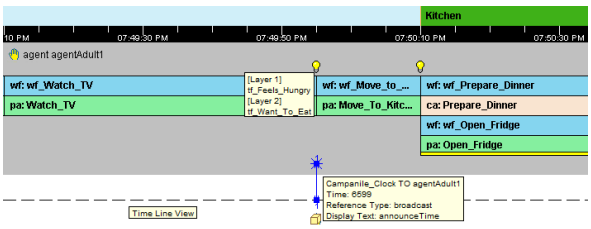

Fig. 3: Brahms simulation output

"Open_Fridge" primitive activity is used to represent the

interaction of agents with some appliances. A brief example of the model presented in figure 2 is presented in section 5, where a link is established between human and appliance behaviour.

4. Fridge simulation model

The activities of inhabitants, their presence at different locations in the house, their control over different appliances and objects, and their communications can be modeled in the Brahms simulation environment. However in order to model the appliance behaviour a physical simulator is required which provides the information about physical aspects such as temperature inside the fridge, compressor states etc. We have developed our physical model as shown in figure 4. The description of the model variables is given in table 1.

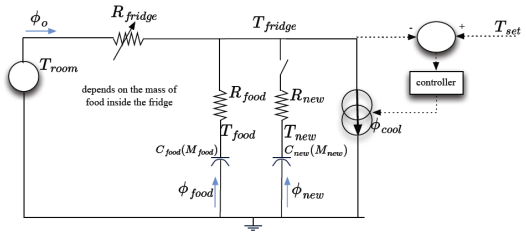

Fig. 4: Physical model for the fridge consumption cycle modeling

In this model we have made assumptions: (i) variation in the quantity of food inside the fridge is negligible, (ii) R_{food} = 0 and food temperature inside the fridge is assumed same as the inside temperature of the fridge. Figure 4 presents

Variable	Description
T_{fridge}(k)	inside temperature of the fridge during reactive time k, $\Rightarrow$ T_{fridge}(k) $\in$ [Tmin; Tmax]
T_{room}(k)	ambiant temperature of the room
T_{new}	New food temperature
C_{new}	$M_{new}C_p$, capacity of a new food added to fridge
R_{fridge}	R_{open} + ζ(Rclose - Ropen) resistivity for heat exchange between inside fridge and room
R_{food}	resistivity to heat exchange between food and fridge
R_{new}	resistivity to heat exchange between new food and fridge
M_{food}	food quantity
M_{new}	quantity of a new food
T_{set}(k)	set-point temperature
$\pm\sigma$	Dead zone: +σ and -σ represent the upper and lower limits, above and below the set point temperature, where the compressor starts or stops respectively

Table 1: Description of model variables

the physical model of the fridge energy consumption cycles. The cooling power ϕ_{cool} is provided by the controller to maintain the setpoint temperature of the fridge. Similarly ϕ_o is the heating power coming from the room and affects the inside temperature of the fridge depending on the resistance R_{fridge}. ϕ_{food} and ϕ_{new} are the heating power coming from the food already present in the fridge and the newly introduced food respectively. Their affect on the fridge temperature depends upon their heat capacity and mass as well as the corresponding resistivity. In modeling the fridge cycles, the heat pump is an important element, let ρ be the performance factor of heat pump that yields C_{elec} = $\rho\phi_{cool}$ and fridge controller is made to follow the following criteria: i) compressor stops working when the fridge temperature goes below the lower limit of the dead zone

$$T_{fridge}(t) - T_{set}(t) < -\sigma \rightarrow \xi(t+dt) = 0 \tag{1}$$

ii) compressor starts working when the fridge temperature goes above the upper limit of the dead zone

$$T_{fridge}(t) - T_{set}(t) > \sigma \rightarrow \xi(t+dt) = 1 \tag{2}$$

iii) otherwise it follows its current state

$$-\sigma \leq T_{fridge}(t) - T_{set}(t) \leq \sigma \rightarrow \xi(t+dt) = \xi(t) \tag{3}$$

cooling power at a particular instance is given by:

$$\phi_{cool}(t) = \xi(t)\phi_{cool} \tag{4}$$

We have modeled three major events for the fridge as (a) permanent mode, where the fridge operates in the normal refrigeration cycles, (b) temporary mode when the fridge door is opened and closed, as a result heat is exchanged and inside temperature rises to impact the instantaneous refrigeration cycles and (c) temporary mode when food is introduced in the fridge.

a) The model for the permanent state or normal cycles is proposed as under that computes the rate of change in the fridge temperature over the simulation period:

$$\begin{aligned}\frac{d}{dt}[T_{fridge}] = \Big[-\frac{1}{R_{fridge}C_{food}} \Big][T_{fridge}] + \\ \Big[\frac{-\rho\phi_{cool}}{C_{food}} \frac{1}{R_{fridge}C_{food}}\Big]\begin{bmatrix} \xi \\ T_{room} \end{bmatrix}\end{aligned} \tag{5}$$

The model of the permanent state (1st order) is obtained when T_{new} = T_{fridge}.

b) The model for the temporary mode when the fridge door is opened and closed. It follows the model for the permanent state with only change in the resistance of the fridge as under:

$$R_{fridge} = R_{new} + \zeta(R_{close} - R_{open}) \tag{6}$$

c) The model for the mode when new food is introduced is proposed as under that computes the change in temperature over time for both the fridge and the new food introduced into the fridge:

$$\begin{aligned}\frac{d}{dt}\begin{bmatrix} T_{fridge} \\ T_{new} \end{bmatrix} = \begin{bmatrix} -\frac{R_{new}+R_{fridge}}{R_{new}R_{fridge}C_{food}} & \frac{1}{R_{new}C_{food}} \\ \frac{1}{R_{new}C_{new}} & -\frac{1}{R_{new}C_{new}} \end{bmatrix} \\ \begin{bmatrix} T_{fridge} \\ T_{new} \end{bmatrix} + \begin{bmatrix} -\frac{\rho\phi_{cool}}{C_{food}} & \frac{1}{R_{fridge}C_{food}} \\ 0 & 0 \end{bmatrix}\begin{bmatrix} \xi \\ T_{room} \end{bmatrix}\end{aligned} \tag{7}$$

We have followed following assumptions wile modeling the fridge: (i) Opening the door modifies R_{fridge} (ii) Removing

food from fridge is assumed to have a very small impact (except the door opening) (iii) Adding food sets a new value to T_{new} and parameters like C_{new} and R_{new} may be adjusted depending on the food.

5. Co-simulation environment

Human behaviour is dynamically modeled and simulated in a multi agent simulation environment (Brahms), as intelligent agents. An agent based approach is well suited since agents are a natural and intuitive way to model humans and their characteristics and are a key towards implementing group behaviour. Agents like humans evolve in the environment, perceive it and act accordingly. The changes in the environment are perceived by the agents, who then take actions dynamically to change the state of the objects and appliances in the building. This dynamic behaviour is fed to the physical simulator containing the model of the fridge using an interface developed in java. It generates energy consumption cycles of the fridge and maintains the setpoint temperature. Physical simulator is implemented in Matlab and simulation results are monitored and analyzed with Simulink. In order to perform certain activities, the

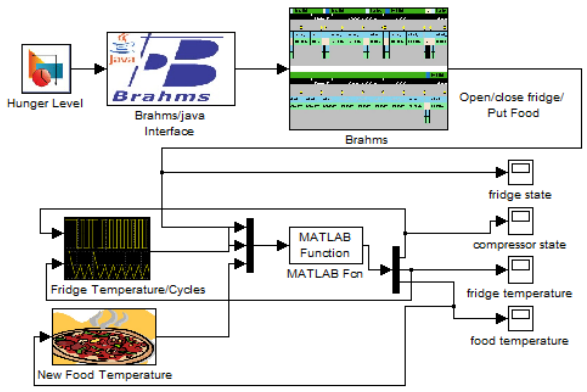

Fig. 5: Co-Simulation Platform to Find High Energy Consuming Activities

inhabitants change their locations, perform certain actions on appliances e.g. opening the fridge, putting food inside etc. As soon as these state changes happen, this information is sent to the physical simulator, where appliance behaviour is changed and its consumption is computed. The proposed co-simulation platform is presented in figure 5 with 3 distinct elements as (i) Brahms MAS, (ii) Brahms Java Interface and (iii) physical simulator (model for the fridge). The Brahms MAS element simulates the agent behaviour for the fridge. The Brahms java interface establishes the connection between Brahms and the physical model of the fridge. This interface actually drives Brahms virtual machine and manipulates different attributes of the occupant's behaviour model to be simulated by setting agents and objects attributes and handling the starting time of the simulation. It also keeps track of the current location of agents and of the current values of different attributes of objects. The physical simulator is created in Matlab/Simulink and consists of the model of the fridge and the controllers for appliances. The model of the fridge is defined in the Matlab function file which uses the output of the Brahms simulation such as opening the fridge, putting food in fridge and based on the inside temperature of the fridge turns the refrigeration cycles on or off. It computes the inside temperature of the fridge to maintain the setpoint temperature.

5.1 Agent based scenario and brahms simulation results

We will now consider a scenario consisting of a 2 person house where husband and wife are modeled as agents. It will show how the decisions taken by the agents affect the energy consumption. Figure 6(a) shows that the husband and wife are sitting in the living room and watching TV. The hunger level for the wife gradually increases with time. When it reaches beyond some threshold, she communicates with the husband to have their meal together. The husband usually likes to eat at restaurant if there is a beautiful weather outside; otherwise he prefers to eat at home. In case husband is agreed based on perception about the weather, she moves to the kitchen, opens the fridge, takes the stuff out and prepares the table for lunch. If however, the husband is not agreed to eat at home, she puts the warm food, which she had already prepared for their meal into the fridge and they go out to restaurant. The simulation results are presented in figure 6. The output is generated randomly based on agents' belief certainty. Belief certainty is the concept used in Brahms which assigns a probability between 0 to 100 to agents' beliefs and the facts in the environment. Beliefs and facts with varying probabilistic values influence agents' actions accordingly. For example, if for the communication between the agents, the fact is that the husband doesn't denies to eat at home as often as he agrees to eat at home based on his perception about the weather, there are more chances that the wife will not put the warm food which she had prepared for the meal into the fridge. Similarly, if the husband is agreed to eat at home, the duration of the activity of opening the door of the fridge and taking the stuff out is a random value between a minimum and maximum duration. Based on this duration, every time the wife will open the door of the fridge for different durations resulting in varying behaviour of the fridge. In figure 6[2], the horizontal bar on the top represents the movements of agents in different locations. Below this is the timeline, which shows the simulation time in the agent world. The vertical bars are used to represent the communication between agents. These are also used to represent the broadcast activity where the

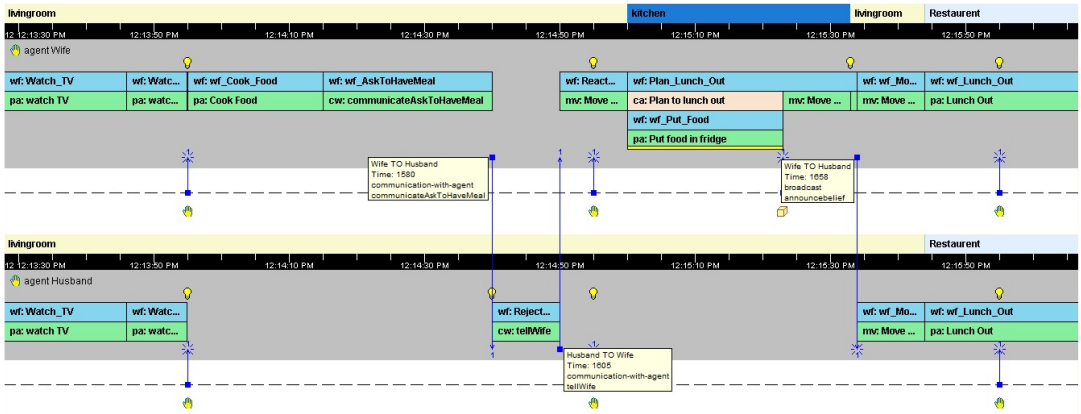
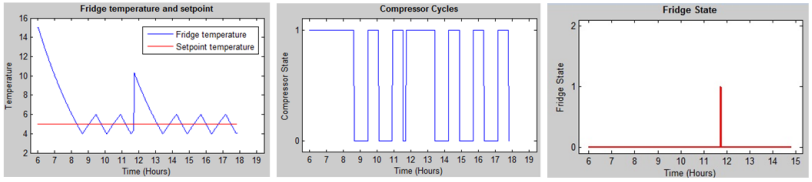
a) Social agreement between agents to have meal at home

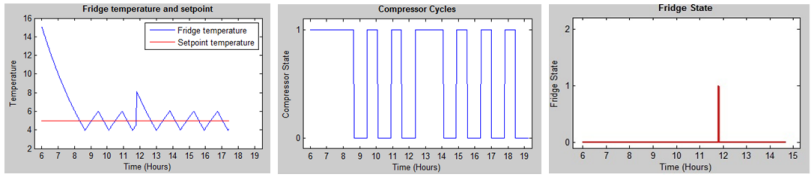


b) Social agreement between agents to eat out

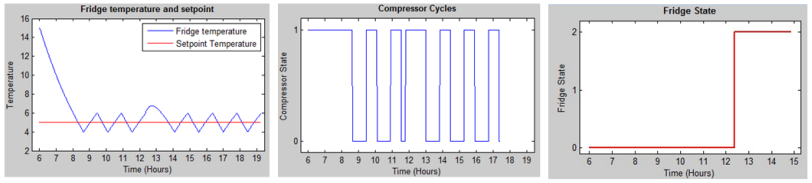
Fig. 6: Simulation Results against Simulated Inhabitants' Behaviour



a) Door opened for 100 seconds



b) Door opened for 60 seconds



c) New food introduced in the fridge

Fig. 7: Simulation Results against Simulated Inhabitants' and appliance's Behaviour

agents transfer their beliefs with each other. For example in the figure 6(b) the vertical bar coming down from agent Wife to agent Husband at the moment when the Wife agent moves from kitchen to living room, represents the Wife agent's belief which she transfers to the husband to move to the restaurant. The bulb symbols are used to represent the thoughtframes or beliefs of agents. Thoughtframes are changed with the passage of the simulation time and based on different perceptions of agents from the environment.

5.2 Co-simulation results

Figure 7 shows the actions of agents on fridge and the resulting effect on the inside temperature and the compressor cycles. Opening the fridge door for different durations affects the compressor cycles accordingly. In figure 7(a) it can be seen that the agent opened the door of the fridge for longer period so the compressor worked longer and hence consumed more energy than as in figure 7(b) where the agent opened the door for fewer seconds. Similarly it can be seen from figure 7(c) that when the agent husband has denied having meal at house, wife put the warm food inside the fridge. As a result, the temperature inside the fridge increased causing the compressor to work longer than usual to bring the temperature back to the setpoint. The fridge states are represented by three levels 0,1 and 2 where $0 \rightarrow$ no action on the fridge, $1 \rightarrow$ door is opened and closed and $2 \rightarrow$ new food is added.

6. Conclusions and future perspectives

Until recently research has focused on active appliances to optimize the energy consumption and reduce energy waste, however cold appliances are not yet explored that constitute a significant source of energy consumption in our daily lives. It is also a fact that to model the cold appliances energy consumption behaviour is not simple as it follows the activity later in time and is quite complex to predict. We believe that these cold appliances have a hidden energy waste component that must be addressed. So, in this article we have presented a co-simulation methodology to demonstrate the hidden energy waste component from actions on the cold appliances linked with the inhabitants' behaviour. This energy waste component is further used to classify the activities as high energy consuming activities and shall help in building the energy advisors within Smart homes to propose alternative actions to the human agents in real life to ensure energy waste reduction and consumption optimization. Our contributions are (i) a multi agent model of human behaviour relating to energy related activities (ii) a physical model for the fridge energy consumption (target cold appliance), (iii) co-simulation methodology to analyze the energy consumption behaviour of cold appliances based on dynamically simulated inhabitants' behaviour. We have demonstrated by dynamically simulating the inhabitants' behaviour using Brahms modeling and simulation environment that actions on the cold appliances do have a hidden energy waste component and can be avoided to support the efforts for energy waste reduction and consumption optimization. Simulation results clearly highlights that opening fridge for long period and putting a hot food in the fridge results in longer compressor refrigeration cycles resulting in the energy waste. In future we shall validate our physical model with experiments on different categories and capacities of the fridge to develop an accurate but generic model for the fridge (cold appliances). We propose the research community to shift their focus towards other cold appliances to model the energy waste component linked with the inhabitants' behaviour.

Abstract— *The global dwelling energy management problem can be formalized as an optimization problem of energy consumption/production. An optimal solution for the home energy management problem is usually solved by centralized solvers. The solver gets the totality of the thermal model of the dwelling but also each appliance composing the system. Nevertheless, this centralized resolution has some limits due to some particular appliances. For example: the appliances with a non-sharable model because of the manufacturer, the appliances that need some precisions that cannot be included in their standard representation used by the solver, the appliances which require specific solvers and the appliances which possess a heuristics solving rules. This work proposes to combine the centralized solving approach for energy management problem in dwellings with a multi-agent solving system. The multi agent system provides the possibility of integrating specific models in the global solving of the problem. The proposed system is a mixed centralized/decentralized approach for the solving of global energy management problem.*

1. Introduction

Reducing housing energy costs is a major challenge of the 21^{st} century. In the near future, the main issue for building construction is the thermal insulation, but in the longer term, the issues are those of "renewable energy" (solar, wind, etc) and "smart buildings". Home automation system basically consists of household appliances linked via a communication network allowing interactions for control purposes [1]. Thanks to this network, a load management mechanism can be carried out: it is called distributed control in [2]. Load management makes it possible for inhabitants to adjust power consumption according to expected comfort, energy price variation and CO_2 equivalent emissions. A home energy management system is able to determine the best energy assignment plan and a good compromise between energy production and energy consumption [3]. In this study, energy is restricted to the electricity consumption and production. [4], [3] present a three-layer (anticipative layer, reactive layer and device layer) household energy control system. This system is both able to satisfy the maximum available electrical power constraint and to maximize a ratio between user satisfaction and cost. The objective of the anticipative layer explained in [5] is to compute plans for production and consumption of services.

Uniqueness of housing systems involves a set of new issues in control system science: it is necessary to develop new tools [6], [7], [8] and algorithms [9], [10] for globally optimized power management of the home appliances, able to anticipate difficult situations and to take into account the actual housing system state and the occupant expectations.

The approaches solving the energy management problem in living places can be split into two groups:

- The approaches solving large dimension optimization problems. It has been tackled using a mixed integer linear programming approach that can manage thousands of binary and continuous variables in [9], [10], [11]. Ways of transforming an energy management problem into a MILP, which is a regular problem, have been shown. These approaches are noted "centralized solving approach of the energy management problem" due to the use of a central MILP solver that contains the general mathematical formulation of the problem. The global solution of the problem is then computed locally in this solver.
- The approaches solving singular problems and proposing "distributed solving of energy management problem". Multi-agent approaches have been used to manage services that can only be modeled by nonlinear equations [12], [6], [7], [13], [8].

The multi-agent approaches have some advantages but cannot ensure an optimal solution of the energy management problem contrary to the centralized approaches. The centralized ones have also some limits due to requirements on models. For example, the appliances with a non-sharable model, the appliances that need some precisions that cannot be included in a linear model (as a washing machine with a lot of perturbations and/or particular actions), the appliances which need non-linear optimization, and the appliances which possess heuristics solving rules.

This work proposes to solve the energy management problem by combining centralized and distributed solving

approaches. This approach is noted mixed solving of the energy management problem.

The organization of the paper is as follows, firstly, the problem is presented and the need of a mixed solving approach is discussed in details (section 2) followed by the principle of mixed solving approach (section 3). The implementation of the approach is presented in (section 4). Finally the conclusion is drawn in (section 5).

2. Problem description

In this paper, energy is restricted to electricity consumption and production. Each electrical activity is represented by an amount of consumed/produced electrical power; it is called service and can be supported by one or several appliances.

Housing with appliances aims at providing comfort to inhabitants thanks to services which can be decomposed into three kinds: the end-user services that produce directly comfort to inhabitants, the intermediate services that manage energy storage and the support services that produce electrical power to intermediate and end-user services. Support services deal with electric power supplying thanks to conversion from primary energy to electricity. Fuel cells based generators, photovoltaic power suppliers, grid power suppliers such as EDF in France, belong to this class. Intermediate services are generally achieved by electrochemical batteries. Among the end-user services, well-known services such as clothe washing, water heating, specific room heating, cooking in ovens and lighting can be found.

A service with index i, denoted as SRV_i, transforms energy in order to meet a user's need via one or several appliances. A service is qualified as *permanent* if its energy consumption/production covers the whole time range of the energy assignment plan such as heating service, otherwise, the service is referred to as a *temporary service* such as cooking or washing service.

A temporary service is characterized by the duration and desired end time of the operation. The flexibility of this service comes from the possibility of shifting its operating time, i.e. bringing it forward or delaying the service.

A permanent service is characterized by a quantity of energy consumed or produced. The flexibility of this service comes from the possibility of modifying the energy quantities consumed/produced throughout all the periods (decrease or increase in energy consumption or production at a given time).

An important issue in Home Automation problems is the uncertainties that have to be taken into account. For instance, solar radiation, outdoor temperature or services requested by inhabitants are not exactly known. In order to solve this issue, a three-layer architecture is proposed in this paper: a local layer, a reactive layer and an anticipative layer.

The *anticipative layer* is responsible for scheduling end-user and support services taking into account predicted events and costs in order to avoid, as much as possible, the use of the reactive layer. Various forecasted information about future user requests and available power resources and costs are needed to compute anticipative plans. This layer has slow dynamics and includes predictive models. Let us assume a given time range for anticipating the energy needs (typically 24 hours). The sampling period of the anticipative layer is denoted $\triangle$. The *reactive layer* aims at adapting the anticipative plans to the actual requests and environmental conditions.

The formulation of the energy management problem contains both behavioral models with discrete and continuous variables, differential equation and quality models with non-linearities such as in the PMV model. In order to get mixed linear programs which can be solved by well known efficient solvers, transformations of the previous equations have to be done. The problem is then solved by a centralized solver. The solver takes the models of different services, constructs the problem, and provides the solution.

This centralized solving problem has some limits:

- the appliances having a model non-shared by manufacturers: usually, manufacturers keep their appliances models. From the centralized solver point of view, the model of these appliances cannot be included in the problem solving. The solver can only take into account an unsupervised service reducing accuracy.
- the appliances that need some precision and cannot be included as linear model. For example, a washing machine, more precision is expected in the control like water temperature set-points, length of some phases,... These fine controls cannot be included in a general linear model.
- the appliances having a non-linear model: for example, a heat pump is modeled by a non-linear model dependant of the outdoor temperature. The local problem solving can be done by using a non-linear optimization method such as Nelder Mead or SQP. These categories gather appliances with non-linear model and appliances that can be managed by specific solvers.
- the appliances that are managed by user-defined specific heuristic rules: These appliances have some "behavioral rules". For example, positions of shutters can be programmed with rules defined by inhabitants. This is the case of "end user programming". In this case, the behavioral rules provide the solution without the need of any optimization. The solver must take into account the chosen solution in the global problem solving.

The following section presents the solution proposed to integrate these types of appliances in the global solving of the problem.

3. Principle of mixed solving approach

The system consists of three main parts (Figure 1):

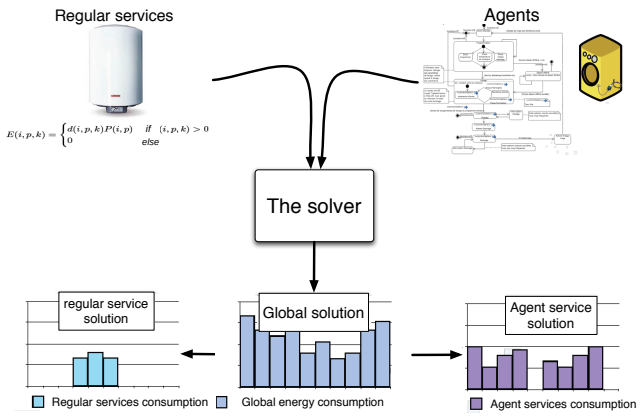

Fig. 1: Global architecture of the mixed solving system

Fig. 2: Solving process during one step

- The regular services:consist of the appliances having a linear model and can be integrated directly into the energy management problem.
- The agents:consist of the services that do not have a linear model and should communicate with the solver to give their *energetic profiles*. The steps of the solving process and the protocol of communication are presented in the following parts.
- The solver consists of a regular solver with the ability to communicate with agents. The solver integrates the information sent by the agent's local solvers with regular service models in order to generate a global problem to solve.

There is only one communication needed between this regular services and the solver. At the beginning of the solving process, the solver receive the linear model from the regular services. The models are used all along the solving process.

In the case of agents, some communications are needed. Each exchange between the agents and the solver is considered as a step in the solving process. In each step, an intermediate problem is created by the solver then computed. The solver decides which information is needed to be sent to the agents in the next step. The agent takes into account the information sent by the solver and sends energetic profiles. The solving process is presented in the following in three parts:

- The progress of the problem solving during one solving step.
- The solver's behavior during the solving process.
- The agent's behavior during the solving process.

3.1 One step solving

Figure 2 presents the information exchanged between the solver and the regular services and the agent services during the first step in the solving process.

First, the solver receives the linear models of the regular service. This operation is the initialization of the problem. Once initialization is done, the solver computes the *relevance indicator*. It is an indicator with the purpose to direct the local solving problem in the agent. When this indicator is computed, it will be sent to all agents.

The agents don't have any information about the environment but they have the ability to solve their own local problem. When agents receive the relevance indicator, they compute their solutions taking into account this indicator serving as information about their environment. They obtain several solutions, which are called *energetic profiles*. It is the consumption for the concerned agent for each period of the optimization horizon. All theses profiles are sent back to the solver. The solver includes them in the problem To be solved at this step. Then the global problem with all the services is solved at this step.

After the first step, the solver begins a new step by computing the relevance indicator. The relevance indicator is computed taking into account the received *energetic profiles* sent by the agents in order to improve the global solution each step in the solving process.

3.2 Solver's role

The solver has two tasks to do in each step. In order to formulate these tasks, we introduce some notations:

- k is the index of anticipative period
- $\mathcal{S}$ is the set of services
- $\mathcal{S}^L$ is the set of *regular services*
- $\mathcal{S}^D$ is the set of *agent services*
- S is a service included in $\mathcal{S}$
- E_k^{max} is the available energy during the period k before any optimisation
- $E_k(S)$ is the consumed energy by the *regular service* $S \in \mathcal{S}^L$ during the period k
- $E_k(S, i, \mathbb{P}_k)$ is the consumed energy by the *agent service* $S \in \mathcal{D}^L$ during the period k for the i^e profile

- C_k is the cost of energy during the period k
- $\upsilon(S)$ is the characteristic of inhabitant request for the service S
- $D(\upsilon(S))$ is the dissatisfaction of the *regular service* $S \in \mathcal{S}^L$
- $D(\upsilon(S), i, \mathbb{P}_k)$ is the dissatisfaction of the *agent service* $S \in \mathcal{S}^D$ for the i^e profile
- $\mathbb{P}_{k,\forall k}$ is the relevance indicator for the current step of resolution

a) Optimisation problem: Each step, the solver computes a linear problem to find a solution. The *regular services* models are represented in [14]. This problem is extended by including *agent services*. Some equations are added to take into account the *agent services*. A new set of variable for each *agent service* is introduced (see equation 1). $\zeta_i(S)$ is a binary variable whose value is 1 if the profile i of the *agent service* S is chosen by the solver, 0 otherwise.Combined with equation 2, ensure the solver to keep only one profile for each *agent service* in the solution.

$$\zeta_i(S) \in \{0,1\}, \forall i \tag{1}$$

$$\sum_i \zeta_i(S) = 1 \tag{2}$$

The criterion to minimise is modified and becomes a two parts criterion (3).

$$J_{iter} = \sum_{S \in \mathcal{S}^L} \left(\sum_k C_k E_k(S, \theta(S)) + \lambda \times D(\upsilon(S, \theta(S))) \right) + \sum_{S \in \mathcal{S}^D} \sum_i \zeta_i \left(\sum_k C_k E_k(S, i, \mathbb{P}_k) + \lambda \times D(\upsilon(S), i, \mathbb{P}_k) \right) \tag{3}$$

There are two different parts in this criterion, one part concerning *regular services* and one part for *agent services*. They are designed on the same scheme to have an a standardized criterion. This scheme split into two influences:

- The influence on the cost: the global energy cost must be minimized.
- The influence on the inhabitants: the dissatisfaction of the inhabitants must be minimized.

Those influences can be found in both *regular services* part and *agent services* part. But there is a fundamental difference between these two parts, and it is symbolized by the sum on the index i in the *agent services* part. The solver keep only one profile for each *service agents*. For each profile, the solver receives one consumption plan and an associated dissatisfaction. The sum in the criterion with binary variables forces to keep only one profile per agent for the minimisation.

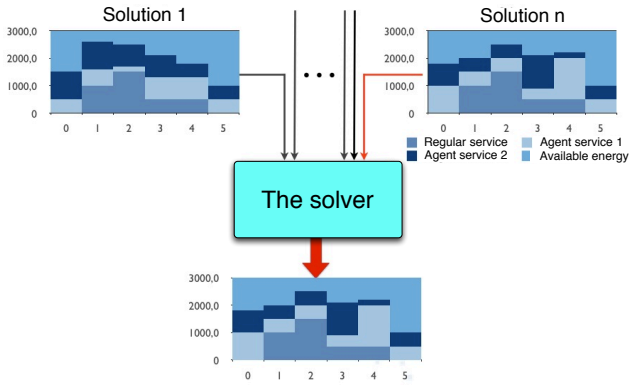

Fig. 3: Solution found by the solver

Figure 3 shows the complexity of the problem to be solved at each step. Each *service agent* provides n profiles, if there are m *singular services*, then there are n^m different solutions. But the solver has to minimise the criterion to keep one.

b) Relevance indicator: The relevance indicator is computed during each solving step to direct the local solving process of service agents for the next step. After the solving step j, the relevance indicator is computed with the equation 4. The purpose of this approach is to share the information about the energy consumption and price between solver and service agents. The service agents integrate the received information in their local solving process of the step j+1. This indicator is high when the consumed energy is important or/and when the energy is expensive. This rules aim to obtain a better solution that minimize J_{iter} in the step $j+1$. During the first step, the consumption of the *agent services* is null.

$$\mathbb{P}_k^j = \frac{1 + E_k^{max}}{1 + E_k^{max} - \sum_{S \in \mathcal{S}^L} E_i^{j*}(S)} C_k \tag{4}$$

3.3 Role of the agents

An agent is dedicated to a specific entity whose behavioral model cannot be linearized and then taken into account directly by the solver. In this part, the algorithm used by agents are explained using an example of washing machine service agent.

The washing machine service agent has its internal state model. The states are shown by figure 4. They consist in:

- some behavioral states like heating, prewash, washing and spin-drying.
- two states representing the begining and the end of the service
- some states denoted *wait i* represent the waiting time between behavioral states
- some states modeling the interuption whithin each state, denoted *interupted state*

The normal behavior of the washing machine service is given by the state sequence scenario [start, heating, prewash, washing, spy-drying, end]. The other states are only visited when the service agent tries to find some neighbouring profiles in order to respond to some criteria sent by the solver.

Each visit to an *interrupted state* has a fixed time period $\tau_{interrupted}$. It is possible to visit the *interrupted state* more than once in order to increase the interruption time in a state. For example, in the state sequence scenario [start, heating, interupted heating, heating, interrupted heating, prewash, washing, spy-drying, end], the time spent in the interupted heating state is $2 * \tau_{interruption}$.

A behavioral profile is the state sequence scenario with the date of each state visit. The behavioral profile is caracterized by:

- the starting time of the service
- the number of visits to each *interrupted state* and the number of visits for each *wait i* state
- the date of each visit to *interrupted states* and *wait i* states.

These characteristics are denoted in the following *parameters of behavioral profile*. It is interesting to note that a behavioral profile is computed in order to be converted into an energetic profile. The energetic profile consists on the energy consumed by the service in each period of the anticipative horizon. The energetic profile is then sent to the solver.

The Agent satisfaction is computed according to the energetic profile. The satisfaction depends on the number of visited interupted states and also on the effective ending time regarding its expected value for the occupants. The increase in the number of interruptions affects the agent satisfaction.

3.3.1 Agent solving algorithm

The agent solving algorithm is presented in figure 5.

Firstly, the agent receives the relevance indicator. The relevance indicator consists of information about the penalisation and the energy price during the anticipative horizon. The agent receives also the choosen energetical profile at step j.

The first step in the algorithm is to normalize the values of relevance indicators (5). The goal of this step is to obtain $RI_{k(normalized)}$ that can be used in the computation of CA_k, the agent coefficient. It is composed both on the information received from the solver and on the local satisfaction computed by the agent.

$$RI_{k(normalized)} = RI_k / Max(RI_k) \quad (5)$$

The second step consists on the computation of the agent coefficient CA_k. The CA_k merges the information about the prenalization, the energy price and the agent disatisfaction denoted I_k (6).

$$CA_k = RI_k + \lambda * I_k \quad (6)$$

In order to generate an enegertic profile, the first step is to compute the behavioral profil. The parameters of the behavioral profile are listed above. The first one in the starting time of the service. We begin by finding the best intervals over 6 periods in the 24 hour horizon according to the values CA_k. For each interval j we compute X_j (7).

$$X_j = (\sum_{k \in [j, j+6]} CA_k)/6 \quad (7)$$

We denote $X_{j_{min}}$ the minimum of the list X_j.

Then we try to find the intervals having no significant difference with $X_{j_{min}}$. We denote L_{min}, the list:

$$L_{min} = \{k / 1 - (X_{j_{min}} / X_k) < 0.1\} \quad (8)$$

The interval χ with the maximum variance in L_{min} is chosen for the optimization. The starting time of the service corresponds to the starting time of the chosen interval χ.

The parameters of the optimization are presented in figure 6 where N_{Si} is the number of interuptions in the state Si. W_{Si} is a value to select the time for interruption within the state.

A branch and bound optimization is achieved on this parameter (Figure 7) within the chosen interval χ. Each agent solves the optimization problem with this function. It represents the minization of the energetic cost and dissatisfaction from a local point of view. The function to be minimized 9 is similar to the one presented for the solver.

$$min_{\theta^{j+1}} J^{k+1} = \sum E_k(\theta^{j+1}) \mathbb{P}_k^j \mathbb{T}_k^j + \lambda D_i(\theta^{j+1})) \quad (9)$$

θ^{j+1} represents the parameters of the user that define the usage conditions. The function is composed of two parts: the first one is the influence of the energetic cost and the second one is the influence of the satisfaction of the agent.

The results of this optimisation is a list of parameters required to generate the behavioral profile (parameters of behavioral profile). Then, the energetic profile can be computed and sent to the solver to be integrated in the global problem solving.

4. Implementation

The implemented system consists of five components (figure 8):

- the classical regular solver used in [14]
- the solver that solves global problem composed from regular problem and agent problems
- the broker agent is a communication component that receives all the local problems from service agents

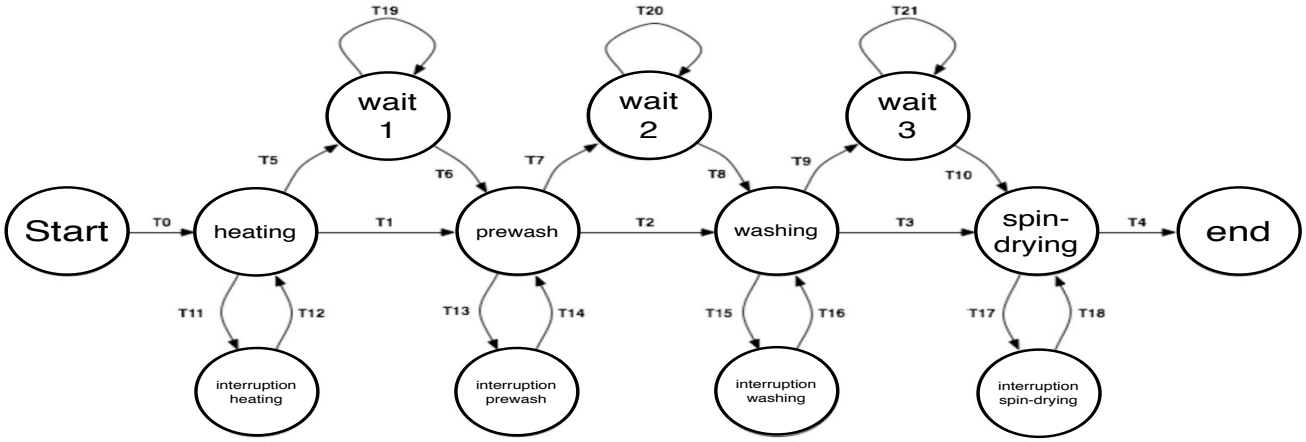

Fig. 4: State model of the washing machineservice agent

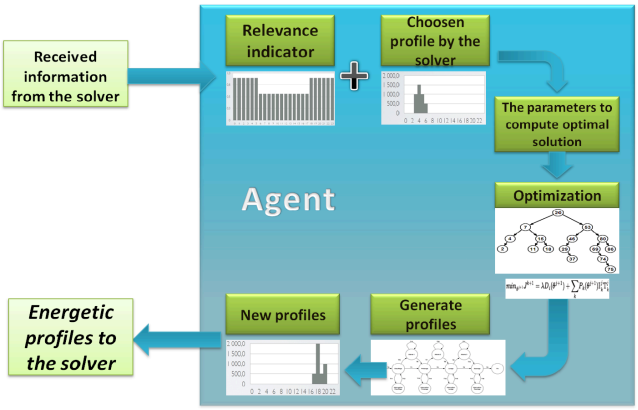

Fig. 5: Solving algorithm in the agent

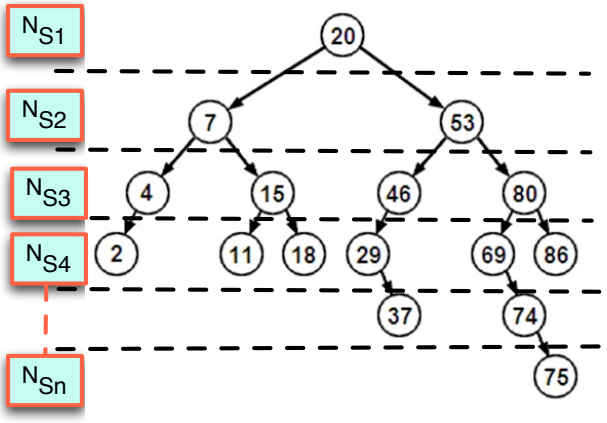

Fig. 7: Optimization using branch and bound

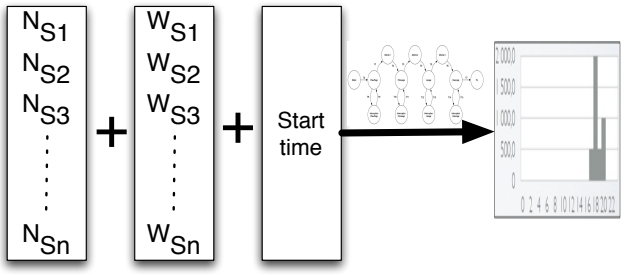

Fig. 6: Parameters of a profile

and construct one global service agent problem. This problem is sent then to the global solver. The broker receives also the relevance indicator from the solver and dispatches the information to service agents

- the service agent with the capabilities to solve a local problem.

The system is tested by using two service agents and some regular services. Figure 9 presents simulation results.

5. Conclusion

In this paper, the energy management problem is solved by combining centralized and multi-agent solving approaches. The multi agent system added to the MILP solver provides the possibility of integrating singular, i.e. not MILP, appliance models in the global energy management problem to

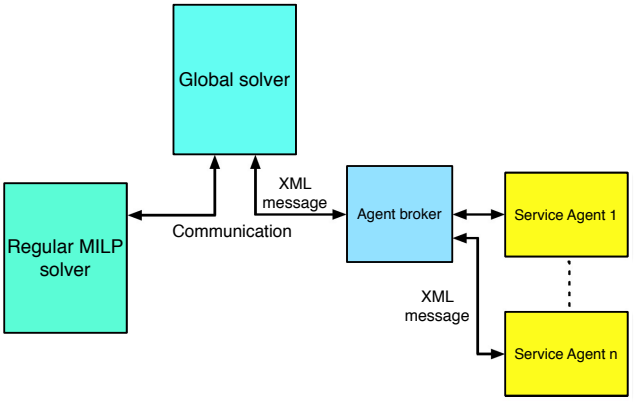

Fig. 8: The composant of the mixet solving system

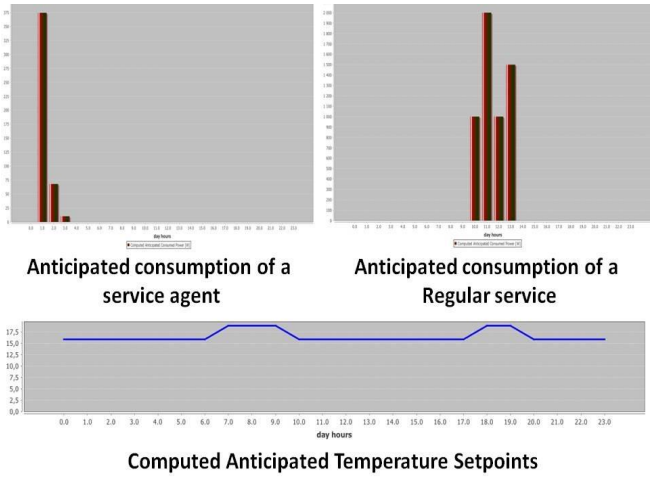

Fig. 9: Anticipating regular and service agents

be solved. The proposed approach has been implemented and tested. Conversely to centralized solution, the solution resulting from a mixed approach is not garanteed optimal solution. The number of steps used in the solving process affects the resulting solution. The algorithm used in the solver to generate the relevance indicator affects also the global solution. Genetic algorithms can be studied and introduced at this stage in order to improve the global solution.

Can Intelligent Agents Improve Persistence?

Dr. Wayne E. Smith
Argosy University, Dallas Campus, 5001 LBJ Freeway, Dallas, TX 75244

Abstract – The coupling of intelligent agents with learning resources create an important synergy with improved persistence as an outcome.

Keywords: Artificial Intelligence Intelligent Agents Electronic Commerce Retention Graduation Persistence

1.0 Introduction

The goal of the work presented in this paper is to offer possible methods to advance the study of intelligent student resources. The use of intelligent agents in e-commerce was designed to facilitate transactions for the buyers as well as sellers. It has been proposed that intelligent agents can assist with this process. Can intelligent agents choose learning resources in furtherance of intelligent learning technologies? The synergistic possibilities offer advances in learning around the globe.

2.0 Literature Review

2.1 Intelligent Agents

Intelligent agents have grown from little known computer programming into a wide variety of agents with multiple characteristics and competencies. Intelligent agents have advanced to even achieve a competitive advantage in the business world. Intelligent agents, like humans, have differing levels of intelligence. At the lowest level, agents merely carry out user assigned tasks. More intelligent agents can perform repetitive tasks and even monitor activity and report results. This last level refers to a semi-intelligent agent. A truly intelligent agent, at the highest level, can maintain user profiles, update the profile based on user actions, and even anticipate a users' action and learn from an error [3][6].

2.2 Intelligent Agents and Students

Studies of intelligent agent use demonstrate that agents can work in tandem to achieve a common task [1]. Original work with agents dealt with simple negotiation systems in a business-to-business or business-to-consumer e-commerce environment. Agents negotiated for simple goods or services. The ability to negotiate the acquisition of specialized goods or services will require more advanced systems. Advanced agent systems are under development with promising possibilities. Agents have also developed into the consumer-to-consumer e-commerce environment [4][5]. This level of sophistication will enable students to progress through higher levels of learning by accessing resources as necessary.

Intelligent agents enable people to maintain contact with the business world while at the same time releasing an individual from social interaction [7]. One study showed that people would rather deal with an intelligent agent than a human when conducting business online [9]. Students that are shy tend to engage online learning more fully when not overshadowed by gregarious classmates [2][8].

2.3 Freshman Success

Less than 60 percent of college freshmen graduate from the college they first entered [10]. There are several factors that mix and match in this failure. An important factor is the availability of resources to bolster weak areas. Many students discover that they left high school unprepared for college-level math and/or writing. Modern students are normally computer savvy from hours spent playing digital games. Many students interact with "online friends" separate from other relationships.

3.0 Synergy

The synergistic possibility of student needs and intelligent agent technologies is promising. In an e-commerce environment, a prospective buyer from one part of the world contacts a seller or seller's agent. In an education environment, a student will access a needed resource regardless of venue. The intelligent agent systems developed today will allow agents to discover the learning resource in the required language in a manner similar to addressing different desires for size, color, or financing options in the e-commerce space.

The combination of intelligent agents with other web intelligences has been proposed. The opportunity to deal with complex real-world education problems is the key. These new solutions will make money, satisfy students, and give educational businesses a competitive advantage [11]. When mobile marketing adopts this technology, products will be offered to students in their preferred language [7]. The ultimate purpose is for agents to anticipate the need for language appropriate learning resources and attained preparedness to meet the need [11].

4.0 Summary

The elements needed to combine intelligent agents with educational resources are in development. The combination opens a world of possibilities to enhance university retention and ultimately graduation rates. The opportunity for competitive advantage in educational venues is ripe as those that move first will reap the first benefits.

Hybrid Reactive-Deliberative Behaviour in a Symbolic Dynamical Cognitive Architecture

Abstract - *Sequentiality and reactivity are features that have been deemed important for cognitive architectures[1]and recent emphasis has been put by the community on their development in cognitive architectures. However, the cooperation and competition dynamic between reactivity and sequentiality remains an open issue in the domain [2]. In this paper, we present a three level cognitive architecture for the simulation of human behaviour based on Stanovich's Tripartite Framework [3], which provides an explanation of how reflective and adaptive human behaviour emerges from the interaction of three distinct cognitive levels. We use two classical psychological tasks to study the reactivity/sequentiality dynamic in our architecture. These show that the two features collaborate in interesting and psychologically plausible ways.*

Keywords: cognitive architecure; hybridism; sequentiality; reactivity

1 Introduction

A cognitive architecture is "the overall, essential structure and process of a domain-generic computational cognitive model, used for a broad, multiple-level, multiple domain analysis of cognition of behaviour" [1] (p.4). Psychologists and other cognitive scientists can use these architectures to study the mechanisms responsible for observed behaviour, and engineers can employ them to endow their systems with cognitive (e.g. decision-making) capacities. Theoretical studies of cognitive architectures [1,3, 4] have identified many general features that architectures should have if they are to efficiently play these roles. Two such features, reactivity and sequentiality [1], have proven difficult to integrate in well-unified cognitive architectures, and, emphasis has recently been put on the development of these features (especially in the guise of reactive abilities and of reflective/deliberative). It is difficult to integrate reactivity and sequentiality because the two features appear to be functionally incompatible: designs that favour one almost inevitably hinder the other. As a result, integration of reactive and sequential processing remains a challenge in the domain [2]. In this paper, we address the challenge by introducing a new architecture, one that implements Stanovich's [3] Tripartite Framework: a framework that aims to explain how reflective (characterized by sequentiality) and adaptive (characterized by reactivity) human behaviour emerges from the interaction of three distinct cognitive levels (autonomous/reactive, algorithmic/cognitive control, and reflective). To demonstrate the flexible and coherent behaviour of the resulting architecture, we study its performance on two classical psychological tasks: the Stroop task, which requires perceptual attention and cognitive control, and the Wisconsin card sorting task, which requires cognitive flexibility and efficient collaboration between the reactive and sequential elements of the architecture.

2 Related Work

2.1 Cognitive architectures

Although there are now a variety of cognitive architectures (see for a review [3]), we chose here to focus on three of the most widely used: ACT-R, SOAR, CLARION [1].

ACT-R (Adaptive Components of Thought-Rational) [5] is a cognitive architecture whose development is oriented towards the understanding of human cognition. ACT-R's components are a set of perceptual-motor modules, memory modules, buffers, and a pattern matcher module, which finds productions that match the current state of the buffers. There are two types of memory modules in ACT-R: declarative memory and procedural memory, consisting of chunks or production (for the procedural memory) and associated sub-symbolic values (connectionist hybridism). A long-term memory of production rules coordinates the processing of the modules. Each module has a chunk holding a relational declarative structure. Each chunk has a set of sub-symbolic parameters reflecting its past activity and influencing its future retrieval from long-term memory. Adaptation in ACT-R occurs thanks to a top-down learning approach. ACT-R has been used to simulate a large number of cognitive phenomena but has seldom been used for the simulation of extended metacognitive processes. Further effort has been put into implementing a unified theory of cognition, perception, and action by integrating perceptual and motor modules working in parallel with cognition; however, cooperation between these modules is limited since their content (perceptual,

motor, declarative memory) is still processed using distinct buffers.

SOAR (State, Operator And Result) [4] is also a rule-based cognitive architecture aimed at the modelization of general intelligence. Knowledge is in the form of production rules, arranged in terms of operators acting in the problem space (set of states representing the task). Operators provide the system with adaptation since they can externally as well as internally modify the system's state. The primary learning mechanism is chunking, which allows the extraction of rules from problem solving traces. A basic processing cycle repeatedly selects, and applies operators, achieving one decision at a time. In SOAR, different types of learning are applied to different types of knowledge: reinforcement learning to adjust preference values, episodic learning to keep track of the system's evolution, semantic learning for declarative knowledge. SOAR is able to perform high-level reasoning task (planning, problem solving …).

As opposed to ACT-R and SOAR, CLARION requires less a priori knowledge. CLARION (Connectionist Learning Adaptive Rule Induction ON-line) [6] is a hybrid architecture with explicit (symbolic) and implicit (sub-symbolic) processes. CLARION is made of four memory modules, with dual explicit–implicit representation: action-centered subsystem, non-action-centered subsystem, motivational subsystem, and metacognitive subsystem. Action and non-action centered knowledge are stored in implicit form (using neural networks) and in explicit form (using symbolic production rules). Two types of learning support the team work of implicit and explicit processes : bottom-up learning (reinforcement learning methods are used to acquire implicit knowledge, the resulting knowledge is used to modify explicit knowledge at the top level through bottom-up learning mechanism), and top-down learning (extracting knowledge by observing actions guided by these rules). As in dual-process theories of mind, two levels (a meta-cognitive subsystem and a motivational subsystem) cooperate to produce behaviour by combining the action recommendations from the two levels or combining bottom-up and top-down learning. CLARION has often been used for the simulation of higher level cognitive phenomena. . However, CLARION's sensory-motor modules are not as developed as one would wish.

