Specific details of the video streams used are as follows: The use of H. 264 codecs [10] is assumed. The initiator node generates video streams as follows. On the "highway" [11] that uses the Quarter Common Intermediate Format (QCIF), 1,000 frames are encoded using jm14.2 [10]. The frame rate is 30 frames/s (i.e., a frame is generated every 33 ms). There are I frames and P frames and the group of pictures (GoP) is 10. Figure 2 shows the packet size distribution for 1,000 initiated packets. The initiator node repeats the transmission of these 1,000 frames 54 times, so generating 54,000 packets, which is equivalent to a 30-minute-long video stream. To take account of the rate at which packets are generated, the value generated by Random() at each node is set to [0, 33] ms.

The remaining battery level of a node is simulated as follows. The maximum battery level (*max_battery)* is 500 W*s. At the start of the simulation, the initial battery level of the initiator node is 500W*s (i.e., 100% full), and those of other nodes are random in the range [100, 400] W*s (i.e., 20% to 80% full).

Table 1 Parameters for each delivery method

	c_threshold	*max_c_threshold*
SF	-	-
C4	4 (fixed)	-
C3	3 (fixed)	-
C2	2 (fixed)	-
LB4	Determined by Eq.(1)	4
LB3	Determined by Eq.(1)	3
LB2	Determined by Eq.(1)	2

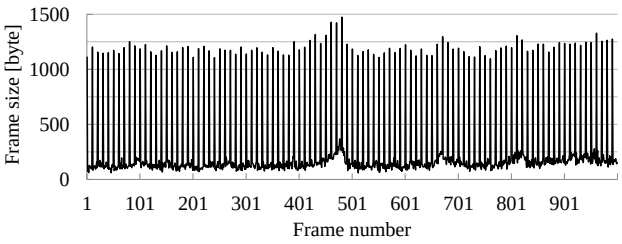

Fig.2 Frame size distribution of generated video

Feeney et al. [12] have indicated that the transmission power, *tp* [μW*sec], and the reception power, *rp* [μW*sec], for a single packet are as follows:

$$tp = 2.000 * \textit{frame length}\ [\text{byte}] + 270 \quad (3)$$

$$rp = 0.500 * \textit{frame length}\ [\text{byte}] + 60 \quad (4)$$

We assume that the above power is consumed by a node each time it sends or receives a packet. Any power that may be consumed while no packet is being sent or received is disregarded. When the remaining battery level of a node is zero, the node ceases to operate.

4.2 Evaluation items

The simulator executes 10 trials for each random seed. The average for all the trials is calculated for each of the following evaluated items.

(i) Average remaining battery level at the end of the streaming [W*s]

This is the average remaining battery level at the end of the streaming for all the nodes in the network. The larger this value, the better.

(ii) Average energy consumed by a node till the end of the streaming [W*s]

This is the average energy consumption per node from the start until the end of the streaming for all the nodes in the network. The smaller this value, the better.

(iii) Percentage of nodes whose operation was stopped due to complete battery discharge [%]

This is the percentage of the nodes that had ceased to operate by the end of the streaming among all the nodes in the network. The smaller this value, the better.

(iv) Average packet reachability [%]

Packet reachability is the percentage of the nodes that have received successfully a packet generated by the initiator node among all the nodes in the network. The average packet reachability is the average for all the packets generated by the initiator node. The larger this value, the better.

4.3 Evaluation results

The evaluation result is shown in Fig. 3.

(i) Average remaining battery level at the end of the streaming

LB2 to LB4 registered higher values than any existing scheme, in both Spaces A and B. In particular, LB2 produced the highest value in both Spaces A and B. These results indicate that the proposed scheme can preserve a higher battery level than the existing schemes.

(ii) Average energy consumed by a node till the end of the streaming

In both Spaces A and B, LB2 to LB4 consumed less energy than the existing schemes. In particular, LB2 consumed the least power, 29.6% down from SF, and 33.4% down from C2 in Space A. 55.4% down from SF and 42.9% down from C2 in Space B.

(iii) Percentage of nodes whose operation was stopped due to complete battery discharge

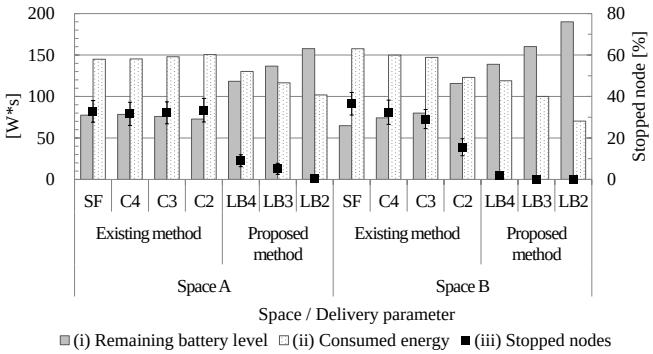
The deviation bars show the (average +/- standard deviation). LB4 to LB2 produced a lower percentage than any existing scheme in both Space A and B. These results indicate that the proposed method results in fewer cases in which nodes become inoperative due to complete discharge of their batteries than the existing schemes.

(iv) Average packet reachability [%]

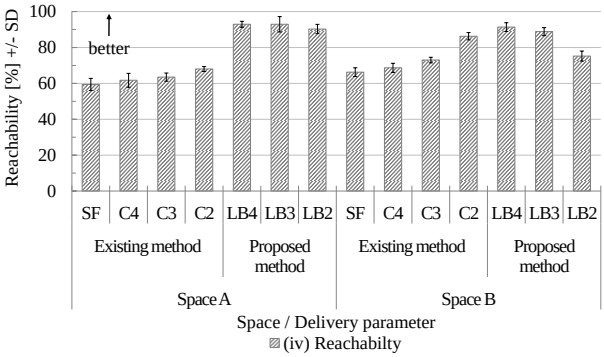
The deviation bars show the (average +/- standard deviation). LB4 and LB3 produced higher average packet reachability than any existing scheme in both Spaces A and B. In Space B, the average packet reachability value of LB2 is lower than that of C2, which registered the highest value among the existing schemes.