The architectures presented above exhibit many of the desiderata [1] for cognitive architectures, but none support all of them, often because of the theoretical orientation took as foundation (strong symbolism in ACT-R, high modularity in CLARION). Several issues for further research were thus identified; here we highlight specifically two of them [2]: (1) Effectors and perceptual attention: the need for "expanded frameworks that manage an agent's resources to selectively focus its perceptual attention, its effectors, and the tasks it pursues" [2]. In SOAR and ACT-R, perceptual systems are isolated channels providing the information from the environment to the Working memory of the system, but their activity is not regulated by the Working memory, like the activity of other productions. Also, in SOAR, perceptual cues match on separate perceptual working memory elements that are independent of context (matched by the other productions). As we will see below, perceptual information processing in our architecture depends on the current task and the context (environment and long term memory of the system). (2) Combination of deliberative problem solving with reactive control: the need for architectures that can combine deliberative problem solving with reactive control by changing their location on the deliberative vs. reactive behaviour spectrum dynamically based on their situation. CLARION, as well as other architectures (see CogAff, Sloman [7]), has chosen to address this problem by using a dual-process theory of mind [1]. It is this duality that allows CLARION to achieve high level reasoning; however, strong modularity prevents the system from really achieving strong reactive/dynamic processing. In our architecture, thanks to the unified cognitive model we chose, we are able to preserve dynamic processing while maintaining a robust (reflective) behaviour. In this paper, to design an architecture that meets the duality challenge with a clear answer to the interface problem, we have modeled our system after Stanovich's Tripartite Framework [3]. We chose this model, precisely because it provides a good account of dynamic of duality (sequentiality/rule-following and reactivity/dynamicity) in human cognition.

2.2 Cognitive Model

We base our cognitive architecture on Stanovich's tripartite framework [3]. This allows us a complete model of the cognitive mind, from automatic and implicit processes to explicit processes involving control (attention and executive functions) to more abstract planning and reasoning. Stanovich's tripartite framework belongs to the "dual-process theories" family of cognitive models, where cognition is characterized by the opposition (duality) between two types of processes or systems [8]. We will follow the latter usage, which often dubs the dual systems "System 1" (fast and automatic reasoning) and "System 2" (abstract and hypothetical reasoning). Stanovich's System 1, which he calls the "Autonomous Mind," includes instinctive behaviours, over-learned process, domain-specific knowledge, emotional regulation and implicit learning. His tripartite framework differs from other dual-process theories in its description of System 2. He divides processes usually ascribed to System 2 in two classes of processes, respectively called the "Algorithmic Mind," responsible for cognitive control, and the "Reflective Mind," responsible for deliberative processes. The Algorithmic Mind acts upon information provided by the Autonomous Mind thanks to two sets of pre-attentive processes (perceptual processes and "processes which access memories and retrieve memories and beliefs" – [9] (p 43), both of which supply content to Working Memory. The Algorithmic Mind is the locus of three processes, each initiated by the Reflective Mind: (1) inhibition of Autonomous Mind processes, (2) cognitive simulation

(decoupling), and (3) serial associative cognition. Performance of these processes leads to an activation of the anterior cingulate cortex (ACC). Decoupling, which seems to be supported by the dorsolateral prefrontal cortex (DLPFC) [3], consist in the creation of temporary models of the world, where different alternative scenarios can be tested. The temporary models created through decoupling do not affect the system's current representation of the world but the decoupling process, however, has a cognitive cost: it is difficult for the Algorithmic Mind to perform other processes while decoupling takes place. Decoupling does not occur in every situation where it would be useful, and when it does occur, it is sometimes incomplete. In these cases, subjects simply apply simple models (rules) that *appear* appropriate for the situation. Serial associative cognition supports the implementation of these simple models. The simple model chosen does not in general provide the best solution in a given situation: a better solution could have been found through decoupling, but the cognitive load of decoupling is higher than that of serial associative cognition and thus subjects will often satisfy themselves with less optimal but cognitively easier solution provided by serial association. Operations supported by the Reflective Mind define the subject's cognitive style. The Reflective Mind performs three processes: (1) initiation of inhibition of Autonomous Mind processes by the Algorithmic Mind (i.e., it tells the Algorithmic Mind: "Inhibit this Autonomous Mind process") and (2) initiation of decoupling in the Algorithmic Mind (i.e., it tells the Algorithmic Mind: "Start Decoupling") and (3) interruption of serial cognition, either by sending a new sequence to the Algorithmic Mind or by initiating a full simulation of the situation through decoupling. According to Stanovich, the division of human cognition into three sets of processes, instead of the traditional two of dual-process theories, provides a better account of individual cognitive differences. Individual differences with regard Algorithmic Mind processes are linked to cognitive abilities and fluid intelligence, while Reflective Mind differences are observed in critical thinking skills. We chose the tripartite model Stanovich, precisely because it provides a good account of the diversity in human behaviour.

3 Architecture

Our architecture is implemented in a multi-layer multi-agent simulation platform [10]. As shown in figure 1, each level presented is composed of groups of agents acting in parallel, each agent having one or more role (an abstract representation of their functionality).

3.1 Reactive level

The Reactive level in our model corresponds to Stanovich's Autonomous Mind. The main roles assigned to agents within this level are "sensor" (C –letters in parenthese in this section appear in figure 1), "effector" (D) and "knowledge" (A).

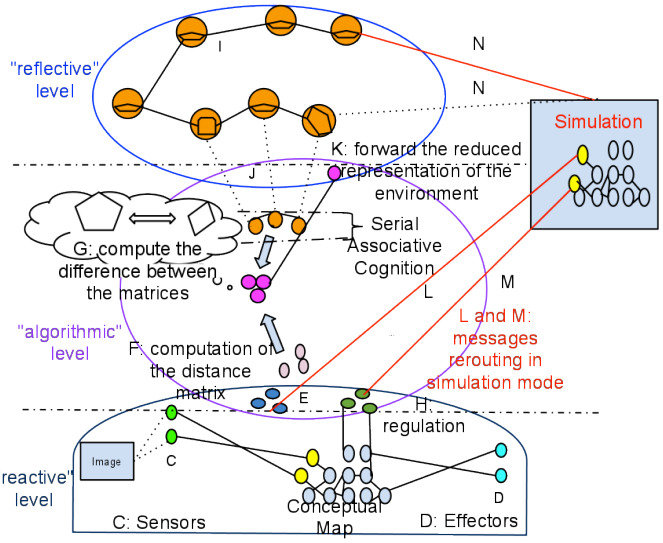

Figure 1: Architecture

The network of Knowledge agents (agents assigned with the "knowledge" role) is initialized with a knowledge base that makes up the system's declarative knowledge (semantic memory): a conceptual map made up of concepts and the semantic links between them. Knowledge agents therefore have two attributes: "knowledge" and a word from the knowledge base (e.g., "Red"); knowledge agents are also connected together according to the links in the conceptual map. Upon receiving a message from a Sensor agent or from another Knowledge agent, Knowledge agents send a message to those Knowledge agents they are connected to, therefore spreading activation in the network (a process similar to that of semantic memories, [11]). The number of messages exchanged between the agents, and therefore their activation, is at first determined by the distance between them in the conceptual map (later on, it will also be determined by the activation signals from higher levels – see below). The system's environment is similar to (portions of) human environments. In the Stroop task simulation described below, the system is presented with cards identical to those human subjects see in real Stroop task experiments. Each Sensor agent is sensitive to some particular type of information in the environment (colors, sounds, texts, etc.). If the type of information to which they are sensitive to is present in the environment, Sensor agents will (at short intervals) extract it and send messages to Knowledge agents with a role associated with the sensor's function ("read" for Knowledge agents connected to *Sensor agents* reading characters, "recognizeColor" for Knowledge agents connected to *Sensor agents* recognizing colors). Activation in the network therefore depends on the number of messages sent by the Sensor agents and the activation of the *Knowledge agents* in the conceptual map. Taken together, the action of Sensor and *Knowledge agents* make up the system's sensory motor level. This means that the system's sensory abilities are always a function of the Sensor agents' information extracting capacities and of the system's knowledge about the environment: the system is fully situated. *Effectors agents*

work similarly: a knowledge agent associated to the function of the effector ("sayRed", "sayBlue") sends messages to *Effector agents* with a similar role, which will then act on the environment.

3.2 Algorithmic level

Corresponding to Stanovich's Algorithmic Mind, the Algorithmic group is responsible for the control of the system. Control is achieved with the help of morphology [12]. RequestStatus agents (E) belong to both the Reactive and Algorithmic organisation. At regular intervals, they query Knowledge agents about their status (that is, number of messages they sent during that interval to each of the Agents to which they are connected). Status agents (F) represent the system's activity at a given time in the form of a distance matrix that describes the (message passing) activity of the system at that time. The distance between two concepts in the conceptual map is measured by the number of messages sent between the Knowledge agents bearing these two concepts as their role. Status agents also send a reduced representation of the activity in the Reactive organisation to the Reflective level. Globally, this matrix thus represents a form or shape, and it is this form that will be transformed to reach the shape describing the goal assigned to the system. At the Algorithmic level, we thus find the short-term goals of the system in the form of a graph of Goal agents sent by the Reflective level. Each Goal agent (I) contains a distance matrix that specifies the distance necessary between each Knowledge agents (that is, the number of messages that must be sent between Knowledge agents) if the system is to reach goal. Graphs of short-term goals in our architecture correspond to Stanovich's serial associative cognition. Delta agents (G) compute the difference between the matrix provided by the Status agents and the one provided by the Goal agents. The resulting difference (another matrix) is provided to Control agents (H), which in turn send regulation messages to agents in the Reactive organisation to modify (i.e., increase) their activation so that their global activity more closely matches the shape describing the current short-term goal. Agents in the Algorithmic organisation constitute the system's attention. They activate elements of the system's semantic memory in relation to its current goal. The system's long term memory is made up of the Knowledge agents in the Reactive organisation, and the system's working memory (WM) at a given time is made up of the Knowledge agents that are activated in the Reactive group at that time. This implementation of working memory is consistent with the work of Engle [13], in which WM is seen as a set of temporarily activated representations in long-term memory.

3.3 Reflective level

Each agent in this last group has a shape (a distance matrix) which represents the state that the system must be in to achieve a simple goal. Goal agents (I) are organized in a direct graph. A path in this graph represents a plan that can be applied to achieve a complex behaviour A set of Goal agents represents a graph of several complex plans or strategies decomposed into a sequence of simple objectives (steps in the plan). The logical and analytical skills of the system will be implemented at this level. A sequence of simple objectives path (J) will be sent to the Algorithmic level, which will take care of its execution. Following Stanovich's Tripartite framework, agents in this last group will have access to a reduced representation of the environment. This representation is provided by the Status agents of the Algorithmic Group to other status agents (K) that carry the reduced representation and announce themselves to the goal agents, which in turn compute their similarity to this representation. The activation of the Goal agents will be determined by the computed similarity between these two matrices. Activation propagates from the Goal agent most matching the reduced representation to those that follow in its path. The last agent in the path will send the parsed path to the Algorithmic level. Thus, the shortest path and the most active (with the most messages exchanged) will be sent first to the Algorithmic level. The shortest path (simplest model) or the one the most activated (model used more recently or more often) will prevail over the other paths. The limited serial associative cognition of the Algorithmic level will execute this path step by step. The path executed by serial associative cognition provides the system with the sequentiality necessary to achieve complex goals. However, the system does not lose its dynamicity. Indeed, the reduced representation of the environment are sent on a regular basis by the Status agents so that the Reflective organisation can interrupt serial cognitive association either by: (1) Setting a new starting point in the path, or by, (2) Taking a new branch in the path, based on the current state of the environment

3.4 Simulation

If multiple strategies (thus two or more goal agents) are selected at the algorithmic level, the goal agent that belongs to the algorithmic and reflective level (which usually contains the goal matrix selected at the reflective level) triggers a simulation of the strategies. The simulation capacity as envisioned in Stanovich's Tripartite Framework is implemented at the algorithmic level. When the algorithmic level is in simulation mode, a possible world is created thanks to the reduced representation sent by the Delta agents. This secondary representation is realized with a limited number of agents (20). These agents are assigned dynamically the same roles and links as those agents from the Reactive level they are replicating, as indicated by the reduced representation. Since this possible world is carried out thanks to distinct agents (SecondaryRepresentation agents instead of Knowledge agents) and a distinct group (Algorithmic instead of Reactive), we can be sure that this secondary representation is totally independent from the current representation of the world (i.e., knowledge agents from the reactive level). To reproduce the cognitive cost of the simulation operation, the cognitive operations (goal inhibition and selection) are carried out by the Control agents, Delta Agents, and the Reflective level. Messages from (L) and to

(M) these agents are branched to the SecondaryRepresentations instead of the Reactive level. Once the simulation is completed, the activation of Goal agents is regulated accordingly at the Reflective level (N), therefore potentially replacing the next action carried out by the Algorithmic level (by the first rule simulated). The WCST realized in this paper illustrates the simulation of an opposite style of thinking. The system first simulates the application of a chosen categorization rule and its negation (negative feedback by the instructor), and is thus able to make a new categorization rule (the alternative) emerge in the simulation.

4 Results and Discussion

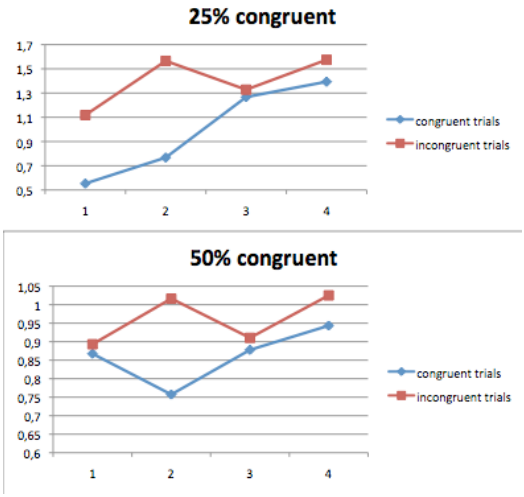

Figure 2: Mean response time per block for congruent and incongruent trials in 25% congruent conditions and 50% congruent condition

4.1 Control and perceptual attention: Stroop task

The Stroop task [14] is used to test attention and inhibitory control. It tests a subject's ability to maintain a goal in mind, suppressing a familiar response in favor of one that is less familiar. The task illustrates the Color–Word Interference effect. The set of trials is a compound of congruent trials (the word "GREEN" written in green) and incongruent trials ("RED" written in green). Two experiments were conducted. In each one, four blocks of 100 cards with a word written in a specific color were shown to the system. 25% of the cards per block were congruent in the first experiment while 50% were in the second.

Control: Set-up this way, we find that the mean response time of the system is longer for incongruent trials, specifically in the 50% congruent condition (Figure 2) (1396 ms) as opposed to the 25% congruent condition (960 ms), a result also found in human subjects. This is because, to achieve the system's goal, Control agents have to send regulation messages to the "recognizecolor" agents to compensate the distribution of agents when the system is initialized for the Stroop task (i.e., with a preponderance of "read" agents to reflect the predominance of the reading ability in normal adult subjects). The system provides an answer once the system has regained its stability, that is, once there is a sufficient difference in activity between the system's two competing responses. During incongruent trials, this stability is harder to achieve (inhibition is a time-consuming operation). Response-time variation is due to the action of the algorithmic level: in incongruent trials, it is particularly called upon to help the system remove perceptual focus on confusing information.

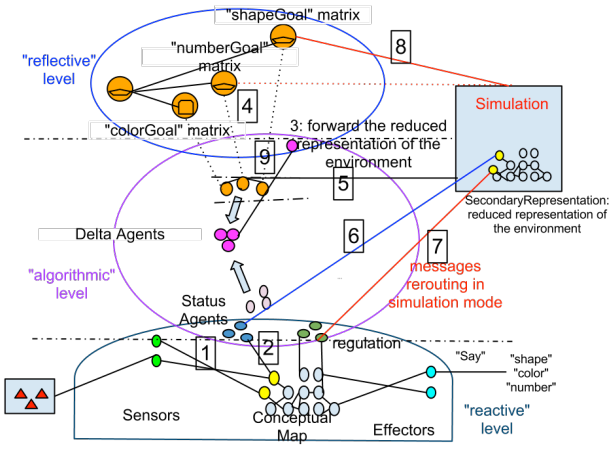
Perceptual attention: the Stroop task especially illustrates the dual nature (orienting and being oriented) of perceptual units in our system. The system gets initial information about its environment through its sensory agents ("recognizecolor" and "read") –the system processes all stimuli in parallel. At first, this leads to an activation of the Knowledge agents that correspond to the external stimulus (e.g., the Knowledge agent that bears the role "Red" will be activated if Sensory agents detect red in the environment). As we mentioned above, when the system is initialized for the Stroop experiment, there is a preponderance of "read" agents. After this initial phase, Control agents, guided by information provided by Status agents, themselves influenced by the system's current goal, can modify the message passing activity between the agents (by increasing the activity of the "recognizecolor" agents). With this experiment, we show that despite an initial setting favoring the "reading " ability and its connected sensor (both belonging to the reactive level), the system is able to change its "natural" tendency (from reading the word to naming the color), thanks to the cognitive control achieved by the algorithmic level. Cognitive control favors the color naming ability by increasing the activation of relevant agents in its goal matrix. Agents connected to them are in turn linked to effectors, therefore achieving perceptual control (perceptual attention) by spreading activation.

4.2 Flexibility: Wisconsin card sorting test

The Wisconsin card sorting test (WCST) [17] is widely used to test executive functioning, especially cognitive flexibility and abstract reasoning. The subject is shown a set of target cards with figures on them, which vary in shape, number and color. The subject has to match stimulus cards to the target cards, one by one. However, he is not told what the sorting rule is and has to discover it. In our experiment, we used material adapted from Dehaene & Changeux [15] representing the context effect of the four reference target cards by adding the following links in the system's conceptual map: Red – triangle – one, Green – star – two, Yellow – square – three, Blue – circle – four. We also linked the shape, color, and number knowledge (already present in ConceptNet) to the sensors. A script provided the system with the series of cards it had to categorize and evaluated the system's answer. The categorization rule was changed after 6 consecutive successes. The experiment consisted of 128 cards with figures varying in shape, number and color. The script attempted to test 6 categorization rules (["shape", "color",

"number"] times 2) on the 128 cards. As in human trials, no warning was sent before a rule change: only the answer "no" was given to the system when his answered was wrong.

Figure 3: Wisconsin card sorting task simulation



Perceptual attention: (Note that numbers in this section refer to figure 3. Please refer to the figure while the following description of the system's activity) When a new card appears in the environment, Sensors (1) forward the information to Knowledge agents in the reactive level. Activation of the different Knowledge agents is thus influenced by the environment's state. Status Agents then (2) provide the algorithmic level with the status of the agents at the reactive level. This information is used by the Delta Agents in the Algorithmic level to calculate a reduced representation (3) of the environment, which is then forwarded to the Reflective level, leading to the activation of various competing rules (4). When there are more than one winning rule/goal (because the system's working memory is loaded with contradictory contextual information), a process of cognitive decoupling (internal simulation) is launched (5) (by the Decoupling agents). A mini-world (decoupled world) -is thus created: agents in this mini-world are modeled after the reduced representation of the world (6) sent by Status agents. Decoupling agents also recreate an environment, to which the agents of the mini-world will react. For this Experiment, the environment was one in which the "no" response was sent after a categorization rulewas proposed by the mini-world. Regulating and status updating messages are rerouted (7) to act on the mini-world instead of the reactive level. The rules that emerge from the cognitive simulation are sent (8) to the reflective level (with different activations) and then the corresponding matrix is sent (9) to the algorithmic level, which is in charge of regulating the reactive level towards achievement of the goal (encouraging agent activity – even agents involved in perception – according to the system's current goal). The average number (for a hundred simulations) of rules the system (for its 128 trials) was able to discover and apply was 5.33; the maximum number was 6. Normal human subject are able to discover an average of six categories [16]. These results illustrate the system's ability to adapt adequately to the changing situation (new card, error notification) in a bidirectional manner: by orienting its executive control according to the information in the environment but also by orienting its perceptual processing according to the goal.

Equilibrium between deliberative and reactive behaviours: It is the system's design, focused on the interaction between the three cognitive levels, that helps preserve this equilibrium in the architecture to make it efficiently adaptive. Perseverationerror in the system are errors due to the reactive level.

Table 1: A simulation's log.

Serie	Trial	Response	Simulation
Color	1	correct	
	2	correct	
	3	correct	(1)color (2) shape
	4	Incorrect : shape	
	5	correct	
	…		
Shape	1	Incorrect : color	(1) shape (2)number
	2	Incorrect : color	(1) shape (2)number
	3	Incorrect : color	
	4	Incorrect : color,number	(1) number(2) shape
	5	Correct	(1) shape (2)number
	…		

However, the system's ability to achieve five categorizations is the result of a good interaction between reactive, algorithmic and reflective processing. Error notifications are sent from the Reactive level to the Algorithmic level, decreasing the activation of the now wrong classification rule, thereby allowing other rules/goals to take the lead. Activations levels of the goals are a memory of those classification rule that work and those that did not work in the past.. Although, the simulation capacity illustrates the interaction between Algorithmic and Reflective levels, it is also primordial for good cooperation between Deliberative and Reactive behaviour. Decoupling helps generate a prediction of the behaviour at the reactive level and therefore prepare an adaptive plan of action (efficient trial-error adaptation): in the third trial of the "color" series, a cognitive decoupling is run because two competing answers ("color" and "shape") are active. The system creates a simulation of a possible world where the color categorization rule is activated and observed as wrong; in this possible world, the second emerging rule was the shape categorization rule. In the first and second trial of the "shape" series, after a first wrong answer, "color" is selected, a cognitive decoupling is run where "shape" is first activated, since the possible world is an image of the system's environment before the simulation process started and where "color" had been marked as a wrong answer, the selected second answer is "number". In the third trial of the "shape" series, after a first incorrect

answer (color), a cognitive decoupling is run where the first rule activated is the "number" categorization rule, and the second is the "shape" rule, leading to a second error. Since the cognitive decoupling had activated the "shape" as second rule, the correct answer is produced.

5 Conclusion and Future Work

Theoretical studies [2,4,1] identified sequentiality and reactivity as two important features cognitive architectures must have if they are to be useful to cognitive scientists and engineers [1]. It has however proven difficult to integrate the two features in coherent architecture due to their functional incompatibility. In this paper, we focused on two such issues: Action attention and perceptual attention and flexibility. To design an architecture that addresses these issues, we sought inspiration from natural minds and modeled our system after Stanovich's Tripartite Framework [3] (reactive, algorithmic and reflective minds).The initial reaction of our system to stimuli is automatic (reactive level). However, as the task goes on, perceptual information processing is influenced not only the environmental stimuli, but by both activity in the reactive level and at the algorithmic level. The same goes for effectors. Therefore, perceptual information helps orient the system's behaviour and the system's gathering of perceptual information is oriented by the its deliberative level (its current plan). The selection of a plan itself is influenced by the information present in the environment. The plan thus depends on perception, but also influences what the system perceives (and of course does): perception and plan selection are dynamically coupled. The hybrid adaptive behaviour of the architecture is achieved through the cooperation of all three levels. Algorithmic cognition allows the system to achieve trial-and-error adaptation and hypothesis testing (e.g. simulation). Although achieved by the algorithmic level, decoupling is launched by the Reflective level from which will emerge the action to be performed by the system. However, achievement of a plan doesn't cancel the system's reactivity and dynamicity, since the algorithmic and reflective level stay up to date concerning the internal state of system at the reactive level, and are able to perform operations to adapt its long term behaviour to the constantly evolving environment. Dynamic behaviour emerges from the competition and cooperation between sequential deliberative processes (reflexive and algorithmic level) and reactive processes. In future work, we plan on addressing another issue which we think is also related to problem of flexibly integrating reactive and sequential processes: the emotional modulation of cognitive processes.

Extended Metacognition for Artificially Intelligent Systems (AIS): Artificial Locus of Control and Cognitive Economy

Dr. James A. Crowder
Raytheon Intelligence and Information Systems
16800 E. Centretech Parkway, Aurora, Colorado 80011

Shelli Friess MA, NCC
Relevant Counseling
P.O. Box 4193, Englewood, CO 80155

Abstract - *Theories into human learning and cognition have led to much research into new methods and structures for Artificial Intelligence (AI) and Artificially Intelligent Systems (AIS) to learn and reason like humans. As we move toward completely autonomous AIS, the ability to provide metacognitive capabilities becomes important [Crowder and Friess 2011b] in order for the AIS to deal with entirely new situations within the environment it may find itself (e.g., deep space, deep undersea). Presented here are theories and methodologies for Constructivist Learning (CL) processes that provide the methodologies to allow completely autonomous AIS to understand, evaluate, and evolve its "Locus of Control [Watts 2003]."*

Presented will be the a discussion of how the use of AI learning systems, like Occam [Crowder and Carbone 2011a] and PAC learning can be combined with Cognitive Economy concepts to provide this constructivist learning process to allow a Locus of Control evolution within the AIS. The goal here is to provide the AIS with a fully autonomous, cognitive framework that would be required for autonomous environmental interaction, evolution, and control.

In addition, provided are the mathematical constructs, based in Banach Spaces and Lebesque's work in Bounded Variability, that will provide the basis for Cognitive Economy structures in Artificially Intelligent Systems (AIS), allowing the AIS to operate in a "Bounded Rationality" mode, similar to humans, that will allow the autonomous system to function in new, unforeseen, and challenging environments it may find itself in. Natural intelligence filters out irrelevant information (either raw sensory perception information or higher-level conception information), and categorizes the problem representations to allow for maximum information processing with the least cognitive effort.

This work is based on the use of Intelligent Software Agents (ISAs) [Crowder 2010a] which will represent the world (its tasks, goals, and information) in terms of the reward values associated with different actions when those features of its abilities are active.

Keywords: Metacognition, Locus of Control, Cognitive Economy

1 Introduction

Intelligence reveals itself in a variety of ways, including the ability to adapt to unknown situations or changing environments. Without the ability to adapt to new situations, an intelligent system is left to rely on a previously-written set of rules. If we truly desire to design and implement autonomous AI Systems (AIS), they cannot require precisely-defined sets of rules for every possible contingency. The questions then become:

- ***How does an autonomous AI system construct good representations for tasks and knowledge as it is in the process of learning the task or knowledge?***
- ***What are the characteristics of a good representation of a new task or a new piece of knowledge?***
- ***How do these characteristics and the need to adapt to entirely new situations and knowledge affect the learning process?***

The ISAs, having bounded cognitive resources, would reacted to three aspects of Cognitive Economy to create a Bounded Rationality set of goals for a given set of ISAs generated to solve a particular problem or situation. These are:

1. The size of the feature set – how many "features" are required to define the success of each task
2. The "fuzzy" relevance of each feature for the tasks
3. The preservation of necessary distinctions for success in each task

The AIS's cognitive components would autonomously define, for each ISA, a Banach Space for that ISA's goals and tasks and would then consider the set of ISA Banach Spaces as a set of bounded variations, the sequence of which (through ISA collaboration) produces an acceptable solution to the situation(s) or task(s) at hand.

The Cognitive Economy methods will be described and a discussion will be provided, illustrating how these Cognitive Economy and Bounded Rationality concepts affect the overall learning aspects of an autonomous AIS.

In addition, when considering autonomous AIS, we must consider its need to interact and learn from its environment, and we have to ask ourselves "what is reality?" We have to establish how the AIS would interpret their reality. One of the issues that humans deal with that assists in their understanding of reality, or their world around them and how they need to interact, is their concept of "Locus of Control." **Locus of control** is a term in psychology that refers to a person's belief about what causes the events in their life, either in general or in a specific areas such as health or academics. Understanding of the concept was developed by Rotter [Rotter 1954], and has since become an important aspect of personality studies.

2.0 Artificial Locus of Control

Locus of control refers to the extent to which individuals believe that they can control events that affect them. Individuals with a high internal locus of control believe that events result primarily from their own behavior and actions. Those with a high external locus of control believe that powerful others, fate, or chance primarily determine events. Those with a high internal locus of control have better control of their behavior, tend to exhibit more political behaviors, and are more likely to attempt to influence other people than those with a high external locus of control; they are more likely to assume that their efforts will be successful. They are more active in seeking information and knowledge concerning their situation.

Locus of control is an individual's belief system regarding the causes of his or her experiences and the factors to which that person attributes success of failure. It can be assessed with the Rotter Internal-External Locus of Control Scale (see Figure 1). Think about humans, and how each person, experiences an event. Each person will see reality differently and uniquely. There is also the notion of how one interprets not just their local reality, but also the world reality [Botella 2011]. This world reality may be based on fact or impression.

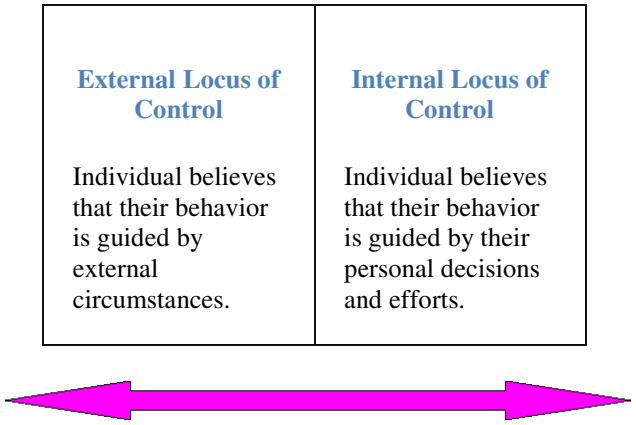

Figure 1 – The Rotter Locus of Control Scale

Take a car accident as an example. There are two people who witness a car hit a motorcycle. The police at the scene are supposed to evaluate the facts to determine what happened. The officer may use measurement tools that are

supported by mathematical equations, such to be able to determine the speed at impact or where the impact happened. The officer may measure skid marks or measure the distance between vehicles. The officer is gathering factual data. Let's consider this juried evidence and legitimate evidence. Given how the world measures and uses universal mathematic equations, this evidence can be measured and re-measured by thousands of people and likely even machines. Back to the accident, when asked by the police officer, each human witness can recall the event as if they were watching it again, a step by step recount. Each person's story likely has unique qualities depending on how they conceptualize the incident. We use eyewitness testimony all the time. Even though each witness talks a slightly different story, we use it. We know, by eyewitness testimony studies, that often times the recalled event is very different than the actual event. Let's say in this example both people recalled the event similarly except the color of the car that hit the motorcycle. Perhaps even whether the car hit the motorcycle or the motorcycle hit the care recount differs. The fire truck blocks the view of each eyewitness so they cannot confirm the color of the car as they recount the event. Each person has had a legitimate experience even if they code the color of the car differently. Factually legitimate the car and bike collided at a specific rate of speed at a specific location. Emotionally legitimate is the witnesses' personal experience. To one witness the car was green to the other it was blue. Thus, with this incident we have three realities. One of the facts that we can measure by juried tools and the reality of each of the players in the scene; all experiencing the same event but each in his own unique way. Each reality is legitimate.

For further thought let's then consider Constructivist Psychology. According to "The internet Encyclopedia of Personal Construct Psychology" the Constructivist philosophy is interested more in the people's construction of the world than they are in evaluating the extent to which such constructions are "true" in representing a presumable external reality. It makes sense to look at this in the form of legitimacies. What is true is factually legitimate and what is peoples' construction of the external reality is another form of legitimacy. Later on we can consider the locus of control in relation to internal and external legitimacies or realities. You are correct if you are thinking that AIS is not human and will not have human perceptions. AIS may have AIS perceptions and realities. Thus, a mentor will be necessary. That mentor will need to understand AIS as AIS and be able to understand AIS in a human way, a human reality. After all, isn't this what makes AIS autonomous?

3 AIS Constructivist Learning

Constructive psychology is a meta-theory that integrates different schools of thought. According to the above cited article:

> Hans Vaihinger (1852-1933) asserted that people develop "workable fictions". This is his philosophy of "As if" such as mathematical infinity or God. Alfred Korzybski's (1879-1950) "System of Semantics" focused on the role of the speaker in assigning meaning to events. Thus, constructivists thought that human beings operated on the basis of symbolic or linguistic constructs that help navigate the world without contacting it in any simple or direct way. Postmodern thinkers assert that constructions are viable to the extent that they help us live our lives meaningfully and find validation in shared understandings of others. We live in a world constituted by multiple realities social realities, no one of which can claim to be "objectively" true across persons, cultures, or historical epochs. Instead, the constructions on the basis of which we live are at best provisional ways of organizing our "selves" and our activities, which

could under other circumstances, be constituted quite differently.

For AIS with Constructivist Learning, the AIS cognitive learning process would be a building (or construction) process in which the AIS cognitive system builds an internal illustration of its learned knowledge-base, based on its experiences and personal interpretation (fuzzy inferences and conceptual ontology [Raskin & Taylor 2010a and Taylor & Raskin 2011a]) of its experiences. AIS Knowledge Representation and Knowledge Relativity Threads [Crowder and Carbone, 2011c], within AIS cognitive system memories would be continually open to modification, and the structures and linkages formed within AIS short-term, long-term, and emotional memories [Crowder and Friess, 2010b], along with its Knowledge Relativity Threads [Crowder and Carbone 2011c], would then form the bases for which knowledge structures would be created and attached to AIS memories.

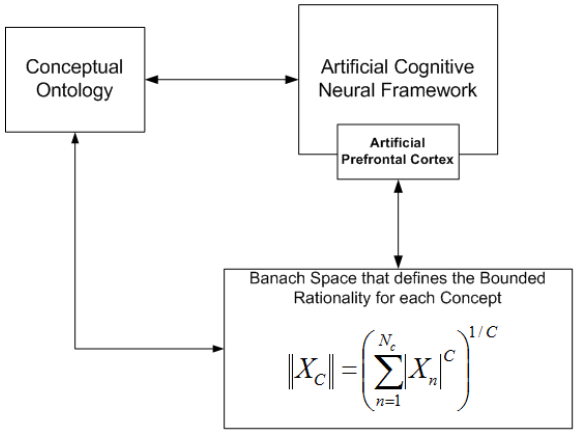
One of the results of the Constructivist Learning process with the AIS would be to gradually change its "Locus of Control" for a given situation or topic, from external (the system needing external input to make sense, or infer, about its environment) to internal (the AIS having the cumulative constructive knowledge-based of information , knowledge, context, and inferences to handle a given situation internally); meaning the AIS is able to make relevant and meaningful decisions and inferences about a situation or topic without outside knowledge or involvement. This becomes extremely important for completely autonomous AIS.

4 Bounded Conceptual Rationality (Cognitive Economy)

Bounded rationality is a concept within cognitive science that deals with decision-making in humans [LaBar and Capeza 2006]. Bounded rationality is the notion that individuals are limited by the information they have available (both internally and externally), the finite amount of time they have in any situation, and the cognitive limitations of their own skills. Given these limitations, decision making becomes an exercise in finding an optimal choice given the information available. Because there is not infinite information, infinite time, nor infinite cognitive skills, humans apply their rationality after simplifying the choices available, i.e., they bound the problem to be solved into the simplest cognitive choices possible [Jones 1999].

Any AIS must suffer the same issues. An autonomous system, by definition, has limited cognitive skills, limited memory, and limited access to information. The Locus of Control concepts discussed earlier assist AIS in determining which situations can be handled internally vs. externally, but still in any situation there is limited information, time, and cognitive abilities. This is particularly true if the system is dealing with multiple situations simultaneously. In order for the system to not become overloaded, we believe autonomous systems must employ strategies similar to human bounded rationality in order to deal with unknown and multiple situations they find themselves in. This involves creating mathematical constructs that can be utilized to mimic the notion of bounded rationality within autonomous AIS.

For this we look to Banach Space theory, tied into Constructivist Learning concepts [Botella 2011] for autonomous AIS. As concepts are learned and stored in the AIS conceptual ontology [Raskin & Taylor 2010a], Banach Spaces are defined that are used to bound the rationality choices or domains for that concept. As we "construct" these concepts and the Banach Spaces that bound them, the combination of Banach Spaces then defines the Conceptual Rationality for the Autonomous AIS. Figure 2 illustrates this concept.



where: $X_n = \frac{1}{N} \sum_{i=1}^{N_c} G(x - x_i, \sigma I)$

and: $H_R(X_C) = \int_{-\infty}^{\infty} p_f(x) dx$

where p_f is the fuzzy membership measurement

Figure 2 – AIS Bounded Conceptual Rationality

These Banach Spaces that define the bounds for each learned concept are utilized when the AIS must reason, or perform decision making. When there are restricting limitations on time, resources (as determined by the resource manager, e.g., artificial prefrontal cortex), and available information, the bounds of these Banach Spaces would be tightened or loosened to allow the AIS to deal with multiple situations, or situations that are time critical. This allows AIS to decide what is a "good enough" solution to a given problem or set of problems, and to adjudicate between competing resources, priorities and overall goals.

6 Conclusions and Discussion

What we have presented here are initial concepts and methodologies for what we believe are essential cognitive skills that autonomous systems must have in order to deal with and survive in real-time extreme environments. As we push for systems that think, learn, and adapt, we must provide these systems with cognitive skills similar to human processes in order to be able to deal with and survive real-time situations they find in their environments. This is very preliminary work and much more remains in order to put these concepts into practice.

Abstract

Due to the important role of commitment and trust in the relationship marketing, the factors which can directly result in a committed relationship along with the factors which can influence the commitment through influencing trust, according to the model of commitment and trust by (Morgan & Hunt, 1994) have been introduced and their level of importance has been investigated here. The article uses fuzzy cognitive maps (FCMs) in the proposed model to find the most important paths leading to relationship commitment. The FCM analyzes the responses of a group of 30 people including general practitioners in dentistry, managers of dental departments in some of the public clinics and hospitals who are the direct customers of 3 distributers of dentistry equipments in Iran to find the most important paths. Also the influence of coercive power, which was not concluded in previous researches, has been examined. The result of this inquires, then, has been provided along with its managerial implications and the impacts of prioritizing antecedents and factors of trust and commitment in relationship marketing.

1. Introduction

It's been suggested that "successful relationship marketing requires relationship commitment and trust." (Morgan & Hunt, 1994) The literature, also, suggests that understanding relationship marketing requires distinguishing between the discrete transaction, which has a "distinct beginning, short duration, and sharp ending by performance," and relational exchange, which "traces to previous agreements [and] ... is longer in duration, reflecting an ongoing process" (Dwyer, Scburr, & Oh, 1987). Hence Relationship marketing refers to all marketing activities directed toward establishing, developing, and maintaining successful relational exchanges.
In this article we, first, conduct a comprehensive literature review on commitment and trust and the respective constructs in section 2. In the next section we will introduce Fuzzy Cognitive Maps and the way we utilize them to find the most important paths leading to trust and commitment. Finally, conclusions regarding the results along with the managerial implications and future studies are presented.

2. A Review of Trust and Commitment

The literature is rife with researches that point to the fact that in the global economy one has to be a trusted competitor to be an effective one, which emphasizes the importance of relational marketing. As the presence of relationship commitment and trust is central to successful relationship marketing (Shelby & Hunt, 1994), and given the importance of relational marketing in today's competitive world and its bearing on CRM, a concept that has seen a great boom over the past two decades (Payne & Frow,

2005), it is important to know the antecedents that affect trust and commitment in relational marketing.
When both commitment and trust—not just one or the other—are present, they produce outcomes that promote efficiency, productivity, and effectiveness. In short, commitment and trust lead directly to cooperative behaviors

Relationship commitment is defined as an exchange partner believing that an ongoing relationship with another is so important as to warrant maximum efforts at maintaining it; that is, the committed party believes the relationship is worth working on to ensure that it endures indefinitely. (Moorman, Deshpande, & Zaltman, 1993): "Trust is defined as a willingness to rely on an exchange partner in whom one has confidence." The literature on trust suggests that confidence on the part of the trusting party results from the firm belief that the trustworthy party is reliable and has high integrity, which are associated with such qualities as consistent, competent, honest, fair, responsible, helpful, and benevolent (Rotter, 1971; Altman & Taylor, 1973; Larzelere & Huston, 1980; Dwyer & LaGace, 1986). (Anderson & Narus, 1990) focus on the perceived outcomes of trust when they define it as "the firm's belief that another company will perform actions that will result in positive outcomes for the firm as well as not take unexpected actions that result in negative outcomes." Indeed, we would expect such outcomes from a partner on whose integrity one can rely confidently.
Trust is so important to relational exchange that (Spekman, 1988) postulates it to be ' 'the cornerstone of the strategic partnership." Why? Because relationships characterized by trust are so highly valued that parties will desire to commit themselves to such relationships (Hrebintak, 1974) Shelby and Hunt (1994) propose that (1) relationship termination costs and relationship benefits directly influence commitment, (2) shared values directly influence both commitment and trust, and (3) communication and opportunistic behavior directly influence trust (and, through trust, indirectly influence commitment).

2.1. Termination Cost

A common assumption in the relationship marketing literature is that a terminated party will seek an alternative relationship and have "switching costs," which lead to dependence (Jackson, 1985; Heide & George, 1988). Termination costs are, therefore, all expected losses from termination and result from the perceived lack of comparable potential alternative partners, relationship dissolution expenses, and/or substantial switching costs. These expected termination costs lead to an ongoing relationship being viewed as important, thus generating commitment to the relationship.

2.2. Relationship Benefits

Competition—particularly in the global marketplace—requires that firms continually seek out products, processes, and technologies that add value to their own offerings. Relationship marketing theory suggests that partner selection may be a critical element in competitive strategy. Because partners that deliver superior benefits will be highly valued, firms will commit themselves to establishing, developing. and maintaining relationships with such partners
it is, therefore, proposed that firms that receive superior benefits from their partnership—relative to other options—on such dimensions as product profitability, customer satisfaction, and product performance, will be committed to the relationship (Shelby & Hunt, 1994).

2.3. Shared Values

Shared values, the only concept that we posit as being a direct precursor of both relationship commitment and trust, is the extent to which partners have beliefs in common about what behaviors, goals, and policies are important or unimportant, appropriate or inappropriate, and right or wrong (Dwyer, Scburr, & Oh, 1987) theorize that shared values contribute to the development of commitment and trust. Moreover, the organizational commitment literature often distinguishes between two kinds of commitment: (1) that brought about by a person sharing, identifying with, or internalizing the values of the organization and (2) that brought about by a cognitive evaluation of the instrumental worth of a continued relationship with the organization, that is by adding up the gains and losses, pluses and minuses, or rewards and punishments. Consistent with the organizational behavior literature, we posit that when exchange partners share values, they indeed will be more committed to their relationships, but our definition of commitment is neutral to whether it is brought about by instrumental or identification/internalization factors.

2.4. Communication

Communication can be defined broadly as the formal as well as informal sharing of meaningful and timely information between firms. Communication, especially timely communication (Moorman, Deshpande, & Zaltman, 1993) fosters trust by assisting in resolving disputes and aligning perceptions and expectations.

Shelby and Hunt (1994) propose that a partner's perception that past communications from another party have been frequent and of high quality—that is relevant, timely, and reliable— will result in greater trust. Anderson & Narus (1990) find that from both the manufacturer's and distributor's perspectives, past communication was positively related to trust. Anderson & Weitz (1989) also find that communication was positively related to trust in channels.

2.5. Opportunistic Behavior

The concept of opportunistic behavior from the transaction cost analysis literature is defined as "self-interest seeking with guile." The essence of opportunistic behavior is deceit-oriented violation of implicit or explicit promises about one's appropriate or required role behavior (John, 1984)

Shelby and Hunt propose that when a party believes that a partner engages in opportunistic behavior, such perceptions will lead to decreased trust. Rather than positing a direct effect from opportunistic behavior to relationship commitment, we postulate that such behavior results in decreased relationship commitment because partners believe they can no longer trust their partners.

3. Fuzzy Cognitive Maps

Fuzzy Cognitive Maps are used here to delineate the order of importance of the paths leading to trust and commitment. In this section, for the purpose of the reader's deeper understanding, an introduction to the concept of FCM is given. It is assumed that the reader is familiar with the fundamental notions underlying the Fuzzy theory, yet this familiarity does not bear upon the understanding of the methodology used in this article.

Cognitive Maps (CMs) were proposed and applied to ill-structured problems by (Axelrod, 1976).

The approach used by Axelrod is to develop CM's, i.e. signed digraphs designed to capture the causal assertions of a person, with respect to a certain domain and then use them in order to analyze the effects of alternatives, e.g. policies, business decisions, etc. upon certain goals. A cognitive map has only two basic types of elements Concepts and Causal Beliefs. The concepts are represented as variables and the causal beliefs as relationships among variables. Causal relationships link variables to each other and they can be either positive or negative. Variables that cause a change are called *Cause Variables* while those that undergo the effect of the change in the cause variable are called *Effect Variables*. If the relationship is positive, an increase or decrease in a cause variable causes the effect variable(s) to change in the same direction. If the relationship is negative, then the change which the effect variable undergoes is in the opposite direction. Fig. 1 is a graphical representation of a cognitive map, where variables (X, W, etc.) are represented as nodes, and causal relationships as directed arrows between variables, thus constructing a signed digraph (Nasserzadeh, Jafarzadeh, Mansouri, & Sohrabi, 2008). A famous example is cited by (Vasantha Kandasamy & Smarandache, 2003) where an expert spells out the five major concepts relating to the unemployed graduated engineers as:

E1 – Frustration

E2 – Unemployment

E3 – Increase of educated criminals

E4 – Underemployment

E5 – Using drugs, etc.

The resulting graph elicited using the expert's opinions and representing variables and corresponding relationships among them is as follows (Figure 1)

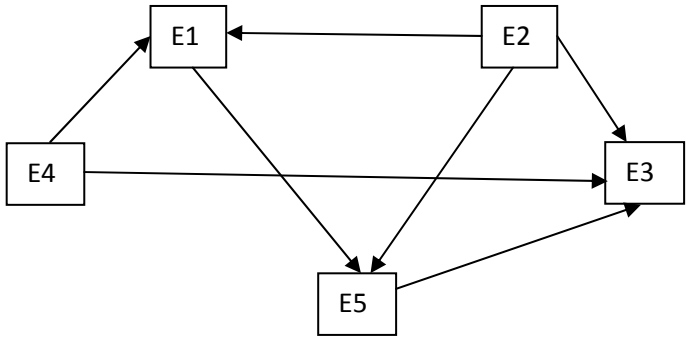

Figure 1-Causal Graph

Cognitive maps were developed in simulation, organizational strategies modeling, support for strategic problem formulation and decision analysis,

knowledge bases construction, managerial problems diagnosis, failure modes effects analysis, modeling of social and psychological processes, modeling virtual worlds and analysis of their behavior, requirements analysis and systems requirements specification (Kardaras & Karakostas, 1999). (Kosko, 1986) introduces FCM, i.e. weighted cognitive maps with fuzzy weights. It is argued, that FCM eliminates the indeterminacy problem of the total effect. Since its development, fuzzy set theory has been advanced and applied in many areas such as expert systems and decision making, control engineering, pattern recognition, etc (Zimmermann, 1991). It is argued that people use fuzzy data, vague rules, etc. and fuzzy sets as a mathematical way to represent vagueness. Fuzzy sets are characterized by a membership function, which is also called the degree or grade of membership.

Different approaches were proposed for the specification of the fuzzy weights in an FCM. One suggestion is to ask the experts to assign a real number from the interval (0, 1) for each relationship and then calculate the average. However, it is difficult for the experts to assign a real number in order to express their beliefs with regard to the strength of relationships. This is the reason why partially ordered linguistic variables such as weak < moderate < strong, etc. are preferred to real number.

It is assumed that a concept in an FCM can be represented by a numerical vector (V), whereas each element (v) of the vector represents a measurement of the concept. Another way of representing a cognitive map is made possible through an adjacency matrix where one can clearly observe the sign of the relationship, while keeping in mind that in case of an absence of relationship between these two factors, the corresponding entry will be empty:

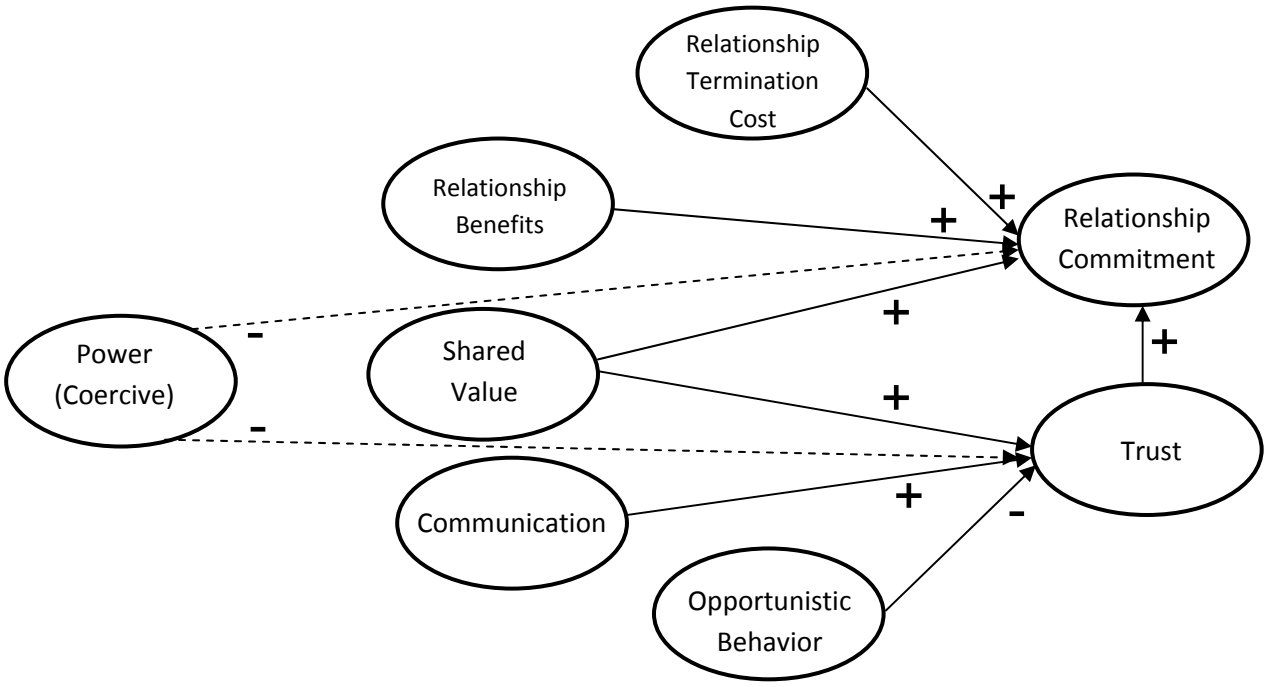

Figure 2- Model of Commitment and trust by (Morgan & Hunt, 1994)

4. Methodology

Fuzzy Cognitive Maps (FCMs) have been used to determine two things. First, the strength of the relationships described in the original Shelby and Hunt paper (1994) (Figure 2).
Second, to determine if there is a strong relationship between "power and commitment," and "power and trust and commitment" as proposed for further study in the Shelby & Hunt paper (1994).

For the purpose of determining the strength of each path in the following fuzzy diagram, the mamdani fuzzy operator has been used.

Based upon paths above a questionnaire has been developed on Likert scale of 1-5, which each of the questions refers to one of the defined relationships. These questionnaires have been responded by general practitioners in dentistry, managers of dental departments in some of the public clinics and hospitals who are the direct customers of 3 distributers of dentistry equipments in Iran. The sample group was composed of 45 people including 20 general dentists, 10 oral surgeons, 8 clinic managers, and 8 managers of dental departments of hospitals.
The questionnaire has been submitted personally to each of the members of sample group, and has been explained to them directly. It has been given one week to each respondent to reply and a reminder telephone call has been scheduled for the 6th day of the week.

The group of respondents is composed of 16 general dentists, 4 oral surgeons, 7 clinic managers and 3 managers of dental departments in 3 different hospitals. (Respondent rate is 67%)

After collecting the responses, using the above function, the linguistic labels corresponding to each of the paths shown in figure 3 are quantified. The aim is to find the path with the greatest impact on the final variable – purchase satisfaction.
Assuming:

C1: power (coercive)
C2: relationship termination cost
C3: relationship benefits
C4: shared value
C5: communication
C6: opportunistic behavior
C7: trust
C8: relationship commitment

The paths are as follows:
I_1 = {C1,C8}
I_2 = {C1,C7,C8}
I_3 = {C2,C8}
I_4 = {C3,C8}
I_5 = {C4,C8}
I_6 = {C4,C7,C8}
I_7 = {C5,C7,C8}
I_8 = {C6,C7,C8}

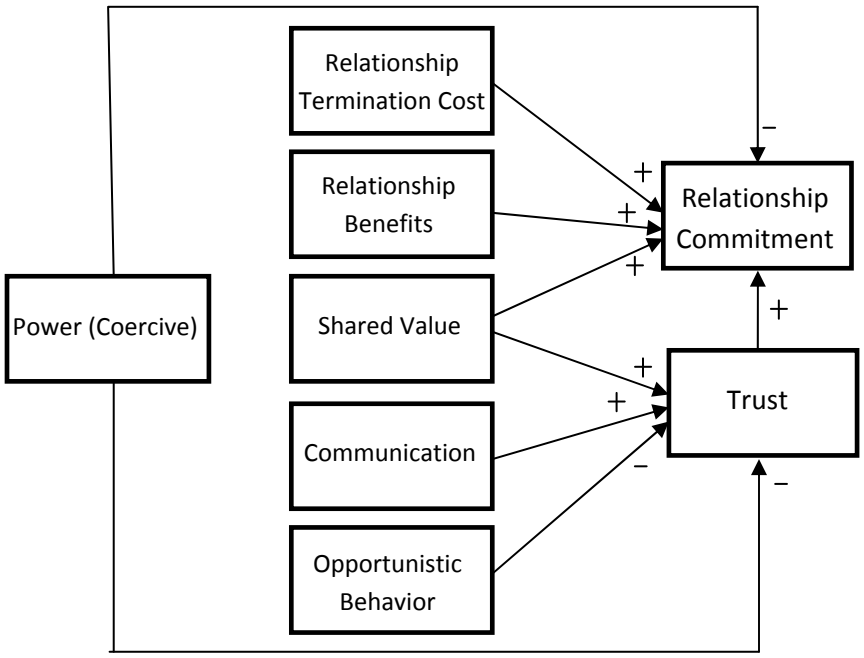

Figure 3 – Investigated Paths

5. Results

5.1. Phase I:

For the original Shelby and Hunt model, the strength of each of the paths leading to commitment has been computed. Based on the mathematics behind fuzzy cognitive maps, the importance weights of each of the paths are computed as follows:

$\Phi^1 = 0.9$ (strong)

$\Phi^2 = \min(0.94,0.97) = 0.94$ (strong)

$\Phi^3 = 0.86$ (strong)

$\Phi^4 = \underline{0.95}$ (strong)

$\Phi^5 = 0.65$ (medium)

$\Phi^6 = \min(0.63,0.97) = 0.63$ (medium)

$\Phi^7 = \min(0.71,0.97) = 0.71$ (medium)

$\Phi^8 = \min(0.93,0.97) = 0.93$ (strong)

$\Delta = \max \{ \Phi^1, \Phi^2, \Phi^3, \Phi^4, \Phi^5, \Phi^6, \Phi^7, \Phi^8 \} = 0.95 =$ strong

5.2. Phase II:

For the relationship between "power and commitment," and "power and trust and commitment," (paths I^1 and I^2) the strength for both of the paths was found to be strong.

6. Conclusion

With the increased penetration of Relationship Marketing philosophies and Relationship Commitment in businesses and organizations and the concomitant rise in spending of people and products to implement them, it is clear that the importance of developing the knowledge about the effective factors in creating such commitment will rise consequently. Each business and organization should be aware of the importance of the factors to be monitored, developed or modified in order to nurture a committed relationship with the customers. It is obvious that knowing the level of influence each factor has can help the managers not spend their priceless resources on unnecessary factors which have little influence on increasing the commitment.

The result of our research has shown that the most positive relationship can be seen when the parties of the relationship find the relationship more beneficial. The findings of this research lead to a series of managerial implications for managers to increase the commitment and trust of the firm's customers. According to these results, although having shared values and communication can be a great motive for customers to initiate a relationship with the firm, it will not guarantee an increase in the commitment the customer might feel toward the firm. This conclusion can guide the managers to put their best attempts to reduce the feeling of coercive power a customer will have about the firm through communication and modification of agreement conditions and terms and several other alternatives. In addition, the managers should be very clear in terms of communicating relationship benefits for the customer and put most of their time, money and energy on emphasizing more and more on these benefits for the customers to grow their sense of trust and commitment.

This research has been conducted on a relatively small sample group specializing mostly in medical equipment distribution and retailing. Although we are confident, to some extent, that sense of trust and commitment in the business relationships are more or less independent of the type of industry, this claim should be tested on various businesses in order to find a general pattern on how to prioritize the influential factors on developing commitment and trust. Furthermore, in the model of trust and commitment by (Morgan & Hunt, 1994) some interrelationships between the constructs have been presumed (i.e., the relationship between relational benefit and coercive power); these interrelations could be explored using the same methodology as the one used here, or using more complex Fuzzy functions. Moreover, this model has an outcome side which shows the influence of commitment and trust on several outcomes such as conflict, acquiescence, propensity to leave, cooperation and uncertainty. These outcomes are the most important reason for the firms to attempt to increase their customers' commitment to the firm.

Shelli Friess MA, NCC
Relevant Counseling
P.O. Box 4193, Englewood, CO 80155

Abstract - *Developing "Warrior Resiliency" has been a focus of armies since the dawn of time. There has been much research over the last decades to understand and provide systems and methodologies to develop and enhance cognitive resiliency in soldiers. The ability to adapt to adversity and overcome barriers in all walks of life is critical to a soldier's overall mental health and strength. And while physical resilience is very important, lack of psychological resilience can cripple a soldier just as easily as physical impairments. In addition to peak physical performance, each soldier must be well-balanced psychologically and socially in order to sustain the intense rigors of military life, especially when it must be balanced with home, family, and community life.*

Keywords: Cognitive Self-Regulation,

1. Introduction

What is described here is an automated, interactive, cognitive system, called the Cognitive, Interactive Training Environment (CITE, pronounced "KITE") that will provide the necessary cognitive psychological training to provide the warfighter with the ability to maintain mission readiness and psychological self-regulation before, during, and after stressful situations, whether in combat or at home. The CITE system utilizes advances in Artificial Cognitive Systems developed by Raytheon combined with Linguistic Ontological Technologies developed by Purdue University to create an interactive environment capable of providing training to and adapting to individual soldier's needs and requirements. CITE will provide automated, interactive training and capture and report metacognitive indicators and metrics that allow complete assessment of psychological resilience. CITE will gather and assess metacognitive indicators like:

- Problem solving skills
- Social skills
- Relationship Skills
- Self-awareness
- Emotional self-regulation
- Cognitive self-regulation

CITE will provide the soldier with training to assist in development of the self-monitoring and self-assessment skills needed for psychological self-regulation. Figure 1 illustrates the block diagram of the CITE system.

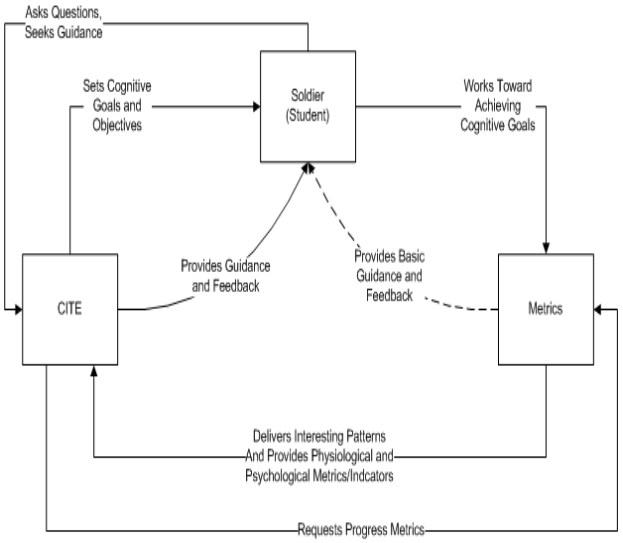

Figure 1 – Block Diagram of the CITE System

2. Warrior Resilience

The Office of Naval Research (ONR) website describes Warrior Resilience[1] as:

> "...improving the cognitive agility, flexibility and capacity of expeditionary warfighters by making them mentally tough, resilient to stress and well-adapted to chaotic, irregular environments"

In order to affect cognitive resiliency among warfighters, that must deal with a host of complex environments, both on and off the battlefield, an interactive training system must have a comprehensive understanding of the psychological, physical, and social elements and their interrelationships with warfighter performance. What we describe here is a comprehensive, Cognitive Interactive Training Environment (CITE, pronounces "kite") that will provide extensive, interactive, cognitive training and evaluation to provide warfighters with psychological self-evaluation, and self-awareness, and self-regulation skills to improve their cognitive performance throughout deployment as well as off the battlefield. We describe advanced instructional methods, based on Dr. Peter Levines [Levine 1997], autonomic nervous system states, that will provide cognitive behaviour training, metrics, and biomarkers that include environmental, contextual, and social components to affect real cognitive resiliency. The CITE system will provide the cognitive training tools to develop cognitive self-regulation and mitigation strategies to reduce cognitive dissonance among warfighters.

[1] http://www.onr.navy.mil/en/Media-Center/Fact-Sheets/Mental-Resilience-Cognitive-Agility.aspx

3. Cognitive Resiliency and Memory Development

Cognitive Resiliency develops in the brain through training that results in the learned ability to respond or self-regulate to severe psychological changes which may result from many forms of trauma and/or change; physical, emotional, environmental, or social. These learned abilities, then, get stored as memories within the human brain. Memories, in general, are divided according to the functions they serve [Newell 2003]. To qualify as a "memory" a cognitive input must cause both enduring changes within the nervous system (affect the autonomous nervous system states) and must also affect emotional and motivational responses and goals [LeDoux 1996]. A memory must induce some change that affects the nervous system and drives some physical change, in addition to modifying the human conceptual ontology, brought about by the memory being in the class of things that are affected by input, and therefore, affect other forms of behaviour. There are no memories that are neutral from a behavioural standpoint (Crowder and Friess 2010a].

4. Procedural Memory Development and Resiliency

One of the main divisions of human memory is "Procedural Memory." Procedural memory is a form of implicit memory that includes classical conditioning and the acquisition of skills. Procedural memory creation contains central pattern generators that form as a result of teaching or practice and are formed independently of conscious or declarative memory. In his work on Procedural Memory and contextual Representation, Kahana showed that retrieval of implicit procedural memories is a cue-dependent process that contains both semantic and temporal components (Kahana, Howard, and Plyn 2008)].

Creation of Procedural Memories is tied to not only repetition of tasks, but also to the richness of the semantic association structure (Landauer and Dumais 1997). In order to provide cognitive resilience, the CITE system provides interactive training that allows warfighters to create procedural memories, or "scripts" that have emotional, social, and psychological triggers and provide the skills required at the time for cognitive self-evaluation, self-awareness, and self-regulation to present or reduce psychological disorders, or problems, caused by trauma, either physical, psychological, or environmental [Crowder and Friess 2011a].

The CITE interactive training will provide a cognitive system that will interact and learn from the warfighter, developing strategies and training scenarios specific to that warfighter, thus allowing the warfighter to develop procedural memory strategies, i.e., implicit procedural memories, that will "kick in" under specific emotional memory queues, based on physical, emotional, psychological, and/or environmental events that the warfighter encounters. CITE will develop a model, or picture, or the warfighter's prefrontal cortex, based on the cognitive interactions with the system. This prefrontal cortex, or mediator, model (see Figure 2) allows CITE to understand the warfighters particular cognitive processes and what drives changes between emotional and cognitive states [Crowder and Friess 2011b] for that warfighter.

Based on these derived cognitive models, cognitive interactions between CITE and the warfigher will affect procedural memory creation, which will allow self-assessment, self-awareness, and self-regulation, driving cognitive self-soothing procedures to be initiated, greatly reducing mental stress and thus the possibilities of mental disorders [Crowder and Friess 2010b].

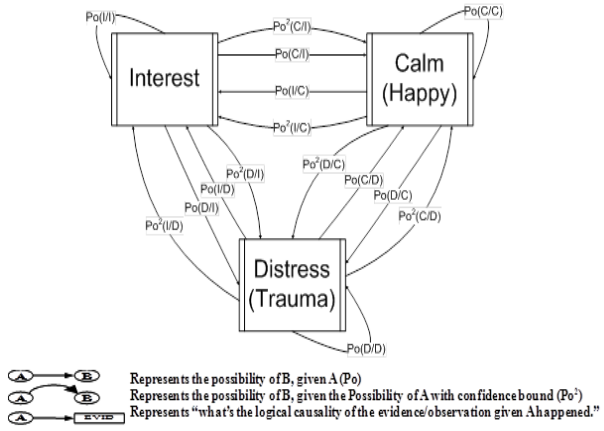

Figure 2 – Derived Warfighter Prefrontal Cortex Model, based on CITE interactions

5. The CITE Artificial Cognitive Neural Framework

The CITE warfighter cognitive models are derived through human-machine interactions and stored within the CITE Artificial Cognitive Neural Framework[2] (see Figure 3). In order to understand the world we live in, humans synthesize models that enable us to reason about what we perceive. Situations warfighters find themselves in, as well as the information they receive comes from a variety of sources, rendering it fuzzy. These diverse sources often do not have consistent contextual bases and this introduces ambiguity into the correlation and inferences the warfighter applies to the combined information. We have the ability to perceive the world we see and form our own concepts to describe and make decisions. To do this, we use language fuzzily and we communicate fuzzily, adapting and evolving our communication and processing to best fit the needs of our personal and conceptual views, along with our goals and vision for where we need to grow and evolve to [Zadeh 2004]. In order to understand and provide individualized resiliency training for

[2] Patent Pending

each warfighter, CITE must be able to organize information from the warfighter semantically into meaningful fuzzy concepts and models that provide a conceptual ontology [Raskin, Taylor, and Hempelmann 2010, and Taylor and Raskin 2010] of the individual warfighters cognitive abilities.

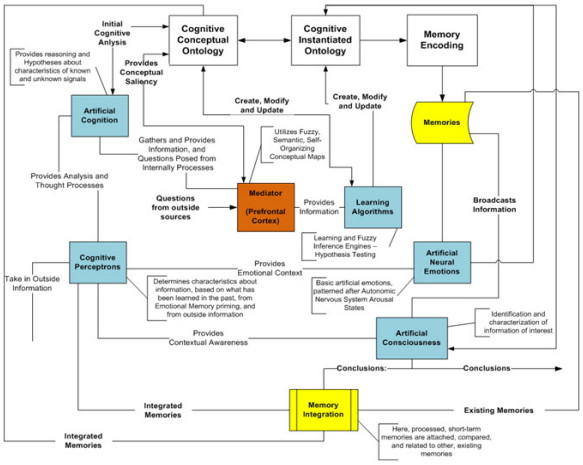

Figure 3 – The Artificial Cognitive Neural Framework

The purpose of these warfighter cognitive models is to provide cognitive knowledge products that reflect the state of being for the individual warfighter that includes metrics to measure cognitive resiliency for all aspects of life, to include battlefield, family and community.

6. Summary

What we have described is a cognitively interactive training system, CITE, that will allow warfighters to develop cognitive resiliency and provide knowledge products that reflects state of the art cognitive conditioning that minimizes injury, maximizes home station performance gains, and enables peak cognitive performance throughout deployment, and in garrison. This includes cognitive procedural memory development that will allow improvement in attitudes and knowledge about the value of proper nutrition, factors and fatigue, and the limits of sleep deprivation, through the use of cognitive self-awareness, self-evaluation, and self-regulation.

Computationally Adjustable Cognitive Inertia

Brian McLaughlan and Sebastian Bossarte
Department of Computer and Information Science
University of Arkansas - Fort Smith, Fort Smith, AR, USA

Abstract - *Cognitive inertia is the tendency for beliefs to endure once formed. This paper proposes that cognitive inertia can be utilized in multi-agent systems as a first derivative of trust. In this role, cognitive inertia provides a mechanism for allowing agents to determine how quickly or how drastically they should re-evaluate their trust in other agents. Appropriate levels of cognitive inertia are experimentally determined for various combinations of high and low risk and reward scenarios. Methods are examined that can allow agents to alter cognitive inertia based on feedback from the environment and other agents. From these experiments, we have identified several variables that appear to be useful indicators of appropriate cognitive inertia as well as inertia determination methods appropriate for various generalized scenarios.*

Keywords: *Multi-agent systems, trust, cognitive inertia*

1 Introduction

The evolution of e-commerce has led to an increased interest in concepts relating to trust. In fact, the ability to computationally define trust has been a major factor in successfully developing electronic and online commerce [1]. These trust models are increasing used by automated agents for making decisions or suggesting courses of action. When looking for inspiration for developing these models it is useful to look beyond traditional artificial intelligence concepts and examine how research in other disciplines may apply.

One potentially useful concept, cognitive inertia, is commonly utilized in managerial science. Essentially, cognitive inertia is the human tendency to maintain previously valid beliefs even when new evidence no longer supports those beliefs. Typically, this concept has a negative connotation, and significant research in this topic is devoted to analyzing its effects [2] or circumventing its symptoms [3]. However, cognitive inertia does have a positive role in the maintenance of trust.

Cognitive inertia is the component that makes long-term relationships of trust possible. For instance, if an individual is considered a trustworthy friend, one mistake would not be enough to invalidate that friendship. Additional confirmation of untrustworthiness is often needed. However, that one offense may prompt a slight raise of one's guard. Additional offenses would then indicate a significant change in attitude toward the individual in question. In this sense, cognitive inertia can be considered the first derivative of trust. That is, it is the rate at which trust is modified when circumstances dictate a change.

Although trust can be defined in many ways, this paper defines trust as follows: Trust is a belief that another agent is reliable in the services it provides, and is honest when given the opportunity to defect [4].

While cognitive inertia is not a one-size-fits-all concept in which a single value is most appropriate in all situations, it may be possible to generate broad guidelines for determining how quickly an agent should alter its trust in a given situation. This ability to modify its reasoning methods in response to feedback from the environment and scenario could allow an agent to avoid costly mistakes from trusting a faulty source or rashly terminating an otherwise sound relationship.

There are many techniques for modeling trust. The techniques in this paper could be best categorized as a learning model, a famous version of which is based on game theory [5] where agents calculate the benefit of cooperating with another agent. However, this work is less like traditional game theory models involving payoffs and defections and is more like the emergent trust models taken from a fusion of complexity theory, marketing, and psychological theory [6].

The research presented in this paper addresses two questions regarding cognitive inertia. First, is it possible to determine broad rules for calculating an appropriate inertia value in a given situation? Second, is it possible to utilize environmental variables, agent performance, or self-examination to adjust inertia to more appropriate levels?

2 Approach

To explore the viability of the concept of cognitive inertia in trust relationships, a generic multi-agent system is proposed. In this system, agents broadcast information to each other. Information presented by some agents tends to be more reliable than information from other agents. Believing false information incurs a penalty while believing true information provides a reward. Conversely, ignoring false information is rewarded while ignoring true information is penalized.

Agents maintain trust levels in each other agent. These trust levels represent the percentage chance that the agent will believe the information provided (Figure 1). After receiving the reward or penalty, the agent has the opportunity to adjust

its trust in the sending agent based on its cognitive inertia. While an agent maintains trust levels for each other agent, it only has a single cognitive inertia value. Future experimentation can determine if this is sufficient or if a more discrete inertia would be beneficial.

Formally, we propose a World $\boldsymbol{W}$ that consists of Agents $\boldsymbol{A}$, a Reward value R, a Penalty value P, and a discrete Time variable T:

$$\boldsymbol{W} = \{ \boldsymbol{A}, R, P, T \}. \quad (1)$$

There exists a set of agents, $\boldsymbol{A} = \{ \boldsymbol{A_1}, \boldsymbol{A_2}, \ldots, \boldsymbol{A_n} \}$, such that

$$\boldsymbol{A_i} = \{ \boldsymbol{M_i}, \boldsymbol{TR_i}, C_i, H_i, S_i, \boldsymbol{F_i} \}. \quad (2)$$

$\boldsymbol{M}_i$ is the set of message observations for $\boldsymbol{A_i}$:

$$\boldsymbol{M}_i = \{ M_i(1), M_i(2), \ldots, M_i(k) \}. \quad (3)$$

$\boldsymbol{TR_i}$ is the set of trust values in other agents:

$$\boldsymbol{TR}_i = \{TR_i^{\,1}, TR_i^{\,2}, \ldots, TR_i^{\,n-1}\} \quad (4)$$

where n is the number of agents in the system. Trust for each other agent is a value from 1 to 100.

C_i is agent $\boldsymbol{A_i}$'s cognitive inertia level on a scale of 1 to 100, representing the percentage chance it will adjust its trust in another agent. S_i represents its fitness score, and H_i is the agent's honesty on a scale of 1 to 100, representing the percentage chance it will present accurate information. Finally, $\boldsymbol{F_i}$ represents the set of functionality available to the agent.

$$\boldsymbol{F_i} = \{ F_i^S, F_i^R \} \quad (5)$$

Each turn, agent $\boldsymbol{A_i}$ will send a true message, M^{true}, or a false message, M^{false}, to all other agents using the Send function, F_i^S:

$$\boldsymbol{M_x}(T+1), \forall\, x \in \boldsymbol{A}, x \neq i \leftarrow F_i^S(M_i^{true}(T)) \Leftrightarrow \quad (6)$$
$$Random(1{:}100) \leq H_i(\mathrm{T}).$$

$$\boldsymbol{M_x}(T+1), \forall\, x \in \boldsymbol{A}, x \neq i \leftarrow F_i^S(M_i^{false}(T)) \Leftrightarrow \quad (7)$$
$$Random(1{:}100) > H_i(\mathrm{T}).$$

Similarly, a Receiving function, F_i^R, is created for receiving messages from agent $\boldsymbol{A_j}$:

$$\boldsymbol{M_i}(T+1) \leftarrow F_i^R(F_j^S(x_j(T), \exists!\, x \in \{M^{true}, M^{false}\})). \quad (8)$$

Next, we define the method in which agent $\boldsymbol{A_i}$ believes or disbelieves a message from $\boldsymbol{A_j}$:

$$\mathsf{BEL}_i\,(M^x{}_j(\mathrm{T}), \exists!\, x \in \{true, false\}\,) \Leftrightarrow \quad (9)$$
$$Random(1{:}100) \leq TR_i^{\,j}(\mathrm{T}).$$

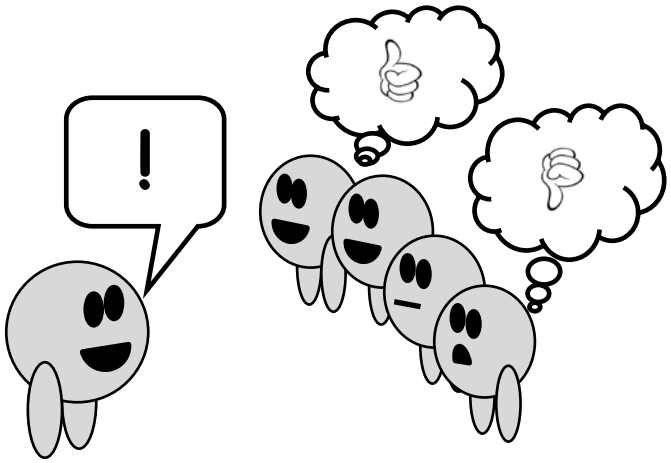

Figure 1: Agents believe or disbelieve messages based on their trust in the sending agent

That is, agent $\boldsymbol{A_i}$ will believe a message from agent $\boldsymbol{A_j}$ if and only if a randomly generated number from 1 to 100 is less than or equal to $\boldsymbol{A_i}$'s Trust in $\boldsymbol{A_j}$. While real-world scenarios would require a significant number of variables to adequately compute the trustworthiness of a message, this experiment abstracts the uncertainty as a stochastic variable.

Next, we define the methods in which the agent is rewarded or punished for the messages it has received:

$$\mathsf{BEL}_i\,(M^{true}(T)) \vee \neg\, \mathsf{BEL}_i\,(M^{false}(T)) \Rightarrow \quad (10)$$
$$S_i(\mathrm{T}+1) \leftarrow S_i(\mathrm{T}) + R.$$

$$\mathsf{BEL}_i\,(M^{false}(T)) \vee \neg\, \mathsf{BEL}_i\,(M^{true}(T)) \Rightarrow \quad (11)$$
$$S_i(\mathrm{T}+1) \leftarrow S_i(\mathrm{T}) - P.$$

When agent $\boldsymbol{A_i}$ believes a true message or disbelieves a false message, its score increases by the reward amount. Conversely, when agent $\boldsymbol{A_i}$ believes a false message or disbelieves a true message, its score decreases by the penalty amount.

Finally, we define agent $\boldsymbol{A_i}$'s ability to alter its trust in agent $\boldsymbol{A_j}$:

$$S_i(\mathrm{T}+1) > S_i(\mathrm{T}) \wedge Random(1{:}100) \leq C_i(\mathrm{T}) \Rightarrow \quad (12)$$
$$TR_i^{\,j}(\mathrm{T}+1) \leftarrow TR_i^{\,j}(\mathrm{T}) + (100\text{-}C_i)/10.$$

$$S_i(\mathrm{T}+1) < S_i(\mathrm{T}) \wedge Random(1{:}100) \leq C_i(\mathrm{T}) \Rightarrow \quad (13)$$
$$TR_i^{\,j}(\mathrm{T}+1) \leftarrow TR_i^{\,j}(\mathrm{T}) - (100\text{-}C_i)/10.$$

3 Experimentation

The proposed model was implemented in a Java simulation. The simulation consisted of 100 agents, each with a different cognitive inertia value:

$$C_i \leftarrow i, \forall\, i \in \boldsymbol{A}. \quad (14)$$

Each agent was given a random honesty value:

$$H_i \leftarrow Random(1{:}100), \forall\ i \in \boldsymbol{A}. \quad (14)$$

The honesty values for the group were weighted in one of three ways:

1. No weighting of honesty
2. Honesty weighted towards 75
3. Honesty weighted towards 25

Also examined was the model's ability to handle different reward and penalty scenarios. The experiment was executed with one of three reward/penalty combinations

1. Equal reward and risk: Reward $R = 1$, Penalty $P = 1$
2. High reward, low risk: Reward $R = 5$, Penalty $P = 1$
3. Low reward, high risk: Reward $R = 1$, Penalty $P = 5$

These parameters allow many different situations to be simulated. For instance, agents might be attempting to discover leads among data records for rooting out a wanted fugitive. In this scenario, there may be many dead-end leads and false positives shared with the group (honesty scores weighted towards 25), and those false positives don't cause significant problems (low penalty). However, a positive lead is a rare and significant event (high reward).

As another example, consider a group of agents that are interpreting and utilizing targeting data. Agents are expected to perform adequately (low reward and honesty weighted toward 75), and errors can cause catastrophic events such as targeting of friendly troops or non-combatants (high penalty).

The experiment was executed with one of five modifications to the method for adjusting cognitive inertia after each received message:

1. No change to inertia possible

2. Change inertia upwards for true received messages, downwards for false messages

$$F_i^R(M^{true}(T)) \Rightarrow C_i(T+1) \leftarrow C_i(T) + 1 \quad (15)$$
$$F_i^R(M^{false}(T)) \Rightarrow C_i(T+1) \leftarrow C_i(T) - 1 \quad (16)$$

3. Change inertia downwards for true received messages, upwards for false messages

$$F_i^R(M^{true}(T)) \Rightarrow C_i(T+1) \leftarrow C_i(T) - 1 \quad (17)$$
$$F_i^R(M^{false}(T)) \Rightarrow C_i(T+1) \leftarrow C_i(T) + 1 \quad (18)$$

4. Inertia moves toward 50 when a false message is received, away from 50 when true

$$F_i^R(M^{true}(T)) \wedge C_i(T) < 50 \Rightarrow \quad (19)$$
$$C_i(T+1) \leftarrow C_i(T) - 1$$
$$F_i^R(M^{true}(T)) \wedge C_i(T) > 50 \Rightarrow \quad (20)$$
$$C_i(T+1) \leftarrow C_i(T) + 1$$
$$F_i^R(M^{false}(T)) \wedge C_i(T) < 50 \Rightarrow \quad (21)$$
$$C_i(T+1) \leftarrow C_i(T) + 1$$
$$F_i^R(M^{false}(T)) \wedge C_i(T) > 50 \Rightarrow \quad (22)$$
$$C_i(T+1) \leftarrow C_i(T) - 1$$

5. Inertia moves toward 50 when a true message is received, away from 50 when false

$$F_i^R(M^{true}(T)) \wedge C_i(T) < 50 \Rightarrow \quad (23)$$
$$C_i(T+1) \leftarrow C_i(T) + 1$$
$$F_i^R(M^{true}(T)) \wedge C_i(T) > 50 \Rightarrow \quad (24)$$
$$C_i(T+1) \leftarrow C_i(T) - 1$$
$$F_i^R(M^{false}(T)) \wedge C_i(T) < 50 \Rightarrow \quad (25)$$
$$C_i(T+1) \leftarrow C_i(T) - 1$$
$$F_i^R(M^{false}(T)) \wedge C_i(T) > 50 \Rightarrow \quad (26)$$
$$C_i(T+1) \leftarrow C_i(T) + 1$$

To allow each agent to stabilize at what it felt was an appropriate configuration, the simulation was executed for 500 time cycles, with each agent sending one message to the group during each time cycle. This number of time cycles gave each agent adequate time to settle into particular trust and cognitive inertia values. At the end of the simulation, fitness scores of each agent were tabulated. Each of the 45 possible scenario combinations was executed 1000 times to get a good average statistic.

4 Results

Figure 2 shows the average scores of agents in a simple low risk/low reward scenario containing agents with a wide range of honesty values. The "No modifier" line shows the baseline desirability of each cognitive inertia value. Thus, a low inertia would be most appropriate here. Agents with an honesty value that clusters around 25 tend to perform similarly. However, agents with high average honesty (Figure 3) tend to perform better with a cognitive inertia in the 65 to 80 range. This trend holds fairly steady for all combinations of high/low risk and reward parameters.

The method of adjusting cognitive inertia is particularly interesting. As summarized in Figure 4, the formula that achieves the best performance varies by scenario. When the average honesty is high, pushing the inertia towards the

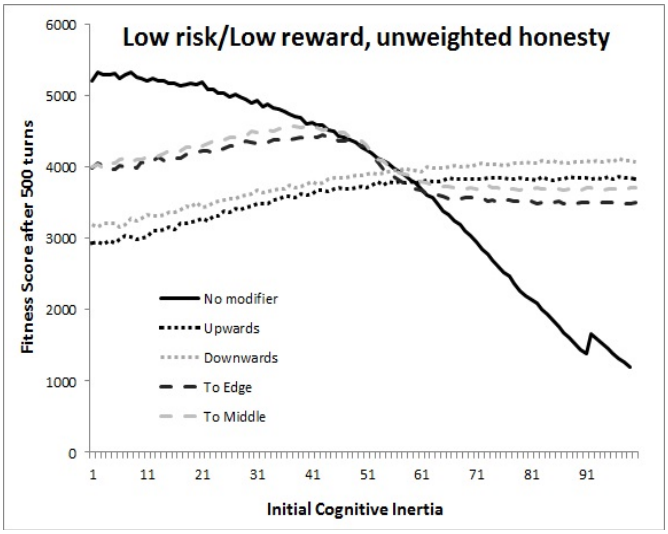

Figure 2: Comparison of inertia modification techniques in a community with random honesty

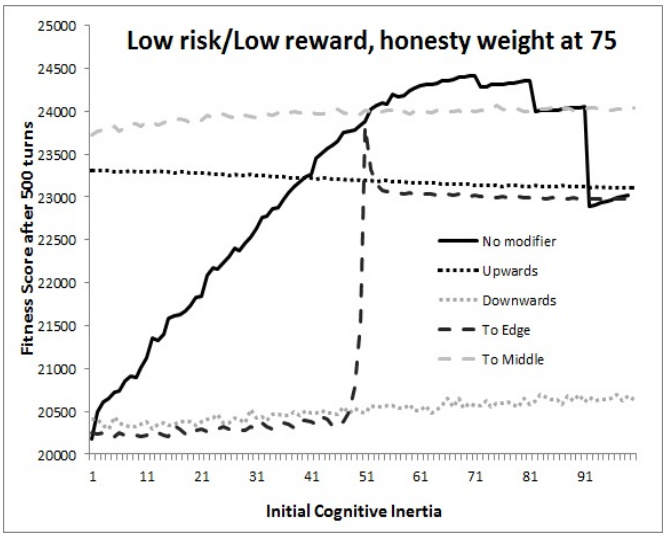

Figure 3: Comparison of inertia modification techniques in a community with honesty weighted towards 75

middle when a true statement is received and towards the edge when a false statement is received works best. This makes sense when considering that an ideal inertia value is slightly above 50, and most statements will be true.

However, other scenarios are less defined. Clustering scores to the edge or middle tends to provide adequate results, but linear pushes upwards or downwards tends to either be very good or very poor. Low risk/high reward scenarios tended to do poorly with linear movement, while high risk/low reward scenarios tended to do excellently with these formulas. As before, high honesty systems didn't follow this pattern.

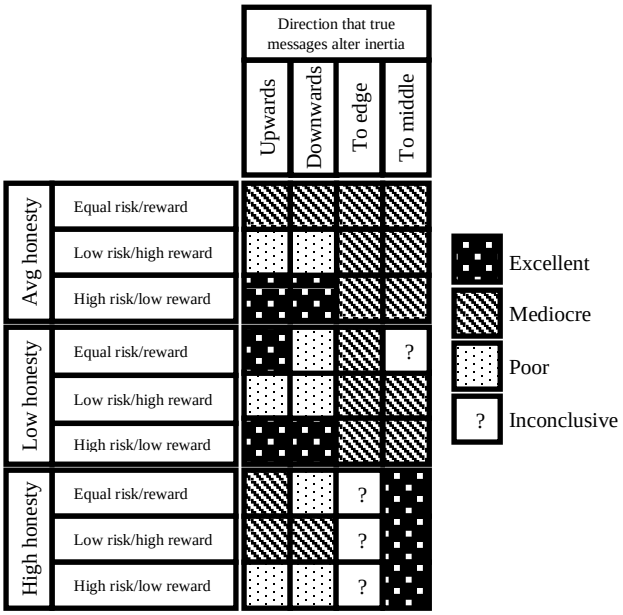

Figure 4: Summary of inertia modification techniques in various scenarios

5 Conclusions and future work

The simulations show that there are patterns in the data, suggesting that the notion of cognitive inertia is a valid method of adjusting trust in multi-agent systems. However, the anomalies suggest that a more complex representation is probably needed. For instance, agents may be better served by a trust vector, combining trust and cognitive inertia for each other agent in the system. Additionally, time may be a valid factor, with agents keeping track of how long they have held a particular trust in another agent. Another concept that may be of use is social distance [7] in which agents are not necessarily directly known to each other. Notions such as these could allow for new algorithms for adjusting trust inertia that might better serve the agents than ones presented here. Our future work in this topic will explore these possibilities.

Abstract–*Timely detection of disease outbreak events is of paramount importance for the defense against infectious diseases and biological threats. Internet-based communications can provide good situational awareness for countries where public data collection is inadequate, unreliable or missing. The key challenge is to sift through this vast amount of unstructured text to identify relevant reports and to extract disease related information into a structured format suitable for analysis. In this work, Natural Language Processing (NLP) techniques are used on data from news feeds, websites, and medical publications to extract key biological event data. We developed the Threat Assessment Dashboard (BioTHAD™) in order to improve detection and monitoring of biological events. We demonstrate that disease outbreak incidence and timing can be effectively extracted from open news sources using NLP. The BioTHAD™ application could serve as a model for tracking not only infectious, but chronic diseases and other types of events worldwide.*

Keywords: Biovigilance, Open Sources Based Surveillance, Disease Outbreaks, Natural Language Processing, Text Mining

1 Background and Significance

Most emerging infectious diseases and agents of bioterrorism present as nonspecific "flu-like illness," thus early detection requires the use of alternative sources of data rather than waiting for reporting of laboratory-confirmed diagnoses [1]. Because syndromic surveillance systems access and analyze data streams not typically available to departments of health, syndromic surveillance has the potential to identify unusual patterns of illness prior to definitive diagnoses and thus potentially closer to "real-time" than traditional surveillance systems [1]. Detection of aberrant activity using statistical tools to identify unusual spatiotemporal distributions of symptoms for further public health investigations augments traditional surveillance [1, 2, 3].

A rich source of data for bio-surveillance is the wealth of news articles posted to or available through the web. While widespread availability is a major advantage for these reports, the sheer volume of information routinely available on the web makes its utilization difficult. The detection of disease outbreaks and other potential biological threats is extremely challenging due to nuances of natural language used in news articles. Automated identification of relevant events would improve surveillance and increase research and response effectiveness. One approach to making that information more tractable for biovigilance community members is to automate the processing of news reports and to flag reports of potential interest, highlighting or tagging relevant elements within reports, and extracting data for subsequent analysis.

Extracting disease and biological event related information from unstructured text is a challenging problem because of the nuances of natural language [4, 5]. According to Kawazoe, et al., "in many cases, disease-related events are mentioned with verbs (e.g., 'infect'), verbal nouns (e.g., 'infection') and verb phrases. There are many synonymous event expressions; for example, infecting events can be expressed by many verbs and verb phrases such as 'infect,' 'transmit,' 'contract,' 'communicate (pathogen/ disease),' 'catch (pathogen/disease),' 'get (pathogen/disease),' as well as verbal nouns such as 'infection,' 'transmission,' 'contraction.'" Event recognition (in this case, finding reports about outbreaks of diseases) also occurs at the noun phrase ("outbreak of ...") and clause ("people died from ...") levels [4]. Also, sometimes, an infecting event is not mentioned directly, but only implied, as in a sentence like "A man died of bird flu" [6].

2 Approach

The BioTHAD™ technology has software agents that can be configured to monitor information sources such as news feeds, and medical publications on a daily basis. Currently, the BioTHAD™ technology monitors and downloads data from 15 sources including ProMed Mail [7], WHO, BBC Health News, CDC Morbidity and Mortality Weekly Reports, The Lancet Infectious Diseases, and BMC Infectious Diseases. HTML files are downloaded from these sites, text is extracted from these HTML files, converted to an XML format, and then processed by an NLP pipeline to extract the relevant information.

Figure 1 shows the process used to extract information from text sources. The first part of the process, shown in the top box, uses our in-house NLP pipeline. The steps involved in this initial part of the process are sentence boundary

detection, tokenization, part-of-speech tagging, phrase chunking, Subject-Verb-Object (SVO) assignment, clause segmentation and finally, named entity recognition. The first four steps internally use OpenNLP (http://incubator.apache.org/opennlp/), while the SVO assignment, clause segmentation and named entity recognition modules have been developed in-house. The SVO and Clause assignment stage involve splitting the sentence into clauses and finding SVOs in the sentence.

The main objective of the initial stages of text processing is to identify and classify the phrases which may be the constituents of event patterns. The steps shown in the green/top box are mostly domain-independent. The named entity recognition module recognizes generic named entities such as Persons, Locations and Organizations. On the other hand, the processes shown in the yellow/bottom box in Figure 1 are components that are domain-specific. The four components required are the domain concept tagger, event pattern matcher, inference of missing data, and data normalization. The following sections briefly outline each component.

2.1 Event Extraction

2.1.1 Domain concept tagging

The first step in domain event extraction (bottom box in Figure 1) is the Domain Concept Tagging. Unlike the named entity recognition module in the NLP pipeline (top box in Figure 1), the domain concept tagger tags concepts that are domain-specific. We identified the following items as key concepts associated with disease and biological events in the context of information extraction: Diseases, Symptoms, Pathogens, Antibiotics, Location, Date, Outbreak terms, Resistance terms, Victim Type and Severity. After identifying such domain-specific concepts, the extraction of domain-specific event frames becomes simplified. For example, the pattern 'disease killed victim' would match the string "cholera killed 7 inhabitants." In a similar fashion, noun phrases that could denote an unidentified disease will also be tagged. This helps to capture reports on outbreaks when the disease type is still unknown.

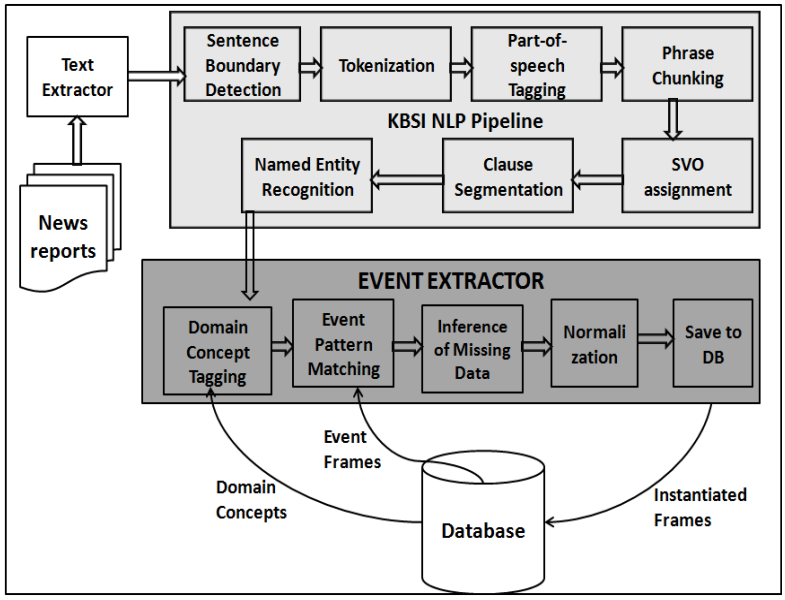

Figure 1. BioTHAD Information Extraction Pipeline

2.1.2 Event pattern matching

The next important step is the Event Pattern Matching which consists of feature extracting and the frame matching. The event pattern matching component will read all the pre-defined event patterns and compare them with the processed text to see if there are any matches. If a pattern is matched, an 'event' is generated

The Feature Extractor extracts relevant textual features that are generally very domain specific from the NLP output. Features such as noun phrases, disease, date, location, verb phrases, root form of verbs, etc., are extracted to produce a simplified representation of the processed text. This is illustrated in Figure 2.

Figure 2 shows an example of how text is processed as it proceeds through the various stages of the process. The input to the Feature Extractor is the tagged parse tree which comes from the NLP pipeline and the Domain Concept Tagger. By this stage, concepts such as disease and location have already been identified and appropriately tagged. The output of the Feature Extractor is:

NP SEGMENT(disease) + VP SEGMENT (surface) + PP SEGMENT (location)

The above feature vector means that this particular sentence contains the following components:

- A noun phrase which contains a disease, followed by,
- A verb phrase which contains the verb "surface," followed by,
- A Prepositional Phrase which contains a location.

The feature vector is then fed to the next module, the Frame Matcher. The Frame Matcher is the key module of the whole processing pipeline. Its main function is to match incoming feature vectors against a set of predefined event frames or templates. Figure 2 also shows the event frame that matches the feature vector from this particular sentence. One important input needed for this step is the repository of event frames that capture disease incidents in news report. The generation of these frames is described in more detail below.

The next step in the BioTHAD™ Information Extraction Pipeline is inferring missing data. Natural language is efficient and hence often key information is not explicitly mentioned because the human can infer it from the context. This is especially true for dates and locations.

2.1.3 Handling incomplete date specification

Heuristics are used to fill out missing or incomplete dates.

- Infer the year. Consider the example: "On 22 August the Ministry of Health (MoH) of the Central African Republic reported a laboratory confirmed case of yellow fever." To complete the date "22 August," the year from the published date is added to it.
- Infer the date from the context. Consider the example "Southern Missouri man dies of rabies." Since the date is completely missing from this sentence, it is assumed that the date is the same as the published date.
- Dereference the relative date. Consider the example "Southern Missouri man died of rabies yesterday." The actual date can be computed relative to the published date. Therefore, in this case, "yesterday" = Published Date - 1

2.1.4 Missing or ambiguous location information

Very often, an instantiated frame does not contain a location. In addition, many frames that do contain an explicit reference to a location, the source text does not contain the context of that location; whether the location is a city, a state or a country. For this reason, it is necessary to tag these three categories based on lookup lists. We created a lookup list of countries and in the case of the United States, the list also includes cities and states. The location lookup list is used to resolve a location and identify its country or state.

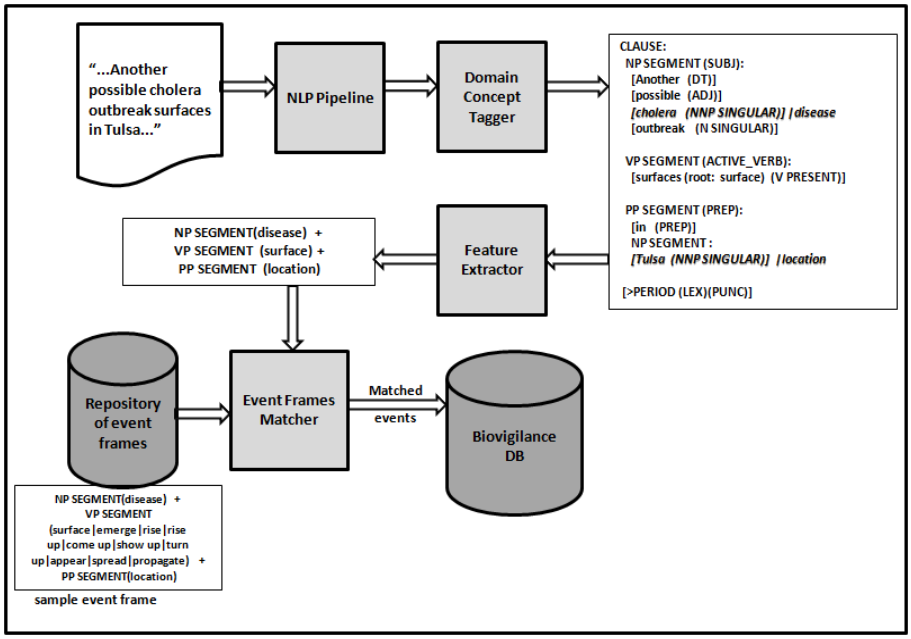

Figure 2. Text Processing and Event Extraction Process

2.1.5 Data Cleaning and Normalization

Once an event is generated, some of the instantiated event slots will need to be further refined or cleaned to generate consistent information. The following examples illustrate the need to normalize the data before saving the instantiated event to the database.

- Dates and date expressions (including dates relative to the report time, such as "last week") should be normalized to a standard form, with explicit day, month, and year.
- One disease could have many names. We designate one canonical name for each disease and normalize all

variants to that standard e.g., "Ebola," "Ebola hemorrhagic fever," "EHF."

- Similarly, some countries have many names; therefore, there is a need to normalize country names, e.g., "U.S.A.," "U.S.," "United States."

Further analysis of the stored data using techniques such as data mining will be performed on this atomic event extracted from the text.

After the frames are extracted, the information extracted undergoes further processing. This involves data cleaning and data filtering.

Open sources like news feeds and medical publications often have information related to statistical updates and summaries, prevention, negative outbreaks (i.e., documents reporting that an outbreak is abating) and reports about general information related to drugs and research, in addition to reports about disease incidents. It is necessary to filter out reports that have information content other than disease incidence reporting. We detail some of the types of filtering and aggregation below.

a) Filtering reports on statistical updates: Reports that provide information about statistical updates, such as total count of cases for a specific disease for a whole year and the worldwide situation of specific diseases are filtered out. This elimination consists of two steps. The first step removes reports that contain the pattern "update yyyy" and "world-wide" in the title. The second step filters out reports that contain the word "update" in the title and more than three locations in the text. Another example of statistical updates is temporal generalizations. For example, "Every year, cholera causes 100 deaths in Zimbabwe." Such instantiated events containing repeating time intervals are filtered out.

b) Filtering reports on prevention: The second type of report that has nothing to do with the outbreak of diseases is prevention related reports. After going through some sample reports on prevention, a list of keywords was created to denote that a report concerns prevention.

c) Filtering reports on multiple diseases: It was also decided that reports that discuss multiple diseases could potentially be noisy reports for the purpose of disease incidence detection. Therefore, these are also filtered out based on the number of diseases extracted from the text. To date we have not processed any report that contained more than three instances of a disease in the text.

d) Filtering reports on negative outbreaks: Another category of documents that must be filtered from the repository is negative outbreaks; i.e., documents reporting that an outbreak is either abating, or being controlled. A report is considered to fall in this category if the title contains one or more of the following words or phrases: under control, is over, waning, officially over, eradicate, recover, etc.

e) Filtering reports on drugs and medical research: Finally, another category of documents to be filtered out from the repository was reports focused exclusively on pharmaceutical and medical research. Reports whose titles contained any of the following concepts were eliminated: research, experiment, drug testing, pharmaceutical research, etc. Some of the reports eliminated might contain important information like approval of a drug or vaccine for a pandemic, but it is not within the current scope of the BioTHAD™ technology and those reports are filtered out.

2.1.6 Spatio-temporal aggregation

Since the disease outbreak information is being extracted from multiple sources, it is likely that multiple records are generated for the same incident by different sources. It is also possible that the same source reports information about an incident over multiple days. While displaying situation awareness information to analysts, the multiple incidents are aggregated and presented as single, major events. The aggregation is based on spatio-temporal proximity. Link list and nearest neighborhood-based clustering techniques are used to form the aggregate events [8, 9, 10].

3 Results

We validated the effectiveness of our approach against well known disease outbreaks. We present results from two of the validation studies in this section. The first analysis was to verify the data against the Haiti cholera outbreak that began in late October 2010 following the earthquake that shook the country in January 2010 [11]. The date range of the cholera outbreak events in Haiti extracted from news reports is shown in Figure 3 along with the actual date range of the outbreak as reported by CDC. The timeline analysis reveals that the date range of the extracted events coincides very well with the recorded date range for the 2009-2010 Haiti cholera outbreak.