4.4 Discussion

The simulation results described in the above section allow us to conclude the following. In comparison to existing methods, the proposed method can (i) increase the average remaining battery level at the end of streaming, (ii) reduce the average energy consumed by nodes from the start to the end of the streaming, and (iii) reduce the percentage of nodes which became inoperative due to complete battery discharge. These affects are due to LBF's mechanism of dynamically setting *c_threshold* according to the remaining battery level of each node -- in particular of avoiding cases when nodes with a low battery level re-broadcast packets. LB2 produced the best performance in these three respects, (i), (ii), and (iii). The delivery quality was evaluated in terms of (iv) the average packet reachability. In networks where nodes are distributed densely (Space A), the proposed method produced higher average packet reachability than Simple Flooding or Counter-base schemes with fixed *c_threshold* (C4-C2). In networks where nodes are distributed sparsely (Space B), LB2 performed the lower packet reachability than C3, LB4 and LB3. To maintain packet reachability at that time, *max_c_threshold* should not be too small value such as 2. On the other hand, packet reachability for LB4 and LB3 are greater than SF and C4-C2. Therefore, LB4 and LB3 should be applied to the delivery parameter in the proposed method.



a. (i) Remaining battery level, (ii) Consumed energy, and (iii) % of Stopped nodes

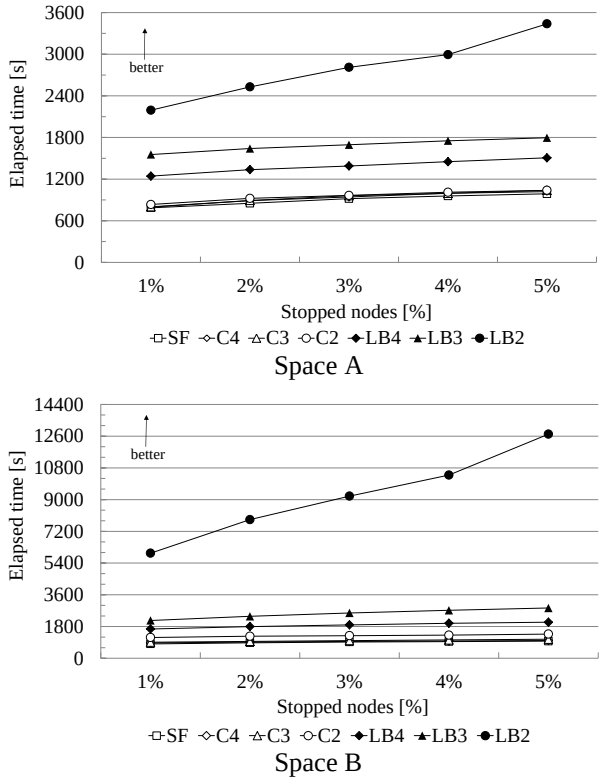


b. (iv) Average Packet Reachability

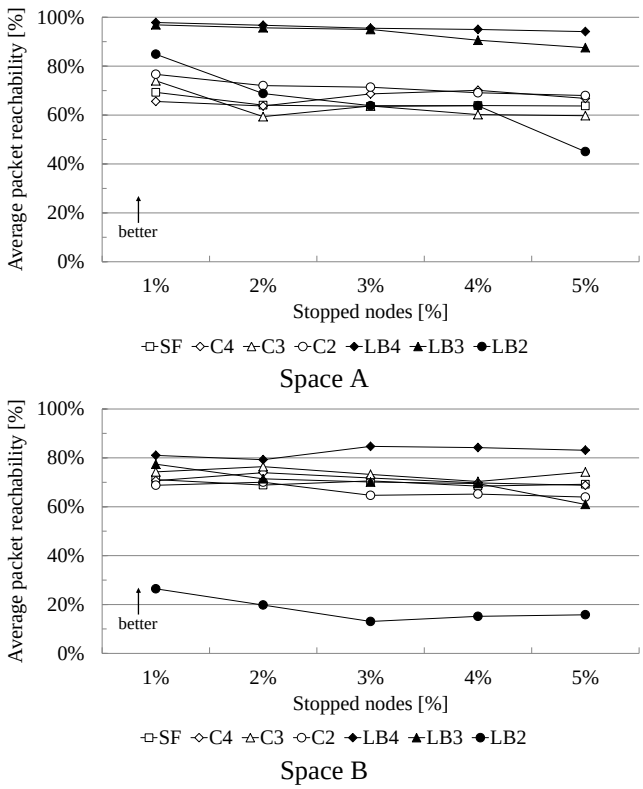
Fig. 3 Simulation result of basic performance for each set of delivery parameters

5 Evaluation of network runninng time and packet reachability

To evaluate the proposed method can prolong network lifetime without degradation of delivery quality, in this section,



a. (v) % of stopped nodes against elapsed time



b. (vi)Average packet reachability against % of stopped nodes

Fig. 4 Simulation result of network life time and delivery quality for each set of delivery parameters

we evaluate the network running time, which is the elapsed time when specific percentage of nodes stopped due to complete battery discharge, and packet reachability.

5.1 Simulation configurations

The simulation configuration is the same in Section 4.1. Each initiator node generates 1,000 frames repeatedly based on the frame size distribution which is shown in Fig.2.

5.2 Evaluation items

The simulator executes 10 trials for each random seed. The average for all the trials is calculated for each of the following evaluated items.

(v) % of stopped nodes against elapsed time

The elapsed times when specific percentages (1-5%) of nodes stopped ware evaluated. The longer time, the better.

(vi) Average packet reachability against % of stopped nodes

The percentage of the nodes that have received successfully a packet generated by the initiator node among all the nodes in the network was evaluated at the time when 1-5 percentages of nodes stopped. The larger this value, the better.

5.3 Evaluation results

The evaluation result is shown in Fig. 4.

(v) % of stopped nodes against elapsed time

LB2 to LB4 performed the longer running time than the existing methods, in both Space A and B. In particular, LB2 performed the longest running time. These results indicate that our methods can prolong the network lifetime.

(vi) Average packet reachability against % of stopped nodes

The result in Fig.4b shows that LB4 performed the highest value regardless of the percentage of stopped nodes. In other words, LB4 is the best in terms of packet reachability. Considering the both results Fig.3b and Fig.4b, the packet reachability for LB4 and LB3 are greater than or equals to that for the existing methods at the time when several nodes stop. This means that LB4 and LB3 can maintain the packet reachability whether several nodes stop or not. On the other hand, as shown in Fig.3b, the packet reachability for LB2 was not as high as that for LB4 and LB3. On the contrary, Fig.4b

indicats that LB2 performs extremely low packet reachability at the time when several nodes stops.

5.4 Discussion

The simulation results described in the above section allow us to conclude the following. In comparison to existing methods, the proposed method (LB2-LB4) can prolong the network running time. LB2 which sets the lowest *max_c_threshold* value performed the longest running time. However, considering the case where several nodes stop due to the battery discharging, LB2 performed the lower packet reachability than any other delivery parameters. To maintain packet reachability at that time, *max_c_threshold* should not be too small value such as 2. On the other hand, packet reachability for LB4 and LB3 are greater than or equal to SF and C4-C2. Therefore LB4 and LB3 should be applied to the delivery parameter in the proposed method.

6 Conclusions

This paper has considered broadcast streaming in ad hoc networks which can achieve to maintain delivery quality and long network lifetime. For this purpose, we have already proposed Load and Battery Charge Oriented Flooding (LBF), in which re-broadcast at the loaded nodes are canceled and the counter threshold used to determine whether a packet should be re-broadcast or not, *c_threshold*, is dynamically set according to the remaining battery level of each node. In this paper, the basic performance of the proposed method has been evaluated using the network simulation. The evaluation results have shown that, in comparison to existing flooding schemes, the proposed method can reduce energy consumption by nodes, reduce the chances of nodes becoming inoperative due to battery complete discharge of node batteries, and avoid degradation of delivery performance. This paper also evaluated the network running time and the packet reachability. The evaluation results have shown that, in comparison to existing flooding schemes, LB4 and LB3 in the proposed method can prolong the network running time without degradation of delivery performance. In future, we will evaluate the QoS of played-back video and audio streams and implement on communication devices.

Abstract— *Ultra-low-power protocol handling is indispensable to realize and sustain the communication in ad hoc network established by battery-operated devices, especially in emergent situations. To realize the ultra-low-power, real-time multiprocessing essential for the protocol handling should be realized with essential power consumption in which power consumption is confined into only target program execution. In this paper, a data-driven processor, named ULP-CUE, is proposed to realize the real-time multiprocessing with the essential power consumption. The ULP-CUE is fully realized by self-timed elastic pipeline which consumes power only for circuits contributing processing as a result of localized and exclusive data transfer, and its instruction execution pipeline is designed to transfer data to only stages essential for executing instructions. The power-performance evaluation with a prototype LSI shows that the proposed ULP-CUE can work with approximately 40% of energy consumption compared to the conventional implementations of the real-time multiprocessing.*

Keywords: data-driven processor, protocol handling, real-time multiprocessing, self-timed pipeline

1. Introduction

Low-power communication protocol handling is indispensable to enhance the sustainability of communication, especially in ad-hoc networks of mobile devices linked by wireless communication schemes such as MANET [1]. To ensure the communication, processors should execute required communication protocol handling in real-time for satisfying both turn-around and response times required, and also realize multi-processing dealing with multiple streams input into the communication protocol handling as long as their processing capability is available in order to satisfy a given throughput.

To realize such real-time multiprocessing without any extrinsic overheads on program execution, a data-driven processor named CUE and its successors are already studied [2], [3], [4]. By fully utilizing the no-extrinsic-overhead real-time multiprocessing of the CUE, the authors conduct a collaborative research project, named ULP-DDNS, to realize an ultra-low-power networking system [5].

The CUE is a realization of data-driven processing scheme in which instruction execution is initiated on the arrival of input data. This passive instruction execution realizes the real-time multiprocessing without extrinsic controls such as context switching violating both the real-time constraint and power saving. The circuit of the CUE is realized only by self-timed elastic pipeline (STP) in which only pipeline stages with valid data drive their pipelined logics autonomously, i.e., the signal gating is provided naturally at pipeline stage level. Moreover, the empty stages without valid data can be powered-off by using a stage-by-stage power gating scheme to reduce leakage current through the empty stages [6].

However, the instruction execution pipeline in the originally-proposed CUE harms power-performance efficiency of the protocol handling. This is because the conventional pipeline executing instructions enforces every data to pass through the matching stage which detects the arrival of two operands for an instruction even though most of instructions in the protocol handling can be executed with single operand. To eliminate the redundant processing time and power dissipation due to the matching-centric instruction execution pipeline, ultra-low-power CUE (ULP-CUE) realized by a circular pipeline with a shortcut to bypass the matching stage is already being studied [7].

In this paper, the power-performance of the ULP-CUE is evaluated by using a prototype LSI chip of the ULP-CUE. To verify the essential power consumption of the ULP-CUE, the power consumption of a protocol handling is measured by using its evaluation board and it is compared with that of the conventional CUE. The rest of paper is organized as follows. Section 2 describes the requirement for a networking platform to realize the ultra-low-power protocol handling, and the architecture of the ULP-CUE is explained in Section 3. The power-performance verification is shown in Section 4, and then our conclusion is discussed in Section 5.

2. Requirement to realize ultra-low-power networking platform

To realize the real-time multiprocessing with ultra-low-power, the power should be consumed only for executing

instructions of target programs. This unique but absolutely necessary feature is called essential power consumption in this paper. The passive behavior realized by data-driven principle makes it possible to realize the essential power consumption.

This section describes how the real-time multiprocessing with essential power consumption is realized based on the data-driven principle.

2.1 Real-time multiprocessing with essential power consumption

The real-time multiprocessing can be achieved if the execution of each target process is initiated as soon as its input data arrive while the target processes are executed simultaneously and independently from each other in a processor. To realize the real-time multiprocessing with ultra-low-power, any overheads on process execution should be eliminated.

The simultaneous and independent process execution can be realized by either concurrent processing scheme or pipeline processing scheme. The former divides spatially a computational resource into multiple computational resources to execute one process on each computational resource, and the latter divides temporally a computation resource into multiple computational resources which are called stages to execute multiple processes at the different stages. In the networking platform to execute protocol handling, the execution order of the processes is undetermined before the execution because it depends on the arrival timing of communication packets, i.e., it depends on user's demands. This fact imposes the dynamic allocation of the computational resources on the processing schemes. To realize the dynamic allocation, all computational resources should be monitored to detect whether they are idle or not, and target processes are assigned to the idle resources in the concurrent processing scheme. In contrast, the dynamic allocation can be realized only by assigning the target processes to the first stage when the first stage is idle in the pipeline processing scheme, and this simplicity results in less power consumption; therefore the pipeline processing scheme is indispensable to realize the real-time multiprocessing with essential power consumption.

To realize the pipeline, the passive behavior of the data-driven principle is exploited for providing the essential power consumption. Self-timed elastic pipeline, which is abbreviated as STP in this paper, is a realization of the passive behavior of the data-driven principle in circuit implementation.