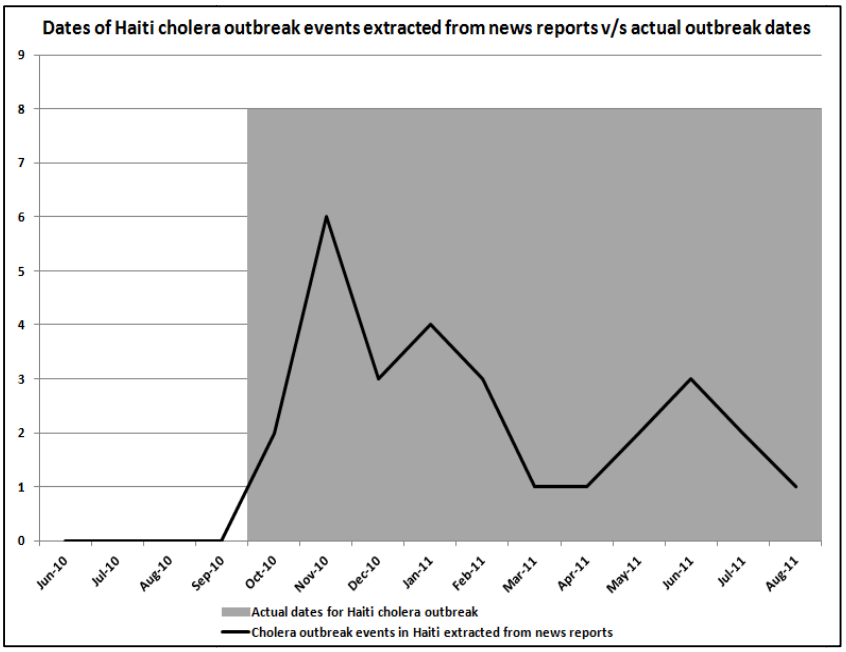

Figure 3. Trend of Cholera Outbreak in Haiti

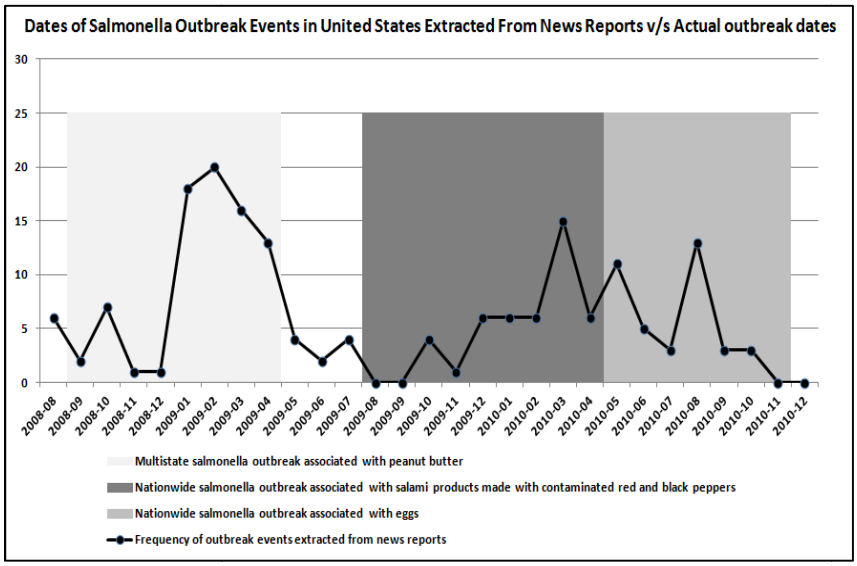

Figure 4. Salmonella Outbreak Events in the United States Extracted From News Reports

The next objective was to verify the trend for salmonella outbreaks in the United States. For this analysis, the date ranges of the extracted disease outbreak events were compared to three different known outbreaks of salmonella in the United States. The results of this comparison are illustrated in Figure 4, which also shows the three different actual salmonella outbreaks, namely:

- Multistate salmonella outbreak associated with peanut butter [12],
- Nationwide salmonella outbreak associated with eggs [13], and
- Nationwide salmonella outbreak associated with salami products made with contaminated red and black peppers [14].

Figure 4 shows a fairly close correlation between the three known outbreaks with the date ranges of the extracted disease outbreak events for salmonella in the United States.

4 Conclusion

Timely detection of disease outbreak events is of paramount importance for the defense against infectious diseases and biological threat events. News reports and medical publications of diseases and biological events are a

valuable source for collecting and organizing information regarding potential disease outbreak around the world. We present the methodology for extracting disease and biological events from open sources. In this paper, we have presented the design and implementation details of Biovigilance Threat Assessment Dashboard (BioTHAD™) that implements this capability. The BioTHAD™ technology provides good situational awareness into the status of disease and biological events across the world and is capable of detecting diverse biological events from open source reports. Analysis supported by the BioTHAD™ technology includes spatio-temporal aggregation and time-line visualization of disease outbreaks. Our approach is validated using a number of known disease outbreaks in recent years.

The BioTHAD™ technology is very effective in extracting disease incidents and their timing and has the potential for broad applications to the early detection and monitoring of not only infectious diseases, but chronic diseases and other events of national and global importance to biosecurity. We are currently validating and refining extracting victim counts and plan to extend our approach to extracting the etiology and nature of disease outbreaks (endemic, nosocomial, community acquired, etc). Another future direction is to design and develop a user interface for epidemiologic analysis and validation of intermediate results from BioTHAD™.

Abstract—*Amblyopia is a neurological vision disorder that studies show affects two to five percent of the population. Several early screening procedures are aimed at finding the condition while the patient is a child, including an automated vision screening system developed by Cibis, Wang, and Van Eenwyk. The system uses artificial intelligence software algorithms to achieve a 77% accuracy in identifying patients who are at risk for developing the amblyopic condition and should be referred to a specialist. Based on later work, two additional feature sets are also extracted from the same data captured with the AVVDA system, both achieving a 67% accuracy. This work explores the application of a multi-classifier collaborative learning architecture on the three data sets. The architecture has been shown to be more successful in problems that exhibit difficulty for single pass classifiers.*

Keywords: Multi-Classifier, AI in Medicine, Applied AI, Lazy Eye, Amblyopia.

1. Introduction

Eye trouble of organic origin must be diagnosed and treated before the onset of an irreversible amblyopia or what is commonly referred to as lazy eye. This condition is a developmental disorder of the visual system caused by ocular abnormalities early in life. While surgery or optical correction of refractive errors can often address the initial cause of amblyopia, once amblyopia has developed, such interventions cannot restore visual function since amblyopia itself is a cortical deficit, a neurological disorder and not a physical one [1]. Amblyopia has two primary causes, namely, strabismus and anisometropia. Strabismus is a misalignment between the two eyes. Anisometropia is when the refractive error between the two eyes is different [2]. The reason that these two conditions can lead to amblyopia is because they cause the brain to begin ignoring the signals from the weaker or blurrier eye. Corrective action after amblyopia has developed becomes problematic, as the brain will not be able to regenerate the neural pathways. Thus, early detection is essential for the patient to have a healthy visual outcome. Fortunately, amblyopia can be successfully treated if identified when the patient's brain is still in the developmental stages, generally when the patient is fewer than six years old, with the non-controversial methods of glasses and patching therapy achieving 80 to 90% effectiveness [3].

The optimal solution for vision diagnosis would be a self-contained, low-cost, completely automated system that could accurately identify disorders with minimum operator training and low patient cooperation. The solution would need to enable widespread use with small children, including infants. One approach for this sort of solution is based on [4], [3], pioneering the science of analyzing images for identifying features that may indicate the development of amblyopia, and using artificial intelligence techniques to automate the process [5].

1.1 Problem Statement

In this work, we utilize a multi-classifier machine learning architecture consisting of a heterogeneous mixture of classification techniques in a team of intelligent agents. This architecture is applied to the problem of accurately identifying the amblyopic condition using three existing data and feature sets. The effort looks to make use of both ensemble and single classifiers on the data sets in order to ascertain the best features for identifying and referring patients to a specialist.

The previous work involved reviewing each individual data set on it's own merits with a subset of classifiers, but here the work looks to take a larger view of the features by measuring them in relation to a number of classifiers. Results between the approaches are compared and conclusions drawn about the efficacy of the feature sets, applied to a variety of classifiers, as well as a multi-classifier decision fusion methodology in the vision diagnosis domain.

2. Background and Related Work

2.1 Vision Disorders

Amblyopia is the primary vision disorder this research attempts to accurately identify. It has two primary physical

causes, anisometropia and strabismus. Anisometropia is a condition where the refractive error in one eye is significantly different than the other. The difference in the refractive errors is difficult to overcome for a developing visual cortex, primarily due to the very different images being presented. Studies have shown that anisometropia is the predisposing condition that leads to amblyopia 50% of the time, and that an undiagnosed anisometropia will lead to strabismus [2]. Strabismus can be identified as a misalignment of the focal point between the two eyes, but the condition is not always identifiable with the naked eye and may require a thorough screening. Strabismus typically involves a lack of coordination between the two eyes and the extra-ocular muscles where the patient is unable to bring both eyes into focus on the same point in space, thus preventing proper binocular vision.

Both of these physical abnormalities in the eye have the potential to cause the development of a patient's visual function to be impaired and cause the image from the amblyopic eye to be disregarded by the visual cortex. If the condition is allowed to persist, the neural pathways become permanently formed and the use of the amblyopic eye is diminished. The degree to which it is diminished varies based on how early the condition developed in the patient's life and if any remediation treatment was used [2].

2.2 Automated Photo-Refractive Screening

Photo-refractive screening is based on a system to interpret the images of the eyes. It does not directly identify amblyopia, but it looks for defects in the eyes that may lead to amblyopia. One such system for identifying strabismus and amblyopia using video images, called Video Vision Development Assessment (VVDA), has been developed [3]. The method involves a consumer-grade video camera with a light source attached to the base of the camera. The patient sits approximately 52 inches from the camera and looks at the light source while approximately two minutes of video is recorded. The video is then digitized and analyzed by specialists or trained technicians to determine if the patient should be referred to a specialist. This processing is generally divided into frame selection and feature extraction.

More recently, research has been performed in order to automate the analysis of the frames using artificial intelligence techniques [6], [4], [5]. These works focused on implementing the image processing and Case-Based Reasoning [7] algorithms that constituted the first version of the Automated Video Vision Development Assessment (AVVDA) system. In a completely automated fashion, they were able to identify the key frames of the video, isolate the pupils, and locate the Hirschberg point [6], [4]. Figure 1 shows the image output from the AVVDA system, where the Hirschberg reflex and iris diameter are highlighted. The automated photo-refractive screening system works by having an operator take a short video of the patient, which is then analyzed automatically by the software in the following manner. Initially, the software identifies the frames where both eyes are open and looking at the light source. These frames are identified as key frames. Next, the software isolates the location of the eyes and pupils in the key frames. Finally, the software uses various techniques to extract the distinguishing features that may be indicators for amblyopia.

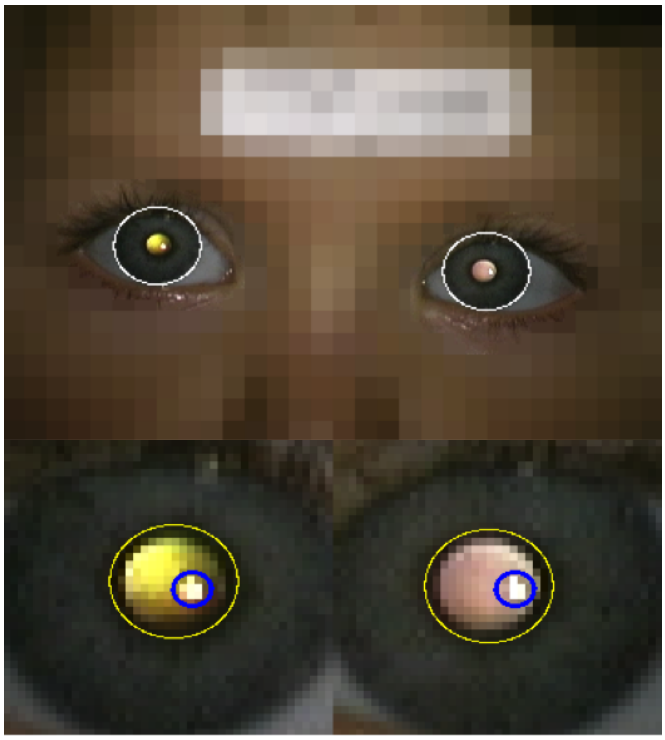

Fig. 1: Key frame output from the AVVDA system [5]

In order to further enhance AVVDA, researchers have investigated using the same feature set with a different set of classifiers, with the overall goal of the AVVDA system being to allow an unskilled technician to operate the system and accurately obtain a decision about patient referral to an optometrist or ophthalmologist [5]. In the current form, AVVDA uses Case-Based Reasoning [7], C4.5 Decision Tree [8], and Artificial Neural Network [9] classifiers to assist in making the decision. 54 features are extracted from the images to train the classifiers.

At this point, various artificial intelligence techniques have been utilized to automatically produce the referral to a specialist [3], [5]. The results reported in this work expands upon the automated photo-refractive screening method, with the goal to evaluate other classifiers, and the use of multi-classifier ensembles, as a means to produce more accurate results from the same feature set.

2.3 Combining Decisions from Multiple Classifiers

Classifier combination is an area in machine learning that has offered advances in classification accuracy for complex data sets. It has been termed differently in the literature, namely, classifier fusion, mixture of experts, committees, ensembles, teams, pools, collective recognition, composite systems, etc. When predictions from multiple classifiers are combined, they are said to form an ensemble that is then used to classify new instances. Several methods have been developed to combine classifiers, the most popular of which are voting, boosting, bagging, and stacking.

One of the primary questions in this area of study is whether combining classifiers is better than selecting the best classifier. Several works support that classifier combination provides an improvement in most cases, assuming that the classifiers exhibit reasonable individual accuracy. One such study utilized stacking with model trees to combine multiple heterogeneous learners [10]. Each learner utilized the full data set to produce a base-level model, the output of which is then combined with other base-level models using a meta-level classifier. Their results also indicated that the number of base-level classifiers did not significantly affect the results. Similarly, [11] found that when using voting and entropy methods as the heterogeneous classifier combination mechanism for word-sense disambiguation, increasing the number of less accurate classifiers adversely affected those with higher accuracy. Use of more classifiers, even if heterogeneous, does not always translate to better results. Depending on the combination method, the relative impact of adding classifiers can diminish as team size increases. Our work attempts to address this by implementing a framework where team configurations can be analyzed to determine what factors make a team of classifiers successful given the application and domain.

Although selection of the best individual classifier is easier and occasionally effective, combination techniques scale better to larger and more complex learning problems. Even combining all classifiers in an ensemble can be improved upon by selecting for combination only those that perform significantly better than others, termed Selective Fusion [12]. Using this technique, together with simple voting methods, enables the fine-tuning of diverse ensembles for specific data sets. It also offers performance comparable to other heterogeneous classifier combination methods such as stacking, without the additional computation and meta-learning costs. Researchers have studied the effectiveness of switching between selection (occurring in regions of the feature space where single classifiers are dominant) and fusion (occurring in every region not dominated by a single classifier) [13].

Other efforts have studied the use of training multiple classifiers on different feature subsets prior to their combination [14]. Focusing on differing and potentially overlapping feature subsets creates additional diversity, which could lead to an improved combined model. Some researchers also found that performance degradation occurs as the percentage of training batches (sets of training examples) overlap [15]. Multi-classifier systems offer a medium for additional study on how knowledge from classifiers with different, potentially overlapping feature and data subsets can be combined. Interaction between the classifiers during the training process may prove to increase learning efficiency, robustness, and accuracy.

3. Research Methodology

This section covers the research methodology followed to analyze and measure the utility of single- and multi-classifier configurations on a set of established features derived from 723 unique patients.

3.1 Features

We study three distinct feature sets in this work. Each originates from the same raw data, but represent three separate concepts on where the necessary data holding the predictive information is to be found. Previous experiments were performed on these data sets using a small set of individual classifiers. Therefore, the goal is to compare the results of various classifier configurations with the original published results.

3.2 The Multi-Classifier Collaborative Learning Architecture

The WEKA machine-learning suite is utilized as a base for the implementation of the proposed Multi-Classifier Collaborative Learning Architecture [16]. The primary uses of WEKA in this architecture are to prepare the data for experimentation and provide implementations of various classification algorithms. Additional Java and script/batch file implementations act as a wrapper for machine learning experiments involving single or multiple classifiers (i.e., for teams of any size), homogeneous or heterogeneous team composition, independent or collaborative learning (with the ability to vary the number of collaboration events during learning), and combining the decisions of the classifiers using a variety of accuracy- and vote-based combination techniques. This offers a robust and flexible architecture for machine learning studies involving multiple, collaborative learning agents.

The Multi-Classifier Collaborative Learning Architecture was utilized to study single- and multi-classifier machine learning configurations for the patient vision data set. By default, each classifier is provided a randomized version (different order of instances for each classifier) of the full training data set. Model creation takes place by training each classifier using the training data set. At this time, each classifier tests its model on the data on which it was trained. Once training is complete, the testing data set is passed

through each classifier's model and the corresponding class probabilities (predictions) are recorded. The final individual testing predictions are then used for combining decisions from multiple classifiers. This acts as the final collaboration step, which fuses the knowledge from multiple classifiers to a single team classifier via accuracy- and vote- based mechanisms.

Decision combination utilizes each classifiers decision/label for each testing instance to arrive at a single team classification per combination method. A classifiers decision consists of a probability that the testing instance belongs to each of the possible classes. The highest probability represents the predicted class for each classifier. The Multi-Classifier Collaborative Learning Architecture calculates team classification accuracy for each of the 12 implemented vote-based combination methods. The combination method resulting in the best classification accuracy is selected, reflecting the overall performance of the team. For a detailed discussion of the 12 vote-based combination methods used for evaluation, consult [17].

While the original architecture offers a number of vote-based methods to be used for combining classifier results for evaluation [17], this research endeavor utilized only the Average method. The Average method averages all predictions for each class from all the classifiers, selecting the class with the highest average value. The class selected by the classifier with the highest accuracy on the testing data breaks a tie.

4. Experiments for Three Feature Sets

4.1 Experimental Setup

The experimental studies followed the process of a series of rounds based on classifier performance. As long as the results of some classifier in the round exhibited reasonable improvement over the previous work, then team configurations exhibiting the highest testing accuracy move on to the next experiment, where larger teams are constructed from the best teams from the previous experiment.

In all experiments the classifiers are provided with the full training portion for model creation, and no collaboration events occurred. The reasoning behind this decision is to keep the experiments focused on measuring machine learning algorithm and decision combination performance without reviewing the effect of collaboration and independent learning. Further work could be done to measure the effect of those additional configuration options of the architecture.

The first step for a specific data set is to coarsely test a variety of individual machine learning algorithms, each with a few settings and initialization seeds, to determine which algorithms perform well in general for the data set. The best settings and corresponding 10-fold cross-validation testing accuracy for each algorithm are recorded, and the top four algorithms are selected to advance to the next experiment.

The next step is to evaluate a team four classifiers in four different configurations. This inherently includes homogeneous and heterogeneous team compositions. The same process takes place for teams of size eight, where the top teams of size four are selected to advance to the experiment of size eight teams. The same process is used with the results of the size eight teams to construct the final sixteen-team experiment. Once the experiment of size sixteen teams is complete, all results are compiled and analyzed.

It is important to note that because this work is primarily a comparison of feature sets, an exhaustive multi-classifier experiment set is not performed. Rather, the methodology looks at a shallow set of initial experiments to determine if further classifier fusion is worth pursuing based on an improvement in overall accuracy. This phased experimentation process results in running fewer round one experiments for Experimental Data Set 1, and more round one experiments Experimental Data Set 2 and Experimental Data Set 3. This is because positive results are discovered early in the Experimental Data Set 1.

In addition to differences in round one, the methodology further results in all three feature sets not following to the final sixteen-team experiment. Since this work investigates the efficacy of the three feature sets for identifying the amblyopic condition, when the results in the early rounds do not advance the state of the previous work, all the rounds are ended and the results are presented.

4.2 Experimental Results

This section presents the experimental results from a variety of machine learning configurations for the three patient vision data sets. The notation used in the subsequent figures and analyses are abbreviations of machine learning classification algorithms. The abbreviations for the ten utilized classification algorithms are: Decision Table (DTB) [18], Decision Tree (DT) [8], Instance-Based KNN (IBK) [19], Logistic Regression (LGR) [20], Naive Bayes (NB) [21], PART Rule Learner (PRT) [22], Random Forest (RFT) [23], Radial Basis Function Network (RBF) [18], RIPPER Rule Learner (JRP) [24], and Support Vector Machines (SVM) [25]. The reader is referred to the referenced papers for the algorithms and details on their underlying structure and theory.

When listing team compositions, the number of classifiers for each algorithm of the team is listed, separated by +. For example, 3IBK+2PRT+2DT+1LGR represents a team of size eight composed of three IBK, two PRT, two DT, and one LGR classifiers.

A total of 39 machine learning experiments were performed, including the variation of team size and composition. Experiments are broken down as follows:

- 29 size one
- 4 size four
- 3 size 8

- 3 size 16

4.3 Experimental Data Set 1: Color Density and Hirschberg Reflex

The first experimental data set finds its genesis in previous work from Wang and the original AVVDA system. A total of 54 key features of patients' eyes (27 features per eye) were extracted from the video feeds and key frames. The two primary features are the pupil radius and the degree of fixation based on the Hirschberg point. The remaining 25 features for each eye are calculated using the color of pixels within 80% of the radius of the pupil. This includes, for example, the average red, green, and blue values throughout the pupil. The reader is referred to [4] for additional details on how these values are calculated. These 54 features for each of the 723 patients and all of the identified key frames were used as input into the multi-classifier architecture.

As described in the previous section, many classifiers where tested on the data set, both single and combined. As a result of the experimental process, the best outcome was distilled to 16 Random Forest classifiers. We can investigate the initial outcome of the four rounds of experiments by reviewing table 1. The results show increasing improvement as the rounds advance (i.e., team size increases), and ultimately show the best results were achieved with a homogeneous, 16-classifier configuration.

In contrast, the results of the AVVDA system represent the original research and cover single instance Case-Based [7], Artificial Neural Network [9], and Decision Tree [8] classifiers. Table 2 is a summarization of the results for comparison, and shows that the use of a multi-classifier decision combination approach improved accuracy and specificity at the cost of sensitivity.

4.4 Experimental Data Set 2: Iris and Pupil Color Slope with Middle Stack Key Frame Selection

The second experimental data set is based on the work of [26]. It utilizes the same 723 patient videos but instead extracts a different set of frame and feature data. The difference begins with the key frame concept. In the previous experiment, a patient will have typically produced many key frames. As described in the Related Work section, the software identifies a key frame based on two primary criteria. First, the patient must have both eyes open. Second, the patient must be looking at the light source so that a reflection off of the retina is clear. From the key frame stack identified for a patient, a single frame is then selected. In the second experiment, the research takes a very simple approach to identify the single frame that will be used for feature extraction. It selects the frame from the middle of the stack of frames. If there are an odd number of frames, it selects the frame that is a whole number division of the entire frame count by two. The goal is to avoid the fringe frames (the first or last), and analysis of a subset of the data shows that the middle frame has the greatest chance of being one of the best images [26].

Now that a frame is selected, the color information is extracted from the image starting at the edges of the iris for both the left and right eyes. The red, blue, and green information is extracted from the eye image in a left to right pattern, representing the rate of change of color across they eye, or color slope. This is illustrated in figure 2. The key frame for each patient is then further processed to produce 552 color features.

Experimental results using the iris and pupil color slope data set are summarized in table 3. The results do not show

Table 4: Comparison of results achieved by the Multi-Classifier Collaborative Learning Architecture on the initial color slope data set.

System	Accuracy (%)	Sensitivity (%)	Specificity (%)
Multi-Classifier Collaborative Learning Architecture	64.73	73.97	50.53
AVVDA Pupil and Iris Color Slope	67.91	82.42	45.61

an improvement over the previous work when the data was applied to a number of classifiers in the Multi-Classifier Collaborative Learning Architecture. The best single classifier from the architecture was the Support Vector Machine with improved specificity at the cost of both sensitivity and accuracy.

In contrast, the results of the work presented by [26] represent the original research and cover single team Decision Tree, Neural Network, and Random Forest classifiers. Table 4 exhibits the summarized observed results using the iris and pupil color slope data set.

Notably, when reviewing the preliminary single-classifier results from the Multi-Classifier Collaborative Learning Architecture on data set two, the results did not warrant further classifier ensembles. The reasoning behind this decision is that the results were not coming reasonably close to the accuracies achieved with data set one. Since this work is to investigate the best features for identifying the amblyopic condition, the results did not advance data set two and did not improve on previous work.

4.5 Experimental Data Set 3: Pupil Color Slope with Level Key Frame Selection

The third experimental data set is also based on the work of [26]. Utilizing the same initial set of 723 patient videos, the goal is to find the best patient and frame sets for selecting a frame. The set of key frames is still identified as described in the Related Work section. However, the frame selection process was altered so that a method different from selecting the middle frame is utilized. In this case, the frame selected out of all the key frames is that where the patient's head is most level. Since the entire classification problem is centered on the reflection of light off the lens and the retina, keeping the angle of reflection the same for both eyes would, theoretically, further enhance any differences between a healthy eye and the eye of a patient who should be referred to a specialist. The important features extracted around the crescent reflection and the Hirschberg point that is measured from that crescent further support this concept. The frame that is most level is determined by the pixel location of the center of the pupil at the Y-axis. The value is compared between the two eyes for each key frame, and the frame corresponding to the closest value is selected. When no key frame could be found where the difference in the height of the eyes was less than five pixels, then the patient data was discarded. The data was discarded so that the classifiers would not be trained with imperfect data and in hopes of further isolating the features that will yield the best results. This process reduced the number of patients in the entire sample from 723 to 499. The key frame is then further processed to extract color data from the pupil only. This process produced 180 features for each patient. Figure 3 illustrates the feature vectors extracted.

Experimental results using the pupil color slope data set are summarized in table 5. The results exhibit similar results

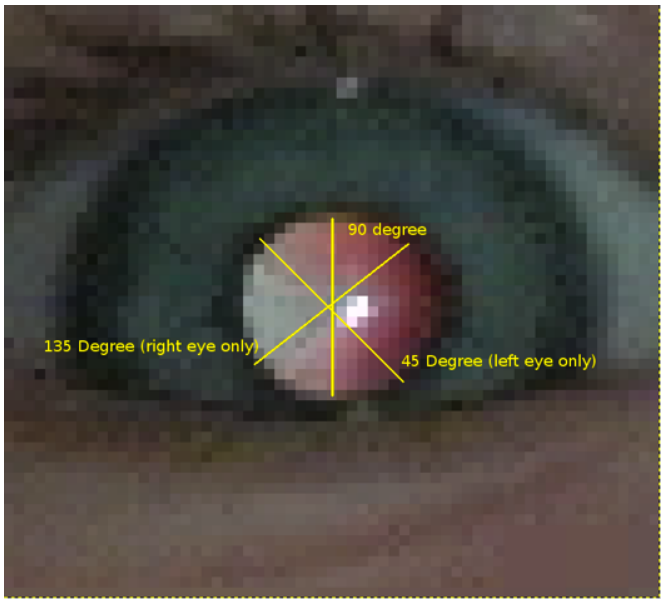

Fig. 3: Illustration of pupil color slope. [26]

as the experimental data set two, an improved specificity at the cost both accuracy and specificity. The best overall result from the Multi-Classifier Collaborative Learning Architecture was from a support vector machine.

In contrast, the results of the work presented by [26] represent the original research and cover single team Decision Tree, and Random Forest classifiers. Table 6 exhibits a summary of the observed results using the pupil color slope data set.

Notably, data set three also does not exhibit reasonable improvement over the data set one to warrant further classifier combination. The reasoning behind this decision stands the same as the experiment two results, lack of reasonable improvement over data set one, and previous work.

Table 5: Results from the experimental study performed using the Multi-Classifier Collaborative Learning Architecture on the pupil only color slope data set.

AVVDA Pupil Color Slope	67.94	37.31	87.25

5. Conclusion

The primary contribution of this work is to take an existing problem, analyze three feature sets produced and find the most predictive set for accurately classifying the markers for the amblyopic condition. The feature sets were processed through a Multi-Classifier Collaborative Learning Architecture system, producing results for many classifiers, some single and some ensemble. As observed in the Experimental Results section, the original AVVDA features were improved upon as the experimental rounds progressed, thus showing promise for the ensemble classification method with certain data sets.

In contrast, the color slope experimental data sets performed worse using the Multi-Classifier Collaborative Learning Architecture. This suggests that the features are not only difficult to use for classification, but do not hold much predictive ability when presented with new patient instances.

Therefore, the results further the understanding of the predictive ability for the given data sets. Notably, of equal contribution to the vision assessment work is to illustrate that there may have been a limit reached in the classification ability of the selected color density, Hirschberg reflex, and color slope features. This conclusion is further supported by the success seen in previous work with the Multi-Classifier Collaborative Learning Architecture against challenging classification problems, and its ability to improve results over previous work on the difficult data sets [17], [16].

Identifying "Comment-on" Citation Data in Online Biomedical Articles Using SVM-based Text Summarization Technique

In Cheol Kim*, Daniel X. Le, and George R. Thoma

Lister Hill National Center for Biomedical Communications
National Library of Medicine, 8600 Rockville Pike, Bethesda, MD 20894

Abstract - *Comment-on (CON), a MEDLINE® citation field, indicates previously published articles commented on by authors expressing possibly complimentary or contradictory opinions. This paper presents an automated method using a support vector machine (SVM)-based text summarization technique that identifies CON data by distinguishing CON sentences from "citation sentences" and analyzes their corresponding bibliographic data in the references. We compare the performance of two types of SVM, one with a linear kernel function and the other with a radial basis kernel function (RBF). Input feature vectors for these SVMs are created by combining five feature types: 1) word statistics, 2) frequency of occurrence of author names, 3) sentence positions, 4) similarity between titles, and 5) difference of publication years. Experiments conducted on a set of online biomedical articles show that the SVM with a RBF is more reliable in terms of precision, recall, and F-measure rates than the SVM with a linear kernel function for identifying CON.*

Keywords: "Comment-on" identification, online biomedical documents, support vector machine, MEDLINE

1 Introduction

MEDLINE is the premier bibliographic online database of the U.S. National Library of Medicine (NLM) containing more than 20 million citations from over 5,500 selected worldwide biomedical journals, and accessed through NLM's PubMed service. With rapid growth of biomedical literature, both the number of journals indexed and the number of citations produced by NLM increase dramatically; 130 journal titles are newly added each year on average and nearly 700,000 citations were added to MEDLINE in 2010. Bibliographic citation data describing the article consists of more than 50 fields such as author names, article title, affiliation, etc. Currently, the majority of data for these fields are provided electronically in XML format from journal publishers. However, publishers leave out data for several important fields: Databank accession numbers, Grant supports/numbers, Comment-on/Comment-in, and investigator names, almost certainly because including these fields would be highly labor-intensive and costly. As manual extraction and entry of bibliographic data missing from publisher-provided XML files would be equally burdensome for NLM, there is a strong motivation to develop automated systems to minimize human labor and to provide bibliographic data accurately and in a timely fashion.

The Lister Hill National Center for Biomedical Communications (LHNCBC), a research and development division of NLM, has developed an automated system—the Web-based Medical Article Records System (WebMARS) that analyzes and extracts bibliographic information from online biomedical journal articles to create citations for MEDLINE [1][2]. This paper presents one of the major components of WebMARS, an automated method for identifying and extracting "Comment-on" (CON) citation data. CON is a field in a MEDLINE citation listing previously published articles commented on by authors of a given paper in a complimentary, or sometimes contradictory, manner. We refer to the "Commented on" articles as CON articles, and the papers in which such opinions are expressed as "Comment-in" (CIN) articles.

Manually extracting the CON list from a given article is time-consuming and labor-intensive, and relies heavily on human operators' linguistic knowledge and their understanding of scientific expressions and writing styles. Generally, authors of a CIN article cite CON articles related to their research as primary external sources on which they may express complimentary or contradictory opinions. Thus the full bibliographic descriptions for these CON articles can usually be found in the reference section of a CIN article. Furthermore, all external sources (journal articles, books, or Web links) listed in the reference section of the CIN paper are generally mentioned at least once within sentences ("citation sentences") in the body text.

From this observation, our idea of identifying the CON list for a given article is to recognize the sentences ("CON sentences") that mention CON articles from the "citation sentences" in the body text using a support vector machine (SVM)-based text summarization technique and analyze the corresponding bibliographic data in the reference section. In our research, we implemented two types of SVMs: one with a linear kernel function and the other with a radial basis function (RBF), and compared their performance in terms of precision, recall, and F-measure rates. Five types of features were employed to create an input feature vector for these SVMs: 1) word statistics representing how differently a word is distributed in CON sentences and other "citation sentences", 2) frequency of occurrence of author names of external sources listed in the reference section of a given input article, 3) sentence positions within an article body text, 4) similarity of titles between a given input article and external sources, and 5) difference of publication years between an input article and each external source.

2 Related work

CIN articles are usually short papers such as commentaries, letters, editorials, or brief correspondences, written mainly for the purpose of supporting, refuting, or discussing other articles (CON). Accordingly, a sentence specifically referring to a CON article, called a "CON sentence", can be considered a key part of a CIN article because it is indicative of the article's subject and purpose. Detecting and extracting such key sentences within a document is a text summarization task. A summary can be loosely defined as text that conveys important information in the original text(s) and is a condensed representation (no longer than half) of the original text(s) [3]. Automated text summarization is the process of automatically constructing a summary for an input text. This summary can either be an "extract" created by merely reusing portions of the input text such as phrases, sentences, or paragraphs that are likely to be most important, or an "abstract" that is a newly generated text after an analysis of the original text.

Since creating such an abstract requires the high complexity of natural language processing techniques and knowledge engineering technology, most text summarization studies have focused on the extraction-based method. Our task of identifying CON sentences from the body text of CIN articles can also be considered as a typical extraction-based text summarization method. Text summarization has been addressed by a variety of methods and applied in different domains and genres of documents. Most early studies were based on surface-level features that do not require linguistic analysis, such as word frequency, paragraph or sentence position, and cue phrases to determine the most important concepts within a document [4][5][6].

There is another group of studies that builds an internal representation of the text by modeling text entities and their relationships to determine salient information. For example, Barzilay and Elhadad [7], and Silber and McCoy [8] employed lexical chains representing semantic relations between words to generate a summary of the original document. In addition, an approach exploiting the global structure of the text such as document format, rhetorical structure, etc. has also been reported [9][10].

All these aforementioned approaches can be implemented as either linguistic knowledge or machine-learning techniques. Linguistic knowledge-based methods that try to semantically analyze the structure of the text involve very sophisticated and expensive linguistic processing. Therefore, most methods employed in the recent literature are based on statistical theories and machine learning techniques; e.g., Naïve Bayes [11], decision tree [12], neural networks [13], hidden Markov models [14], and SVMs [15].

3 CON and CIN articles

CIN and CON articles are indicated in MEDLINE citation fields as "Comment in" and "Comment on" respectively, and linked together. As an example, Fig. 1(a) is the MEDLINE citation of an article (CIN) in which a "Commented on" article is cited. This CON information, shown enclosed in a dotted box, consists of abbreviated journal title, publication year, volume and issue number, and pagination. Conversely, as shown in the dotted box in Fig. 1(b), the MEDLINE citation for this CON article cites the CIN article in which it is mentioned. Thus readers may get to either citation from the other.

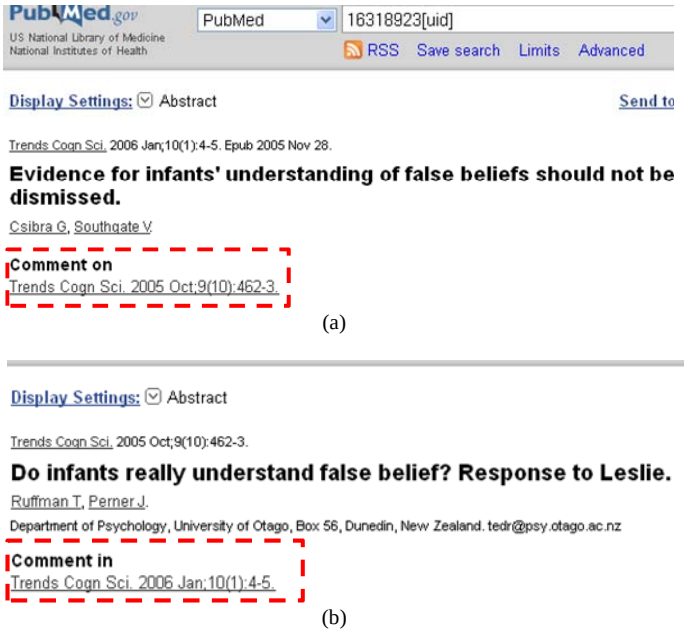

Fig. 1. (a) "Comment on" and (b) "Comment in" citations in MEDLINE

3.1 Issues

Currently, the CON list is created manually, based on certain linguistic clues and contextual patterns; operators are required to look for a particular sentence that contains a cue phrase expressing either complimentary or contradictory opinions on other articles from the body text of a given article. Typical examples of such cue phrases are listed in Table 1.

Table 1. Examples of cue phrases frequently found in CON sentences.

We congratulate [authors] for …
We question the interpretation by …
The {article | paper | letter | study | research} by …
We read with interest …
We would like to {reply | comment} to …
We agree with …

This manual method is highly labor-intensive and time-consuming. Furthermore, owing to a wide variety of linguistic expressions, and linguistic and contextual similarity between CON sentences and "citation sentences" generally citing other external sources, the overall performance relies heavily on human operators' experience, linguistic knowledge, and their understanding of scientific expressions and writing styles. In order to minimize manual efforts and to improve

accuracy and processing speed in detecting sentences that comment on other articles, we propose an automated method using a support vector machine (SVM)-based text summarization technique.

4 Method

As mentioned earlier, authors of a CIN article cite CON articles as primary external sources. Accordingly, full bibliographical descriptions for these CON articles can usually be found in the reference section of a CIN article. Note that in the scientific literature, all external sources listed in the reference section are generally mentioned at least once within sentences ("citation sentences") in the body text. The "citation sentence" that specifically indicates an article commented on by a given article is defined as the CON sentence. CON sentences are therefore a subset of "citation sentences". Based on this observation, our approach to identify a CON list for a given article is to first extract all "citation sentences" from its body text, and then to recognize the sentences among these that mention CON articles, using SVMs and to analyze the corresponding bibliographic data in the reference section. Figure 2(a) shows an example of a CON sentence (solid underline) and Fig. 2(b) shows its corresponding reference (solid box).

Hyperinsulinaemic normoglycaemic clamp in coronary artery surgery

* *E-mail:* george.carvalho@mail.mcgill.ca

Editor—We congratulate Visser and colleagues on applying glucose–insulin–potassium (GIK) therapy using a hyperinsulinaemic normoglycaemic clamp.[1] Their study confirms our findings that the clamp technique is an effective, and to date the only, method of maintaining normoglycaemia in patients undergoing coronary artery bypass grafting surgery.[2] In addition, they demonstrated, for the first time in this population, the attenuation of systemic inflammation with perioperative GIK therapy. More importantly, this effect

(b)

Fig. 2. (a) A CON sentence and (b) its corresponding bibliographic description in the reference section

Our method consists of four main steps: 1) extraction of text zones of interest, 2) extraction of "citation sentences" and the corresponding bibliographical description of external sources, 3) creation of input feature vectors for SVMs, and 4) classification of CON sentences by SVMs.

Since our method takes advantage of clues from the article title, the body text, and the reference section in a given HTML-formatted online article, we need to segment the entire article into smaller logical zones, and detect such zones first. In our research, these text zones of interest are extracted using Zoning and Labeling modules detailed in [1] and [16]. Here, we focus on and provide details about the remaining three steps.

4.1 Extraction of "citation sentences" and the corresponding external source's description

In the scientific literature, each "citation sentence" is usually associated with a citation tag (such as "(1)" or "[1]") that points to the complete bibliographical description of the cited external source in the reference section. In addition, in HTML-formatted online articles, such a "citation sentence" is hyperlinked to its corresponding external source as shown in Table 2. A hyperlink consists of both a source anchor and a destination anchor. The source anchor specified by an "A" HTML element with a "*href*" attribute appears before or behind a citation tag in a "citation sentence" and points to the destination anchor. The destination anchor specified by an "A" element with a "*name*" attribute can be found at the beginning of the external source's description. The source anchor and its destination anchor should have the same unique name. Therefore, by recognizing this anchor name, we can reliably detect its associated "citation sentence" and its corresponding external source.

4.2 Feature extraction

In our research, five types of features were employed to build an input feature vector for SVM: 1) word statistics representing how differently a word is distributed in CON sentences and other "citation sentences", 2) frequency of occurrence of author names of external sources, 3) sentence positions within the body text, 4) similarity of titles between an input article and its external sources, and 5) difference of publication years between an input article and its external sources. These features were experimentally found to be effective to distinguish CON sentences from other "citation sentences". The first feature—word statistics—is based on a

Table 2. An example of a "citation sentence" and its hyperlinked external source.

bag of words, a vector of words. Using words as an input feature requires a very high dimensional feature space (21,314 dimensions in our case). Although SVM can manage (lead to a convergence) such a high dimensional feature space, many have suggested the need for word selection or dimension reduction to employ other conventional learning methods, to reduce the computational cost, to improve the generalization performance, and to avoid the over-fitting problem. A typical approach for word selection is to sort out words according to their importance. Many functions have been proposed to measure the importance of a word, including term frequency (TF), inverse document frequency (IDF), χ^2 statistics, and simplified χ^2 ($s\chi^2$) statistics [17]. The use of $s\chi^2$ has been reported as delivering the best performance since it removes redundancies, and emphasizes extremely rare features (words) and rare categories from χ^2 [18].

In our task, $s\chi^2$ of word t_k for CON sentences (class c_0) and other "citation sentences" (class c_1) can be defined as follows;

$$s\chi^2(t_k, c_i) = P(t_k, c_i) \cdot P(\bar{t}_k, \bar{c}_i) - P(t_k, \bar{c}_i) \cdot P(\bar{t}_k, c_i) \quad i = 0, 1 \qquad (1)$$

where $P(t_k, c_i)$ denotes the probability that, for a random sentence *x*, word t_k occurs in *x*, *x* belongs to class c_i, and is estimated by counting its occurrences in the training set. The importance of word t_k is finally measured as follows;

$$s\chi^2_{max}(t_k) = max_i s\chi^2(t_k, c_i) \qquad i = 0, 1 \qquad (2)$$

Accordingly, the more differently a word is distributed in CON sentences and other "citation sentences" classes the higher its $s\chi^2_{max}(t_k)$. Our 21,314 words are sorted according to their $s\chi^2_{max}$ and a bag of words feature is created by selecting words having highest $s\chi^2_{max}$ scores. A series of experiments to investigate the influence of word reduction and to discover the number of words showing the best classification performance is also performed. These experiments are described in Section 5. A bag of words feature is converted to a binary vector; each vector component is assigned 1 if the corresponding word is found in a given sentence, or 0 otherwise.

The second feature is based on the sentence position. In many cases, CON sentences are located at the beginning of the body text of an article. Thus such position information can also serve as a good feature to distinguish a CON sentence from other "citation sentences". The position information of each sentence is expressed as

$$P(s_i) = 1 - \frac{BD(s_i)}{|D|} \qquad (3)$$

where $|D|$ is the total number of characters in the given document *D*, and $BD(s_i)$ is the number of characters located before the sentence s_i.

Next, the frequency of occurrence of author names of external sources listed in the reference section is employed as another feature. Based on our observation, author names of CON articles are more frequently mentioned in the text of a CIN article. The frequency score of author names of external sources is defined as follows:

$$TF(s_i) = \frac{tf(s_i, D)}{tf_{max}(s, D)} \qquad (4)$$

where $tf(s_i, D)$ and $tf_{max}(s, D)$ denote the number of occurrences of author name of the external source associated with the "citation sentence" s_i and the maximum number of occurrences of an author name in the given document *D*, respectively.

The next input feature is based on similarity of titles between an input article and its external sources in the reference section. Basically, CIN and its CON articles have the same research topic because a CIN article is mainly for commenting about particular external sources (some CIN articles explicitly mention author names and/or titles of CON articles in their titles). Therefore, it is expected that their titles would be quite similar or have common keywords closely related to their research topic.

The similarity score between titles of CIN and external sources is simply measured using the ratio of the number of common words to the total number of words in the title of an external source excluding stop words, as shown below;

$$TS(t_{IN},\ s_i) = \frac{W_c(t_{IN},\ s_i)}{W(s_i)} \qquad (5)$$

Here, $W(s_i)$ denotes the number of words in the title of the external source associated with the "citation sentence" s_i in a given input article and $W_c(t_{IN}, s_i)$ is the number of words commonly found in the titles of input article and the external source for "citation sentence" s_i.

Each of the aforementioned three features, $P(s_i)$, $TF(s_i)$, and $TS(t_{IN},\ s_i)$, has a real value ranging from 0 to 1 and is converted to a 10-bit binary vector for SVM (*i*-th bit position corresponding to real values between *i*/10 and (*i*+1)/10). For $P(s_i)$ and $TF(s_i)$, one more bit component is additionally attached to represent if a given "citation sentence" is located at the first paragraph of the body text, and if this "citation sentence" includes the author name of its corresponding external source, respectively, thereby resulting in an 11-bit binary vector for each feature.

Lastly, the difference of publication years between an input article and its external source is also employed as an input feature. Based on our findings from the training dataset, authors of many CIN articles are found to be interested in and comment on recently-published articles. This feature would not be used alone because other recently-published general external sources are also found in the reference section. However, it is expected to be helpful for improving the accuracy of identifying CON sentences when combined with other features. The difference of publication years is represented using a 10-bit binary vector of which the index of each bit corresponds to the years of difference; bit 0 is set to 1 if the input article and its external source are published in the same year, and bit 9 is set to 1 if there is a difference of 9 or more years.

Finally, all these feature vectors are concatenated to build an input feature vector for the SVM-based training and classification tasks.

4.3 SVM classifiers

SVM [19] was originally introduced as a supervised learning algorithm based on the structural risk minimization principle for solving a two-class problem, though it can be easily extended to handle multi-class problems. Owing to its consistently superior performance compared to other existing methods, SVM has been widely used in many text categorization and summarization tasks. The basic idea of using SVM to solve a non-linear pattern recognition problem is to map a non-linear separable input space to a linear separable higher dimensional feature space using a predefined kernel function, and to find the optimal hyperplane that maximizes the margins between the classes in that feature space.

As mentioned earlier, we employed two types of SVMs: one with a linear kernel function and the other with a RBF. These two kernel functions, defined in equations (6) and (7) below, respectively, have been commonly used in SVM-based pattern recognition applications. We implemented these SVMs using MYSVM (for linear kernel function) and LibSVM (for RBF), free software packages for non-commercial use [20][21], and evaluated their recognition performance using HTML-formatted online biomedical journal articles.

$$K(x_i, x_j) = (x_i^T \cdot x_j) \quad (6)$$

$$K(x_i, x_j) = exp(-\gamma \|x_i - x_j\|^2) \quad (7)$$

5 Recognition experiments

5.1 Database

To build a dataset for our experiments to distinguish CON sentences from "citation sentences", we first collected a total of 5,848 HTML-formatted biomedical articles containing CON citations from a collection of indexed articles in MEDLINE. These online articles appeared in 414 different biomedical journal titles, and their publication types were Letter (49.0%), Review (2.1%), Editorial (25.4%), Commentary (14.5%), and others (9.0%). Full-length articles were not included in our dataset because CIN articles are generally letter-like short papers and MEDLINE does not typically acquire CON data from conventional full-length articles. We also developed an automated text categorization system to distinguish CIN articles from regular ones and to submit only articles classified as CIN to the proposed method of extracting CON citation data [22].

From these articles, 11,939 "citation sentences" were extracted; among them, 8,531 sentences (4,184 CON sentences + 4,347 other "citation sentences") were randomly selected to train the SVMs. The remaining 3,408 sentences (1,659 CON sentences + 1,749 other "citation sentences") were used to evaluate and compare the performance of the SVMs.

5.2 Experimental results

We evaluated the performance of SVMs in terms of precision, recall, and F-measure rates that are defined as follows:

$$precision = TP/(TP + FP)$$
$$recall = TP/(TP + FN)$$
$$F - measure = \frac{2 \times (precision \times recall)}{(precision + recall)}$$

Here, *TP*, *FP*, and *FN* denote true positive, false positive, and false negative, respectively. False positive means that a "citation sentence" is misrecognized as a CON sentence. False negative is the reverse of the above.

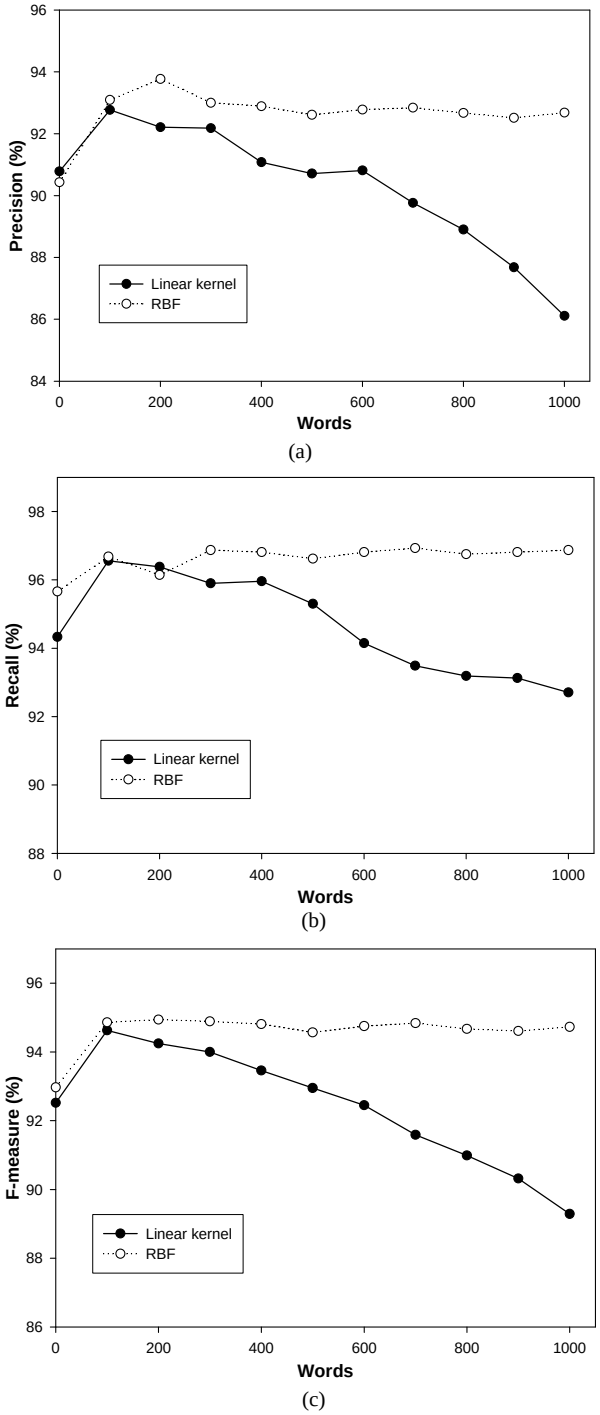

Fig. 3. (a) Precision, (b) recall, and (c) F-measure rates plotted against different word dictionary sizes.

Figure 3 shows precision, recall, and F-measure rates as functions of the size of the word dictionary in the bag of words feature ($s\chi^2_{max}$). We can see that the SVM with a RBF is slightly better than the SVM with a linear kernel, but both yield the best performance overall when the word size is 100, the performance in all three measures exceeding 93%. The SVM with a RBF shows consistent and reliable performance with respect to word selection in $s\chi^2_{max}$; its precision, recall and F-measure rates do not significantly vary with dictionary size. In contrast, the performance of SVM with a linear kernel function deteriorates as the word dictionary size increases. Therefore, we conclude that the SVM with a RBF is a more reliable classifier than the SVM with a linear kernel function for identifying CON sentences.

Table 3 shows examples of false-negative and false-positive errors. Two CON sentences shown in Table 3 (a): CON-I and CON-II, belong to the same input article and have a similar expression to comment other articles. However, unlike CON-I, CON-II is misrecognized as a general "citation sentence". It can be seen from its feature values that CON-II is located in the middle of the body text ($P(s_i)$ = 0.57), the frequency of occurrence of author name of the corresponding external source ($TF(s_i)$) is significantly small relative to other author names. Moreover, there are no words in common ($TS(t_{IN}, s_i)$) found between titles of input article and the external source corresponding to CON-II.

In contrast, the "citation sentence" (CIT-I) shown in Table 3 (b) is misrecognized as a CON sentence. CIT-I is found to contain several words frequently found in many CON sentences and located at the upper middle of the body text. Specially, it has a high similarity score ($TS(t_{IN}, s_i)$ = 0.83) between titles of CIN and its corresponding external source.

In order to minimize such problems, we recommend the addition of heuristic rules based on cue phrases and other linguistic information in future work.

Table 3. Error examples showing (a) false negative error and (b) false positive error

Input article	Growth attenuation: a diminutive solution to a daunting problem
CON-I	Now examine the proposed treatment: in this issue of the ARCHIVES, Gunther and Diekema (1) offer a medical solution to families who will likely face the harrowing choice of what to do when their child becomes too big to care for at home.
	Ref.: 1. Gunther DF, Diekema DS. *Attenuating growth in children with profound developmental disability: a new approach to an old dilemma*. Arch Pediatr Adolesc Med. 2006;160:1013-1017.
	$P(s_i)$ = 0.91 | $TF(s_i)$ = 1.00 | $TS(t_{IN}, s_i)$ = 0.10|
CON-II	Indeed, as Lee and Howell (2) point out in this issue of the ARCHIVES, estrogen has long been used to attenuate growth in girls destined to be taller than average.
	Ref.: 2. Lee JM, Howell JD. *Tall girls: the social shaping of a medical therapy*. Arch Pediatr Adolesc Med. 2006;160:1035-1039.
	$P(s_i)$ = 0.57 | $TF(s_i)$ = 0.29 | $TS(t_{IN}, s_i)$ = 0.00|

(a)

Input article	Ischemic hepatitis and collateral damage to the liver in severe viral respiratory tract infections
CON-III	Polakos and colleagues (1) investigated immunological causes of hepatic involvement by influenza virus respiratory tract infection manifesting itself in alanine and aspartate aminotransferase elevation and found evidence for a role of antigen-specific T cells in their pathogenesis.
	Ref.: 1. Polakos NK, Cornejo JC, Murray DA, Wright KO, Treanor JJ, Crispe IN, Topham DJ, Pierce RH: *Kupffer cell-dependent hepatitis occurs during influenza infection.* Am J Pathol 2006, 168:1169-1178
	$P(s_i)$ = 1.00 | $TF(s_i)$ = 1.00 | $TS(t_{IN}, s_i)$ = 0.17|
CIT-I	Adams and Hubscher (2) mention in their commentary on the work of Polakos and colleagues (1) our observational study, (3) in which we reported on the finding of elevated transaminase levels in 46% of children ventilated in the pediatric intensive care unit with severe respiratory syncytial virus bronchiolitis.
	Ref.: 2. Adams DH, Hubscher SG: *Systemic viral infections and collateral damage in the liver*. Am J Pathol 2006, 168:1057-1059
	$P(s_i)$ = 0.69 | $TF(s_i)$ = 0.5 | $TS(t_{IN}, s_i)$ = 0.83|

(b)

6 Conclusions

CON ("Comment-on") is a MEDLINE citation field showing previously published articles commented on by authors of a given article ("Comment-in" or CIN) as primary external sources on which they may express complimentary or contradictory opinions. Manually extracting the CON list from a given article is time-consuming and labor-intensive, and the overall performance relies heavily on human operators' experience, linguistic knowledge, and their understanding of scientific expressions and writing styles.

In this paper, we have presented a SVM-based text summarization method to automatically identify such CON data from online biomedical documents, thereby minimizing manual effort and improving accuracy and processing speed. Our main idea is to extract "citation sentences" using hyperlink information and then to recognize from the "citation sentences" CON sentences using SVMs. In our research, we have implemented two types of SVMs: one with a linear kernel function and the other with a radial basis function (RBF), and compared their performance in terms of precision, recall, and F-measure rates. Input feature vectors for these SVMs are created by combining five types of features: 1) word statistics representing how differently a word is distributed in CON sentences and other "citation sentences", 2) frequency of occurrence of author names of external sources listed in the reference section of a given input article, 3) sentence position within the body text, 4) similarity of titles between a given input article and external sources, and 5) difference of publication years between an input article and each external source.

Through a series of experiments on HTML-formatted online articles collected from 414 different biomedical journal titles, we can see that the SVM with a RBF and the SVM with a linear kernel both yield the best performance overall (over 93%) when the word size in the bag of words feature is 100. In addition, we found that the SVM with a RBF yields consistent and reliable performance in terms of precision, recall, and F-measure rates than the SVM with a linear kernel function with respect to word selection in the bag of words feature. Future work is planned to develop a rule-based method for compensating for recognition errors made by SVMs.

Abstract - *PCA (Patient Controlled Analgesia) is a delivery system for pain medication that makes effective and flexible pain treatments possible by allowing patients to adjust the dosage of analgesics themselves. Unlike previous research on patient controlled analgesia, this study explores patient demand behavior over time. We applied clustering methods to disclose demand patterns among patients over the first 24h of analgesic medication after surgery. We first identified three demand patterns from patient controlled analgesia request log files. We then considered demographic, biomedical, and surgery-related data to evaluate the influence of demand pattern on analgesic requirements. We recovered several associations that concurred with previous findings, and discovered several new correlations*

Keywords: postoperative pain, patient controlled analgesia, PCA demand, clustering

1 Introduction

After operations, pain is one of the most commonly reported symptoms [1]. It is a highly personal experience influenced by multiple factors, including sensitivity to pain, age, genetics, physical status, and psychological factors [2-4]. As the progress of medical science, people gradually become aware of the importance of pain management.

PCA (Patient Controlled Analgesia) is a delivery system for pain medication that makes effective and flexible pain treatments possible by allowing patients to adjust the dosage of anesthetics themselves. According to previous research [5-6], PCA has become one of the most effective techniques for postoperative analgesia. It is widely used in hospitals for the management of postoperative pain, especially for major surgeries.

Most research on postoperative pain management is limited to evaluating the correlation of patient characteristics, such as demographic attributes, biomedical variables, and psychological states, with postoperative pain intensity or analgesic requirement. Several studies have identified the preoperative predictive factors for postoperative pain and analgesic consumption in various patient groups of different genders, ages, or psychological states [7-11]. However, none of these studies analyzed continual patient demand behavior throughout the PCA therapy. Time-series data analysis is a common practice in various research fields. For example, in the study of sleep in patients with insomnia, time-series data derived from sleep diaries were used to compute conditional probabilities of having insomnia [12]; in biology, a temporal map of fluctuations in mRNA expression of 112 genes during central nervous system development in rats provides a temporal gene expression fingerprint of spinal cord development [13]. Few studies of PCA examined patient demand behavior and its relationship to analgesic drug use [14,15]. We hypothesized that patient demand behavior over time provides different and useful information in PCA administration that is missing in the preoperative factors analyzed earlier.

Our study, unlike previous research, focuses on continual analgesia demand behavior during the postoperative PCA medication. The current study explores and characterizes patient demand behavior. Patient demand behavior is represented by a series of PCA requests over time. We discover distinct and conserved demand patterns from the time-series data and identify the significant patient factors that influence demand behavior. In addition, we compare the predictors for PCA demand behavior and analgesic requirements and evaluate the contribution of demand pattern to analgesic consumption prediction

2 Materials and Methods

We restricted the study subjects to conscious hospitalized patients at Changhwa Christian Hospital (CCH) during the years from 2005 to 2010. All patients were instructed to operate the PCA device manufactured by Abbott (Abbott Pain Management Provider, Abbott Lab Chicago, IL, USA) prior to the surgery. With the assistance of Acute Pain Service, we collected more than 3000 patient records, each of which contained attributes such as basic health status, age, gender, weight, department code, doctor ID, PCA control parameters, amount of anesthetics used in different time intervals, etc. Since not all the attributes are relevant to our study or have correct values, after consulting the

anesthesiologists, we discarded irrelevant attributes, e.g. doctor ID and department code, before further investigation. We processed thousands of medical charts and PCA log files collected at CCH, and obtained 1655 complete records. Each patient was described by demographic and biomedical attributes besides PCA-related variables. Their values are either categorical or numeric. The attribute descriptions are shown in Table 1. All the statistical analyses were performed using the Statistical Package for the Social Science 10.0 (SPSS Inc. Chicago, IL, U.S.A.).

Table 1. Summary of Patient Attributes.

Attribute Name	Description	Number	Mean
Demographic:			
gender	patient's gender	986(F)/669(M)	-
age	patient's age	-	56.9±15.8
weight(kg)	patient's weight	-	63.0±12.6
Biomedical:			
sbp (mmHG)	systolic blood pressure	-	135.8±22.6
dbp (mmHG)	diastolic blood pressure	-	69.4±13.8
pulse(beats/min)	heart rate	-	81.0±15.4
ASA class[a]	1: healthy 2: mild systemic disease 3: major systemic disease	184(1)/837(2)/634(3)	-
OP-related:			
op_type[b]	surgery type: 1 ~ 8	107(1)/126(2)/411(3) 127(4)/427(5)/109(6) 212(7)/136(8)	-
ans_type	SA: spinal anesthesia GA: general anesthesia	1470(GA)/185(SA)	-
op_time(hr)	surgical duration	-	4.2±2.6
urgency	E: emergency surgery R: regular surgery	136(E)/1519(R)	-

[a]ASA class is the commonly used preoperative index of physical status defined by American Society of Anesthesiologists.
[b]1: intrathoracic, 2: upper intra-abdominal, 3: lower intra-abdominal, 4: laminectomy, 5: major joints, 6: limbs, 7: head & neck, 8: others

Given the PCA demand frequency within each unit of time, we can represent each patient's PCA demand profile as a time course. By applying clustering algorithms to the time courses, we identified different patient groups. Patients in the same group are expected to demonstrate similar demand behavior; in contrast, demand behavior of patients in different groups is different. We used k-medoids algorithms [16,17] to partition the patients into clusters according to their demand behavior. A medoid is a real data point that has the minimum average distance from all other points in the same cluster. Unlike the k-means algorithm [18], k-medoids mitigates the effect of outliers on the resulting prototypes and ensures that all the resulting clusters are non-empty [19]. To find the appropriate number of clusters, we performed a series of k-medoids clustering algorithm with the value of k varying from 2 to *K*.

The number of clusters was determined by reproducibility and stability [20]. We generated bootstrap samples from the dataset by random sampling with replacement [21]. We ran k-medoids on the sample to obtain a clustering solution. From B pairs of bootstrap samples from the original data, we produced *B* pairs of clustering results. Given two clustering solutions C_1 and C_2 from a pair of bootstrap samples, we obtained two partitions of the original data by assigning each observation to the nearest medoid. We used the adjusted Rand Index [22] to measure the similarity between the two partitions. To assess how stable a partition of the original data was, we compared the adjusted Rand Index values of the *B* pairs of bootstrapped partitions. By iterating the value of k from 2 to *K* and repeating the same procedure, we obtained different distributions of the adjusted Rand Index values. First, we performed analysis of variance (ANOVA) to determine whether significant statistical evidence existed to show that at least two adjusted Rand Index means differed. Then, we conducted sequential *t*-tests corrected for multiple comparisons to identify a significant gap between successive differences in bootstrapped adjusted Rand Index values. The most significant jump indicated the most likely number of clusters in the original data.

After identifying the PCA demand patterns using the k-medoids algorithm and bootstrapped stability tests, we examined the association between demand patterns and the patient attributes listed in Table 1. We ran chi-square tests for the dependence of the demand behavior on those patient attributes, and we conducted ANOVA tests to compare the attribute values among different patient groups according to demand patterns. For all the analyses, a level was set at 0.05 for statistical significance.

Little research explores the relationship between PCA demand patterns and PCA analgesic consumption. We applied stepwise linear regression to compare demographic, biomedical, operation-related, and PCA demand behavioral influences on PCA analgesic consumption. The criterion for inclusion or elimination of patient attributes was that a patient attribute would be included if its partial regression coefficient was significant at the $\alpha = 0.05$ level or eliminated if it was

not. To evaluate further the individual effect of PCA demand pattern on analgesic consumption, we performed stepwise regression only on patient demographic, biomedical, and surgery-related attributes. We compared the R^2 and adjusted R^2 before and after removing demand patterns. A substantial drop in R^2 and adjusted R^2 indicated that the demand patterns played a significant role in predicting analgesic consumption.

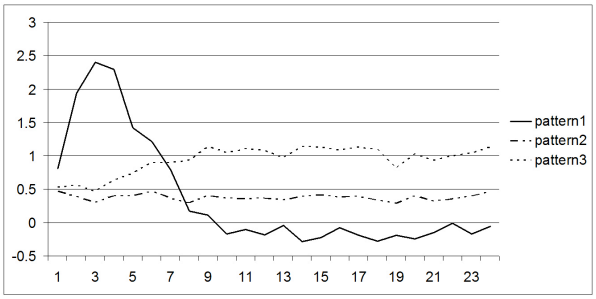

Figure 1. PCA demand patterns discovered from 1655 subjects. Three patterns are identified from 1,655 PCA patient-demand log files. Ninety-one patients' PCA demand behavior matches Pattern 1, 1,205 patients' demand behavior matches Pattern 2, and 359 patients' demand behavior matches Pattern 3. The X-axis indicates the 24h time line (1^{st}h to 24^{th}h). The Y-axis represents the normalized standard score (z-score) of the PCA demand frequency in a particular hour.

3 Results and Discussion

We performed bootstrap sampling with replacement on the 1,655 patient records and generated 100 pairs of samples. Varying k from 2 to 6, we ran k-medoids on the bootstrap samples and calculated their adjusted Rand Index values. We performed sequential *t*-tests (with Bonferroni correction) on the adjusted Rand Index groups. The test results were presented in Table 2. From the sequential *t*-test results, we observed a significant gap between k = 3 and k = 4. The mean of the adjusted Rand Index of the four cluster partitions dropped by 0.12, with $p << .000001$. It indicated that when k = 3, the clustering result was the most stable. We thus selected k = 3 as the number of clusters and identified three PCA patient groups by maximizing the demand behavior similarity among the patients in each group. The group size is 91, 1205, and 359 respectively. Patients in the same group showed a similar demand pattern that was different among different groups. Figure 1 presents the average demand pattern of each group. The X-axis represents the 24h time line, and the Y-axis is the normalized standard score (z-score) of the PCA demand frequency in a particular hour.

Different PCA demand patterns define different patient groups. We identified three demand patterns from 1,655 patients and produced three patient groups. The chi-square test was performed to test the dependence of the patient groups on the categorical patient attributes in Table 1, for example, gender, ASA class, and surgery type. ANOVA was used to compare the differences in weight, age, blood pressure, pulse, and surgical duration among different patient groups. Table 3 shows the results of the chi-square and ANOVA tests. We observed statistically significant differences among PCA demand pattern groups in gender, diastolic blood pressure, surgery type, and surgical duration respectively. The Student t-test for differences between means was performed with Bonferroni correction ($\alpha/N = 0.016$). The results indicated that Demand Pattern 1 (shown in Fig. 1) was associated with shorter surgical duration than the other two patterns ($p = .0012$; $p = .008$), and Demand Pattern 2 was more associated with lower diastolic blood ($p = .05$) than Pattern 3 ($p = .09$), but showed no significant difference from Pattern 1 ($p = .91$). In contrast, age, systolic blood pressure, and urgency showed only a weak association with PCA demand behavior. No significant difference in weight ($p = .47$) or pulse ($p = .43$) was found among demand pattern groups. In addition, no significant statistical evidence was found to reject or accept the hypothesis that the ASA class ($p = .37$) and the type of anesthesia ($p = .36$) were independent of PCA demand pattern.

Multivariate stepwise linear regression was used to identify major factors influencing PCA analgesic consumption. All demographic, biomedical, and surgery-related attributes and PCA demand patterns were included for regression analysis. We found that PCA demand pattern played the most significant role in predicting PCA analgesic consumption. The other major factors at the $\alpha = 0.05$ level were weight, age, surgical type, urgency, and anesthesia type, as presented in Table 4. To validate further the individual effect of PCA demand pattern on analgesic consumption, we performed stepwise regression only on patient demographic, biomedical, and surgery-related attributes. Three factors were selected at the $\alpha = 0.05$ level, as shown in Table 5. They were weight, age, and surgical type, in the order selected. The R^2 and adjusted R^2 are 0.05651 and 0.05479, respectively. Compared with the results ($R^2 = 0.18761$ and adjusted $R^2 = 0.18465$) in Table 4, it is clear that PCA demand pattern made a significant contribution to analgesic consumption prediction.

To our best knowledge, this study is the first to introduce an analysis of time-series data derived from PCA demand log files. We have used a clustering method to analyze the 24h PCA demand profile of 1,655 patients. The advantages of a clustering-based approach to data analysis are that it is adaptable to change and helps extract crucial properties that distinguish different data groups. Cluster analysis has been widely used in various applications. In biology, it can help biologists categorize genes or proteins with similar functionality into families or derive a hierarchical organization [23]. In business, it helps market analysts identify distinctive groups in their customer databases and characterize customer groups according to purchasing patterns [24]. Many clustering algorithms have been developed. In general, they can be classified into methods such as partitioning methods, hierarchical methods, density-based methods, model-based methods, and constraint-based methods [19,25].

The demographic, biomedical, and surgery-related predictors for analgesic consumption are not necessarily a predictor for PCA demand pattern, though a relationship between analgesia requirements and demand behavior exists.

Several studies have discovered a significant correlation between age and the dose of opioid required in the postoperative period [4,26-28]. For example, Gagliese et al. and Chang et al. both observed that age was significantly negatively correlated with morphine consumption in their studies [11,29]. However, our study only indicated a weak correlation of age with PCA demand patterns. As mentioned in previous studies, possible causes of the discrepancy in the results could be lack of understanding or misuse of PCA by older and younger patients [8], and a difference in pain sensitivity to morphine between young and elderly patients should be considered in the correlation analysis [30]. More specific studies should be restricted to a narrower age range such as 20 to 60 years, and pain intensity should be included in the correlation modeling to alleviate the limitation of a simple two-variable (age and morphine dose) model.

Table 2. Sequential *t*-test for Successive Differences in Adjusted Rand Index Means.

Number of Clusters	Adjusted RI Mean Difference	*t*-value	*p*-value
3 vs. 2	-0.07	3.63	.00037
4 vs. 3	-0.12	5.55	<< .00001
5 vs. 4	-0.06	3.32	.00106
6 vs. 5	-0.06	4.00	.00009

Table 3. Chi-Square and ANOVA Tests on Patient Attributes and Demand Patterns.

Attribute Name	Chi-Square *p*-value (DF[a])	ANOVA *p-value*
Demographic:

urgency	0.18(2)	-

[a]DF: degree of freedom

The relationship of gender with postoperative pain and analgesic consumption varies among different studies. We found that gender was a significant correlate of PCA demand behavior. This concurred with Chia et al.'s report that gender was an important predictor of postoperative morphine requirement [8]. The chi-square test indicated that significantly more females than expected demonstrated PCA Demand Pattern 1 (see Fig. 1) in our study. Because Demand Pattern 1 indicates an early sharp increase of PCA requests, it suggests that PCA dosage for the first 3 h could be increased for the female patients whose characteristics match those in the Demand Pattern 1 group to increase their satisfaction. We found a significant association between PCA demand pattern and surgical type as well as surgical duration. These findings agreed with the lessons learned from pain management [31,32] and previous studies of PCA consumption [11,29].

Some researchers have derived predictive models of analgesic requirements or postoperative pain from regression analyses [8,10,11]. Although they identified several positive preoperative correlates, such as age and gender, their coefficients of determination were small, and in some cases, no significant predictors were found. For example, in an analysis of the first 6 h of intravenous patient controlled analgesia required in the ward, no predictors were found to meet $\alpha = 0.05$ level [9]. This suggests that predictive factors other than demographic, physiological, and surgical attributes are present that have not been analyzed. We included PCA demand pattern in the multivariate stepwise regression analysis to compare the influence of these factors on PCA consumption prediction. Our results showed that PCA demand pattern played the most significant role in predicting analgesic consumption. It increased the value of coefficient of determination from 0.05651 to 0.18761.

There are a number of limitations in our current study. First, though the patient records have been carefully reviewed, the PCA data used in our analyses were not guaranteed to be free of errors. A small amount of noisy data could occur due to human errors in data entry or misuse of PCA devices by patients. They were not recognized or resolved in the data preprocess. To mitigate the effect of data noise, we used bootstrap replications to ensure the reproducibility and stability of clustering solutions, and statistically significant results were obtained. However, data cleaning is still a crucial step before any form of data exploration, including clustering, and results of this type should be applied with caution within the imitations of

clustering algorithms. Second, most previous studies of PCA were conducted on Western patients. Little research focuses on Eastern people such as Taiwanese patients [8,29]. The discrepancy in the analysis results or conclusions might be attributable to the impact of different sociocultural origins. Third, our current study of PCA demand behavior is based on the first 24 h of PCA therapy after surgery. Shorter or longer periods of PCA medication may contain different demand behavioral patterns. Distinct and conserved demand patterns among patients over various lengths of PCA therapy are likely to correlate with different regularities in postoperative pain relief and patient satisfaction. Information of this type may be useful for predicting analgesic requirements and postoperative pain. Last, as a retrospective study, the surveyed variables were not under control, and the medical meanings of the correlation between demand patterns and demographic, biomedical, or surgery-related predictors were still unclear.

4 Conclusion

Most research on correlates of postoperative pain has been limited to identifying the correlation of patients' characteristics, such as demographic attributes, biomedical variables, and psychological states, with postoperative pain intensity or analgesic requirements. Our study, unlike previous works, focused on the continual analgesia demand behaviors during the postoperative PCA therapy. The main finding was that there were conserved PCA demand patterns that partitioned the study subjects into three patient groups, each presenting distinctive PCA demand behaviors.

We advocate the analysis of PCA demand behavior. To demonstrate its feasibility and significance, in our current study we used clustering algorithms to identify demand patterns. The stability and reproducibility of the clustering solution have been verified by repeated random bootstrap sampling. The results suggest that PCA demand behavioral patterns exist over time among patients. They are correlated with specific demographic, biomedical, or surgery-related attributes, and have influence on analgesic consumption. In the future work, we will investigate other factors that can possibly explain the inconsistency, and improve postoperative pain relief.

A Case Study: Building a Web-Based Dietitian Expert System

Robert Jackson and Eman El-Sheikh
Department of Computer Science, University of West Florida, Pensacola, Florida, USA

Abstract - *This paper presents the development of a TeleHealth system built using an open source web-based expert system framework called Tohu. The expert system works by providing individualized diet and health recommendations to users based on each user's responses to a simple auto-reporting questionnaire. A comparison is given between the development and features of this system and similar systems. A description of the system development illustrates how a complex web-based expert system can be easily constructed using open source tools such as JBoss Drools and Tohu. Following a depiction of how the system can be used, the paper concludes with a discussion of opportunities for future work.*

Keywords: Web-Based Expert System, Drools, Tohu, Rule-Based System, Health Assessment, Diet Assessment.

1 Introduction

This paper presents an open source behavior monitoring and modification system in which patients can self-report their measurements and receive personalized diet and exercise feedback. TeleHealth systems are an emerging method of delivering health services to patients using telecommunications (e.g. chat, web-based expert systems, and video consultations). TeleHealth systems have seen increased use as health tools in recent years and have been shown to perform quite well [1]. In the Journal of the American Medical Association (JAMA), researchers at the Weight Control and Diabetes Research Center at Brown Medical School reported that a system in which patients submitted a weekly weight loss diary via email lost significantly more weight than those only given weight loss information [2]. Further results from studies published by Haugen et al. [3] and Digenio et al. [1] prove that TeleHealth systems are valuable and effective tools for bringing health services to a larger population.

These so-called TeleHealth systems may be a part of the solution, for the Center for Disease Control states that, American society has become characterized by environments that promote increased food intake, non-healthy foods, and physical inactivity [4]. Furthermore, the Journal of the American Medical Association observed that 72% of American men and 64% of American women are overweight or obese [5]. Also, for American men, this figure is increasing as time goes on. Research has shown that persons whose weight approaches levels classified as "overweight" or "obese," tend to increase their risks of diabetes, heart disease, cancer, and stroke [6]. Without more effective health aides, there could be a huge economic and medical impact as the population ages and starts to see the negative effect of this type of lifestyle.

The proposed TeleHealth system developed is called eDietitian; it leverages the Internet and existing tools to provide dietitian consultations to a larger population. The software performs a virtual consultation with the user by mimicking a consultation with a dietitian and asking the user a dynamic series of questions related to their lifestyle and habits. After the consultation, the user is given a customized list of recommended practices they should try to incorporate into their lifestyle to achieve and maintain a healthy lifestyle.

2 Related Works and Tools

This section describes tools that are similar to eDietitian; it also provides information about the tools used to build eDietitian.

2.1 Background Software and Tools

The eDietitian system is written in Drools [8] (see Figure 1), a Java Virtual Machine (JVM) rules engine and language. Drools provides a Java implementation of the Rete Algorithm for efficient pattern matching of facts with rules. It's similar to other rule engines such as CLIPS and Jess. The other major tool used is the Tohu [7] framework. The framework provides classes (see Figure 2) for constructing the question-and-answer tree and rendering the user interface via jQuery.

2.2 Related Systems

One of the systems that inspired eDietitian was WebMD's Personal Diet Evaluator [9]. The Personal Diet Evaluator's approach is a little different from eDietitian's but they share a similar questions-and-answer format. The big difference between the Personal Diet Evaluator (PDE) and eDietitian is that PDE is an Adobe Flash application while eDietitian is rendered with pure HTML. Also PDE is not as dynamic to the user's responses as eDietitian. eDietitian's screens react at a much more granular scale than PDE's.

Another system which bears a resemblance to eDietitian is the "Mozambican Diet Assessment Tool" [10]. It was developed by the Mozambican Ministry of Health as a quick way to measure the diet of rural and urban communities. Donald Rose et al describe how the system works as follows:

"The Mozambican Diet Assessment Tool (MDAT) is based on a simple, qualitative 24-hour recall of household food intake. The person in charge of food preparation in each household is asked to recall all foods eaten by household members at each meal and snack time in the previous 24 hours. Field personnel, usually the provincial nutritionists, then assign points to each food consumed, using a simple scoring system."

The eDietitian system differs from the Mozambican Diet Assessment Tool because it takes a different route during the evaluation by inquiring about exercise and BMI rather than strictly measuring the amount of nutrients consumed. The goal of MDAT is different from eDietitian's - which is mostly the reinforcement of a healthy lifestyle - rather than nutrient assessment.

Denning et al developed BALANCE, a smart phone application which measures caloric expenditure using sensor and activity sensing technology [11]. Their system can predict how much time a person has spent sitting, walking, jogging, or cycling each day and can recommend serving size to the patient to keep their caloric intake in balance with their expenditures.

3 eDietitian Design and Architecture

This section describes how the eDietitian system was designed and constructed using the Tohu framework and Drools language to generate the web application.

3.1 Knowledge Base

The knowledge base for the system was built using a rule-based approach. The final system contained approximately 80 rules of varying complexity. Rules came from numerous sources, but the main sources for rules are US Government sources such as: PubMed Health from the U.S. National Library of Medicine [12], the "Dietary Guidelines for Americans" from the US Department of Agriculture [13], and the Center for Disease Control's Obesity and Overweight website [14].

3.2 Architecture

3.2.1 Server-Side

Figure 1 (right) shows the server-side stack of the system. Everything runs in a Java Virtual Machine (JVM) instance. On top of the JVM, a Tomcat container serves the normal web files, but also runs a RESTful web-service called the Drools Execution Server. This service provides an interface to the Drools knowledge-base via XML.

3.2.2 Client-Side

The client-side of the system could essentially be any program that knows about the RESTful interface used by the Drools Execution Server. However, this project made use of the Tohu's jQuery library as shown in Figure 1 (left) for UI development. The Tohu project provides a JavaScript framework which can dynamically create the HTML and manipulate the Document Object Model (DOM) based on the responses given from the Server-Side. The Tohu JavaScript library uses the popular jQuery library for client-side scripting.

The big advantage of having the system run as a web application is how easily the UI can be easily changed using Cascading Style Sheets (CSS). The view can be easily modified using just style sheets; without any modification of the rules or logic classes.

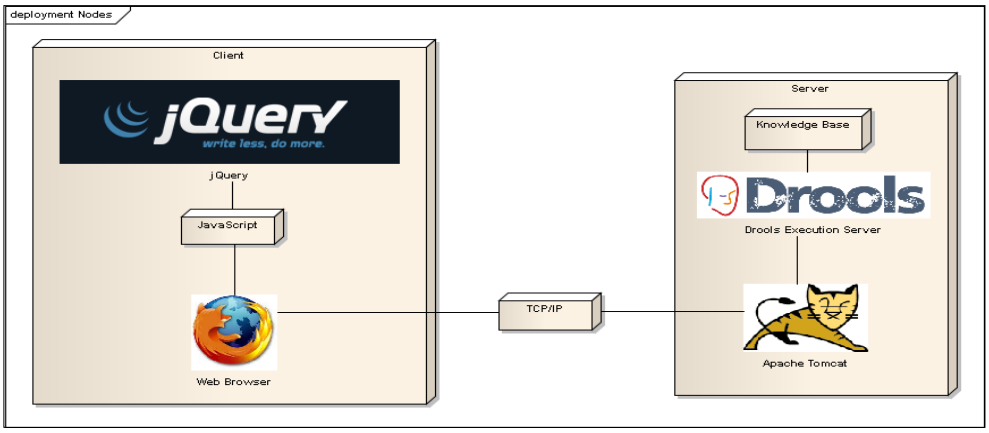

Figure 1 Client-Server stacks used in the eDietitian system. All components are open source.

3.3 Rule Workflow

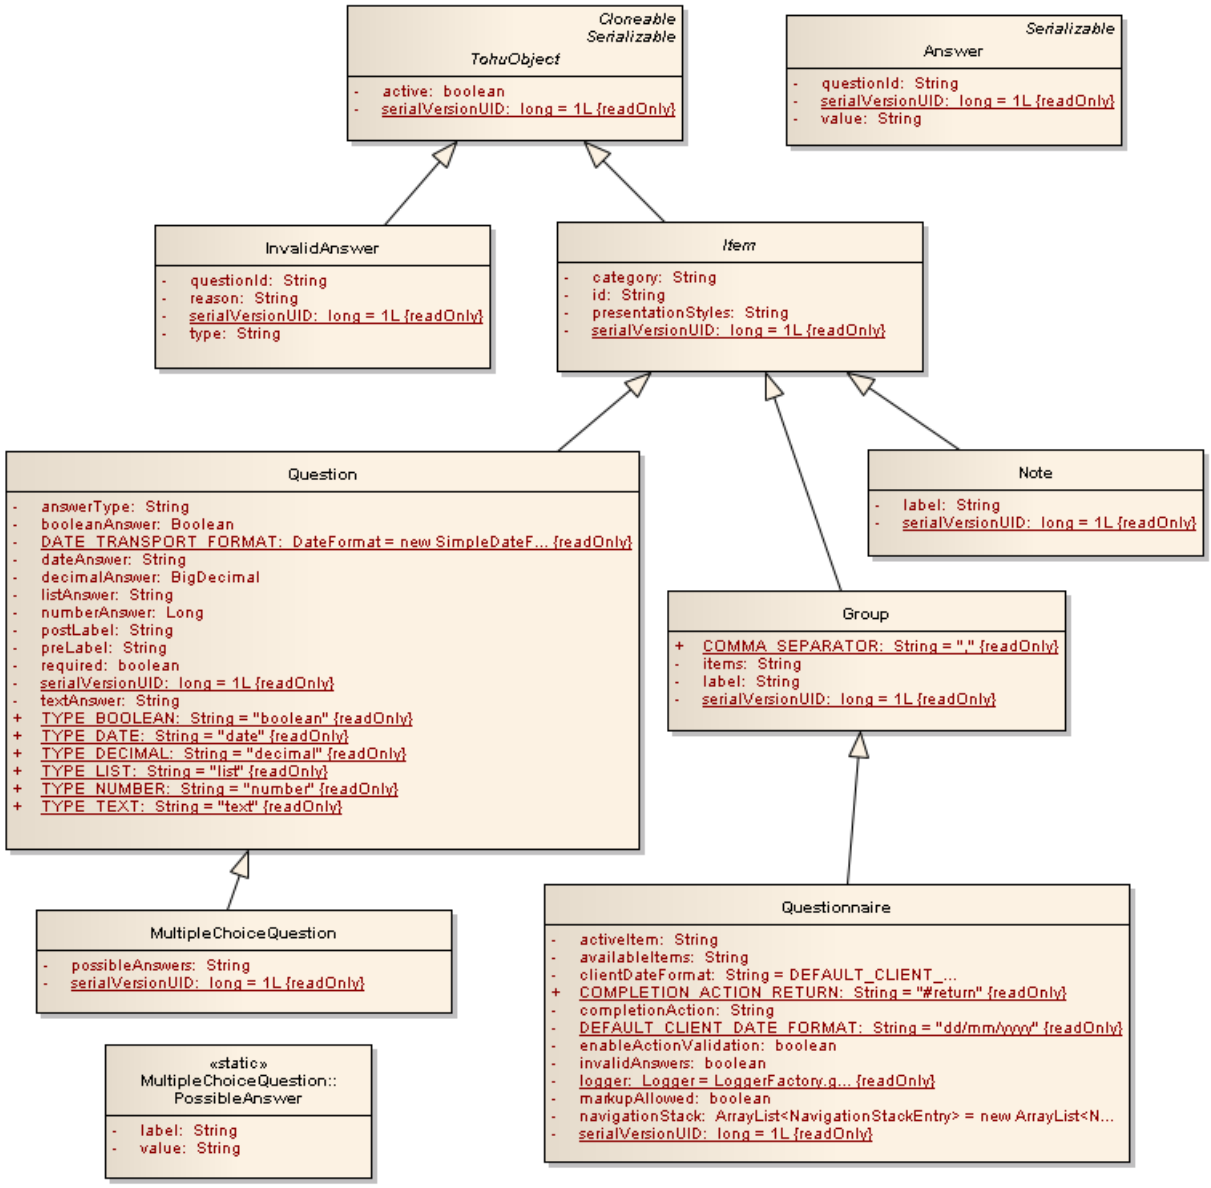

Figure 2 Class diagram of the Tohu core classes. These classes are used to build the decision tree.

The Java classes from Figure 2 are used to code the decision tree. A snippet of the Drools code is given to demonstrate this. Suppose we want to ask the user whether they exercise or not and provide a recommendation if they answer "no" to the question. Figure 3 shows the final screen with the recommendation at the bottom. Using the Tohu classes (Figure 2) to code the rule into the knowledge-base, we create a rule that inserts the `Question` object into the knowledge base as follows:

```
rule "ask if user exercises"
dialect "mvel"
then
Question question = new Question("exercise");
question.setAnswerType(Question.TYPE_BOOLEAN);
question.setPreLabel("Do you exercise?");
question.setPresentationStyles({"radio"});
```

```
insertLogical(question);
. . .  // similar code cut out for space
end
```

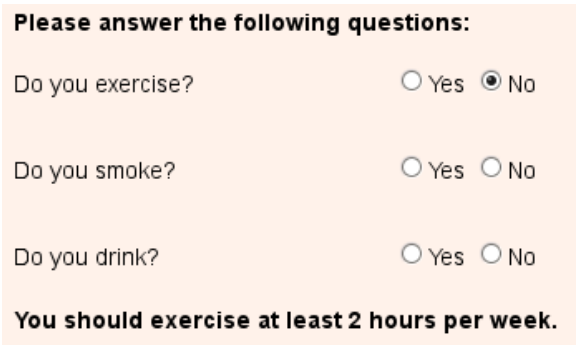

Figure 3 How Tohu renders the above code with the recommendation at the bottom. A Boolean datatype is displayed as a radio button with Yes/No values.

Once the `Question` objects are in the knowledge base and some event changes their state, such as an `Answer` object being inserted into the knowledge base, other rules that have them as an antecedent will fire which we can use to add yet more questions, facts, or recommendations into the knowledge base, for example:

```
rule "everyone should get at least 2 hours of exercise per week"
dialect "mvel"
when
  // if there is a Question with id==exercise and answer is false, then…
  Question(id == "exercise", answer == false);
then
  // display a note to the user that…
  insertLogical(
       new Note(
             "exerciseNote",
             "You should exercise at least 2 hours per week."
       )
  );
  // and give them a new exercise recommendation to be displayed on complete
  insertLogical(
       new ExerciseRecommendation(
             "needToStartExercising",                    // recommendation id
             Priority.HIGH,                              // priority
             "You should start an exercise regiment.",   // text to show
             new Source(                                 // link to source
                   "http://www.cdc.gov/physicalactivity/everyone/guidelines/adults.html",
                   "Physical Activity for Everyone: Guidelines: Adults"
             )
       )
  );
end
```

4 eDietitian Usage

The following section describes how eDietitian can be used, illustrated using screen-shots of the eDietitian system through various stages of the consultation session.

Once a user starts the questionnaire, he/she is asked some initial information, as shown in Figure 4, which is used to determine the user's Body Mass Index (BMI), Basal Metabolic Rate (BMR), and weight type (underweight, normal, overweight, obese). Next, the user is presented with questions which gather information on exercise, as illustrated in Figure 5, and high-risk conditions including tobacco use and alcohol use. After this point in the conversation, the user's answers lead him to individually-determined questions based on their specific responses to the previous questions. This would mimic the way a doctor's consult would proceed – dynamically – from question to question. At the end of the session, the system displays the results of the questionnaire, and the user's exercise, eating and any other recommendations are displayed in a jQuery "accordion" widget, as depicted in Figure 6.

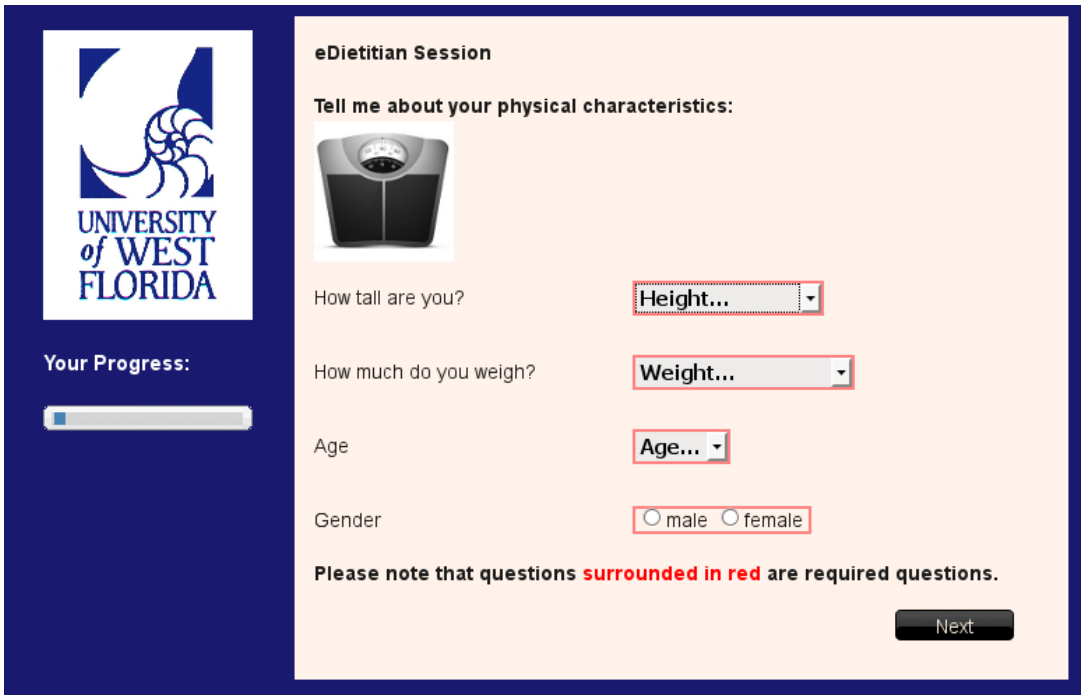

Figure 4 The initial screen of eDietitian gathers some initial information from the user.

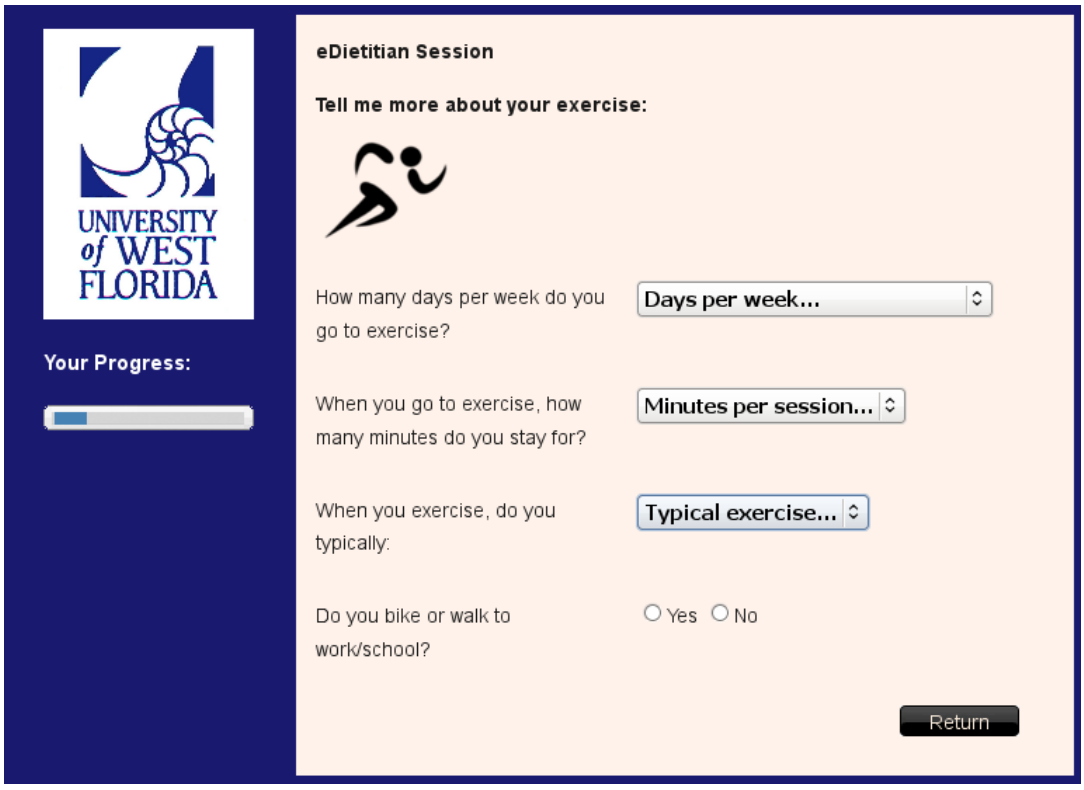

Figure 5 eDietitian asks questions related to the user's exercise output (used to calculate BMR).

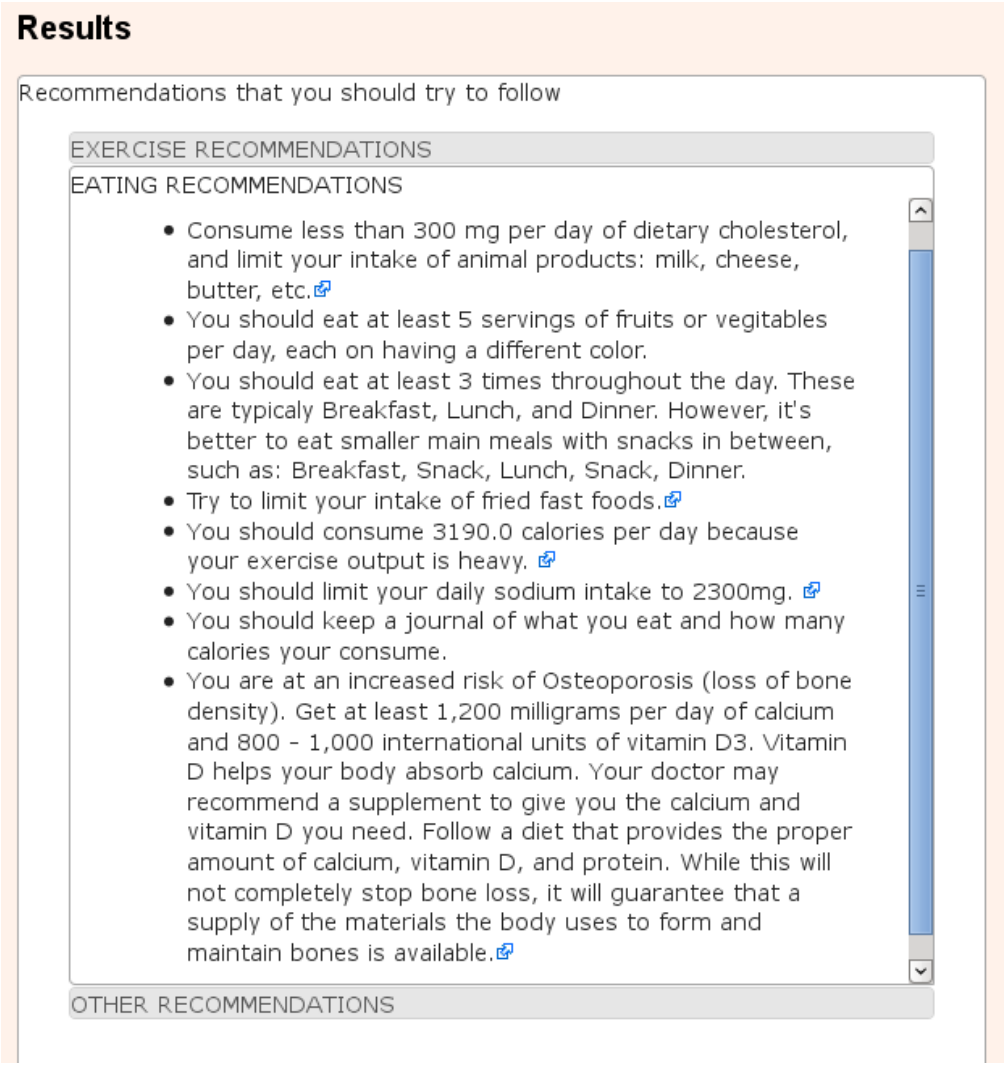

Figure 6 eDietitian shows the results of the questionnaire, along with the user's exercise, eating and any other recommendations. The blue arrow at the end of each recommendation is a hyperlink to the source of the rule, and a "tooltip" shows the reference when the user hoovers over it.

5 Review and Quality Assurance

One of the most vital issues that may impact the usability and successfulness of an expert system is the accuracy of the knowledge which it encodes. The knowledge base for the eDietitian system was based on trustworthy information from US Government sources, including the U.S. National Library of Medicine [12], the "Dietary Guidelines for Americans" from the US Department of Agriculture [13], and the Center for Disease Control's Obesity and Overweight website. Also, for review and quality assurance, a licensed dietitian was contracted to review the system. The review involved periodic live feedback sessions with the licensed dietitian, during which the developer and dietitian would go through the system screen-by-screen and inspect the wording, flow, correctness, and usability of the system.

The review followed a cyclic model, where the developer would revise the system based on the dietitian's feedback, and then have another feedback session with the expert. Cyclic reviews were performed four times until the dietitian's feedback was fully incorporated.

6 Conclusions and Future Work

This paper presents the development of a TeleHealth system called eDietitian, a system built using an open source web-based expert system framework called Tohu. TeleHealth systems are an emerging method of delivering health services to patients and have been

shown to perform quite well [1]. The system uses a rule-based approach to provide individualized diet and health recommendations to users, based on completion of a simple auto-reporting questionnaire. A comparison was given between this system and similar systems. The architectural design and implementation were described, as well as usage of the system. This project demonstrates how a complex web-based expert system can be easily constructed using open source tools such as Tohu and Drools. eDietitian uses a web-based approach and leverages existing tools to make dietitian consultations more accessible to a larger audience.

Opportunities for future work include extending the system to allow for display of video resources and selections based on pictures. These enhancements would help make the questionnaire more user-friendly, and potentially increase system usability. In addition, the user interface can be refined by adding related pictures and video content that explain conditions clearly using rich content. Another potential path for future work is the addition of an explanation facility that could provide additional information to users about why certain recommendations were given.

Computerized Clinical Decision Support in a Hospital Information System

Christian J. Schuh, Walter Seeling
Center for Medical Statistics, Informatics and Intelligent Systems (CeMSIIS),
Medical Expert and Knowledge-Based Systems,
Medical University of Vienna, Spitalgasse 23,
A-1090 Vienna, Austria

Abstract - *Since the big potential of medical decision making was first realized, hundreds of articles introducing Clinical Decision Support Systems (CDSSs) have been published in the last three decades. But even today, only few systems are in clinical use. Even fewer are in use outside their site of origin, and their full potential for optimizing the healthcare system is far from realized.*
Clinician's acceptance and utilization of CDSSs depends on its workflow-oriented, context-sensitive accessibility, and availability at the point of care, integrated into a Hospital Information System (HIS). Commercially available HIS often focus on administrative tasks and mostly do not provide additional knowledge based functionality. This paper works out advantages and disadvantages of several approaches and compares them against possible alternatives. Finally, experiences, gained by clinical use of two introduced systems, integrated in the HIS of the Vienna General Hospital, to analyze the little use of CDSSs in today's clinical routine practice.