In the STP, only pipeline stages with valid data are driven exclusively, and thus power consumption is confined into the circuit essential to execute the target processes. This exclusive driving is realized as a result of the local negotiation between adjacent stages. Figure 1 shows the basic structure of the STP whose each stage consists of a

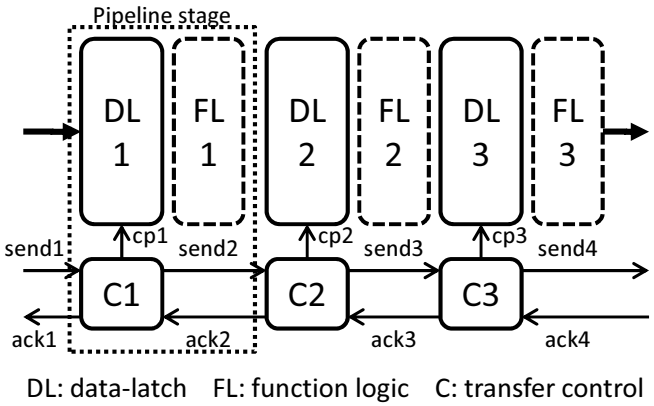

Fig. 1: Self-timed elastic pipeline.

data-latch (DL), functional logic (FL) and transfer control unit (C). The STP is a kind of asynchronous bundled-data pipelines, and the local negotiation is realized by a four-phased handshake [8]. The valid data in the STP are transferred between adjacent stages as follows.

- Reset: After the assertion of the reset signal, the C negates both its send signal representing transfer request and ack signal representing acknowledge.
- The C asserts its ack signal after its send signal is asserted.
- After the assertion of the ack signal, the preceding C negates its send signal.
- After the negation of the send signal, the C asserts both its gate open signal and its send signal and negates concurrently its ack signal, only if the ack signal is negated. As a result, the token is latched in the stage to which the C belongs.
- The succeeding C repeats the above steps similarly to the C.

This localized data transfer naturally results in the signal gating at the stage level, and thus the STP confines the power consumption by transistor switching into only the stages executing the target processes. Moreover, the stages in the STP can be powered off only when they are empty, i.e., they latch no valid data [6]. Therefore the essential power consumption can be realized by the STP.

2.2 Data-driven processing scheme for essential power consumption

In the real-time multiprocessing with the pipeline processing scheme, target processes should be divided into finer processes which can be executed concurrently, and the pipeline execution of each finer process should be initiated immediately after the process become executable, i.e., the input data for the process arrives. Figure 2 illustrates the real-time multiprocessing with pipeline processing scheme.

To keep the real-time processing of each target process, the target processes should be finely divided for sharing a

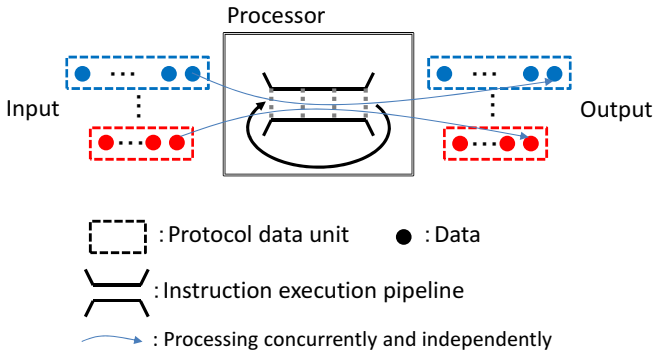

Fig. 2: Real-time multiprocessing.

pipeline among the target processes, and thus fine-grain parallelism inherent in the target processes should be exploited. That is, instruction level parallelism (ILP) which is the parallelism of instruction should be exploited exhaustively because instruction is the finest executable unit of processes.

The arrival timing of the input data depends essentially on the user's communication demands and thus it is unforeseen and determined at runtime. Therefore, the data-driven processing scheme in which instructions become executable only after their input data arrive is a natural processing scheme and thus should be introduced to realize the real-time processing with pipeline processing scheme.

Figure 3 illustrates how the programs are executed by the data-driven processing scheme. As illustrated in the figure 3, the programs are defined by data-flow graph (DFG). The DFG consists of nodes and arcs, and each node describes an instruction while each arc represents the data-dependency between two nodes. The data-dependencies between instructions represent naturally the ILP inherent in the programs, and thus describing target program by using DFG results in extracting the ILP in the target programs. To execute instructions concurrently at the different pipeline stages, the instruction execution logic is pipelined. In the figure 3, the first stage of the pipelined instruction execution logic is illustrated with the passage of time, by supposing the number of pipeline stages is 3 for ease of explanation, i.e., the execution of each instruction is completed after 3 ticks.

The figure 3 shows that the instructions are executed only after their input data arrive. Based on the data-driven processing scheme, the instructions with input data can be executed independently from each other, and thus the execution of each instruction is independent of that of the others in the same pipeline. Therefore, the instruction execution can be realized without any extrinsic control which stops and resumes the execution of instructions, and the power is consumed only for the instruction execution in principle.

In contrast, conventional non-data-driven processing schemes are essentially the extensions of von-Neumann type sequential processing scheme in which single program is executed in a pipeline, and they achieve real-time processing

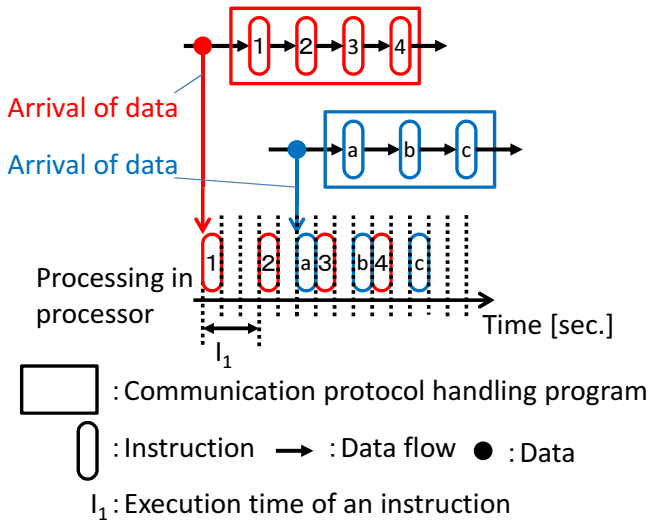

Fig. 3: Data-driven processing scheme for real-time multiprocessing.

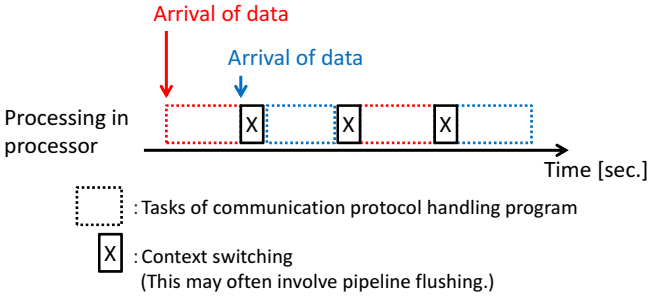

Fig. 4: Conventional quasi-multiprocessing scheme.

by switching divided executable process units called tasks in a pipeline. In such conventional quasi-multi-processing schemes, data transfer among instructions is realized by using a temporal memory mechanism called registers, and the content of the registers, called context, belongs to one program basically; therefore, the context of the currently executed program should be saved and then the context of another program to execute should be recovered into the registers. This saving and recovering of the context is called context-switching. Moreover, the pipeline should be flushed before the context-switching if instructions are being executed in the pipeline, and this pipeline flushing depends on the arrival timing of input data. That is, to switch the tasks, the context-switching is executed as illustrated in figure 4, and the power is consumed not only the instruction execution but also the context-switching and pipeline flushing. This fact violates obviously the essential power consumption.

Consequently, the data-driven processing scheme with the self-timed pipeline is necessary to realize the real-time processing with essential power consumption.

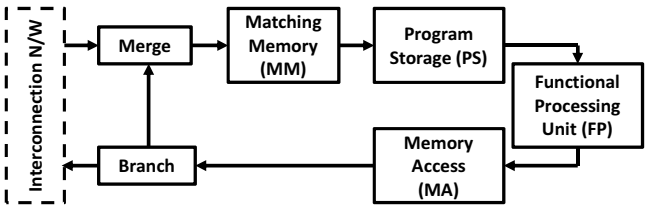

Fig. 5: Block diagram of CUE processors.

3. Ultra-low-power CUE

As described in the previous sections, the CUE and its successors, collectively called CUE processors in this paper, are already proposed as the implementations of the data-driven processing scheme with the STP. The CUE processors are designed by focusing on the performance efficiency within a given circuit area, and thus the essential power consumption is unrealizable by using them.

This section reveals how the CUE processors can be optimized for the essential power consumption, and presents an optimized CUE processor, named ULP-CUE.

3.1 Optimization of CUE processors

Figure 5 shows the functional block diagram of the CUE. The CUE processors represents directly the data flow of tracing the data-dependencies between instructions, and it consists of matching memory (MM), program storage (PS), functional processing unit (FP) and memory access (MA). As shown in the figure 5, the CUE processors are realized by a circular pipeline connecting the MM, PS, FP and MA by using merge and branch stages. The merge stage accepts tokens from two preceding stages in order of arrival and transfers the tokens to a succeeding stage while the branch stage transfers each token to one of two succeeding stages selectively.

In the CUE processors, each data is packetized with information required to execute instruction in order to process every data independently, i.e., instructions are executed independently from each other. This self-contained data is called token, and the contained information is called tag. The tag consists of operation code, destination node number and generation. The generation is the number used to identify the stream to which the data belongs and specify the order of the data in a stream. On the other hand, every instruction is assigned unique number which is called destination node number, and the destination node number is used to identify an instruction to which the data is input.

The MM, PS, FP and MA are used to execute an instruction according to the tag. The MM provides temporal storage to keep tokens whose operation code represents binary operation, until the arrival of the paired tokens, and it outputs either a token containing two operands for binary operation or a token containing single operand for unary operation. To realize the pairing of tokens, the MM is realized by a content-addressable memory (CAM) whose key consists of the generation and destination node number. The operand or a pair of operands in the token output from the MM is processed according to the operation code in the FP, and the FP outputs a token whose data is the result of the operation. After that, the operation code of the token is replaced with that of an instruction specified by the destination node number of the token in the PS storing instructions of the target programs.

In contrast to the original circular pipeline proposed in [2], the PS is placed between the MM and FP to reduce power dissipation. The MM outputs a token for binary operation after two tokens input to the binary operation arrive, i.e., the operation code of one of the tokens is discarded; therefore, the power dissipation to read the operation code from the PS can be eliminated if the PS is placed after the MM. This change has no effects on the function of the circular pipeline because the function of the PS is independent from that of the FP and MA.

The circular pipeline is commonly used to execute every instruction in order to reduce the circuit area which is rather limited in early sub-micron process technology era and is becoming inconsequential compared to power consumption in deep sub-micron and beyond era. As for the power consumption, the MM may occupy more than a half of the power consumption required to execute an instruction because the detection of the arrival of the tokens in the MM is typically realized by using the CAM in which the keys stored are thoroughly compared to the input key for every incoming token.

Fortunately, more than a half of the instructions of the protocol handling can be executed without driving the MM. Such instructions are classified into two types: single-operand instructions and single-operand with constant instructions. An example of the former is an instruction to realize increment/decrement operation and that of the latter is an instruction to read/write memory with absolute address. In this paper, these two types of instructions are collectively called single token instructions, because they can be executed after an input token arrives. Our previous implementation of the protocol handling reveals that the single token instructions occupy the most part of the DFG. For example, a DFG of UDP/IP handling shows that approximately 80% of the executed instructions is the single token instruction. Consequently, the circular pipeline of the CUE processors should be revised to realize the essential power consumption.

3.2 Optimized circular pipeline

To realize the essential power consumption, the circular pipeline to connect the MM, PS, FP and MA should be optimized. Obviously, the PS to fetch instructions and the FP to operate data are indispensable to execute every instruction. The PS and FP are used repeatedly to execute instructions

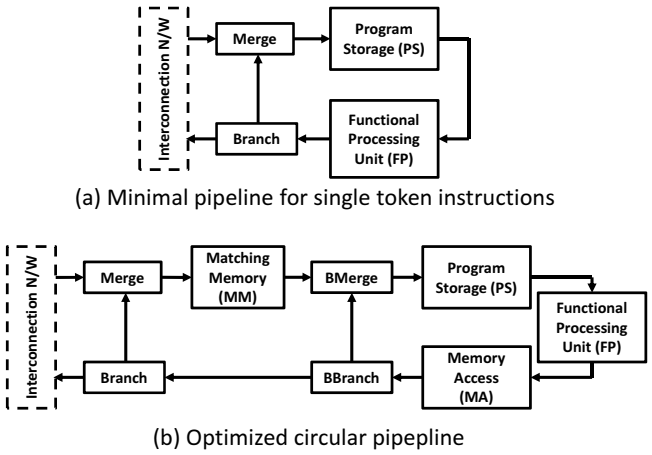

Fig. 6: Block diagram of ULP-CUE.

in programs by tracing the data-dependencies between the instructions. To realize this repetition directly and naturally, the PS and FP should be connected by using a circular pipeline as shown in figure 6(a).

To actualize the operation between two operands, the operand arrived first should be temporally stored until the other operand arrives. As described in the previous section, the real-time multiprocessing is realized by concurrent execution of multiple instructions. To make it possible to execute instructions concurrently, the operands arriving first should be stored separately for each instruction, and they should be drawn after companions arrive. The storing and drawing operands should be realized immediately after the operands arrive in order to avoid any delay on the instruction execution. This requirement leads to the introduction of the MM because the CAM of the MM can realize the dynamic allocation of memory space for newly arrived operands and all contents of the CAM can be searched concurrently and thus the storing and drawing can be realized without any delays.