Keywords: Clinical decision support, Hospital Information Systems, Knowledge Acquisition, Medical Applications.

1 Introduction

In modern health care environment, the amount of information available is very large, and in order to manage it computers are used in medicine in almost all areas. It is generally assumed that every patient generates around 20,000 different data values on a daily base. Over 236 different variable categories in a medical ICU record are common and conclude that this far exceeds human intellectual capability [1]. Physicians and nurses are still performing time consuming manual data analysis for making the most optimal medical decision for each individual patient [11-13]. They must choose from and interpret a huge variety of clinical data, while facing pressure to decrease uncertainty, risks to patients and costs. The true essence of healthcare delivery is decision making - what information to gather, which tests to order, how to interpret and integrate this information into diagnostic hypotheses and what treatments to administer. Moreover, current ICU platforms are not offering an infrastructure for infection surveillance, data-driven guidance and modeling of critical illness.

The provisioning of Clinical Decision Support Systems (CDSSs) would enable the discovery of patterns in health data which might be important for the fight against nosocomial infections, incorrect diagnosis, unnecessary prescriptions, and improper use of medication.
Since the potential of medical decision making was first realized, hundreds of articles introducing CDSSs have been published in the last three decades. But over the years' experience has shown that the expectations were not always fulfilled. Even today, only few systems, so asserted, are in clinical use. Even fewer are in use outside their site of origin, and their full potential for optimizing the healthcare system is far from realized.
Shortliffe [20] outlines, that ''the greatest barrier to routine use of decision support by clinicians has been inertia; systems has been designed for single problems that arise infrequently and have generally not been integrated into the routine data-management environment for the user''.
The Clinicians' acceptance and utilization of CDSSs depends on its workflow-oriented, context-sensitive accessibility and availability at the point of care, integrated into a Hospital Information System (HIS). Commercially HIS often focus on administrative tasks and mostly do not provide additional knowledge based functionality [33, 36]. This paper surveys on two concrete applications the capabilities as well as limitations of CDSSs. Both presented systems are established as real-time applications. They are fully integrated in the HIS, and have reached the state of extensive clinical testing at the Vienna General Hospital. Finally, experiences, gained by clinical use of the systems, are used to analyze the little use of CDSSs in today's clinical routine practice.

2 Methods

2.1 Clinical Decision Support Systems (CDSS)

CDSS can be broadly defined as software applications that integrate patient data with a knowledge-base and an inference mechanism to produce patient specific output in the form of care recommendations, assessments, alerts and reminders to actively support practitioners in clinical decision-making.
Generally CDSS are any type of application that support the decision making process. A generic DSS receives a certain

amount of data as input, processes it using a specific methodology and offers as a result some output that can help the (physicians) decision-makers. A typical therapeutic cycle in a simplified view is shown in Fig.1.

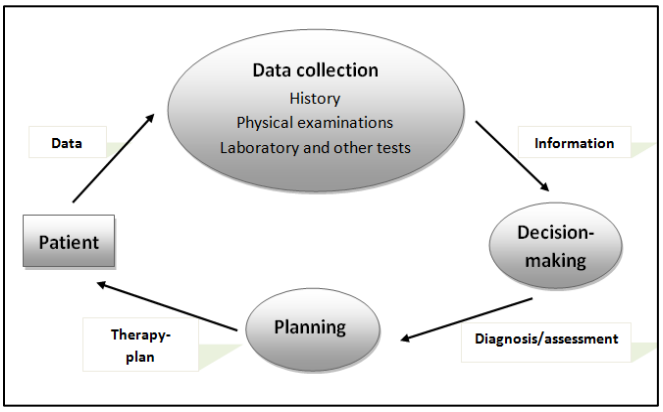

Fig. 1: The Diagnostic-Therapeutic Cycle (a simplified view)

In principle a DSS can be classified into the following six frameworks [22]: Text-, Database-oriented, Spreadsheet-oriented, Solver-oriented, Rule-oriented, and into a Compound DSS. A compound DSS is the most popular classification for a DSS [37, 38]. It is a hybrid system that includes two or more of the five basic structures of DSSs. Patient data can be input by digital entry, queried from a HIS, Patient Data Management Systems (PDMS) or transmitted from other medical devices. Patient data are compared against a knowledge-base and made sense of by an inference mechanism. The inference mechanism can be highly variable in sophistication ranging from simple 'if Rules 'Yes' or 'No' and 'If 'Then', 'Else' statements to Bayesian prediction techniques and/or with fuzzy logic [8], [21]. Expert or knowledge-based systems are another type of DSS capable of being programmed to perform decision making at the level of a domain expert [24]. These systems represent the most prevalent type of CDSS used in medical clinical practices today. Though CDSSs can include different components, and though domain knowledge can be structured in a variety of ways, certain elements are common to all: *a user interface, a knowledge base, a database*, a knowledge acquisition facility, and an *inference mechanism*. In the next section two CDSSs integrated via web services in a HIS are presented. Both systems are established as real-time applications and have reached the state of extensive clinical testing at the Vienna General Hospital. The first one is to hyperglycemia management system for critically ill surgical patients. The second gives immune-suppressive therapy for kidney-transplant patients.

2.2 Maintaining Hyperglycemia

Hyperglycemia has been shown to be an independent risk factor of mortality in patients with stroke and myocardial infarction. There is increasing evidence that tight blood glucose (TBG) control improves outcomes in critically ill adults. Furthermore, strict control of hyperglycemia reduces the rates of infectious complications in surgical Intensive Care Unit (ICU) patients. The risk of mortality or significant morbidity is high among critically ill patients who are treated in the Intensive Care Unit (ICU) for more than 5 days. These patients are susceptible to sepsis, excessive inflammation and multiple organ failure, the latter often being the cause of death. Most intensive care patients, even those who did not previously suffer from diabetes, are hyperglycemic.

Hyperglycemia caused by insulin resistance in the liver and muscles is common in intensive care patients [2]. Van den Berghe showed that Tight Glycemic Control (TGC) i.e. Controlling Blood Glucose Levels (BGLs) within 80–110 mg/dl using intensive insulin therapy, provides significant improvement in mortality (8 to 4.6%) and morbidity in surgical ICU patients.

Several published clinical trials have demonstrated morbidity and mortality benefits of moderate-to-tight glycemic control in an intensive care environment [3, 4], [6], [9, 10].

Tight Glycaemic Protocols:

The tight management of hyperglycaemic crises requires expensive and labor-intensive procedures that are not achievable in all clinical settings. The currently implemented algorithm for achieving and maintaining hyperglycemia and the used tight glucose protocol at our hospital's ICU is shown in Table I.

Table I: Algorithm for archiving and maintaining normo- glycemia in the ICU

Test	Result of BG measurement	Action
Measure BG an admission to ICU	> 220 mg/dl	Start insulin 2 – 4 | U/h
	220 – 110 mg/dl	Start insulin 1 – 2 | U/h
	< 110 mg/dl	Don't start insulin but continue BG monitoring every 4 h
Measure BG every 1 -2 h until in normal range	> 140 mg/dl	Increase insulin dose by 1 – 2 | U/h
	110 – 140 mg/dl	Increase insulin dose by 0.5 – 1 | U/h
	approaching normal range	Adjust insulin dose by 0.5 – 1 |U/h
Measure BG every 4 h	approaching normal range	Adjust insulin dose by 0.5 – 1 |U/h
	normal	Insulin dose unchanged
	falling steeply	Reduce insulin by half and check more frequently
	60 -80 mg/dl	Reduce insulin dose and check BG with 1 h
	40 – 60 mg/dl	Stop insulin infusion, assure adequate baseline glucose intake and check BG within 1 h
	< 40 mg/dl	Stop insulin infusion, assure adequate baseline glucose intake, administer glucose per 10 g IV boluses and check BG with 1h

In general protocols to assist in management of hyperglycemia are becoming more widely used and have been shown to improve outcomes for hyperglycemic patients. Several protocols for glucose control have been adapted [7], [25, 26], [28]. In a pilot study [5] was found that the majority

of patients were not achieving target BGL consistently and although the incidence of hypoglycemia was rare, the range of insulin infusion rates prescribed was often greater than patient requirements presenting a risk of overdose. This audit aims to further assess the success and safety of TGC in ICU [7].
As with any protocol, this algorithm alone does not guarantee improvement in quality of care or clinical outcome. However, in the context of the treating physician's knowledge and experience, this approach could be expected to realize significant reductions in mortality and morbidity.

2.3 Immune-Suppressive Therapy for Kidney Transplant Patients

Many chronic kidney disease patients profit from a kidney transplantation. A necessary component after transplantation is an immunosuppressive therapy. As there is a narrow range between kidney transplant rejection and the side effects of over-immune-suppression (such as an increased vulnerability to infections), therapeutic drug monitoring is another necessary component [11].

The most frequently used immune-suppressive drugs are Calcineurin inhibitors, which inhibit the cell-mediated and humoral immune responses. One of those is Tacrolimus. Since the drug absorption rate varies, close therapeutic drug monitoring is necessary. According to Satohiro [14] the therapeutic range of Tacrolimus is located between 10-20ng/ml blood concentration to avoid rejection and infections. These Calcineurin inhibitors have many side effects, one of the most popular include reversible disturbances of liver function, cardiac toxicity, edema, blurred vision, depression, sleep disturbances and nephrotoxicity, neurotoxicity, and hyperglycemia [15, 16].
Currently the immunosuppressant dosage is determined on the basis of the actual medication level and various factors (immunological situation, time after transplant rejection reactions, laboratory values, etc.). The ultimate goal is to develop a theoretical model that maps the therapy with their influencing factors [16]. A theoretical model of the dosage determination will enable physicians to gain new insights into the treatment monitoring of immunosuppressive drugs and potentially enable automation of drug dosing.

2.3.1 Data Description

To create a immune-suppressive therapy model historical patient therapy data and laboratory parameters could be used within a period of 13 years from the General Hospital of Vienna. Data from 492 patients and 13.053 consequent examination dates were available for evaluation. These data include the measured blood levels of the administered medication and the daily medications, as well as the time of the medication measured and medication administered.

2.3.2 Data Processing and Analysis

In current clinical praxis, medication adaptations are based on preliminary medication levels and other characteristics of the patients.

Consequentially, medication adaptation and preliminary data have a strong correlation, thereby confounding each other. This makes a simple estimate of the effect of a medication adaptation almost impossible. The problem is illustrated in Figure 2 (left side), where in the x-axis (-1) means to adjust down, (0) to stay and (1) to adjust upward medication. The boxplot shows that if you lower the medication, a higher medication level could be expected.
Avoid using too many capital letters. All section headings including the subsection headings should be flushed left.

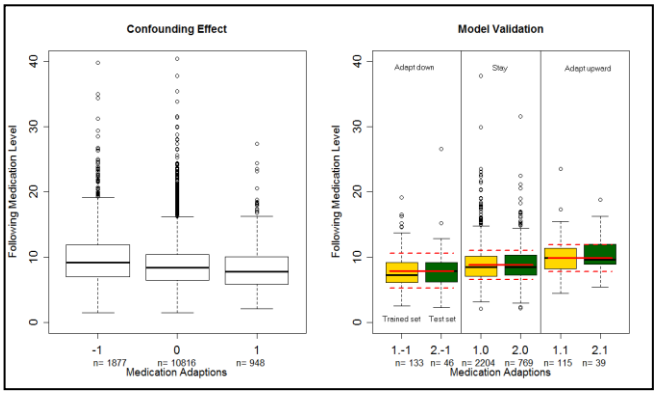

Fig. 2: Confounding Effect & Validation

This could be explained by the fact that physicians only lower the medication if the medication level is already quite high, but this action generally does not completely normalize the medication level. The main problem is to obtain the pure biological response of the patients. Since only a few medication adaptations are frequent, these were divided into three categories: upward adaptations (1), down (-1) and retention of the medication (0).

3 Conclusions

3.1 Technical Aspects

There are many different methodologies that can be used by a CDSS in order to provide support to the health care professional.
In our case the inference mechanism, i.e. a set of rules derived from the physician's (experts) and evidence-based medicine, and the knowledge base itself, are implemented through medical logic modules (MLMs) based on a language such as Arden syntax [18]. The Arden Syntax Server represents therefore the reasoning and inference mechanism with MLMs and processes the patient data, which is received from the HIS via web services. The communication mechanism of a CDSS will allow the system to show the results to the users as well as have input into the system. The HIS at the General Hospital of Vienna is i.s.h.med. This fully featured HIS represents the CDSS- communication mechanism. It provides a framework for medical documentation which can be easily customized in form of parametric medical documentation (PMD) to the special needs of the respective clinical departments.

3.2 Hyperglycemia Decision Support System

The communication mechanism of the CDSS is realized as a PMD of the HIS. The system is used for postoperative cardiac patients in an ICU at the Vienna General Hospital [29]. The advantages of the system are its easy application and generation of more specific knowledge bases with MLMs, which allow smoother treatment.
The CDSS is currently being tested with a sample of prospective randomized cases currently undergoing treatment (Fig. 3).

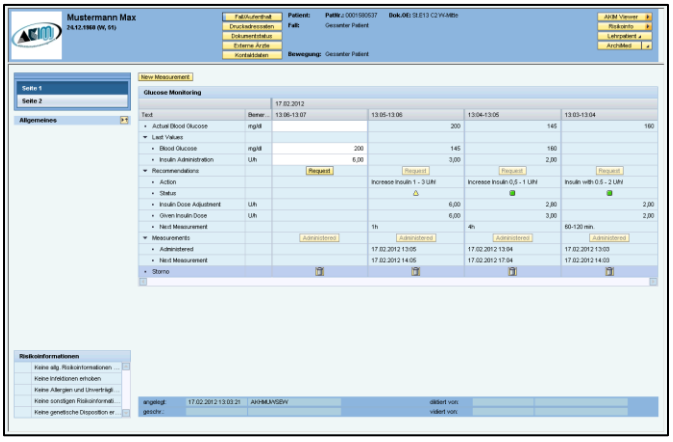

Fig. 3: HDSS Application

The results confirm the applicability of the application to represent medical knowledge, thus rendering the glycaemic process transparent and comprehensible. A direct connection, for instance with an insulin perfusion pump, would allow smooth adaptation continuously. The hyperglycaemic control may be better if appropriate safety controls can also be put in place. Safe implementation of tight glycemic control requires appropriate monitoring to reduce the risk of this complication [39]. Several protocols for glycemic control have been adapted [5], [9, 10], [25], [27], [32]. In a pilot study could be found that the majority of patients were not achieving target BGL consistently and although the incidence of hypoglycemia was rare, the range of insulin infusion rates prescribed was often greater than patient requirements presenting a risk of overdose. This audit aims to further assess the success and safety of TGC in ICU [32].
Alerts are triggered within several time depended columns of the application. The actual values and proposals and alerts are displayed in different coloured symbols.
Currently the implemented colours are red, yellow and green. These colours represent an urgent, a warning, and an information level (Fig. 4). If there is no reaction within a defined time period, i.e. column on an urgent (red) information level an acoustic alarm is activated also to force an urgent reaction.
With the control unit itself it's possible to change the glucose level, according to the proposals of the program. If different settings to the proposed one have to be set, there is also a possibility to log this information. The logging feature allows a fine tuning of the knowledge bases off line.

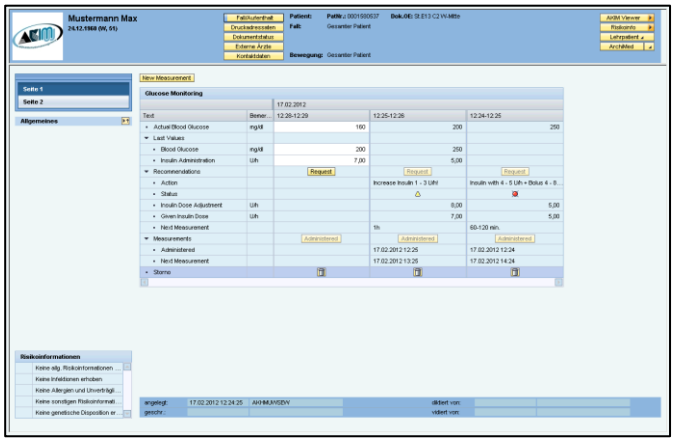

Fig. 4: HDSS alert screen

3.3 Immunosuppression Therapy System

To create a knowledgebase for immunosuppression therapy the medication blood level thresholds has been estimated statistically by a regression tree. Since this is an ordinal outcome variable, the method of Conditional Inference Trees (CITs) [17] has been chosen. Classes could be formed where the statistical relationship between preliminary data and the medication adaption isn't longer significant. The determined classification is shown in Table II.

Table II: Classification determined from the CIT

Class	BL	Additional Decision Parameters
1	≤3.8	
2	(3.8,4.7]	TSS: ≤27153
3	(3.8,4.7]	TSS: >27153
4	(4.7,6.9]	TSS: ≤6490
5	(4.7,6.9]	TSS: (6490,49281]
6	(4.7,6.9]	TSS: >49281
7	(6.9,9.3]	TSS: ≤4544
8	(6.9,9.3]	TSS: >4544
9	(9.3,10.9]	TSS: ≤34018
10	(9.3,10.9]	TSS: >34018
11	(10.9,13.9]	APR: ≤7.5 & PRO: 0,1,2
12	(10.9,13.9]	APR: ≤7.5 & PRO: 3,4
13	(10.9,13.9]	APR: >7.5
14	>13.9	LT: ≤2
15	(13.9,15.2]	LT: >2
16	>15.2	LT: >2

The CIT took the following parameters into account: Tacrolimus blood level (BL) [ng/dl] now and at the last ward round [ng/dl]. The dose of the proliferation inhibitor [mg], of the additional Aprednisolon (APR) [mg] and of the last Tacrolimus (LT) [mg] administered. Further parameters are sex, age at – and time since surgery (TSS) [h]. A model validation was performed with 80% of the data for the training set and 20% for the test set. To test the model, the ensuing medication blood levels were compared to the respective medication adaption [23].
The CIT formed homogenous classes to eliminate the confounding effect. When we performed model validation for one of the calculated groups, the distribution behave largely

normal. The box plot has a prediction interval with a coverage probability of 80%. Out of these consolidated finding knowledge could be developed through MLMs. A specific PMD of the HIS i.s.h.med acts as communication mechanism for the CDSS.
The application, shown in Figure 5 is in evaluation since June 2011.The results have to be seen as a first approach of more accurate forecasting models for the medication blood level of the respective medication.

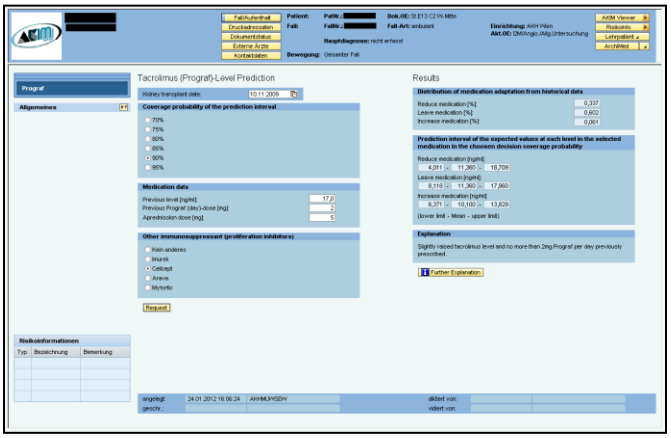

Fig. 5: Application (PMD) in i.s.h.med

The next step could be to add weights, data of rejections or other covariates, which may be able to improve the model even further.

4 Conclusions

When CDSS or DSS in general where initially developed, each knowledge base and inference mechanism required programming before the knowledge base content could be written. As the field evolved, researchers found that it was possible to separate the inference mechanism from the domain specific knowledge and databases. This key design feature became responsible for the commercial success of decision support systems.
Producing standard inference mechanism and knowledge bases made it possible to unplug one knowledge base and then connect a different one. Based on the literature, current computer-based clinical CDSS are limited in application. Roughly seventy known proprietary medical CDSS exists. Only ten out of seventy CDSSs geared towards routinely use. There is no information available about a real daily average usage of these systems.
A well-designed CDSS should have the potential to assist physicians who can and do use it as often as possible in the daily routine work. In some situations physicians learns from using a CDSS about criteria, facts or process issues that need to be considered in a specific decision situation. CDSSs encourage and promote "rationality" in decision making. CDSSs are intended to support not replace physicians, so the users need to consciously interact with a CDSS to use it effectively.
A big issue is that the expectation needs to be created that the physicians are the ultimate authority and that the physicians can anytime "over rule" or choose to ignore analyses and recommendations of the CDSS.
The greatest anticipated benefit of a CDSS lies in the constituency and uniformity in applying decision criteria of a given situation. Physicians have difficulty making decisions because they cannot exhaustively consider every factor relevant to the decision, due to either limited memory or limited information.
Anticipated limitations of CDSSs are that an optimal physician's treatment requires that physicians be able to have the following information, in real time, if possible: What is happening right now? What will happen in the future? What do I need to create the future I want? To answer these questions effectively, physicians requires data that are factual, factual inferential (why type questions) and predictive (what if questions). To date, the best support that a CDSS has been able to provide is data that answer factual and maybe some forms of predictive questions [30], [35], [39].
Physicians have no shortage of data available to them. Thus, physicians have found that currently available CDSSs are not able to meet their more complex information needs. As mentioned above one big argument of the rare utilization at this time is that most of the CDSSs have not progressed beyond the prototype stage. There are no standards or universally accepted evaluation or validation methodologies to ensure that the system's knowledge base is complete and correct.
Further questions about CDSSs are: Does the use of a CDDS improve the quality of decisions produced? And are the economic or other benefits, as for instance patients comfort, attributable to the use of the CDSS?
The absence of a well-defined or universal evaluation methodology makes these questions difficult to answer. To date, an examination of the literature indicates that there is virtually no information available related to the cost or cost effectiveness of CDSSs. Most of the CDSSs are university-based developments, and still in prototype stage. These costs regarding the initial investment of CDDSs tend to be hidden and therefore difficult to access.
This frightens or hinders the industry's interest in funding and encouraging the development of CDSSs in health care in general [19]. Still, many physicians have a real positive outlook on the potential for these systems, particularly relating to practitioner performance. However, until the use of CDSS is a routine as the use of the blood pressure cuff, it is important to be sensitive to resistance to using these systems.

dostrows@ford.com

Abstract

This paper examines the structural qualities of Social Networks towards the identification of trends. We consider a collection of Twitter messages towards the trending of technologically-related topics. For each individual topic, network cohesiveness is explored over time. We demonstrate that structural qualities reflecting community dynamics can provide insight to the prediction of long term trends. The goal of this work is to lend insight to the characterization of consumer behavior, particularly in the area of technology forecasting.

I. INTRODUCTION

Online Social Networks have increased substantially in recent years with the top Social Media sites acquiring hundreds of millions of users [1][2]. Through the increased accessibility of the internet, these outlets have encouraged users to interact and build relationships. Considered in depth by the sociological community, these relationships are closely compared to those found in real-life society [3]. As such, it has become increasingly important for organizations to understand these networks for the purpose of predictive analytics for internal as well as external application [4][5].

Such networks can be represented as graphs where nodes represent individuals and edges represent their relationships [6]. Given this network representation, prior work has demonstrated that the combined knowledge of community structure and relationship strength has important application to the area of web analytics [7]. In particular, when studied over time, this structural information can be informative towards suggesting what influence it will have on the future.

In the context of community as viewed from the perspective of a graph, there are qualities that are present among people who are highly influential which can be formally considered as power. Being a fundamental property of social structures, it has been suggested that power is relational [10][11]. Through research, a relationship has been established between power and density of a described structure [12].

Influence and power are strongly associated with transformation in the context of a community. Such a phenomenon is termed as emergence and is best described as a local action influencing an overall behavioral pattern. Through the examination of connections, research has also demonstrated that emergence can be objectified [12].

The study of such structural dynamics present strong support to what we know about the predictive nature of the internet [13][14][15]. Currently, a number of examples exist in the relation of trends as compared to the development of patterns [16][17][18]. Such patterns that exist around structures are highly indicative of the concept of communities [19]. These communities have been demonstrated across many studies as integral to the study of sustainability as well as economic opportunities.

The methodology outlined in this paper describes a means of examining the structural qualities within an online community. We apply this methodology to a collection of unstructured communication acquired from a web-based resource (Twitter) [20]. Our three primary inputs include topics of interest, web-based communications as well as the consideration of between whom the communication is directed. Building a graph-based structure based on communication, structural analysis is applied. From here, we examine the relationship over time of the

network structure to that of the interest of the concept.

The remainder of this paper is as follows: In Section Two we detail current work in the field. Section Three provides an examination of our methodology. Section Four presents our case studies and Section Five provides our conclusions.

II. CURRENT RESEARCH

Due to its constrained size and minimalistic attributes, a number of research efforts in Social Analytics have been directed at Twitter as a means of predicting trends. Among such efforts, (Achrekar et. al.) utilized Twitter to assist in the prediction of flu virus trends. This was accomplished by devising auto-regression models to predict data published by the Center of Disease Control (CDC) to the percentage of 'visits' to physicians [21]. (Iyengar et. al.) determined when an event started and ended by analyzing the content of Twitter messages using an SVM classifier and hidden Markov Model. Here, event boundaries in Twitter data were predicted for a set of events in the domains of sports, weather and social activities [22]. (Peng et. al.) demonstrated that conditional random fields could be used to improve prediction effectiveness by incorporating social relationships[23].

Focusing directly on structural qualities, (Gloor, Nann, Schoder) leveraged betweenness centrality of actors by weighing the context of their positions in a network. Through this application, they were able to extract and predict long term trends on the popularity of relevant concepts such as movies and politicians [7]. (Mislove et. al.) analyzed the structure of multiple online social networks. This involved the comparison of in-degree to out-degree representation though the investigation of side-free, power-law and small-world properties [24]. (Cantanese et. al.) applied social network techniques to analyze specific properties of social networking graphs. Among the qualities examined included centrality measurements, scaling laws and distribution of friendship [25].

A substantial amount of research from Link Mining has been leveraged to support Social Network concepts. These algorithms have supported performance among a number of activities including question answering, information retrieval and web-based data warehousing [26]. (Erbs et. al) demonstrated that data volume as well as training data is vital to link discovery with text-based approaches yielding superior results [27]. (Qian et. al) relied on the application of link mining to the Enron mail corpus to determine communities within linked nodes. Further work supported the identification of 'common friends' by relying on clustering. [28] Additional methods have explored link-predicates with applications among exploring data, distributed environments and spam analysis [29][30][31].

Research in Social Networks has also expanded on current search technology including PageRank and HITS [32][33][34]. Building on these methodologies, (Bharat, Henzinger and Chakraborti) proposed variations that exploit web page context to weight pages and links based on relevance.[35][36]. Relying on the topological structure of a graph (Sugiyama et. al.) successfully integrated several methods including network, quantitative, semantic, data processing, conversion and visualization-based components [37].

Investigations in Semantic Web technologies have also greatly affected development in Social Networks. Among them, (Zhou, Chen and Yu) integrated an ontology-based Social Network along with a statistical learning method towards Semantic Web data. This involved utilization of an extended FOAF (friend-of-a-friend) ontology applied as a mediation schema to integrate Social Networks and a hybrid entity reconciliation method to resolve entities of different data sources [38]. (Thushar and Thilagam) also relied on Semantic Web technology for the identification of associations between multiple domains within a Social Network [39].

A number of efforts in Relational Learning have supported Social Network analysis predicated on the concept of homophilly-based associations to support learning. Among them include the application of probalistic modeling [40] collaborative relationship [41] and inference-based approaches [42].

Visualization techniques also provide for a substantial level of support in studying Social Networks. (Batajelj and Mrvar) developed tools for the visualization of large-scale networks allowing for support to identify vertice extracts and relations between clusters [43]. (Noel et. al.) calculated inter-item distances among combinations of elements from which hierarchical clustering dendrograms are visualized to enhance measurement consistency between clusters and frequent itemsets [44]. (Levng et. al.) developed Social Viz which provided users with a means to view frequency relationships among multiple entities in a network [45].

III. METHODOLOGY

Our methodology consists of four key areas: network representation, tie strength, key players and cohesion [46]. To support the generation of a network, we first consider the application of basic data filtering techniques including matching on keywords and hashtags. After the data set is paired

down to a topic or set of topics we construct the networks. Here, all interactions may be considered. Frequently, this is addressed in the form of users who happen to 'follow' or 'like' other users or their communications. A secondary means of edge generation is where a direct (personal) message exists between two entities. This exists in our test case in the form of a 'reply' to an existing post.

From our established network, tie strength is considered to evaluate strength/weakness of edges in our network, both as a means for graph reduction as well as clarity. Several methods are suitable among our data to serve as a proxy for the strength of a tie:

- Frequency of interaction
- Recipriocity in interaction
- Type of interaction (e.g. intimate or not)
- Relationship between entities (e.g friends, co-workers, relatives)
- Node Structure (neighborhood/relations/ affilliations)

Among the listed attributes, our main focus is to consider is frequency and recipriocity by generating a graph among entities (identifiers) who have replied to a message.

After consideration to our graph construction, we leverage the metric of centrality in understanding how key players interact in the graph. as well as their influence on the entire network. Centrality can be defined individually as a ratio of paths containing a point between two linking (separate) points. This can be formally expressed with g_{jk} as the number of geodesics linking points x_j and x_k in a graph along with $g_{jk}(x_i)$ where,

$$b_{jk}(x_i) = g_{jk}(x_i) / g_{jk}$$

is the proportion of geodesics linking x_j and x_k that contain x_i [47].

To support the overall evaluation of a graph, an index of the centralization of a complete graph C_B is considered. It is based on the intuition that a graph is centralized to the degree that its communication flow is overwhelmingly dominated by a single point. The measure is defined as the average difference between the normalized centrality of the most central point C'_B (p^*) and the normalized centralities of all other points in the graph

Where,

$$C'_B(x_i) = \sum_{i=1}^{n} [C'_B(p^*) - C'_B(p_i)] \ / \text{n-1}$$

Finally, the networks structure is examined from the perspective of cohesion by the evaluation of connectiveness in a graph. Connectivness is defined as the maximum number of elements which need to be removed to disconnect the remaining nodes from each other and is evaluated along Krackhardt's connectedness scoring. Existing as a means of expressing reachability in the termed graph, it represents the proportion of nodes (actors) that cannot be reached by other nodes. This is defined where a digraph G is equal to the fraction of all dyads { i , j } such that there exists an undirected path from i to j in G [48].

As opposed to comparing static metrics, both centrality and connectivity are evaluated over monthly intervals. Here the structural variation is considered as an indicator for changes in trends.

IV. Case Study

Our study consists of the application of stated methodologies towards a collection of 100M Twitter messages with time stamps ranging between 1/1/2010 and 6/31/2010 [49]. Our subject matter of interest was mobile Operating Systems. We focused on the three major competitive dominant (high presence) technologies – the Iphone, Blackberry and Android OS-based mobile devices. Figure one presents the market share for the three Operating Systems for the period between Jan 2010 and June 2010 [50].

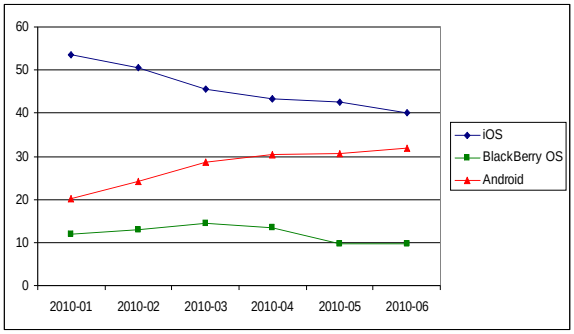

Figure 1. United States Market share for Mobile OS (Jan 2010 – Jun 2010)

Each of these topics were identified by employing filtering on terms and phrases. The collection of messages were filtered on three topics and then separated by month. The volumes of filtered messages per each month are presented in Figure 2.

Within each data collection, we considered messages which were associated with a 'reply'

communication. As such the resulting adjacency metrices maintained at least one edge (minimally) between each node. To demonstrate the graphs, a reduced sample of 100 nodes from a selected month is presented for both the Android and Iphone collection. (Figures 3 and 4) Our approach in graph generation is reflected in this graphical presentation as each node has at least one connection with the Android sample presenting a higher degree of connectiveness and centrality.

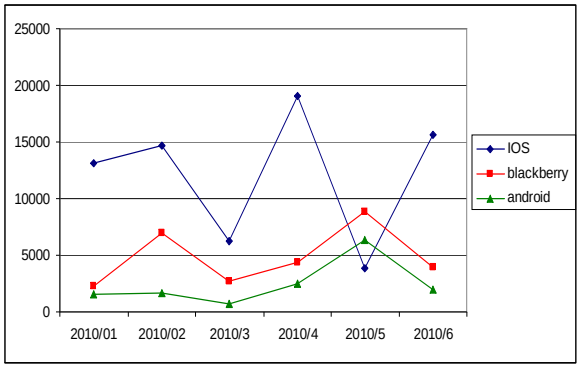

Figure 2. Data Sample Sizes (Jan 2010 – Jun 2010)

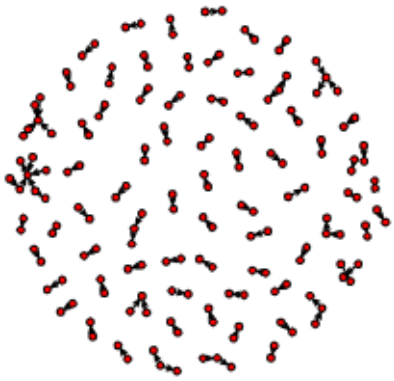

Figure 3. Android Graph (100 nodes)

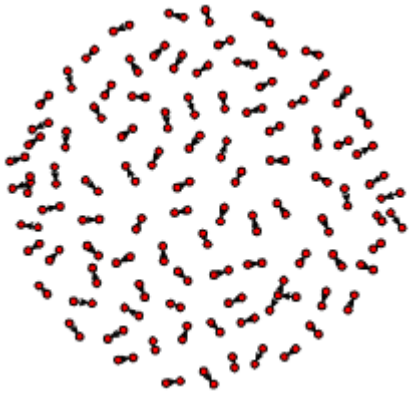

Figure 4. Iphone Graph (100 nodes)

Centrality was applied to view the properties of key players by employment of the Social Network Analysis ('R' programming) library [48]. The metric was considered for each topic across monthly intervals (Figure 5). This was examined over the entire sample for each month only including entities that had engaged in a reply conversation. Given our sample size, the metrics were very low as they ranged between .018 and .0122 among our three networks. This was in part due to our selected means of graph generation and secondly due to our sample size of approximately 1% of the entire Twitter feed (given the estimation of approximately 50M Twitter messages per day for the first and second quarters of 2010 as compared to our data set of 100M). Even though IOS maintained the largest overall sample size, the centrality measurement was the lowest, the graphs generated around the topic of Blackberry were highest corresponding to its gains in market share over the six month period.

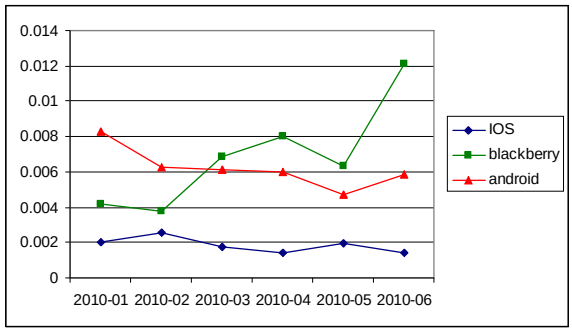

Figure 5. Centrality Measurements (Jan 2010 – Jun 2010)

Next, cohesion was examined, relying on the Krackhardt scoring mechanism for each monthly period as compared to each data set. Here, the Blackberry demonstrated a substantial increase corresponding to the US market share as determined earlier. Although maintaining the largest market share and sample size, the IOS maintained the lowest connectivity between all three ranging between 0.008 and 0.001.

Next, correlations were generated among the six sets of data, presented in figure 7, 8 and 9. First, the message sample sizes were compared against the market shares providing very little to negative correlation ranging between -.39 to .16. Corresponding to the relative volume collected, the IOS scored highest among centrality with the scores ranging between .71, .62, .85 for IOS, Android, and Blackberry. Although considering relatively moderate sample size, the BlackBerry metric scored extremely well in correlation with the market share. Connectedness was also directly correlated to the market share percentages with .91, .70 and .66 for

IOS, Android and Blackberry respectively. In spite of the relatively low connectivity metrics, IOS performed much higher than the other two mobile Operating Systems indicating that investigations in structural metrics as they change over time presents a substantial opportunity to understand their predictability.

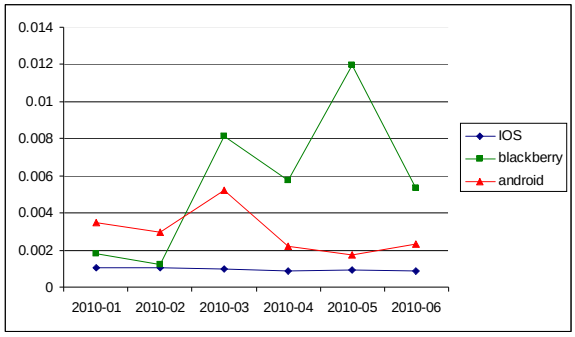

Figure 6. Connectivity Measurements (Jan 2010 – Jun 2010)

Volumes Correlation	
IOS	0.16
Android	-0.39
Blackberry	0.24

Connectedness Correlation	
IOS	0.91
Android	0.7
Blackberry	0.66

Figure 9. Correlation of Connectedness metrics to Mobile OS marketshare (Jan 2010 – Jun 2010)

V. Conclusion

We have considered the application of structural metrics to the trending of topics. This was accomplished by extracting topic-related data from a collection of 100M Twitter messages. Graphs were generated among the filtered collection by selecting only the messages that existed in the form of a reply. We then applied metrics to determine the effect of key players (Centrality) as well as metrics for cohesion (Connectedness). We were able to successfully correlate our graph structure metrics to the market share of three major mobile Operating Systems for the defined period. The disparity in correlation between volumes and our assigned structural metrics support that structure is a substantial indicator that is independent of changes in volumes within a given sample. As such, our metrics suggest that our Social Networks (utilized in real-time) could serve a means of predicting future consumer behavior.

Future work includes the incorporation of semantics on the filtering portion (graph generation) as well as reassigning weights to associated edges. Opportunities in this area also include examination of metrics (e.g. betweeness) among graphs integrating all three topics of comparison.

Detection of Malicious Beacon Node Based on Intelligent Water Drops Algorithm

S.Qureshi[1] , Azzam ul Asar[2]
[1] International Islamic University Islamabad
[2]University of Engineering & Technology, Peshawar, Pakistan.

Abstract:--*Security of the wireless sensor network is emerged as a crucial issue due its resource-constrained nature. Number of localization techniques suffers from security threats when there are compromised beacon nodes in the network. This paper presents a technique for detection and revocation of compromised beacon nodes using the concept of Intelligent Water Drop algorithm. The results are very promising and show great potentials towards offering a more secure localized solution of wireless sensor networks.*

Keywords: Wireless Sensor Networks, Malicious Beacon Node, Network Security

I. INTRODUCTION

Wireless Sensor Networks (WSNs) are made up of numerous sensors with wireless communication facilities. The networks created by these sensors are ad-hoc by nature, allowing seamless communication between them. The diversity of WSNs potential applications is immense. Due to this diversity, each application may have a very different set of goals to achieve and challenges to overcome. Localization of sensors is important for large number of WSN applications [1-2]; however it has become a crucial issue due to its resource-constrained nature. To equip every sensor with GPS receiver makes the application uneconomical. Thus beacon/anchor nodes which know their location are used for localization of other sensor nodes. Different schemes and models have been developed for this purpose but these schemes cannot ensure correct localization in an environment where some of the beacon nodes are compromised. Thus researchers are struggling to find ways to overcome the affect of malicious nodes in a network and have presented a number of approaches for secure localization.

In this paper we present a scheme for detection of malicious beacon node using the concept of Intelligent Water Drops (IWD). The scheme uses the same basic method employed by Peng Ning [3]; however by using IWD concept, the scheme has become more reliable. Using simulation we verify that our scheme detects malicious nodes correctly.

II. RELATED WORK

Due to limited resources, wireless sensor networks exhibit unique operational challenges and are prone to localization attacks. Researchers have been introducing new protocols and techniques to ensure correct localization in hostile environment. The approach of robust localization has been introduced by Li et. al.[4]. It assumes presence of malicious nodes in the network and presents scheme that may tolerate the malicious behavior and still makes correct location discovery. This scheme consists of statistical methods. Liu et.

al. [5] presented a method to key out and bump off malicious information. The technique uses minimum mean squared estimation to calculate the location of sensor nodes. Lazos and Capkun have designed a robust decentralized localization system [6] which is robust to Sybil and wormhole attacks. Although this method does not involve statistical methods, it accomplishes robust localization in the presence of malicious nodes.

Another approach is based on the verification of the estimated position. Capkun et. al. [7] have designed an algorithm which is verification based. Lazos and Capkun [6] have presented hybrid algorithm which utilizes cryptographic methods for secure communication between sensors and locators and then devises an algorithm for location determination using verification. However authors of ROPE and SPINE have neglected the scenario where a number of locators themselves are compromised and that may collude.

Sastry et. al. [8] presents an algorithm named Echo which verifies the area of location of claimant. However the verification process sometimes may also be attacked by the adversaries. Wenliang du and associates [9, 54] propose a scheme which uses pre-deployment knowledge for the verification of specific location of sensor. The scheme checks the consistency of the location found by any location scheme and its actual location threshold. If the deviation is significant, it is anomaly. The scheme is dependent on probabilistic distribution of nodes; if these values are not correctly obtained, the results will critically change [10].

Fang liu et. al. [10] have presented an algorithm in which they detect localization anomaly which is followed by detection of malicious nodes responsible for this anomaly. It is grounded on clustering and thus called LADBC. The Network is grouped and has into clusters . However the clustering algorithms have the problem of being dependent on few cluster heads which can run out of battery due to

much processing and communication and can also be captured by adversaries.

Liu et. al. [3] have come up with more genuine approach to detect and revoke the malicious nodes. Three solutions have been presented in this regard by various researchers [3, 11, 12]. Liu et. al. [3] propose a technique for identification and removal of malicious beacon nodes. The detecting node on receiving the location reference from target node calculates distance between them using the signal received and location information sent by the target node. If the two are consistent with difference less than maximum distance error, it is considered benign otherwise malicious. They then developed revocation scheme which is based on the suspiciousness of a beacon node calculated at the base station through alert based scheme. However the detection scheme has a shortcoming. It has not considered the environmental affect. WSN are mostly deployed in an unattended environment; For worse weather changes, there would be much measurement error in distance and two distances may differ much larger than maximum measurement error. In this way, many alerts would be reported to the base station which may increase suspiciousness of benign node and as a result, a number of benign nodes would be revoked from the network.

Srinivasan et. al. [12] have extended the work in [3]. They introduced for the first time the concept of trust and reputation for removal of malicious beacons. They have proposed distributed reputation beacon trust system in which beacon nodes help sensor nodes to decide whether to use given beacon's location information or not by maintaining reputation of their neighbor beacon nodes misbehavior. However since WSNs pose unique challenges in terms of memory, computational capability and battery the reputation based mechanisms usually can add overhead. Also without being globally informed, it is usually hard to cope with local majority and collusion of nodes that have been compromised.

Satyajayant Misra and associates [11] proposed a scheme to detect and remove malicious beacon nodes using a mobile verifier. Authors have shown through simulations that their proposed method detects almost 80% of malicious locators while the false positives percentage is almost zero. However, this scheme has some drawbacks. Mobile verifier needs preprogrammed paths to be stored to follow through the network. Due to restricted number, there is repetition of paths which weakens the algorithm's effectiveness. An additional requirement is that the mobile verifier needs to be charged after every iteration which makes it unsuitable for most of the unattended wireless sensor networks applications. Above all, the whole scheme is dependent on single mobile verifier which is assumed to be uncompromised failing which, the whole scheme will collapse.

III PRINCIPLE OF IWD

Naturally existing rivers, lakes and seas are made up of numerous water drops. These water drops change their environment as they move along their path. Rivers join lakes or sea following paths full of twists and turns. The ideal path for river is the shortest path to its destination following the law of force of gravity. However due to several obstacles, the real path is different from this ideal path. Water drops always try to change this real path to make it better to reach destination. Continuous effort by the water drops change the river paths as the time passes by. Water drops while travelling remove soil and transfer it to another part in front. Deeper parts attract more volume of water. Clearly water drops opt for easier path when choosing between different existing branches. Based on natural water drops, artificial water drops are developed which encounters some of the characteristics of natural water drops. These Intelligent water drops are characterized by the property of amount of soil they carry. IWD prefers the path with low soils rather than higher soils on its beds and probability of next path to choose is inversely proportional to the soils of available paths. The lower the soil of the path, more chance it has for being selected by the IWD. Thus IWDs depicts intelligent behaviour to select next position in their path [13].

Utilizing the IWD algorithm for the detection scheme presented in this paper, we can consider the amount of distance-error as a factor equivalent to the amount of soil in the original IWD algorithm [14]. Greater distance-error means that a particular node is providing more malicious information and chance of that node to be compromised is much higher.

IV NETWORK MODEL

The Sample Network is shown in Figure 1. Network consists of sensor nodes including legal and malicious beacon nodes. The node taking detection can be called as detecting and the one being investigated as target node. We consider same assumptions for this network as in [3]. These include two communicating nodes sharing pair wise key. Communication is two way. Multiple detecting IDs are provided to the beacon node along with keying material. Beacon signals from target node are unicasted to the detecting node and are encrypted. Temporal leashes or RTT technique is used to detect replay attacks (stealing both ID & location).

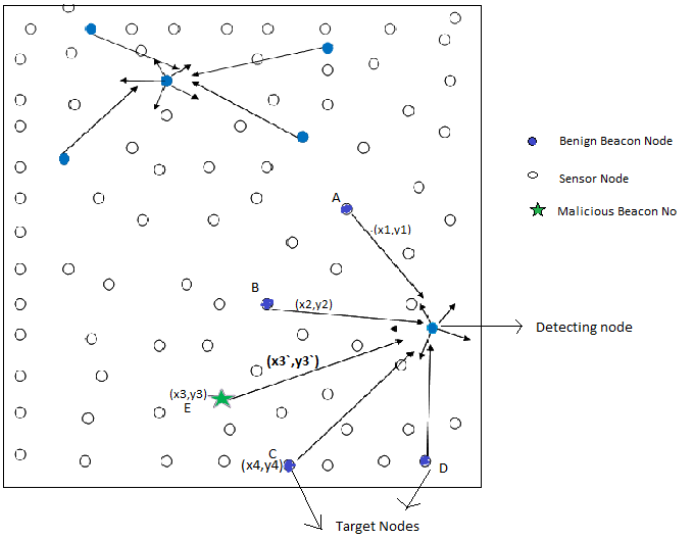

Fig. 1: Network model

V DETECTION SCHEME

The detecting node sends request for location of beacon nodes. The requesting node uses an ID other than its own because if it uses its own ID, the target node will send its correct location and will thus clear the detection test. For this purpose, every beacon node is provided with multiple IDs and all keying materials (assumption). The scheme works as follows. The detecting node first sends request message for location pretending as a non beacon node. The target nodes within range of this detecting node receive this message and reply with beacon signal carrying their ID and location. The malicious node obviously sends wrong location. The detecting node estimates the distance between them, from the beacon signal upon receiving it using TOA technique called actual distance. Since the detecting node knows its own location error due to environment, it can also calculate the distance, based on its own location e.g. (x, y) and target node (x1, y1), using distance formula.

$$D=\sqrt{(x-x1)^2+(y-y1)^2} \qquad (1)$$

The malicious signal detector (comparator) then compares the actual distance and the calculated one. Obviously there will be some error between the two values, since the range estimation techniques do not result in accurate estimations.

$$\text{Error} = |d_{(ij)\ \text{calculated}} - d_{(ij)\ \text{actual}}| \qquad (2)$$

These error values are relatively compared to each other using IWD formula to recognize the nodes with most error. Most error producing nodes will result in lower probability of trustworthiness. Probability of selecting a next position by IWD is calculated by

$$\text{Pi (j)} = \frac{f(soil(i,j))}{\sum_k f(soil(i,k))} \qquad \text{.....(3)}$$

Function of soil between two points *i* and *j* can be considered as the error of distance between two nodes [14]. Every node can be considered as intelligent water drop which calculates the goodness of the other node. According to the formula, the node producing more error will give less '*P*' value challenging its trustworthiness. Calculation of trustworthiness of a particular node is represented by:

$$P(i,j)=\frac{f(e(i,j))}{\sum_k f(e(i,k))} \qquad (4)$$

Where

$$f(e)=\frac{1}{e_s+g(e)} \qquad (5)$$

In equation (5), *k* is the number of replying nodes and e_s is a small constant value between 0 and 1.

VI REVOCATION

If the probability is below threshold value, the detecting node will generate negative vote against it and will inform base station about it. The base station keeps record of the negative votes and its originator. If several numbers of votes (above threshold) generate vote against a particular node(s), then that node(s) will be considered malicious. Next the base station informs the network about the declared malicious node. Thus the sensor and beacon nodes will stop processing any data from the declared malicious nodes.

VII ANALYSIS

Like [3], IWD based detection scheme can be used for security of localization schemes, which are based on location references from beacon node. Small communication overhead will be introduced as the nodes have to send alerts to the base stations and it can be considered as a trade off for security of localization process. Also the sensors nodes will have to maintain and store a banned list. Our scheme cannot detect malicious nodes reporting alerts against a benign node; however, since the detection of malicious beacon node is based on number of votes from several nodes and not from single node thus will prevent wrong detection of benign node as a malicious node.

Our detection scheme seems to have an inherent problem. If the actual and calculated distances are logical, even then there is possibility that the beacon signal is from a malicious node, i.e. malicious node has stolen ID of another node. However, this will not affect the localization process. In order to make incorrect location estimation the node will have to change its location and thus will be caught. Nevertheless, we can assume temporal leashes or round trip time technique (RTT) to detect replay attacks.

VII SWARM INTELLIGENCE AND REVOCATION SCHEME

In this scheme, we have used the concept of swarm of intelligent water drops. The advantage of this concept is that

the distance errors are compared relatively and the nodes with most malicious behavior are considered most untrustworthy. Since the errors are compared relatively, so if environment is hard all nodes are producing error greater than in normal conditions than these would not be wrongly detected as malicious nodes, since all nodes facing same environment will generate closer error values. Only the node which is actually compromised would generate larger error thus will be considered malicious by lower P value. Also the swarm intelligence concept employs the sharing of local or personal experience to produce a global best solution. This concept is utilized here by sending information about the locally detected node to the base-station, when other nodes have also shared their experience so the base station on basis of local experience produces a global solution i.e. declares a node to be malicious.