Unfortunately, the MM realizes such fast storing and drawing at the expense of a large amount of the power consumption as described above. In contrast, memories realized by SRAM can store relatively large amount of data with less power consumption, and thus they are indispensable to store large size data. For example, the payload data of a packet should be buffered during header manipulation of the packet. In addition, they should store data commonly used among the target programs. The table of IP addresses is an example of such data. Moreover, the data determined before the program execution, such as constants or default values should be also stored into the SRAM-based memories. These facts lead to the instruction of the MA stage to realize the read/write of the SRAM-based memories.

In principle, the single token instructions can be executed without the MM, and thus the MM should be bypassed during the execution of them. On the other hand, the MA is required by not only the single token instructions because the result of the operation may be stored into the SRAM-based memory at least. To realize the bypass for the single token instructions, the circular pipeline shown in the figure 6(a) should be extended as illustrated in figure 6(b). Consequently, a data-driven processor realized by the optimized circular pipeline can execute the protocol handling with the essential power consumption. This data-driven processor is named ULP-CUE, which stands for ultra-low-power CUE, in this paper.

4. Evaluation on energy consumption

The ULP-CUE proposed in the previous section realizes the protocol handling with the essential power consumption. As a result, the ULP-CUE can reduce the energy and execution time of the protocol handling in comparison with the CUE processors because the single token instructions are executed without the MM in the ULP-CUE. The reduced execution time makes it possible to supply low-voltage resulting in less energy. To verify the power-performance efficiency of the ULP-CUE, the energy and execution time of the ULP-CUE is compared to that of the CUE processors, and the energy reduction is estimated based on a prototype LSI of the ULP-CUE.

As a target protocol handling, UDP/IP handling is focused on because its connection-less communication realizes streaming with less energy in comparison to TCP/IP handling and thus it is indispensable for the broadcast-type information transfer in the ad hoc networks especially in the emergent situations.

4.1 Prototype LSI

To verify the ULP-CUE experimentally, a prototype LSI housing four ULP-CUE's in a $4.2mm^2$ die is designed and fabricated by using a 65nm CMOS 7-metal-layer process. Figure 7 shows the layout of the ULP-CUE which is consisted of a 13-stage circular pipeline realizing the PS, FP, MA, MM, Merge and Branch. The ULP-CUE has an instruction set sufficient to execute the UDP/IP handling, and the function of the ULP-CUE is verified by checking that the outputs of the UDP/IP handling on the ULP-CUE are identical to the expectation values of the UDP/IP handling.

Although the prototype LSI's of the CUE processors are already fabricated to show the feasibility and effectiveness, they have different instruction sets and are fabricated by using different process and CAD tools. To eliminate these differences and clarify the difference derived from the circular pipeline, the energy and execution time of the CUE processors are estimated based on the measured results of the prototype LSI of the ULP-CUE.

The difference between the circular pipeline of the ULP-CUE and the CUE processors is a bypass realized by the BMerge and BBranch stages. To estimate the energy and execution time for the CUE processors, the energy

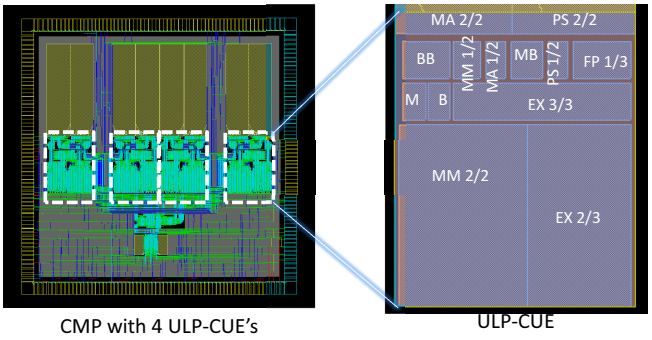

Fig. 7: Layout of prototype LSI.

and processing time of both the BMerge and BBranch is subtracted from the energy and execution time of the UDP/IP on the prototype LSI without any drawbacks on the CUE processors.

4.2 Power-performance verification

To verify the essential power consumption of the ULP-CUE, the energy required to execute the UDP/IP on the ULP-CUE is measured by using the prototype LSI. The program of the UDP/IP handling is consisted of two independent parts, sending-side and receiving-side programs. Figure 8(a) shows the measured energy for the sending-side and receiving-side programs. On the other hand, the total amount of executed instructions is shown for each program in figure 8(b). The energy increases approximately in proportion to the amount of executed instructions. This strong correlation is an evidence of the essential power consumption, i.e., the power is consumed only for instruction execution.

Additionally, the energy and execution time of the UDP/IP handling on the ULP-CUE is compared that of the UDP/IP handling on the CUE processors to show that the essential power consumption results in the energy reduction or ultra-low-power consumption. As discussed at the front of this section, the reduction of the execution time results in the energy reduction because the slack time can be used to lower the supply voltage. To show the total energy reduction, the energy required to execute the UDP/IP is estimated and then the energy reduction with low-voltage supply is estimated.

To estimate the energy of the UDP/IP handling on the CUE processor, the energy is measured by using the prototype LSI in which the bypass of the ULP-CUE is disabled and then the energy consumed by the BMerge and BBranch is subtracted from the measured energy. Generally, SPICE simulators are used to estimate energy of circuit but their transistor-level simulation requires tremendous amount of time to simulate the whole circuit of the practical processors with specific programs, and thus they are impractical in this estimation. In the circular pipeline, the energy is consumed mainly in the data-latch and logic circuit in every stage. The

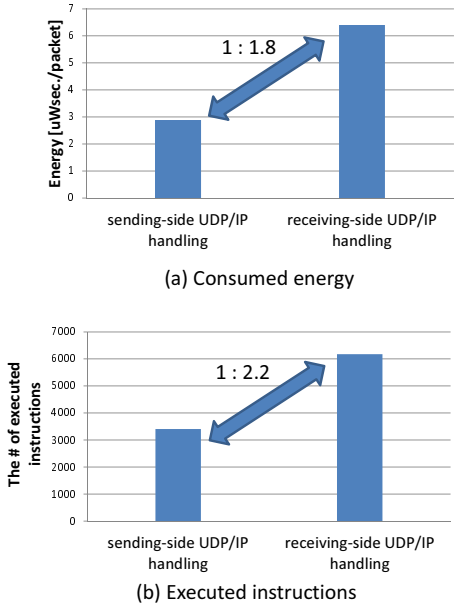

Fig. 8: An evidence of essential power consumption.

logic circuit of the BMerge and BBranch is consisted of only a MUX, and its circuit size is equal or smaller compared to the logic circuit of the other stages; therefore it has less energy consumption compared to the others. To estimate the energy consumed in the CUE processors without drawbacks on the CUE processors, the logic circuits are ignored and the energy consumed in the data latch is simulated by using the SPICE simulator. Table 9 shows the ratio of the simulated energy of the data-latch in every stage, and it reveals that the energy consumed in the BMerge and BBranch is 11.78% of the energy of the ULP-CUE. That is, the 11.78% of the energy measured with the bypass disabled should be subtracted to estimate the energy of the UDP/IP handling on the CUE processors. The result of the subtraction is shown in the figure 10.

As for the execution time of the UDP/IP handling, the time required to execute the instructions in the critical path of the UDP/IP handling is measured by using the prototype LSI and the measured results are shown in figure 11. Similarly to the energy estimated, the execution time of the UDP/IP handling on the CUE processors is estimated by subtracting the processing time of the BMerge and BBranch stages from the measured execution time. The processing time of the BMerge and BBranch is revealed by conducting gate-level simulation with the gate-net-list and delay information extracted from the layout of the ULP-CUE. The ratio of the revealed processing time of every stage is shown in table 9 in which it is shown that the processing time of the bypass is 6.89% of that of the circular pipeline of the ULP-CUE. Figure 11 shows the execution time estimated by subtracting the 6.89% execution time from the execution time of the UDP/IP handling on the ULP-CUE. Generally, the execution time of

Fig. 9: Estimated energy and processing time of each stage.

	Energy (ratio)	Processing time (ratio)
Merge	3.99%	18.59%
MM1/2	6.20%	9.20%
MM2/2	4.75%	5.92%
BMerge	3.93%	3.54%
PS1/3	4.45%	3.25%
PS2/3	3.77%	10.94%
PS3/3	8.47%	11.75%
FP1/2	10.20%	9.70%
FP2/2	31.95%	5.92%
MA1/2	4.65%	3.29%
MA2/2	4.08%	10.85%
BBranch	7.85%	3.35%
Branch	5.72%	3.70%

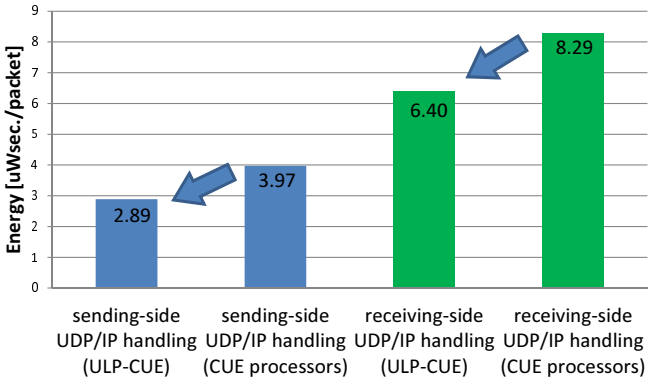

Fig. 10: Reduced energy.

programs is assumed to be in proportion to the supplied voltage, which is denoted by V_{DD}, and the energy required to execute the program is assumed to be in proportion to $(V_{DD})^2$. Based on these assumptions, the energy of the UDP/IP handling on the ULP-CUE is estimated as follows: $2.89 \times (\frac{344}{466})^2$ approximately equals 1.57 for the sending-side, and $6.40 \times (\frac{34,590}{47,581})^2$ approximately equals 3.38 for the receiving-side; therefor, $\frac{1.57+3.38}{3.97+8.29}$ approximately equals 40% for the UDP/IP handling.

Consequently, the essential power consumption of the ULP-CUE reduces the energy required to execute the UDP/IP handling to approximately 40% compared to the CUE processors.

5. Conclusion

In this paper, an optimized circular pipeline is revealed to realize real-time multiprocessing with essential power consumption toward ultra-low-power protocol handling, and its essential power consumption and power-performance is evaluated by using the prototype LSI of a data-driven

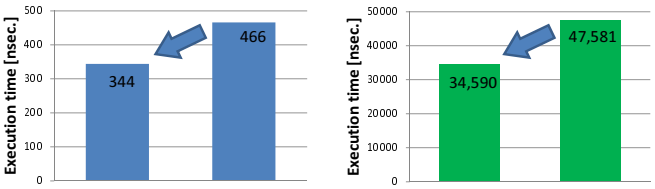

Fig. 11: Reduced execution time.

processor, which is named ULP-CUE and realized by the optimized circular pipeline. As a result of the evaluation, it is revealed that the ULP-CUE can execute the UDP/IP handling indispensable for ad hoc networking by consuming 40% of energy in comparison with ever-proposed implementations of the real-time multiprocessing.

The ULP-CUE is the central core to realize the networking platform in the ULP-DDNS project, and its circuit level power control scheme is also proposed in the project. The total energy of the networking platform realized by both the ULP-CUE and the power control scheme will be evaluated in our future works.

Abstract— *This paper describes a runtime fine-grain power supply scheme based on the self-timed pipeline (STP) circuits. The STP works with its local hand-shake signal so that it does not require the global clock distribution, i.e., centralized control. Therefore, various power supply control for the STP can be naturally localized in both spatial and temporal domains without stopping its effective data transfer, e.g., program execution in case of microprocessors. As a result, the power supply scheme proposed in the paper can efficiently incorporate both commonly used voltage scaling and power gating techniques and it can further produce synergetic effects on its total power saving nature.*

In the paper, effective power-performance characteristics of the STP supported by the proposed scheme are discussed and analyzed in terms of break-even model for power reduction effect against its control overhead. Furthermore, the scheme is applied to an ultra-low-power data-driven networking processor, named ULP-CUE, designed in 65 nm CMOS process and then it is evaluated through typical UDP/IP traffic of a wireless ad hoc network. In this case, total power can be reduced to about 13% compared with the normal-STP-based data-driven processor.

Keywords: self-timed pipeline, runtime power gating, runtime voltage scaling, file-grain power-supply

1. Introduction

Lowering power dissipation of LSI systems is now more and more crucial to realize greener devices, while fully utilizing the potential speed of transistors under deep-submicron process technologies. In order to facilitate such low power consumption of the LSI chips, both dynamic and static power dissipation should be cut or reduced as much as possible. The main causes of the dynamic power dissipation are the transistor-switching unnecessary for processing and the excessive switching frequency higher than required processing speed, while the leakage current through inactive transistors increases the static power dissipation mainly.