The revocation method in our scheme is different and better from [3], because revocation is based upon number of alerts from several nodes and malicious node can be detected in a single transmission/iteration. Also now there is no need of report counter at base station.

VIII THRESHOLD: A CRITICAL PARAMETER

In our proposed scheme, threshold probability and threshold number of votes is very important and critical since, a node is declared compromised based on these P values. Threshold P values is also very difficult to determine however it can be considered as a function of number of factors which can help to determine this value e.g. topology, application, environment, transmission range.

IX SIMULATION RESULTS

Simulation has been run for about 200 times to analyze the results. Different scenarios were considered in which nodes were distributed randomly. Variable parameters including thresholds, transmission range, beacon nodes density, malicious nodes density have been varied sufficiently to analyze the performance of proposed algorithm.

A Detection Rate vs. Transmission range

We begin by examining detection rate i.e., no of nodes banned or revoked from the network vs. transmission range. (Detection rates are average values for a number of simulations)

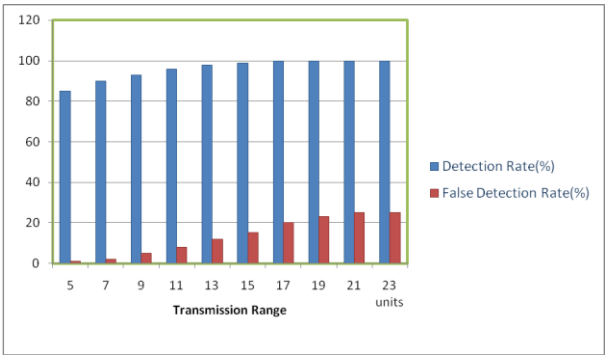

Fig. 2: Detection rate vs. Transmission range

Figure 2 shows that detection rate increases with transmission range (T.R.) till certain value .This is because if the no of neighbor nodes required to generate alerts is less than specified alert threshold, then malicious node will not be detected . But when number of neighbor nodes is enough, then transmission range will not affect the detection range. However, increasing transmission range also increases false detection rate. This is because the detection is highly dependent on threshold number of votes which have been selected for particular T.R. So if T.R. is increased, more number of false votes will be received, which will be counted in to get trust value of a node. Thus if T.R has to be changed then threshold also requires to be changed.

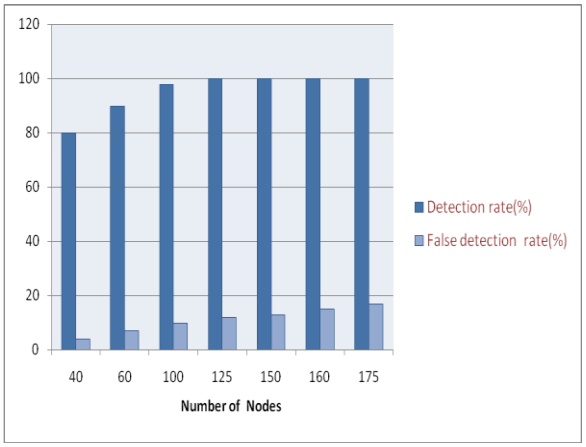

Figure 3: Detection rate vs. Network size

B Detection Rate vs. Network Size

Figure 3 shows the trend of detection rate for a particular arena size. We can observe that detection rate increases with increased no of neighbor nodes.

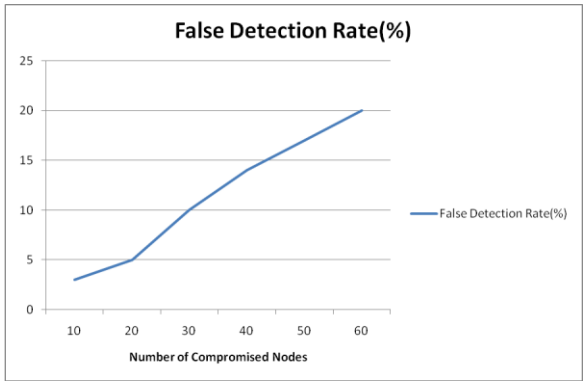

Fig. 4: False detection vs. Compromised Node Density

XI CONCLUSION AND FUTURE WORK

A novel IWD based algorithm for detection of malicious beacon node has been presented. IWD has been used for the first time in area of Wireless Sensor Networks. Also the algorithm for the first time incorporates the environmental effects in wireless communication while detecting compromised beacon nodes. The algorithm has space and potential for development and improvement. The scheme is suitable even for hard weather conditions. However a complex IWD mathematical model can be used instead of the simpler one which may improve results. Also a mechanism can be included in the algorithm to detect the malicious `` if a node generates alerts against another node again and again while no other node is reporting, then the node itself is malicious.

Abstract - *This paper addresses the minimum energy network connectivity (MENC) problem. This problem consists of minimizing the transmission power of each sensor in a wireless network, which results in minimizing the energy consumption of the network, while keeping its global connectivity at the same time. The MENC problem is NP-hard in the strong sense and it motivates us to apply heuristics algorithms, based on evolutionary optimization, to obtain near-optimal solutions. We use two algorithms, the first is a Genetic Algorithm proposed in the literature and the second is a Particle Swarm Optimization algorithm proposed in this work. Computational tests were conducted using a set of 50 instances of the problem and the performances of the algorithms are evaluated. The results reveal that the proposed algorithm is very competitive, achieving the best solutions for some instances.*

Keywords: wireless sensor networks, topology control, meta-heuristics, combinatorial optimization

1 Introduction

Wireless sensor network (WSN) is a class of wireless ad hoc networks in which sensor nodes collect, process and communicate data acquired from the physical environment to an external base station, thus allowing for monitoring and control of various physical parameters [2]. WSNs are mainly characterized by their limited and non-replenishable energy supply. Hence, the need for efficient energy infrastructure is becoming increasingly more important since it impacts upon the network operational lifetime.

Topology Control (TC) is one of the most important techniques used in wireless ad hoc and sensor networks to reduce energy consumption which is essential to extend the network operational life time [1][4]. The main goal of TC is to design a good network (graph representing the communication links between network nodes) with high connectivity and low power consumption.

A WSN is regarded strongly connected if for each sensor node, there is a route to reach any other node in the same network. The strongly connected topology problem with minimum total energy consumption was defined and proved to be a NP-complete problem [1][8].

Comprehensive surveys of topology control can be found in [9] and [10]. Accordingly, most topology control approaches can be classified into two groups: physical topology control (PTC) and logical topology control (LTC) [13]. PTC satisfies the goal of topology control by adjusting transmission power; it reduces interference and energy consumptions. In other hand LTC also based on the approach used by PTC along with it consider the neighbor set of a node, and restrict it to a certain number to satisfy the network connectivity. This neighbor reduction mechanism helps to reduce the routing overhead.

In the literature, some heuristics methods have been developed to solve different topology control problems. In general, the energy metric to be minimized is the total energy consumption or the maximum energy consumption per node. In [1] two heuristics are proposed, one based on a Minimum Spanning Tree (MST) algorithm and a other a Broadcast Incremental Power method. A conventional genetic algorithm and a quantum genetic algorithm are compared in [5]. In [15] and [7], topology control is considered as a degree-constrained minimum spanning tree problem. An improved discrete Particle Swarm Optimization algorithm for generating topology schemes is presented in [15]. A simulated annealing algorithm was designed in [7]. [14] proposes a genetic algorithm to logical topology control. In [11], ant colony optimization, a framework inspired by the ant foraging behavior in the area of Swarm Intelligence, is applied to physical topology control. In [12], simulated annealing is applied to the problem of minimizing broadcast tree, a problem very similar to physical topology control.

In [4] the same MENC problem is addressed and a genetic algorithm with local search is developed. This algorithm is called Topology Control Memetic Algorithm (ToCMA). ToCMA algorithm generates many different solutions and explores in an effective manner the solution space by using searching and genetic operators. Then ToCMA employs different procedures to maintain the global connectivity of the network. It checks if the network is strongly connected and if it is not then it is repaired. Furthermore, ToCMA employs an improvement procedure (local search) to further minimize the overall energy consumption of the network. In [4], the results obtained by ToCMA are compared with the solutions of the MST heuristic. The results imply that ToCMA has better performances than MST.

In this paper, a Particle Swarm Optimization (PSO) heuristic algorithm is adopted to solve the MENC problem.

This algorithm uses procedures similar to those used in the ToCMA algorithm, to maintain the global connectivity of the network and to improve the overall energy consumption of the network. The experimental results of PSO algorithm are compared with the solutions of ToCMA and MST algorithms. The comparisons show that our algorithm obtains more robust topology schemes.

The paper is organized as follows. Section 2 briefly introduces the problem. Section 3 provides a description of the proposed PSO algorithm. Section 4 presents simulation results to demonstrate the effectiveness of the approach. Section 5 concludes the paper.

2 Problem description

Please The formal definition of the minimum energy network connectivity (MENC) problem is given as follows [1][4]: A graph $G = (V, E)$ is given where $V = \{n_1,\ldots,n_n\}$ is a set of n wireless nodes and is a set E of edges or links constructed in such a manner that there is a directed edge from $u \in V$ to $v \in V$ if and only if u can reach v using its maximum transmission power. The graph G sets an upper bound on the maximum connectivity that a wireless network can have. The MENC problem consists in determining a topology T (a subgraph of G) strongly connected with minimal total energy consumption. The total energy is computed as follow:

$$TE = \sum_{i=1}^{n} p_i, \quad (1)$$

where p_i denotes the power assigned to sensor node n_i. The network model and energy consumption follow similar assumptions as proposed in [1] and [4]. The sensors in the network are stationary and located in a two-dimensional plane (the location of each sensor is fixed after deployment). The location information will be used for calculating the distance between two sensor nodes. The sensors radiate and receive equally in all directions (omnidirectional antenna). If a sensor i transmits with a power level

$$p_i = d^2, \quad (2)$$

then any sensor within the distance d can receive the signal. Suppose there are two nodes n_i and n_j then the distance between these two nodes can be calculated by using the Euclidean distance,

$$d = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}, \quad (3)$$

where (x_i, y_i) e (x_j, y_j) are the position coordinates of sensors n_i and n_j, respectively. Sensor nodes can operate in different initial power levels, with a lower and an upper bound.

3 The proposed PSO algorithm

Particle swarm optimization (PSO), first proposed by Kennedy and Eberhart (1995) [6], is an evolutionary optimization heuristic, which is inspired by adaptation of a natural system based on the metaphor of social communication and interaction.

The basic principle of PSO is founded on the assumption that "information is shared by the entire swarm", which was derived from research into the behavior of a flock of birds or a school of fish while foraging for food. PSO algorithm uses a population (swarm) of individuals (solutions) called of *particles*. Each particle has information about its own position, velocity and fitness. With this information, each particle updates its *personal best* (best value of each individual so far) if an improved fitness value was found. On the other hand, the best particle in the whole population with its position and fitness value is used to update the *global best* (best particle in the whole population). Then the velocity of the particle is updated by using its previous velocity, the experiences of the personal best, and the global best in order to determine the position of each particle.

The current velocity (at iteration t) of the particle i is updated as follows:

$$v_i^t = W v_i^{t-1} + c_1 r_1 (xb_i^{t-1} - x_i^{t-1}) + c_2 r_2 (g^{t-1} - x_i^{t-1}), \quad (4)$$

where, xb_i^{t-1} denotes the best position that particle i has obtained until iteration t-1; g^{t-1} denotes the best position obtained from particles in the population at iteration t-1; W is the inertia weight which is a parameter to control the impact of the previous velocities on the current velocity; c_1 and c_2 are acceleration coefficients and r_1 and r_2 are uniform random numbers between [0, 1].

The current position of the particle i is updated using the previous position and current velocity of the particle as follows:

$$x_i^t = x_i^{t-1} + v_i^t. \quad (5)$$

Algorithm PSO
01. Generate a population of N particles $\{x_1^0, \ldots, x_N^0\}$;
02. For each particle i, (i := 1,…,N) set $xb_i^0 := x_i^0$;
03. t := 0;
04. While *StoppingCriterion* = *false* do
    05. For each particle x_i^t, apply ***repairing*** procedure (if necessary) and ***improving*** procedure;
    06. Find the global best particle g^t;
    07. $t := t + 1$;
    08. For each particle i, update the velocity v_i^t and the position x_i^t;
    09. For each particle i, find the personal best position xb_i^t;
10. End-While.
11. Return the best particle.

Figure 1: Pseudo-code of the PSO algorithm.

In this article, an adaptation of PSO heuristic is proposed to solve the MENC problem. A pseudocode description of the PSO algorithm is presented in Figure 1. The algorithm has five input parameters: the population size, the inertia weight parameter, the two acceleration coefficients and the stopping

condition of the algorithm. The best obtained particle is returned by the algorithm.

In the next subsections, we described the main steps of the PSO heuristic.

3.1 Solution representation and initial population

For the MENC problem, a particle (solution) i is represented by a string of n integer numbers: $x_i = (p_1^i,\ldots, p_n^i)$, where n is the total number of nodes in the sensor network. The number p_j^i is the power level (maximum power transmission) assigned to the sensor node j. The assignment of power to the sensor nodes becomes the only factor that affects the connectivity of the sensor network [4].

The quality (fitness) of a solution is measured by the sum of the power assigned to each sensor node (total energy consumption of the network), namely:

$$f(x_i) = \sum_{j=1}^{n} p_j^i , \qquad (6)$$

where p_j^i denotes the power assigned to node n_j, in the particle i, and it is calculated according to Equation (2).

The initial population of the N particles is generated randomly (N is the size of the population). For each node is randomly assigned a power within the interval $[0, 500^2]$, where 500^2 is the maximum energy that a sensor node can take [4]. This procedure does not guarantee the feasibility of each solution. Then a repairing procedure has to be applied.

3.2 Repairing procedure

A solution (particle) must be feasible, that is, the topology network must be a directed strongly connected. There are four possible cases of infeasibility [4]: case (i) there is one or more totally isolated node in the network; case (ii) there is one or more one-way isolated groups of nodes in the network; case (iii) there is one or more loop in the network; case (iv) partition occurs in the network, that is, there are two or more sub-networks.

If a solution is infeasible, as in [4], a *repairing procedure* (that includes these four cases of infeasibility) is applied. In the PSO algorithm, the repair of a solution is done as follows.

First, the repairing procedure checks if there is a node sensor with zero in-degree and/or out-degree. If the out-degree of a node x is zero, then the power of this node is increased until it reaches its nearest neighbor node y, e.g., the procedures calculates the necessary power needed by x to be able to communicate with its nearest neighbor y. Similarly, if the in-degree of a node x is zero, the power of its nearest neighbor node y is increased until it reaches node x. In both cases, the degrees of both nodes, x and y, are updated. An example of an infeasible topology is shown in Figure 2. In this network, nodes 1 and 2 have both, in-degree and out-degree, equal to zero (these nodes are totally isolated). The node 4 has out-degree equal to zero and node 5 has in-degree equal to zero. Figure 3 shows the topology partially repaired. The power of nodes 1, 2 and 4 were modified. It is worth noting that "longest output arc" of a node represents the assigned power to this node.

After checking the in-degree and out-degree of the nodes, the repairing procedure checks for partitioned groups and one-way isolated groups. These groups are sub-networks strongly connected that do not communicate with the rest of the network. For example, Figure 4 shows the three groups of the topology in Figure 3. The communication between these groups has to be set up. To set up the communication from a group g_1 to a group g_2, the procedure tries to find a node y in a group g_2 which is the nearest neighbor of a node x in group g_1. Then, the procedure calculates the power needed for x to communicate with y and assigns this power value to x. Similarly, the communication from g_2 to g_1 can also be set up. This repairing is applied to all partitioned groups (or one-way isolated groups) until network connection is established. Figure 5 shows the repaired network obtained from the network shown in Figure 4. In this example, the communications from Group 1 to Group 2 and Group 2 to Group 1 are set up. Also, the communication from Group 3 to Group 2 is set up.

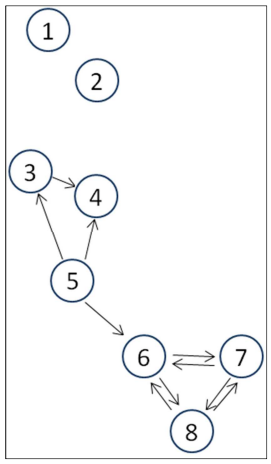

Figure 2: Infeasible topology.

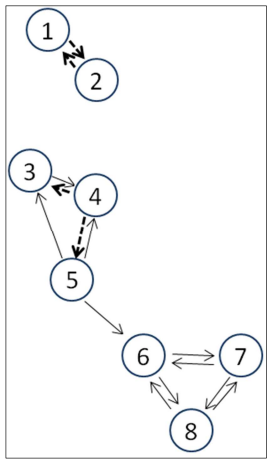

Figure 3: Topology after the first repairing.

3.3 Improving Procedure

Feasible solutions are improved by a local search method. This method tries to reduce the energy of each sensor node, while maintaining the network connectivity. The same improvements have been adopted by [4].

There are two basic improvements that can be executed in each solution (network). First, a node sensor may be using more energy than necessary to communicate with its farthest neighbor. Suppose that nodes 1 and 2 are at a distance d, and node 2 is the farthest neighbor of 1. Then, the maximum power requested for node 1 is $p_1^r = d^2$. If the current power of node 1 is $p_1 > p_1^r$ then p_1 is replaced by p_1^r, this is, the power of node 1 is decreased to the power level that is just enough to reach its farthest neighbor. Figure 6 illustrates an example in which the current power of node 1 is greater than the power needed to reach its farthest neighbor node 2.

The second improvement occurs when the power needed for a node *x* to reach directly its farthest neighbor *y* is more than the power needed if *x* follows an alternative route to *y*. For example, in Figure 7, the node 5 has a direct route to the node 3, which is its farthest neighbor. However by using an alternative route, shown in bold, the node 5 communicates with the node 3. Thus, the energy of node 5 can be reduced ("unnecessary links are removed").

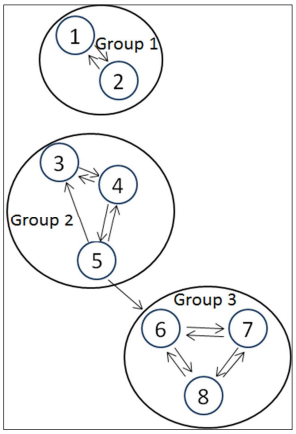

Figure 4: Network with three groups.

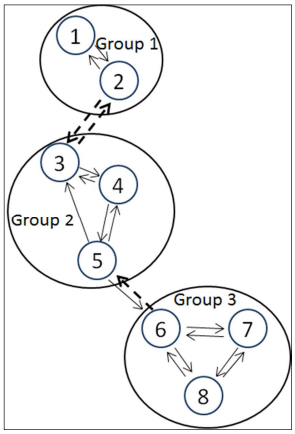

Figure 5: Network with the resumed connection.

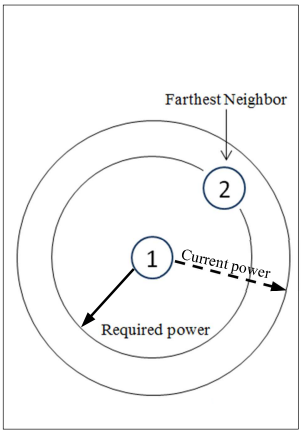

Figure 6: First improvement. Reduction of unnecessary power.

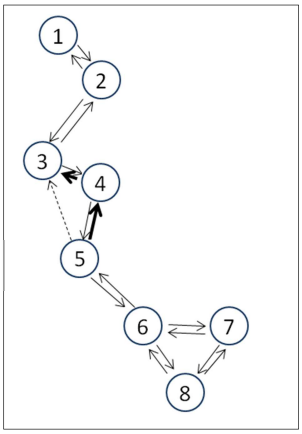

Figure 7: Second improvement. Energy of node 5 is reduced.

4 Computational results

In this work we carried out a study of the proposed PSO algorithm, ToCMA [4] and MST heuristic [1] to establish which ones show better performance for the MENC problem. All the tested algorithms are coded in C++ language and the experiments have been executed on a Intel Core i7 2.8GHz computer with 4GB of RAM memory and running with Windows 7 64 bit O.S.

The experiments were performed on 50 instances of the problem, where the number of sensor nodes *n* varies from 10 to 100. For each *n*, 5 instances (graph with all possible communication links) were generated. The coordinates of the nodes were randomly generated on a two-dimensional plane 500×500, so the power that could be randomly assigned to a sensor is between the boundaries of 0-500^2.

The PSO and ToCMA algorithms were run with the same stopping criterion which is based on an amount of CPU time. This time is giving by $2n^2$ milliseconds, where *n* is the number of sensors (size of the instance). In this way, it is assign more time to larger instances that are obviously more time consuming to solve.

In the reimplementation of the ToCMA algorithm, we use the same operators and parameters presented in [4]. In the PSO algorithm, the number of particles created at each iteration was fixed in $N = 30$. In order to find appropriate values for the parameters W, c_1 and c_2, the PSO algorithm was executed using different combinations of these parameters. Five independent executions were performed for each combination of W, c_1 and c_2. The obtained results are compared using the Relative Percentage Deviation (RPD) which is computed in the following way:

$$RPD = 100 \times \frac{TE - TE_{best}}{TE_{best}} \quad (7)$$

where TE is the total energy consumption of the network obtained by the algorithm, TE_{best} is the total energy consumption of the best solutions obtained among all the runs.

The performance of the algorithm (for different values of W, c_1 and c_2) is compared by average RPD (ARPD) over all the instances. In order to validate the results, an Analysis of Variance (ANOVA) [16] has been carried out employing the ARPD as response variable. All the tests have been executed with a confidence level of 95%. The result of ANOVA shows that there are no statistically significant differences among the means determined by the combinations of the parameters W, c_1 and c_2. Figure 8 depicts the mean plots confidence intervals with a 95% confidence level from the ANOVA test. From Figure 8, it can be seen that the best RPD means are obtained with $W = 0.5$, $c_1 = 0.2$ and $c_2 = 0.2$.

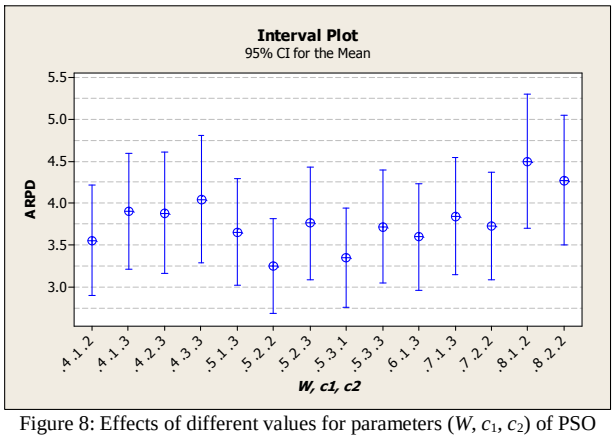

Figure 8: Effects of different values for parameters (W, c_1, c_2) of PSO algorithm.

Figure 9 shows the average (of each group of 5 instances of the same size) of the total energy consumption of the networks obtained by the three algorithms, MST, ToCMA and

PSO. We can see that for all instances, the ToCMA and PSO algorithms perform better than the MST algorithm.

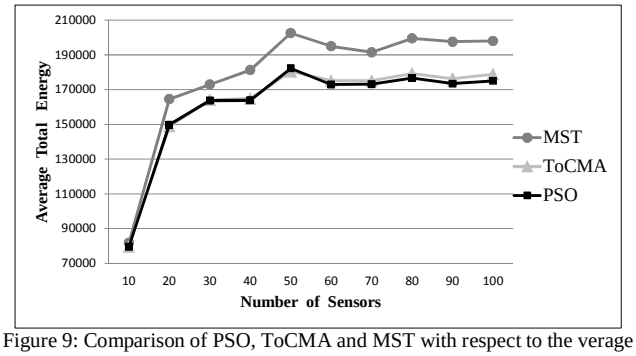

Figure 9: Comparison of PSO, ToCMA and MST with respect to the verage of total energy consumption of the obtained networks.

The efficiency of the ToCMA and PSO algorithms are evaluated by the relative percentage improvement with respect to the MST algorithm. This improvement is calculated using the following formula:

$$Improvement\ Percentage = 100 \times \frac{TE_{MST} - TE_{Alg}}{TE_{MST}} \qquad (8)$$

where TE_{Alg} is the value of total energy consumption of the network obtained by ToCMA or PSO, and TE_{MST} is the total energy value obtained by MST algorithm.

Table 1 shows the average percentage improvement of ToCMA and PSO compared to MST algorithm. We can see that ToCMA obtains better average improvement in 2 sets of instances with 20 and 50 nodes. And PSO obtains better average improvement on 6 sets, with 30 40, 60, 70, 90 and 100 nodes. Besides that, PSO obtains an overall improvement of 9.30% whilst ToCMA 8.90%. These results show that, regarding the total energy consumption of the network, the algorithms PSO and ToCMA are comparable and PSO performs slightly better.

Table 1: Improvement percentage of ToCMA and PSO with relation to MST

Number of nodes: *n*	**Improvement Percentage**	
	ToCMA	**PSO**
10	**2.87**	**2.87**
20	**9.55**	8.96
30	5.12	**5.36**
40	9.10	**9.59**
50	**10.90**	10.01
60	10.18	**11.31**
70	8.55	**9.59**
80	10.15	**11.46**
90	10.74	**12.21**
100	9.69	**11.61**
Average	8.69	**9.30**

We analyze the obtained network topologies by considering the length of the edges and the physical degree of the nodes.

Figure 10 compares the algorithms by considering the average edge length. We can see that PSO generates network topologies with small length edges for instances with 40 - 100 nodes. We can also see that, for instances with 60 - 100 nodes, MST has better performances than ToCMA in terms of the average edge length. This situation can happen because in the MST algorithm the total length of all the edges is minimized.

We also note that, the average edge length decreases as the number of nodes increases (the network density increases as the number of nodes increases). This is a consistent fact, since the coordinates of the nodes, for all the instances, were generated on the same two-dimensional plane.

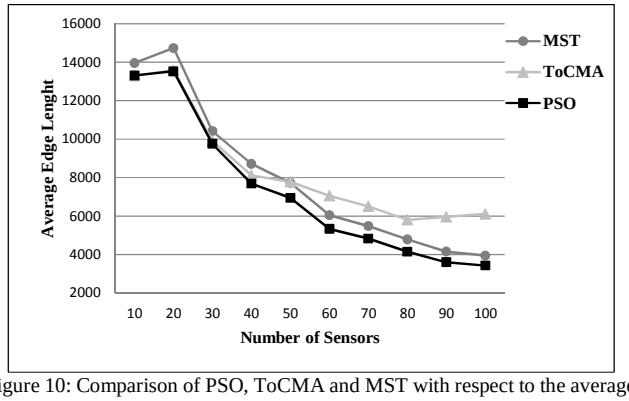

Figure 10: Comparison of PSO, ToCMA and MST with respect to the average edge length.

Figure 11 compares the algorithms with respect to the average physical degree of the nodes. The PSO algorithm generates network topologies with smaller degrees for instances with 40-100 nodes. The maximum obtained average degree was 4. Although this degree is maintained as the number of nodes increases, the average degree increases in the networks obtained by the other algorithms.

As the number of nodes increase, PSO has better performances than ToCMA and MST in terms of the total energy consumption, average edge length and average physical degree. Based on that, we can conclude that PSO has generated a more robust network topology structure than others.

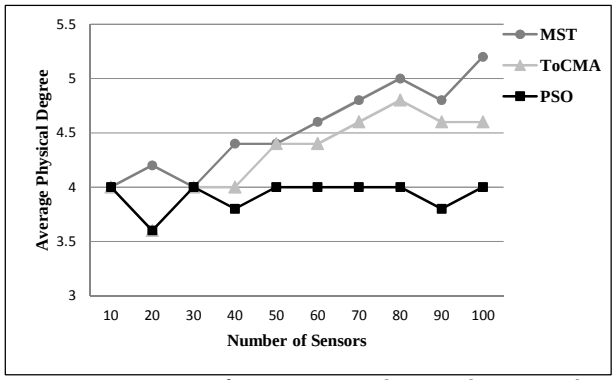

Figure 11: Comparison of PSO, ToCMA and MST with respect to the average physical degree.

5 Conclusions

In this paper, we have addressed a NP-complete problem on Topology Control in ad hoc wireless networks, with the objective of minimizing the total energy consumption while obtaining a strongly-connected topology. We have proposed a Particle Swarm Optimization algorithm in order to reduce the total power consumption. The experimental results verified the efficiency and competitiveness of the proposed algorithm by comparison with ToCMA and MST algorithms. The PSO generated networks not only with better total energy consumption (the main considered objective) but also with smaller average edge lengths and smaller average degree of nodes, indicating a better topology.

Abstract— *Complex network has been used in phono-semantic compounds in this paper, especially the degree correlation, hierarchical structure, diversity of the function of nodes and their relationships has been studied. We found that high degree nodes tend to be connected to low degree nodes, displaying a disassortative mixing property in the whole; some nodes can act both as phonetic radical and semantic radical, leading to a more complicated structure; and the hierarchical structure makes the disassortative mixing property more obvious. This paper reveals that phono-semantic compounds are optimal combination of phonetic radicals with semantic radicals, and they bear the merits of easy remembering, easy spreading and easy understanding. The phono-semantic compounds follow the principle of least effort [1] and characteristics of human cognitive mechanism.*

Keywords: Disassortative Mixing, Hierarchical Structure, Complex Network, Phono-semantic Compounds, Degree Correlation

1. Introduction

There are various complex systems, whose internal members interact with each other to reach a dynamical balance. This phenomenon is common in nature and human society, to name a few, brain structures, food chain networks, the Internet and WWW. The properties of those complex systems could be described by theories of complex network. A node is utilized to demonstrate an entity and an edge to depict their connection. Nodes and edges connectively form the entire network. Recently, quite a lot of work have been carried out making a more detailed analysis of the structure of complex networks[2][3][4]. People find that social interactions[5][6][7][8] and technology structures[9][10] characterize the assortative mixing, others such as brain networks[11], food chain networks, cell networks[12] and online social networks(OSN)[13] reflect disassortative mixing. Besides, some networks, such as metabolic network[14] and Chinese character network[15], even have hierarchical structure.

Chinese characters are carriers of Chinese culture and visualization of Chinese way of thinking. Study their formation and construction are very meaningful. Research of Chinese characters could disclose the behavior, lifestyles and ideology of ancient Chinese. For example, the existence of so many derogatory characters constructed with "女" (e.g. "奸", "嫉", "妓", etc.) in Chinese characters reflect the thousands-year-old traditional ideology of patriarchy. When ancient Chinese created characters, usually they constructed them based on the objects' appearances intuitively. These objects are common in people's daily life such as "氵" (water), "艹" (grass), "木" (wood). That's why a great deal of characters were constructed with the radicals "氵", "艹", "木" etc.

Quite a lot of contribution has been made in analysis of the Chinese language using complex networks theory. Li[16], Yamamoto[17], and Wang[18] built phrase related networks which display scale free and small world features. In [16], the nodes are meaningful words which may be single Chinese character or multi-character combination. Jianyu Li [15][19] found that Chinese phrase networks display some important features: not only small world and the power-law distribution, but also hierarchical structure and disassortative mixing. But in the area of Chinese characters not many results are yet reported. More than 80 percents of Chinese characters is phono-semantic character. Phono-semantic compounds consist of phonetic radicals and semantic radicals, which could be treated as nodes in our network. This paper mainly investigates the degree correlation, diversity of the function of nodes, hierarchical structure and their relationship in phono-semantic compounds network.

2. Data preparation

2.1 Concepts

Complex network is different from regular network and random network, because it has some special features, such as small world and scale free, etc. Recently, people studied more properties of complex network, for example, degree distribution, average path length (APL for short) and clustering coefficient, etc.

The degree of a node in a network is the number of connections or edges the node has to other nodes. If one node has a high degree, and widely connected, it must be good at composing characters in Chinese characters structure network. The degree distribution is very important in studying both real world networks, such as the Internet

and social networks, and theoretical networks.The degree distribution $P(k)$ of a network is then defined to be the fraction of nodes in the network with degree k. Thus if there are N nodes in total in a network and N_k of them have degree k, we have

$$P(k) = \frac{N_k}{N}. \tag{1}$$

Average path length is the average shortest distance of two nodes.

$$APL = \frac{1}{N(N-1)} \sum_{i \neq j \in V} d_{ij}(ij), \tag{2}$$

where d_{ij} is the shortest distance of node i and node j. The correlation is characterized by the

$$C_i = \frac{2e_i}{k_i(k_i - 1)} \tag{3}$$

and defined as the rate of edges e_i actually connected with node i and all links over i, where k_i is the degree of i. And average clustering coefficient of the whole network is

$$C = \frac{1}{N} \sum_{i=1}^{N} C_i. \tag{4}$$

2.2 Network construction

Semantic radicals and phonetic radicals are treated as nodes to construct a phono-semantic compounds network. If two nodes could construct a Chinese character, that means they are relevant. According to Xinhua Dictionary, the most widely used dictionary in China, we divided 4000 Chinese characters into 211 semantic radicals and 1084 phonetic radicals. We construct the networks in the following senses.

- Two nodes are connected if relevant.
- Self-connections are ignored.
- Variants (such as 足, 𧾷) of a semantic radical are treated as two different nodes.
- Node which can be used as both semantic radical and phonetic radical (e.g. "木" is semantic radical in "桦", and it is phonetic radical in "沐"), will be treated as one single node.

Based on above, we construct a phono-semantic compounds network:

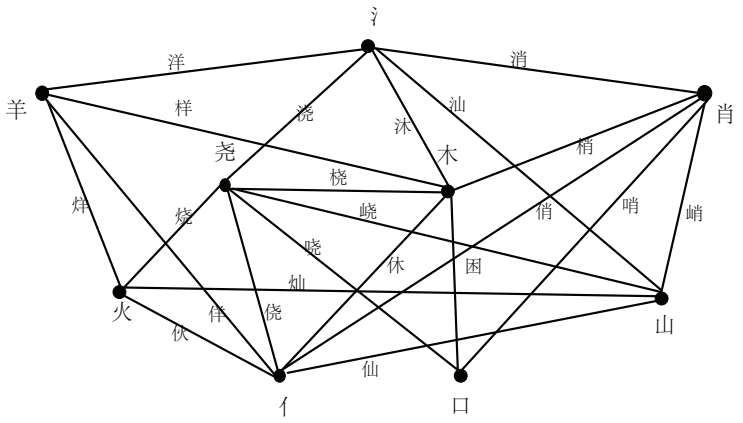

Fig. 1: Part of phono-semantic compounds network

3. Analysis

3.1 Degree Correlation

There are several correlation coefficients, often denoted r, measuring the degree of correlation. Pastor-Satorras[20], describe degree correlation using a straightforward method, which calculate degree of nodes connected to node that degree is k, and the result is a function of k. If high degree nodes tend to be connected to low degree nodes, we call the network to have a disassortative mixing pattern, and when high degree nodes tend to link to other high degree nodes, it appears assortative mixing feature. If the network has an assortative mixing pattern, the value of function is increase by degrees, vice versa. An uncorrelated network exhibits the neutral degree-mixing pattern whose function is constant. After that, Newman[21][5] simplified the method of calculating degree correlation. The correlation could be characterized by the assortativity $r(-1) \leq r \leq 1$ and defined as the Pearson correlation coefficient:

$$r = \frac{M^{-1} \sum_i j_i k_i - [M^{-1} \sum_i \frac{1}{2}(j_i + k_i)]^2}{M^{-1} \sum_i \frac{1}{2}(j_i^2 + k_i^2) - [M^{-1} \sum_i \frac{1}{2}(j_i + k_i)]^2}, \tag{5}$$

where j_i and k_i are the remaining degrees at the two ends of an edge and M represents the number of all links. r range from -1 to 1. When $r > 0$, we call the network to have an assortative mixing pattern, and when $r < 0$, disassortative mixing. An uncorrelated network exhibits the neutral degree-mixing pattern whose $r = 0$.

According to statistics, there are 1295 nodes in our phono-semantic compounds network, and the average number of links between semantic radicals is 18.8768, while that between phonetic radicals is only 3.6744. Obviously, semantic radicals could construct more Chinese characters than phonetic ones, which quite directly leads to the observation that semantic nodes have higher degree. The correlation coefficient is $r = -0.4155$, which is negative. Table 1 lists many concrete examples in real social network and TechNet, etc.

Table 1: Degree assortativity coefficients of various kinds of networks. N indicates the number of nodes, r is degree assortativity coefficient[15][21].

Chinese character network	4892	−0.4097
Chinese phrase network	4858	−0.0645

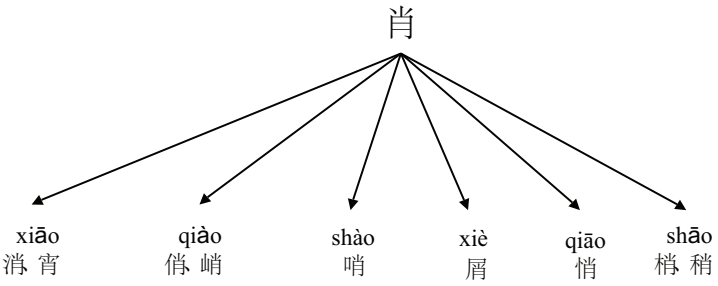

Fig. 2: Pronunciations of characters constructed by the phonetic radical "xiao".

Compare with social network, phono-semantic compounds network is similar to Chinese phrase network [15]. It is disassortative mixing, which means the high degree nodes tend to be connected to low degree nodes. Generally speaking, semantic radicals are nodes of high degree and phonetic ones are low degree nodes. Disassortative mixing in this paper means high degree semantic radicals prefer to be linked to low degree phonetic radicals. The semantic radical suggests only a general category of meaning of the compound character and it does not provide a specific meaning or definition. Their degrees tend to be higher. But the phonetic couldn't be higher, otherwise it could be a big challenge for people to remember so many characters with the same pronunciation. Therefore the disassortative mixing tendency in constructing Chinese characters follows the principle of least effort [1]. The constructed characters are easy to be recognized by their semantic radicals and their low degree phonetic radicals.

3.2 Diversity of nodes' function

Table 2 lists the top ten of characters construction capability. Study reveals that the characters constructed by the same phonetic radicals may not pronounce uniquely (22 characters constructed by "肖" have 6 pronunciations).

Table 2: Top ten of the highest characters construction of nodes in phono-semantic compounds network. The number of characters these nodes can construct has been given in brackets.

radicals	Top ten
semantic radicals	氵(270), 木(202), 扌(191), 口(168), 艹(162), 亻(151), 钅(134), 讠(108), 月(102)
phonetic radicals	肖(22), 非(21), 令(21), 各(20), 古(20), 且(19), 交(18), (18), 青(18), 包(17)

This phenomenon not only exists in high degree phonetic nodes, but also in low degree ones. We divided this case into four categories:

- Character with the same pronunciation as their phonetic radical (消xiāo and 宵xiāo e.g.);
- Character with pronunciation differs only in tone from their phonetic radicals(such as 匪fěi and 痱fèi);
- Characters with pronunciation differs only in consonants or vowels from their phonetic radicals (俏qiào, 悲bēi, 冷lěng e.g.);
- Characters with pronunciation differs both in consonants and vowels from their phonetic radicals (罪zuì, 排pái e.g.).

According to statistics, Type.1 accounts for about 38.5%, Type.2 accounts for 17.6%, Type.3 accounts for 26.3%, Type.4 accounts for 17.6%. Evidently, it is extremely common that characters with the same phonetic radical pronounce differently. In fact, such differentiation is good for understanding and memorization. For instance, people can hardly understand what are you talking about if 22 characters constructed by "肖" all pronounce xiāo. Beyond that, one semantic radical may have multiple meanings too. For example, "日" could construct a large number of characters as semantic radical. "昭", "晴", "昕", "晞", "曦", "曜" and "晓" all have meaning of bright, while "晚", "昏", "暗" and "暮" have meaning of dusk. However, they are all relevant to light. So instead of indicating the accurate meaning of characters, semantic radicals can only show a general concept.

In phono-semantic compounds network, we also found some nodes which can be used as both semantic radicals and phonetic radicals (such as "木" is a semantic radical in "桦", but it is a phonetic radical in "沐"). There are 119 this kind of nodes approximately. It accounts for 56.4% of the semantic nodes, accounts for 11.0% of the phonetic nodes and accounts for 9.3% of the whole network nodes. Almost half of semantic radicals are this kind of nodes and they play a very important role in our network. Because the average number of characters which are connected to them is 21.9160, while semantic and phonetic nodes' is only 18.8768

and 3.6744. That's why the semantic radicals can construct more characters than phonetic ones. This kind of feature not only makes phono-semantic compounds network more complex, but also makes nodes' function more various.

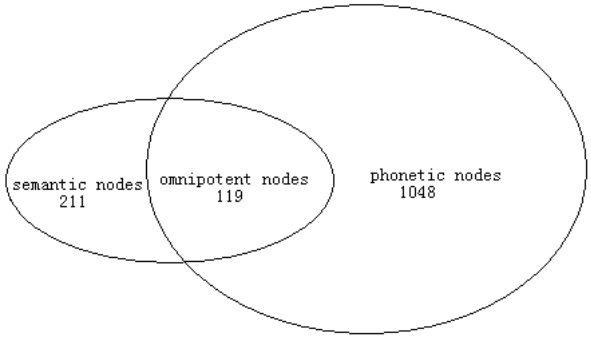

Fig. 3: Relational graph of semantic, phonetic and omnipotent nodes(nodes can be as both semantic radicals and phonetic radicals)

3.3 Hierarchical structure

As we know, several concepts are proposed to measure the hierarchy in a network, such as the hierarchical path[22], the scaling law for the clustering coefficients of the nodes[23], etc. These measures can tell us the existence and the extent of hierarchy in a network.

In this paper our networks are multilevel. Like Fig.4, simple components are used to form complicated components (phono-semantic characters), then the complicated components are used to form more complicated ones. For example, "付" and "广" are used to construct "府", and "府" are used to construct "腐". We call the phono-semantic characters such as "付" and "府", the "mid-components" provisionally. "Mid-components", 194 in network, are all phonetic radicals, which tend to be connected to semantic radicals. They generally have low power on phono-semantic compounds construction, the average number of characters they can construct is only 2.4536. Compare with simple components, the mid-components have a tendency of stability. The more complicated the components are, the less characters they can construct. Because too complicated structure of Chinese characters is not convenient for writing.

Table 3: Average degrees of different radicals.

Nodes	Average degree
Phonetic radicals(total)	3.6744
Phonetic radicals(except "mid-components")	4.7072
Semantic radicals	18.8768
"Mid-components"	2.4536

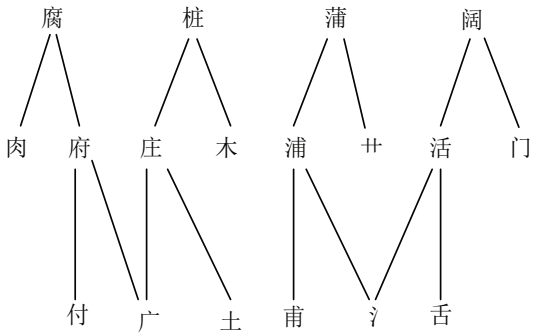

Fig. 4: Illustrating how a "mid-component" is constructed and how a "mid-component" constructs a new phono-semantic character

The intrinsic hierarchy can be characterized in a quantitative manner using the recent finding of Drogovtsev, Goltsev, and Mendes[24]. If the clustering coefficient of a node with k links follows the scaling law, like

$$C(k) \sim k^{-1}, \tag{6}$$

so the network have hierarchical structure. We found our phono-semantic compounds network have following characteristics like Fig.5.

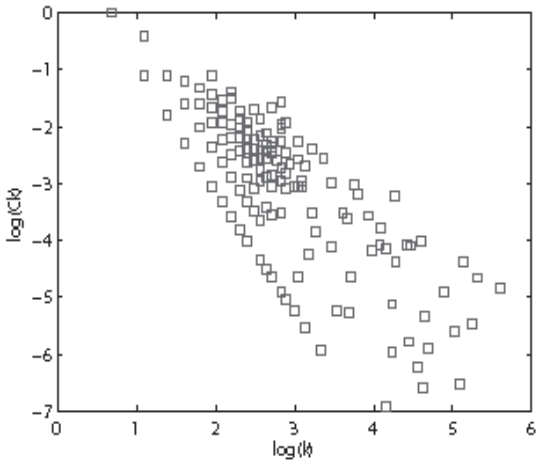

Fig. 5: Relationship between degree and clustering coefficient of nodes

We can see the phono-semantic compounds network has the tendency of hierarchy. The Chinese ancients reuse the preexisting simple characters to construct the new ones. It reduces the burden of the memory of people and improves the efficiency of creating characters.

4. Conclusion

We have already known that phono-semantic compounds network has diversity of the function of nodes. It is also hierarchical and disassortative mixing. Some nodes can be

used as both phonetic radicals and semantic radicals. Thus the network is more complicated. Moreover, some “simple components" are uses to form “complicated components" and the “complicated components" are relatively harder to combine with other components than the simple ones. So their degree is relatively low. The emergence of these nodes with low degree makes the disassortative mixing of the network more obvious.

We use complex network to analyze phono-semantic characters. We can not only learn extensive and profound Chinese culture better, but also understand the unique and creative formation of Chinese characters from ancient Chinese. Moreover, it will help us devise more interesting Chinese character learning course. And based on the differentiation of different radicals' degree, we can improve the layout of “Five-stroke Coding System", a well known character input method.

***Abstract*— In this paper we use binary sensor networks, in which sensors send only one bit for tracking a particular target, passing through a field of sensors. We show that there are some geometric properties in binary sensor networks which help us improve the tracking in this kind of network. This algorithm differs even further from the previous method in that all nodes in the network are the same. The performance of this algorithm was tested with a large set of Monte Carlo simulations. Another, smaller set, of Monte Carlo simulations were generated, and those for which this algorithm could not give an answer with certainty were re-analyzed by a human in a series of blinded tests, using data from a Range Doppler plot, i.e. data about the targets' range and radial velocity over time. It was determined that the performance of both tests increased as the targets' relative radial velocities and track times increased.**

I. INTRODUCTION

Sensors are used to measure many things such as temperature, humidity, light, sound and many other things.in binary sensor networks , there is no need to send all the data which is sensed , instead , just one bit gives us a good minimal description . In target tracking subjects, binary sensor networks are used to track objects pass a trajectory in the network environment. Sensors only send one bit, 1 – if the object is getting nearer to the sensor or, 0- if the object is going away from the sensor. Obviously, we can see that this method of tracking only inform us about the direction which the target is going along, but does not give enough information about the exact location of target. Although the direction information is enough for some situations, we can have the location information by adding another binary sensor to the primary sensor. By knowing this, we can assume the location of the object too.

Besides using particle filter method, we have three assumptions implicitly. First, the sensors distributed within a region are able to sense the object which is getting near or getting far. The sensing radius of sensors forms the size and scope of this region.

Second, all the data gathered by the sensors, are sent to a processing station – a base station. Since our information is just one bit, it is possible to send this information easily.

And the third assumption is that we can use a secondary sensor to define the location of the object passing along a trajectory. That kind of a sensor may be implemented as an IR sensor with thresholding that depends on the favorite proximity range, and can also be derived from the same basic sensing element that provides the original direction bit of information.

A second method of viewing targets is by a Range Doppler plot. This plotting technique again uses scatterer range as one axis but instead of time for the second, it uses the Doppler return of the scatterer at that range. Range Doppler plotting is rooted in the practice of target identification, decision making on what is and is not an object of interest. Although it has been used heavily for target imaging, cases have been made for its usage as a tool for tracking. A tumbling and/or spinning target will have returns from scatterers on its body, which can lead to an image that is similar in dimension to the object that sourced the signal returns.

Analogous to a Range Time plot, target history can be recorded in the form of a track showing past data in Range Doppler plotting. Much like the Range Time plots, Range Doppler plots contain tracks that may bear no resemblance to the Newtonian trajectory of the targets. As with the Range Time plot's tracks which cross, the crossing tracks of a Range Doppler plot may not reflect targets' doing so in reality. The true area of interest is whether the two plotted crossings are brought about by different situational parameters.

II. RELATED WORKS

In some cases like sensor networks [7], tactical battlefield surveillance, air traffic control, perimeter security and first response to emergencies, target tracking is used as an essential point of interest.

Many methods such as Kalman filter approaches about how a target can be tracked, has been proposed .one of the recent methods is particle filtering. This method which is introduced in the field of Monte Carlo simulations quantizes probability deployment of the target location rather than maintaining the whole feasible position space. This matter would be obtained by maintaining multiple copies of an object. These copies which own a specific weight are called particles. Whenever an event occurs (usually sensor reading), a new set of particles are generated, and also the corresponding weights are updated. The main paper about this method is [9].from that time to now, many papers used this technique, but some of the most important are variance reduction scheme [8] and auxiliary particle filter [12].

There has been number of probabilistic approaches applied in robotics for simultaneous localization and mapping (SLAM), where the robot try to track itself using observed location of numerous landmarks.in some cases like [10], particle filtering is used as a successor method, if the Kalman filter had failed.

Sensor networks encounter two main problems. The first problem is the energy efficiency of the whole network and sensors.in [3] some schemes for developing the network energy saving with a little loss in tracking quality is proposed. The second problem is considering efficient processing in gathering data by sensors.in [2], a location-centric approach ,dynamically divides the sensor set into geographical cells run by manager.

In [4] , a method for tracking a target in a clustered area , run by 3 sensors to track the object. This approach uses a distributed protocol.

Track crossings can come from a single target which splits apart into multiple targets. It may seem counter-intuitive at first that targets moving away from each other would result in crossings on a Range Time plot, but the crossing occurs for the same reason as before; radar loses spatial separation because it reduces three dimensional trajectories to one dimension range measurements.

As you might guess, since we use binary sensor networks and in these kinds of networks only one bit of information is transmitted to the base station, many of the issues mentioned above are not a major problem.

III. The Binary Sensor Network Model

As we said earlier, in binary sensors only one bit is sent. From this one bit information , we decide the type of sensor. We call the sensor a "plus sensor" , whenever the target is moving toward that sensor (getting nearer) and we call the sensor a "minus sensor" , whenever the target is moving away from that sensor . All the information from this area of sensing – namely "active region of sensor network" – is sent to base station . The data bit along with sensor id , is contained in the message transmitted to the base station . Since the sensor detection might be noisy , thresholding and hysteresis is used to detect the movements of the object and computing the direction .we assume the base station is informed about the location of each sensor . We also assume that all the sensors are able to sense the target movement over the same space .

Let consider m binary sensors $S= \{S_1,S_2,\ldots,S_m\}$ are distributed inside a 2D environment, object U is moving within the region along a curve Γ and $X(t)$ is one of its parametric representations . sensors do not sample the environment all the time , instead, environment is sampled only in specific intervals of time , creating a sequence of binary m-vectors $s \in \{-1,1\}^m$ (with $s_i^{(j)} = +1/ -1$ denoting U is getting close/ going away from sensor i at time t_j). Afterward we would like to achieve a measure of the trajectory X of U for the given position of the sensors.

A. The Instantaneous Sensor Network Geometry

First of all , we show one of important properties of plus and minus sensors in the form of a lemma .

Inductive proximity sensors are designed to have a type of hysteresis in their circuitry that is used to eliminate output chattering. As a target approaches the sensor's detection face, it eventually triggers a sensor output. When the target moves away from the sensor's detection face , the triggered output holds until a certain distance has been passed.

The distance, called the "reset distance" or "distance differential," can be as high as 10% if the sensor's total sensing distance. This holds proportionally true for detection objects that cause reduced sensing distances. Make sure that the target object is completely removed beyond the sensor's reset distance to avoid all potential chattering from detectable object vibrations or other environmental factors.

When using a multitude of inductive proximity sensors in an application, be aware of an effect called mutual interference. This occurs when one proximity sensor's magnetic field affects another sensor's magnetic field causing it to trigger an output. This false triggering can be erratic and difficult to detect.

Look for inductive proximity sensors that feature alternate frequency models. These alternate frequency sensors oscillate their magnetic fields in different frequencies and do not interfere with one another as much as two inductive proximity sensors with the same frequency. Simply take one frequency proximity sensor and mount it next to one of a different frequency. Inductive proximity sensors are a simple and effective sensing tool. Avoid application problems by planned implementations, and your applications will be a success.

Like the super node algorithm implementation this algorithm also assumes that cluster head nodes have more power than normal sensor nodes. However, sensor nodes are not assigned to clusters in this algorithm. Instead, they are invited to join a cluster by the cluster head. The cluster head does this by broadcasting a join message that includes the time and signature of the target the cluster head detected [7]. Those sensor nodes that have stored data that matches the data in the broadcast message respond to the broadcast by sending their captured data to the cluster head node.

Interestingly, the cluster head only waits for a certain number of replies and when that number of replies has been received the cluster head calculates the target's location. Also, unlike the supernode algorithm, this algorithm only has one active cluster head at a time. In other words, cluster heads do no work together [7].

Considering constraint noted in Section 3, we can use a "Particle filter -like" algorithm to track the object.

The main idea in particle filter is to represent the location of density function which can be done by set of random points called "Particles". Each time a sensor event (For example a reading) occurs , these particles are updated , and the algorithm calculates an estimation of actual location based on these samples and weights. We can keep a sample set with all weights equal to each other (like what is represented in [9]) , or , use the idea of each particle being assigned different values (like what is proposed in [8]) . At each phase a set of particles (or possible positions) with weights updated according to the probability of going from the location at time $k-1$ (represented by $xk-1\ j$) to the location at time k (represented by x^k_j). This probability is estimated by $p(y_k|x^k_j)$. The first particle set is generated by drawing N independent particles outside the sensing circle of the "plus" and "minus" sensors at the time of the first sensor observing. Next, with each sensor observing , a new set of particles is produced as follows:

1. A previous position is selected according to the "old weights"
2. A probable successor is selected for this position
3. If this successor respects verification conditions (which is problem-specific and will be explained in next Subsection add it to the set of new particles and calculate its weight.

The above order of phases is repeated until N new particles have been created. The last phase is to normalize the weights so they sum up to 1.

Algorithm 1 Particle Filter Algorithm

Initialization: A set of particles $(x^1_j, w^1_j = \frac{1}{N})$ for $j = 1, \ldots, N$
$k = 1$
while y_k (sensor readings) $\neq \emptyset$ (sensors still active) **do**
  $k = k + 1$
  repeat
    choose j from $(1, 2, \ldots, N) \sim (w^{k-1}_1, \ldots, w^{k-1}_N)$
    take $x^k_j = \hat{f}_k(x^{k-1}_j, y_k)$
    if x^k_j respects "goodness" criterion **then**
      accept it as a new particle
    end if
  until N new particles have been generated
  for $j = 1 : N$ **do**
    $w^k_j = w^{k-1}_j * \hat{p}(y_k|x^k_j)$
  end for
  Normalize vector $(w^k_1, \ldots, w^k_N)$
end while

Sensor observations are aggregated to only one bit vector shown as y_k (k is the time parameter). The target's movement f is measured by taking x^k_j within the zone given by the following restrictions :

- x^k_j has to fall outside the "minus" and " plus" convex hulls (from Theorem 2)
- x^k_j has to fall *inside* the circle of center $S+$ and of radius the distance from $S+$ to $x^{k-1}{}_j$ (from Proposition 4), where $S+$ can be any "plus" sensor at sampling times $k-1$ and k
- x^k_j has to fall *outside* the circle of center $S-$ and of radius the distance from $S-$ to $x^{k-1}{}_j$ (from Proposition 4), where $S-$ can be any "minus "sensor at sampling times $k-1$ and k

Proximity sensing is the ability of a robot to tell when it is near an object, or when something is near it. This sense keeps a robot from running into things. It can also be used to measure the distance from a robot to some object. This sensing capability can be engineered by means of optical-proximity devices, eddy current proximity detectors, acoustic sensors or other devices.

Proximity sensors currently come in four flavors:

1. inductive

operates by detecting the eddy current losses when a material enters to an electromagnetic field

2. capacitive

operates by generating an electrostatic field and detecting changes in this…field caused when a target approaches the sensing face.

3. ultrasonic

Ultrasonic sensors detect objects by emitting bursts of high-frequency sound . waves which reflect or "echo" from a target.

4. optical

designed to be sensitive to different wavelengths of light

IV. Tracking With a Proximity Bit

As we discussed earlier in Theorem 7, under some special conditions , two trajectories may be indistinguishable from each other. Therefore , we add another feature to identify the target's location. This is done by adding another sensor , namely Proximity sensor , for each binary sensor in the field . the sensing range of these sensors may vary , and are usually smaller than binary sensor's range itself .

A. Algorithm And Implementation

Algorithm 2 is just the modified version of Algorithm1 for every sensor node. In this algorithm, we have proximity bit (provided by Proximity sensors) and a motion direction bit (provided by motion direction binary sensors) .so if we remove the proximity feature, Algorithm 2 is simply equal to Algorithm 1.

Algorithm 2 Algorithm for Binary Sensors with Range

```
Use Algorithm 1 as basis.
if sensor S sees the object then
  for all accepted particles P not inside the range of S do
    Let P' (a new particle) be the intersection between the range of S and semi-line (PS]
    Let P_1, ..., P_k be the ancestors of P since the last time the object was spotted.
    for i = 1 to k do
      P_i = P_i - (P - P')/(k+1)
    end for
  end for
end if
```

B. Experiments

Initially, transition probabilities are set as $\pi_{11} = 0.95, \pi_{12} = 0.05, \pi_{21} = 0.05, \pi_{22} = 0.95$ and the simulation result is shown in Figure 4.3. Since it is assumed that the probability that a target keeps its current mode is high, mode changes occur in short period and clearly presented in Figure 4.3. On the other hand, when different values are chosen as transition probabilities, the mode changes have different characteristics. As expected, the difference between marginal values of each mode probability decreases as transition probabilities between two modes increases. In Figure 4.5, two mode probabilities during uniform motion (0 ~ 4 seconds and 8 ~ 12 seconds) are almost mixed, which makes it delicate to distinguish the current mode from the figure. In addition, transient response speed changes. In the first simulation, the actual mode change occurs at 4 seconds but the conversion point is at 4.8 seconds. That is to say, there is 0.8 second time delay. However, this time delay is vanishing as different transition probabilities are adapted. In the second and third simulations (Figure 4.4 and Figure 4.5), time delays are 0.4 and 0.1 seconds, respectively. Even though these three simulations assumed that there is no measurement noise, it helps us understand the influence of transition probabilities. The next chapter deals with the case when measurement noise is presented, and it shows that the result is more complex and more uncertain.

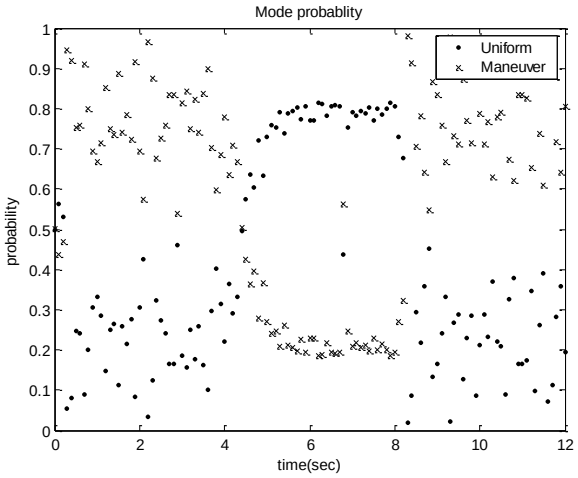

Fig. 4. Mode Probability: $\pi_{11} = 0.9, \pi_{12} = 0.1, \pi_{21} = 0.1, \pi_{22} = 0.9$

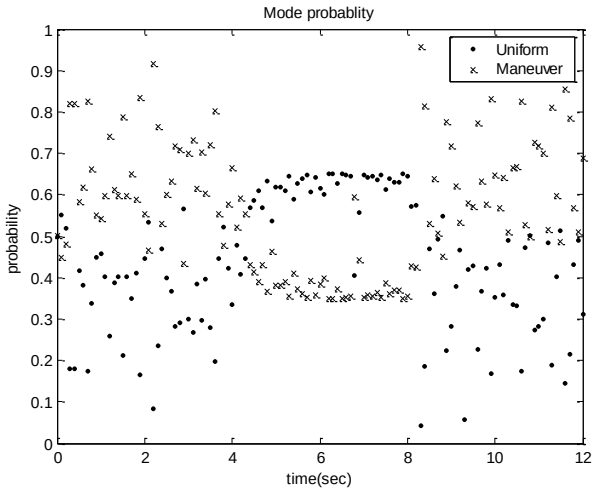

Fig. 5. Mode Probability : $\pi_{11} = 0.8, \pi_{12} = 0.2, \pi_{21} = 0.2, \pi_{22} = 0.8$

For simulation, three sensors are modeled under the assumption that they are radars, which is most commonly used in target tracking. Since radar measures the range and azimuth, they should be converted to the Cartesian coordinates. In simulation, predetermined target trajectory is converted to the polar coordinates and then converted to the Cartesian coordinates again after mixing with measurement noise. The most crucial value of the sensor is the standard deviation of the range measurement and the azimuth measurement, σ_r and σ_θ, respectively.

This algorithm deviates even further from the previously discussed algorithms. Cluster heads are special high powered nodes that know the location of every node within their cluster [10]. This algorithm takes advantage of the fact that the cluster head knows these locations. When sensor nodes detect a target, they send a very small notification message to their cluster head and store the target location

data, time and other relevant data in their local memory [10]. Upon receiving several notifications, the cluster head performs a probabilistic localization algorithm to determine which sensor nodes to query saved data from [10]. In other words, the cluster head runs an algorithm that helps it predict which sensor nodes are closest to the target and will therefore have the best data to use in order for the cluster head to calculate an accurate estimation of the target location. When the cluster head determines which nodes to query, they are asked for the data they saved in their local memory and the cluster head uses this to calculate the location of the target [10].

V. Conclusion

The main idea is that each sensor request information from only a subset of nodes which are more probable to flick on the basis of its local information. *S* supposes that the target moved on the same direction and traveled the same distance between times $t-2$ and $t-1$ as between times $t-1$ and t. so the requested information are only requested to the sensors flip base on this trajectory. We should also mention that the sensors request from a fixed number but randomly selected nodes .

At first each node is assigned a different region as possible starting place of the target. At first two time intervals every node gets the observations from all nodes so that the starting information is correct.

Abstract - *This work investigates the effects of surface topography of the distributed sensor networks on perception through the differences in sensor readings. Compound eyes are found in some insects and crustaceans. Lateral inhibition is a biological signal processing which can increase contrast, enhancing perception. It is known that eye convexity helps increase field of view (FOV). A series of experiments were carried out to understand the effect of surface topography on local contrast gradient. Two sets of sensor networks of 5 x 5 were constructed. In the first network the board holding the sensors was a flat circuit board, whereas the second one was given a radius of curvature of roughly 30 cm. All readings were recorded in a dark chamber. Sensor networks were illuminated by a light source whose coordinates could be adjusted. Results are tabulated. It is seen that eye convexity in compound eyes improves perception, as well as FOV.*

Keywords: Lateral Inhibition, Distributed Sensor Networks, Contrast Enhancement, Convexity, Compound Eyes, Contrast Enhancement

1 Introduction

Haldan Keffer Hartline have studied the underlying principles of compound eyes for over thirty years by analyzing horseshoe crab (Limulus polyphemus) that has compound eyes. Hartline has shown that the photoreceptor cells in each ommatidium are connected in such a way that these cells drive down the output of the neighboring cells when stimulated. This leads to an increase in contrast and sensitivity in peripheral processing [1].

The literature search has found that almost no work exists about compound eyes with regards to topography and perception sensitivity. In fact the authors have failed to find one. One of the partially related research is about poly-visualization. Multi-lens visualization device used in medicine was designed by Joseph Rosen and David Abookasis. Their study has focused on the imitation of the visual processing of flies. Researchers combined individual photographs after scanning an object, and obtained a representative good picture. Images were averaged and dispersed beams were eliminated. This means strays at image were eliminated. This technique has been a solution for the problem on present devices [2]. But this study is about image improvement instead of increasing sensitivity in multiple sensing.

Another worth mentioning may be found in Istanbul Technical University. Ozcelik was inspired by the compound eyes of the insects in his thesis of subpixel information gathering and resolution improvement. The spinoff was a high-resolution low-cost camera in the similar working principles of a fly obtaining a single image from a multitude of images [3].

Last study models compound eyes and contrast enhancement. Workers there try to find a cost-effective sensory information processing setup for an engineering application. Coskun et al. [6] show that a low-cost but sensitive distributed sensor network is feasible. Nevertheless, there is also no link between surface topography and sensitivity increase in perception, given that everything else is the same.

2 Compound Eyes and Lateral Inhibiton

Ommatidium is a single simple eye unit of a wider ommatidia in a faceted compound eye. The number of ommatidium varies. There are roughly 4000 ommatidia in stablefly (Musca domestica). This number comes down to 300 at glowworms. It may reach 5000 for chafers, 9000 for Dytiscus, and up to 28 000 ommatidia for certain species [4].

Every ommatidium in a compound eye has a specific optic system. Every ommatidium has the basic anatomy form of a simple eye. There are retina and retina cells, rhabdomeres, masking pigments and axons, Figure 1.

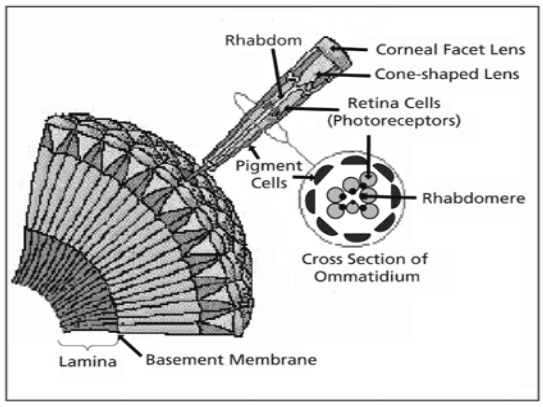

Figure 1. Form of Ommatidium [7]

Perceptions at compound eyes are somewhat different from simple eyes. Each ommatidium transmits the reverse images cast on retina to the brain. Number of images transmitted to the brain, is equal to the number of ommatidia. The brain stiches one image with the other. This composed new image is thought to be a mosaic-like image compared to what we see. This in turn likely to mean that the eventual composition is a high-resolution and high-contrast picture.

Contrast in mosaic-like vision is higher than the image formed by a simple eye. The main reason of this contrast difference is basicly Lateral Inhibition. Lateral inhibition (L.I.) is the dominant feature of biological distributed sensory networks where each individual receptor drives down each of its neighbors in proportion to its own excitation. The strengths of these connections are fixed rather than modifiable and are generally arranged as excitatory among nearby receptors and inhibitory among farther receptors. In other words, when any given receptor responds, the excitatory connections tend to increase its response while inhibitory connections try to decrease it [4, 5, 6].

The frequencies of discharge of each of two ommatidia were measured, for various intensities of illumination, when each was illuminated alone and when both were illuminated together. The below expressions show the amount of inhibition exerted upon ommatidium A by ommatidium B, as a function of the degree of activity of B, and shows the converse effect upon B of the activity of A [1, 5].

$$r_A = e_A - \beta_{AB} * (r_B - r_B^0) \quad (1)$$

$$r_B = e_B - \beta_{BA} * (r_A - r_A^0) \quad (2)$$

- r_A and r_B values are reactions of A and B ommatidiums after lateral inhibition,

- e_A and e_B are reactions of A and B ommatidiums without lateral inhibition,

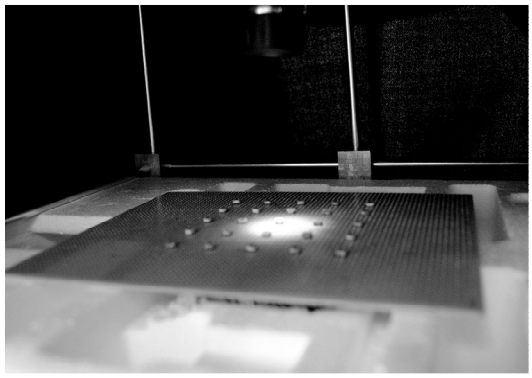
- β_{AB} is inhibition coefficient of B ommatidium for A ommatidium,

- β_{BA} is inhibition coefficient of A ommatidium for B ommatidium,

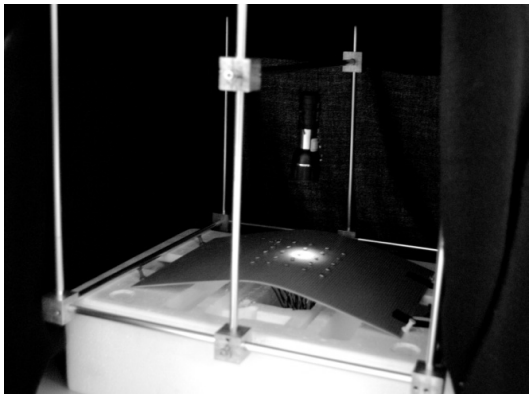
- r_A^0 and r_B^0 are threshold frequency of A and B ommatidiums

3 Experiments on Surface Topography

At this study, photoresistors (LDR) were used to represent ommatidia in compound eyes. The test rig is composed of an aluminum frame, a light source whose height and position could be adjusted. Down below, there is a flat board to allow LDRs. The whole rig was then covered by a thick black cover in a darkened lab environment. In each setup, a total of 25 sensors were used. Light source was tuned in position so that sensor number 13 receives a maximum amount of light, and neighboring sensors give off a close reading, Figure 12 a. In Fig 12 b, the same test rig is used except that the board that all the sensors were mounted upon is convex with a rough radius of curvature of 0.3 meters. Sensor outputs were measured by a Keithley 2700 multimeter with multiplexers.



(a)



(b)

Figure 2 a, b. Compound Eye on Flat(a) and Convex(b) Surface

All the experiments were performed at two height levels for the light source, 196 and 100 mm. The convexity in the board was formed when the board was allowed to soak moisture and then shaped under a heat gun.

It is worth mentioning that if the Table 1 is inspected carefully, even though symmetrical, not all the neighbors received the same amount of light. This may be due to the fact that the light source may be slightly off the vertical, or the sensor normals do not coincide with the surface normals. To have a meaningful comparison, lower right quarter of the Table 1 was assumed to be measured from all the remaining three quarters, leading to Table 2. Table 1 gives resistance values (KOhm). Table 2 shows symmetrized version of Table 1. Table 3 gives the reciprocals of the resistance values, 1/R which is used at signal processing. Table 4, on the other hand, reflects these above-mentioned reciprocals after LI was applied with (α = 0,15 and β = 0,05). Including Table 4, the distance of the light source has been 196 mm and it is kept right above the 13th sensor. Then, to compare the convex and flat compound eye systems, the light source has been adjusted to 100 mm from the surface, and tabulated on the Table 5.

4 Experiment Results

The first four tables reflect the trials for flat circuit board with sensors. So as to understand the influence of the surface curvature on the sensory perception, light source was pulled down to 100 mm distance from the nearest sensor, located at the center (number 13). These results may be seen on Table 5. The first column on Table 5 gives the ratio of certain resistance values. When no signal processing is made, raw independent readings show that the ratio of the 2nd sensor to the 3rd one is 1.67. This means, the 2nd sensor has 67 % more resistance than the 3rd one. The second and the third columns reveal ratio of resistance values at flat and curved surfaces. The last two columns display the cases of lateral inhibiton applied on flat and curved systems. Table 5 helps gather some important information. This information can be stated as follows:

When light is shed on the board centrally, light intensity naturally dies out toward the distant sensors. Even when there is no signal processing, this weakening of light from the center generates a natural contrast difference.

Table 5. Comparison Table

Contrast Between	Crude Data (Flat)	Crude Data (Curved)	Flat Data (After Lateral Inhibiton)	Curved Data (After Lateral Inhibiton)
R2 / R3	1.67	2.06	5.33	21.5
R7 / R8	3.20	3.18	10.52	8.75
R12 / R13	3.06	4.83	4.03	7.27

Second and third columns are the proof that curvature has a very positive effect on the contrast augmentation. If the ratio of R7/R8 is considered to be roughly the same, there is a 50% rise at R12/R13 value. With lateral inhibition, contrast is seen to wax even more for both flat and curved systems, but notably more so for the curved one. In our opinion, the discrepancy in R7/R8 ratios in all the four columns is due to misalignment of sensor 7 during surface mounting and soldering. Sensor 7 must slightly be off from the surface normal towards the light source in couple of degrees.

5 Conclusions

As seen from the experiments, contrast is being enhanced when a sensor network and lateral inhibition signal processing are adopted. It is also observed that when the radius of curvature of the board where the sensors were mounted gets smaller, the difference in consecutive sensor outputs increases. This is another way of saying that convex eyes not only allow a wider field of view but also augment the total light difference between light and dark areas in perception. Even though not reported here, another obvious advantage of a curved system is the capability of better localization of sources (light, for example), on the grounds that it simply makes the contrast gradient sharper. Curved facetted compound eyes thus must be quite an advantage in nature to both hunter and the prey alike. Hence, a good engineering application with a sensor net so as to have a sharper perception may involve a curved sensor board architecture, as well as an implementation of LI.

Abstract - *In recent years, various networks have come to exist in our surroundings. Not only can the internet and airline routes be regarded as networks; protein interactions are also networks. A network is defined as a structure of nodes (points) and links (lines). As described in this paper, an airline network is used as an example of an "economic network design problem." For the airline network, modeled based on a connection model proposed by Jackson and Wolinsky, a utility function can be defined as the sum of profits obtained from each route. Furthermore, an optimization simulation using the evolutionary computation is presented for a domestic airline in Japan.*

Keywords: Airline Network, Simulation**,** Network Game Theory, Evolutionary Computation

1 Introduction

In recent years, the Japanese aviation industry has been in dire straits, and the failure of Japan Airlines (JAL) has been well publicized. Although JAL has announced abolition of one loss-producing line one after another, All Nippon Airlines (ANA), which had been expected to replace JAL, has shown bad financial health. In such a situation, finding optimal airline networks that maximize profits is extremely important. Because the profits of other routes might also be affected by abolishing a loss-making line, it is necessary to consider transitions in an aviation network. Properly speaking, when abolition of a route is determined, it is desirable to consider not only the influence of the direct flight, but the concomitant increase and decrease of passenger traffic by effects on transit passengers. Therefore, this paper defines a profit function that regards the influence on transit passengers explicitly. We seek the optimal airline network that maximizes profits. In modeling of the airline network, connections models of Jackson and Wolinsky (1996) are extended to a model in which profits generate on a link and the utility function of the network is defined.

In the paper "airline network optimization problems," analyses were conducted for the network to maximize network utility, but finding optimal network theory is difficult when assessing real-world problems. Therefore, we propose a solution using evolutionary computation to resolve "airline network optimization problems." Furthermore, optimization simulation using evolutionary computation is demonstrated for a domestic airline in Japan. Optimal networks obtained when only the rate of the passenger discount by the transit was changed were found using the proposed algorithm.

The remainder of this paper is organized as follows. Section 2 formulates an "airline network optimization problem." Section 3 presents a description of a method of an "airline network optimization problem" using an evolutionary computation. Simulation results are presented in Section 4. Finally, we state the important conclusions in Section 5.

2 Airline network

An airline network is modeled in this paper based on Jackson and Wolinsky's (1996) connections model. In Jackson and Wolinsky (1996), the form that a stable network takes is analyzed under the situation in which formation of the link with a new each node (player)(relation) and an existing link disconnection are selected in the strategy. The network formation game theory proposed by Jackson and Wolinsky (1996) can become a substantial framework when dealings between varieties of economic agents are analyzed. For example, the conclusion distribution of the Free Trade Agreement in an international trade is foreseen, and it is applied to the analysis of the decision of the best airline line network etc. In the following, after first describing the utility function in the connections model, the airline network is modeled.

2.1 Connections model

As described in this paper, an economic network is denoted as a non-directed graph $G = (V, E)$ according to the graph theory. Graph G consists of node set V and link (edge) sets E. For example, a node in a graph represents an economic player (individual, group, city, and nation), and the link stands for a transport link, a telecommunication net, an economic regional alliance, etc. A link $e \in E$ is sets of node pairs $e = \{i, j\}$. A link between i and j is simply denoted ij. Considering a complete graph that consists of node set V, an economic network that consists of nodes (players) is subgraph G of complete graph K. The values of w_{ij} is an intrinsic value to obtain node i from node j by a direct link, and c_{ij} is the running cost of link ij. The utility function to obtain node i in graph G is defined as shown below.

$$u_i(G) = \sum_{j=1|i\neq j}^{|V|} \delta^{s_{ij}(G)} w_{ij} - \sum_{j=1|ij\in G}^{|V|} c_{ij} \qquad (1)$$

$|V|$: number of nodes in V
δ: decay rate of the gain
$s_{ij}(G)$: shortest path length in G
w_{ij}: gain to obtain node i from node j through link ij
c_{ij}: running cost of link ij

Furthermore, $\delta \in [0,1]$ is the decay rate of the gain. Considering the shortest path length s_{ij} between ij, $\delta^{s_{ij}(G)} w_{ij}$ is the gain to obtain node i from node j through the shortest path s_{ij}. Only when the link exists directly between ij is the link running cost c_{ij} needed. The graph value (utility of the entire network) is a summation of utilities of all nodes that exist in the network. The graph value is defined by the following equation.

$$u_{net}(G) = \sum_{i=1}^{|V|} u_i(G) = \sum_{i=1}^{|V|} \sum_{j=1|j\neq i}^{|V|} \delta^{s_{ij}(G)} w_{ij} - \sum_{i=1}^{|V|} \sum_{j=1|ij\in G}^{|V|} c_{ij} \quad (2)$$

The economic network design problem above can be formulated as follows.

$$\arg\max_{G \subseteq K_{|V|}} u_{net}(G) \quad (3)$$

2.2 Airline network model

There was a problem of lacking concreteness, although the connections model of Jackson and Wolinsky (1996) was able to assume various networks. Therefore, the analytical object is focused on the airline network. In the following, the airline network is modeled based on a connections model. The point in which the airline network model differs greatly from the utility function of connections model is to examine the utility obtained from a link.

In the airline network model, a node and a link respectively signify an airport and a route. The airline route with only the outward or homeward journey is a rare case. Therefore, the airline network is assumed to be a non-directed graph that does not incorporate the direction of the connection of the link. A link $e \in E$ of non-directed graph is a set of node pairs $e = \{i, j\}$ ($i, j \in V$ and $i \neq j$) without the order. A link between i and j is denoted simply as ij, and $ji = ij$. Furthermore, r_{ij} is an income of link ij; c_{ij} is an operation cost of link ij. The profit obtained between links ij in graph G is defined as

$$\pi_{ij}(G) = \begin{cases} r_{ij} - c_{ij} & if \quad ij \in G \\ \delta^{s_{ij}(G)-1} r_{ij} & otherwise \end{cases} \quad (4)$$

$|V|$: number of nodes (airport)
δ: decay rate of the profit
$s_{ij}(G)$: shortest path length in G
r_{ij}: income between i and j
c_{ij}: operation cost of link ij

Also, $\delta \in [0,1]$ is the decay rate of the profit. Considering that the shortest path length s_{ij} between ij, $\delta^{s_{ij}(G)-1} r_{ij}$ is the income got from node i by a passenger who goes to node j. Only when a direct flight exists between ij is operation cost c_{ij} needed. For these analyses, it is assumed that operation cost c_{ij} is necessary only for the direct flight's existing according to connections model. It is assumed that a flight need not be increased even if the number of passengers increases by an indirect link. Consequently, for aircraft that are not used over capacity, the load factor is at the 60% level also for the main route.

In addition, the income is the product of ticket price p_{ij} and the number of passengers q_{ij}. Also, δ is the product of the decay rate of ticket price δ_1 and the passenger decay rate δ_2. Equation (4), showing the price of the airline ticket and the number of passengers, can be rewritten as the income as follows.

$$\pi_{ij}(G) = \begin{cases} p_{ij} q_{ij} - c_{ij} & if \quad ij \in G \\ \delta_1^{s_{ij}(G)-1} p_{ij} \cdot \delta_2^{s_{ij}(G)-1} q_{ij} & otherwise \end{cases} \quad (5)$$

δ_1: decay rate of ticket price
δ_2: passenger decay rate
p_{ij}: ticket price between i and j
q_{ij}: passengers between i and j

Also, $\delta_1 \in [0,1]$ is the decay rate of the ticket price. The fare that a passenger must pay indeed gives a discount if the number of times of connection increases. In addition, $\delta_2 \in [0,1]$ is the passenger decay rate. Whenever the number of connections to the destination increases by δ_2, it is included in the model that the number of passengers decreases.

Next, operation cost c_{ij} is defined. Actually, c_{ij} is the operation cost of one year for the route between i and j, and the cost function is defined by the following equations.

$$c_{ij} = OP_{ij} \cdot FY_{ij} \quad (6)$$

OP_{ij}: cost per flight
FY_{ij}: number of annual flights

$$OP_{ij} = W(d_{ij} \cdot FU) + B \quad (7)$$

W: change of the weight by the number of passengers
d_{ij}: straight line distance between i and j
FU: fuel cost per km
B: airport landing fee

$$FU = LMX(FP + TAX)/RMX \quad (8)$$

LMX: maximum fuel capacity of the aircraft
FP: price per liter of jet fuel
TAX: fuel tax per liter
RMX: longest cruising range of aircraft

$$W = \frac{WE + PF_{ij} \cdot PW}{WE + PMX \cdot PW} \quad (9)$$

WE: operating empty weight of the aircraft
PF_{ij}: number of passengers per flight
PMX: number of seats of aircraft

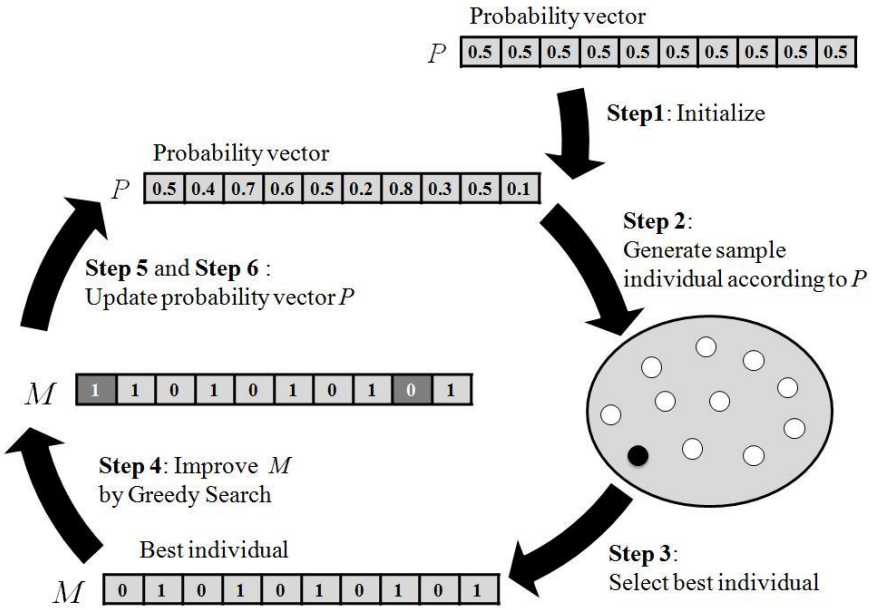

Fig. 1. Schematic diagram of algorithm.

PW: weight per passenger

The graph value $\pi_{net}(G)$ (profit of the entire airline network) is the summation of profits of all links in the network. The graph value $\pi_{net}(G)$ is defined by the following equation.

$$\pi_{net}(G) = \sum_{i=1}^{|V|}\sum_{j=1}^{|V|}\pi_{ij}(G) = \sum_{i=1}^{|V|}\sum_{j=1|j\neq i}^{|V|}\delta^{s_{ij}(G)-1}r_{ij} - \sum_{i=1}^{|V|}\sum_{j=1|ij\in G}^{|V|}c_{ij} \quad (10)$$

In equation (4), the profit when the direct link (direct flight) exists between *ij* differs when the direct link does not exist. However, no problem as $\delta^{s_{ij}(G)-1}r_{ij}$ exists because the shortest path length $s_{ij}(G) = 1$ when a direct flight exists. Equation (10) and equation (2) are the same structures if it is excluded that the exponent of δ is $s_{ij}(G)$-1. It is understood that the airline network model is a pure application of the connections model.

The airline network optimization problem above can be formulated as follows.

$$\arg\max_{G\subseteq K_{|V|}} \pi_{net}(G) \quad (11)$$

3 Evolutionary computation for "airline network optimization problem"

It is extremely difficult to analyze the network where the utility of the entire network is maximized in non-symmetric node (player) theoretically. One kind of evolutionary computation method, Population-Based Incremental Learning (PBIL) with a local search for the approximate solution method, is applied. Optimization of the network is tried. The basic operation of the improved algorithm is almost identical to that of the usual PBIL, but there is a difference in the update process of the probability vector. The difference point is to do a greedy search based on the selected excellent individual before the probability vector is updated. The former excellent solution is replaced if a better solution is found from the former excellent solution as a result of a greedy search. However, a local search examines the range of Hamming distance 1 as the neighborhood. This proposed algorithm is called G-PBIL. In the following, the schematic diagram of algorithm is presented in Fig. 1, and detailed processing of each Step is described.

Step 1: Initialization of probability vector $\vec{P}$

The probability vector $\vec{P} = (p_1, p_2, \ldots, p_{nbit})$ is the probability that each bit of the gene becomes 1. When the search begins, the probability vector is set to all 0.5. *nbit* is the gene length, which changes according to the scale of the problem. The probability vector in *t* generation (cycle) is written as $\vec{P}^t = (p_1^t, p_2^t, \ldots, p_{nbit}^t)$.

Step 2: Generate the sample population according to probability vector $\vec{P}$

Each individual is expressed by the bit string of 0 or 1 that is called a gene, and the probability vector is simply a description of the appearance probability of 1 by the vector.

Step 3: Evaluate the population, and select an excellent individual

The population is evaluated, and an excellent individual with the best fitness in the population is selected. The selected excellent individual is the notation

$M^t = (m_1^t, \ldots, m_{nbit}^t)$. A term called *fitness* is used because the right and wrong of an objective function values change with a minimization problem or maximum problem.

For a minimization problem, it is considered that a smaller objective function value has higher fitness.

Conversely, for a maximization problem, a greater objective function value indicates higher fitness.

Step 4: Greedy search based on a selected excellent individual.

First, the population that changes the gene of M^t by only one bit is generated. Next, fitness of the population that newly generates it is calculated, and the individual with the best fitness among former M^t and newly generated populations is new M^t. Greedy search is stopped if former M^t has best fitness. Otherwise, greedy search is tried again based on new M^t. However, when trying greedy search again, changing a bit again that has already changed from M^t from the first received from PBIL is forbidden. This rule limits the frequency of a greedy search. Even if it is the maximum, the frequency of a greedy search under this rule is gene length. The reason to adopt such a rule is that it is thought that the frequency of a greedy search becomes every high if the bit is changed unrestrictedly.

Step 5: Update probability vector

The probability vector is updated using excellent individual M^t improved by a greedy search.

$$p_i^{t+1} = (1.0 - LR)\, p_i^t + LR \cdot m_i^t \tag{12}$$

LR stands for the learning rate. When *LR* is large, the search will converge rapidly to the generation's excellent individual. To evade the initial convergence, *LR* should be set to a small value. However, because a generation number required for search increases when the value of *LR* is small, setting it to an extremely small value hinders the search.

Step 6: Mutation

Mutation occurs at a constant mutation probability, and the value of each element of the probability vector updated with Step 5 is changed further according to the following equation.

$$p_i^{t+1} \leftarrow (1.0 - MR)\, p_i^{t+1} + rand \cdot MR \tag{13}$$

Mutation Rate (*MR*) is a degree of the change by the mutation. The probability vector changes greatly by *MR* large. $rand \in \{0,1\}$ is a uniform random number.

Step 7: Repetition of Step 2 – Step 6

The processing of Step 2 – Step 6 is repeated until the termination condition is satisfied. It is defined as the first generation to repeat the processing of Step 2 – Step 6 once in PBIL. The termination condition of processing when the set number of generations is passed or the convergence of the search is admitted by the convergence criterion is usually adopted as a termination condition.

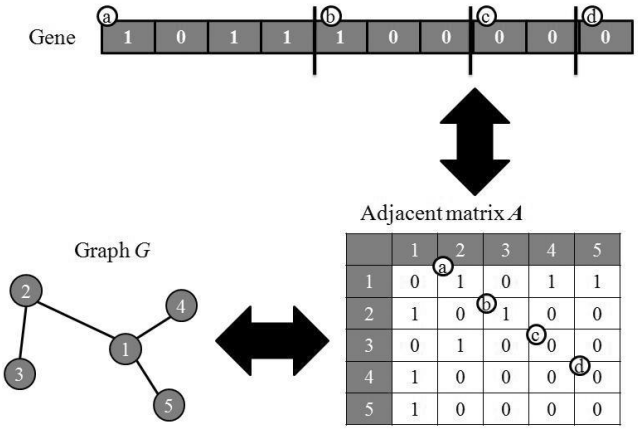

Fig. 2. Coding for a network graph with 0–1 design variable.

When this algorithm is adapted to the "network optimization problem" for which a design variable takes the discrete value of 0–1, it is necessary that a gene correspond to a graph as presented in Fig. 2. Denoting a graph by an adjacent matrix, and also making an adjacent matrix correspond to a genotype can express a graph with a gene. The adjacent matrix *A* of a graph *G* (airline network) is the matrix of |V|×|V|, where a_{ij} represents element of row *i* and column *j* of matrix *A*. It is assumed that a_{ij} =1 when the link (edge) exists directly between vertices *i* and *j*. It is also assumed that a_{ij} =0.

$$a_{ij} = \begin{cases} 1 & if \quad ij \in G \\ 0 & otherwise \end{cases} \tag{14}$$

When G-PBIL is adapted to the "network optimization problem" in which a design variable takes the discrete value of 0–1, the gene length is set as *nbit* = |*V*|(|*V*|-1)/2. In Step 3 of an algorithm, as presented in Fig. 2, a gene is changed to a graph, and the graph value is computed using equation (10). Making a computed graph value into the goodness of fit of a gene is synonymous with optimizing a graph to optimize a gene.

4 Simulation analysis of the optimal airline network

Here, the proposed algorithm is used and simulated. The simulation is targeted to 19 airports of Japan with domestic routes serving 1.5 million passengers or more annually. Figure 4 shows the existing network among the 19 airports.

4.1 Data

To conduct a simulation, some data are necessary: the ticket price p_{ij}, number of potential passengers q_{ij}, and straight line distance d_{ij} between *i* and *j*. First, we consider the ticket price p_{ij} between *i* and *j*. If between *i* and *j* is an existing route, p_{ij} examines the price of the airline ticket. However, the price cannot be examined about the route that does not exist. Then, the airline ticket price of the non-existent route is estimated by

the following regression by making the distance d_{ij} into an explanatory variable.

$$p = \alpha + \beta d \tag{15}$$

A single regression analysis that uses a straight line distance based on Google Map was done with the price of the airline tickets of All Nippon Airways (ANA). A significant result was obtained statistically by α = 15562.75 and β = 21.21 with correlation coefficient 0.89 and a coefficient of determination 0.80.

Next, passenger q_{ij} travelling between i and j is considered. Data existing for passengers between existing routes can be determined using data of the Ministry of Land, Infrastructure, Transport, and Tourism. Passenger q_{ij} of the non-existent route is estimated using the gravity model used well in aeronautic demand forecasting. A passenger can be estimated using the following formula and turns into the correlation coefficient 0.806 by a= 0 and b = 2.631×10^{-8}. However, only routes of not less than 300 km of distance can be estimated, and passenger q_{ij} for routes less than 300 km are set to zero.

$$q_{ij} = b\frac{pop_i \cdot pop_j}{{d_{ij}}^a} \tag{16}$$

pop : quota population of each airport

Data used as explanatory variables are the quota population of each arrival-and-departure airport and the distance in a straight line d_{ij} between airports. Because the quota population of each airport is needed here, we presume that the following methods are used. In this paper, a Voronoi diagram is drawn by setting each airport to the generatrix (node): the population of each area residing with a nearby airport is used most. The quota population (Table 1) of each airport was calculated by the figure of the area divisions and population data are given by Asahi Shimbun Publications. Data of the existing route are obtained using data provided by the Ministry of Land, Infrastructure, Transport and Tourism. Data estimated using the gravity model are used only for the non-existent route.

Each datum used for a cost function is set to a jet fuel value rank FP = 50 yen/liter, an aviation fuel tax TAX= 26 yen/liter, the landing fee B = 400,000 yen, and weight per passenger PW = 100 kg.

4.2 Optimization simulation

we simulate the case of one kind of aircraft. Data of the aircraft are computed from the average value of the main aircraft (Table 2). The determined optimal network by the simulation is presented in Fig. 3 – Fig. 6.

When the fare discount rate (1 - δ_1) and the passenger decrease rate (1 - δ_2) become small, the optimum network is clarified as centralized on Tokyo International Airport (Haneda). The fare discount rate (1 - δ_1) and the traveler decrease rate (1 - δ_2) become small as $\delta = \delta_1\delta_2$ becomes large. That relation corresponds to the previous work clearly to make the network excessively concentrated by growing of δ. The change to Fig. 4 from Fig. 3 occurs when the passenger decrease rate (1 - δ_2) becomes small. This change shows that the direct flight from the main island of Japan to Naha Airport is decreasing by two routes. The change to Fig. 5 from Fig. 3 changes when the passenger decrease rate (1 – δ_1) becomes small. This change shows that the direct flights from the main island of Japan to Naha Airport are decreasing by four routes, and that numerous direct flights between the airports in the main island of Japan are also decreasing. Furthermore, the change to Fig. 6 from Fig. 3 occurs when both the fare discount rate (1 - δ_1) and the passenger decrease rate (1 - δ_2) become small. The change to Fig. 5 from Fig. 3 and a difference are not apparent. Consequently, among the fare discount rate (1 - δ_1) and the passenger decrease rate (1 - δ_2), the fare discount rate (1 - δ_1) has a stronger influence on the optimal network. If the fare discount rate (1 - δ_1) is small, then because the airline can gain greater profits also from a transit flight (indirect link), it will be expected that the number of a direct flights will decrease. However, if it is expected that there is negative correlation in the fare discount rate and the passenger decrease rate, then the passenger decrease rate will become large when the fare discount rate becomes small.

Moreover, graph values of all the optimal network of Fig. 3 – Fig. 6 have exceeded graphed values of the existing network. Compared with the existing network, the optimal network by a simulation has a tendency with few routes in the graph of the optimal network. The tendency is notably apparent for the route involving Ishigaki Airport. Although a direct flight exists between each airport and Ishigaki Airport in the main island of Japan in the existing network, only the transit flight through Naha Airport exists in the optimal network graph. Therefore, cost cutting is possible by losing a direct flight with a great distance between Ishigaki Airport and the airport in the main

Fig. 3. Optimal network ($\delta_1 = 0.50$, $\delta_2 = 0.50$).

Fig. 6. Optimal network ($\delta_1 = 0.90$, $\delta_2 = 0.90$).

island of Japan. However, in this experiment, the passengers of a non-existent route are estimated using the population around an airport, and it cannot be considered that Ishigaki Island is a tourist resort. The route between Haneda Airport and Ishigaki Airport is known for a seat-occupancy rate being high, and probably, it is not realistic to abolish the route. Regarding this point, the seat-occupancy rate is included in a cost function, and improvement with a different seat-occupancy rate for every route can be considered.

5 Conclusion and Future work

As described in this paper, an airline network is modeled based on Jackson and Wolinsky's (1996) connections model. Moreover, the optimal network in an existing airline network is found using the airline network model. Results of simulations show that because a realistic network identified, the possibility exists that a connections model can be used as a framework for airline network analysis. Although Jackson reported that the connections model can be applied as a framework of various network analyses, few examples have been presented in which a connections model is actually

TABLE II
Aircraft data

	Boeing 747-400D	Boeing 777-300	Boeing 777-200	Average	Used data

(Source: Japan Aircraft Development Corp.)

applied to actual network analysis. This paper has contributed a research example using a connections model. The G-PBIL algorithm that extended PBIL was used for optimization of an airline network. In the simulation, a network that is more efficient than the existing network can be found. When the fare discount rate and the traveler decrease rate were small, the optimum network was shown to centralize to Tokyo International Airport (Haneda).

Future works will expand the simulated range. With the G-PBIL algorithm, although improvement in search performance was sought using a local search together to PBIL, the time which search takes has also increased. The search time by local search increases as the network scale becomes large, and it becomes difficult to perform a simulation. Therefore, it is necessary to consider the proper balance of the evolutionary computation and the local search in G-PBIL. Moreover, although this simulation of only a domestic flight was performed, the international role of Haneda Airport can be clarified by adding main airports of the world. As a subject for other future work, analysis of the optimal airline network when an airport is closed or built is also possible by application of estimation of passengers using a Voronoi diagram and gravity model.

Abstract—*A novel algorithm based on bimatrix game theory has been developed to improve the accuracy and reliability of a speaker diarization system. This algorithm fuses the output data of two open-source speaker diarization programs, LIUM and SHoUT, taking advantage of the best properties of each one. The performance of this new system has been tested by means of audio streams from several movies. From preliminary results on fragments of five movies, improvements of 63% in false alarms and missed speech mistakes have been achieved with respect to LIUM and SHoUT systems working alone. Moreover, we also improve in a 20% the number of recognized speakers, getting close to the real number of speakers in the audio stream.*

Keywords: speaker diarization, bimatrix game-theory, data fusion.

1. Introduction

1.1 Speaker diarization

Speaker diarization is the process of splitting an audio recording with an unknown number of speakers into time segments according to a recognized speaker, and then clustering those fragments by speakers. It is known as the task of determining *Who spoke when?* [1]. This technique distinguishes between instants of speech, music or silence. Initially, it emerged as an initial process for the speech recognition, but over recent years has become an important independent task used in many fields, such as information retrieval or navigation. In fact, it has been mainly developed for broadcast recorded meetings [2], news audio and telephone conversations [3]. Generally, speaker diarization is a very useful tool in every field in which it is necessary the determination of the number of speakers, along with the time periods when each one is active.

The most remarkable applications for speaker diarization systems are reflected in the Rich Transcription evaluation series (RT) [4], a community which promotes and gauges advances in the state-of-the-art in several automatic speech recognition technologies. This community is sponsored by the National Institute of Standards and Technology (NIST) in the Unites States [4].

Unfortunately, few speaker diarization systems are available for public general use. Two of them are LIUM [5] and SHoUT [6], which are open-source systems available on the Internet, mainly developed for applications on broadcast news that use audio streams. In this paper, both LIUM and SHoUT systems are used for obtaining speaker diarization output data on audio streams from movies. We use a fusion system to select the best decision at every second of our input audio from LIUM and SHoUT programs, in order to reach a better reliability and accuracy in our whole speaker diarization system. This fusion is carried out by means of a novel algorithm based on bimatrix game theory.

1.2 Game theory

Game theory is the study of mathematical techniques for analyzing situations of cooperation or conflict (games) between two or more rational intelligent individuals (players) [7]. It was introduced by von Neumann in 1928 [8], and improved later together with Oskar Morgenstern by considering cooperative games of several players [9]. Subsequently, Nash introduced the *Nash equilibrium* criterion [10], which supposed an important advance. Game theory has been widely used in a great variety of fields, such as economics, political science, philosophy or engineering. One of its main goals is the study of intelligent rational decision making, since it allows the understanding and modeling of different rational strategies performed by diverse agents. This involves a considerable help and support in decision making systems.

The three main elements in a game are the players (typically two), their played strategies, and the pay-off matrix, which contains the received prize by each player for each strategy. *Zero-sum games* [7] are a particular case in which the interest of both players are strictly opposed, hence the pay-off matrix contain the same values in opposite signs. Players in this kind of games strictly play in a competitive way. On the other hand, *non-zero-sum games* [11] can contain some strategies which are equally beneficial or detrimental for both players. Therefore, in *non-zero-sum games* competitive and cooperative strategies are generally performed.

The modeled game in this paper is *non-zero-sum*. It executes a data fusion algorithm based on the comparison of two data outputs from two systems. These data can be processed

in a cooperative way, taking into account the outcome from both data sources, or in a competitive way, analyzing the different properties of every system, and selecting the best of them.

Fusion data systems related to game theory have been widely studied, mainly in military and general security fields. For instance, a data fusion aided platform routing algorithm based on game theory for cooperative intelligence is proposed by Shen et al. [12]. Other example is using a Markov stochastic game method to estimate the belief of possible cyber attacks patterns [13]. Although similar algorithms to the proposed in this paper have not been found in the literature, game theory is a powerful tool that can be successfully used for improving speaker diarization by means of fusion data algorithms.

2. Speaker diarization systems

2.1 LIUM

LIUM [14] is an open toolkit [5] for speaker diarization developed by the *Laboratoire d'Informatique de l'Université du Maine* [15] for the French ESTER2 evaluation campaign [16]. It obtained the best results for the task of speaker diarization of broadcast news in 2008. It is written in Java and performs methods such as Mel-frequency cepstral coefficients computation, speech/non-speech detection and speaker diarization, using some tools from the speech recognition system Sphinx-4 [17]. The main algorithm follows next steps:

1) Segmentation based on BIC (Bayesian Information Criteria): speaker change points are detected and the audio signal is split into segments.
2) BIC clustering: similar segments are joined together.
3) Segmentation based on Viterbi decoding: a new segmentation is generated.
4) Speech detection: in order to remove music and jingle regions, a segmentation into speech / non-speech is obtained using a Viterbi decoding with 8 one-state Hidden Markov Model.