Voltage scaling and power gating are well-known techniques for reducing switching power and static power respectively[1][2]. Mostly those techniques have been applied to relatively coarse grain power domain of the LSI chip, e.g., a whole die or processor core, and they are assumed to be controlled by the operating system. In order to achieve ultimate reduction of the power consumption, it is essential to control power supply more finely in terms of both spatial and temporal domains. To realize such fine control, a powered circuit block itself has to behave autonomously without any centralized control such as a global clock signal. Therefore, in our collaborative research project to establish ultra-low-power data-driven networking system (ULP-DDNS)[3], we have fully introduced self-timed pipeline (STP) circuits to implement our ultra-low-power data-driven processor (ULP-CUE) without any global clock signal. To minimize overheads caused by the fine-grain power control, our ultra-low-power self-timed pipeline (ULP-STP) circuit has been designed to work in part even during supply voltage scaling or power gating. That is, the ULP-CUE processor core can execute programs without evacuation of their contexts even when the power supply voltage is altered or power supply is cut in part.

Because of self-timed elastic data-transfer mechanism of the original STP [4], it can work well under variable voltage without adjusting clock frequency even if the altered voltage could transiently fluctuate at individual pipeline stage. Since the pipeline throughput can be adaptive to its processing load only by altering supply-voltage appropriately, a power-aware pipeline scheme can be realized naturally in terms of runtime power saving. For instance, the proportional-integral-derivative (PID) controller can be applied to such voltage control by monitoring consumption current of a target power domain within the chip.

The STP is also suitable for gating power-supply to fine grain circuits since its stage-by-stage data-transfer control independently activates only pipeline stages with valid data. We therefore proposed a stage-by-stage power gating scheme adopted in the STP [5]. This scheme provides natural signal gating, i.e., it stops the unnecessary signal propagation and transistor-switching at pipeline stage level without any global control mechanisms resulting in both power dissipation and processing speed degradation. Moreover, it makes it possible to scale the voltage even when the stages are activated because it can be realized without any global oscillator such as phase-locked loop (PLL) circuit, which forces pipeline flush ahead of the frequency and voltage change.

By introducing both the voltage scaling and power gating

into the STP, synergetic effects on its total power saving nature will be further expected. Apparently power gating will be conducted at the lowest voltage scaled so that the power overhead of power gating will be minimized.

As for the remaining part of this paper, the following section describes the circuit design of the ULP-STP with runtime fine-grain power-supply. Section 3 discusses a break-even model for power reduction effect against its control overhead to implement various ULP-STP systems. Section 4 shows the quantitative analysis of the ULP-CUE implemented by the optimized ULP-STP under 65 nm CMOS process and then we conclude in the final section.

2. Runtime fine-grain power-supply scheme for STP

By the runtime fine-grain power-supply scheme proposed in the paper, voltage scaling and power gating will be adaptively performed along with the present processing load within a system. In general, the processing load in the system may alter due to both the intrinsic parallelism of a program and the extrinsic request traffic to the program.

In this section, the autonomous behavior of the self-timed elastic pipeline (STP) is briefly introduced and then its natural contribution to the runtime fine-grain power-supply control is discussed.

2.1 Self-timed elastic pipeline

Each pipeline stage of the STP consists of a data latch as a pipeline register, function logic, and transfer control unit named C-element. The basic structure of the STP is shown in figure 1. The data latch, function logic, and C-element are denoted by DL, Logic, and C, respectively. The data is packed with tag into packet form, and the packet is transferred between the pipeline stages as a result of the communication between the C's in the adjacent stages. The communication is performed stage-by-stage according to the 4-phase handshake protocol [6] by using transfer request and acknowledge signals which are called send signal and ack signal respectively. The stage-by-stage transfer control changes the states of each pipeline stage independently, and the states of the stages are defined below according to the handshake protocol. Here, the C-element in the i-th stage is denoted by C_i.

- Reset state: The send and ack signals are negated after the assertion of the reset signal.
- Idle state: The C_i waits until the $send_{i-1}$ is asserted.
- Busy state: The $send_{i-1}$ is asserted at the beginning of the transfer of the packet from the precedent $(i-1)$-th stage. After the assertion of the $send_{i-1}$, the C_i asserts its ack signal (ack_{i-1}). In response to the assertion, the C_{i-1} negates the $send_{i-1}$. After that, if and only when both the $send_{i-1}$ and ack_i are negated, the C_i asserts the $ToDL_i$ to open the DL_i and it asserts $send_i$ at the same time. As a consequence, the packet is latched in the i-th stage, and the i-th stage goes to idle state. Otherwise, the C_i waits until the ack_i is negated while it keeps its send and ack signals.

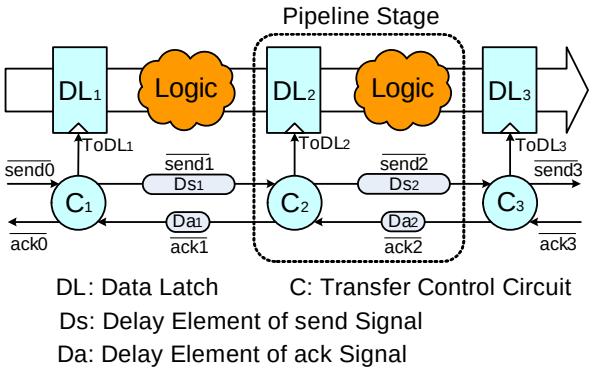

Fig. 1: Basic structure of self-timed pipeline.

The successive stages receiving the assertion of the send signal go to busy state and their C's repeat the same transfer control sequence individually. During the handshakes, the send signals are delayed to assure the completion of the primitive logic function and ack signals are delayed to assure the setup-hold timing of the DL's.

This stage-by-stage transfer control of the STP suggests the timing of the power controls. That is, in the idle stages, the circuit of the DL, and combinational Logic can be powered-off, i.e., the supply-voltage can be cut while that of the C and sequential Logic can be powered-down, i.e., the supply voltage can be lowered enough to keep the circuit's states. Moreover, in the busy stages, those circuits should be powered-down enough to assure the switching of the transistors, i.e., the supply-voltage can be lowered as long as the required switching speed is achieved.

2.2 Stage-by-stage power gating

To realize stage-by-stage power controls finely, we have already proposed an ultra-low-power self-timed pipeline (ULP-STP) structure illustrated in figure 2 [5]. In the ULP-STP structure, V_{DD} supplied to all circuits is scaled by using DVS technique. In addition, to cut the power-supply to the DL and Logic, a high threshold NMOS transistor, called power switch (PS), is placed between V_{SS} and the ground-side terminals of the DL's and combinational logics which are composed of low-threshold transistors. In this case, an isolation element (ISO) must be inserted between adjacent stages in order to block the propagation of the electrically unstable signals from the gated stages to the other active stages. This ISO function can be implemented in a part of a data-latch so that the circuit overhead (i.e., power and delay time) for the ISO is negligible. Each power switch is controlled by its power control circuit (PC) which observes the send and ack signals.

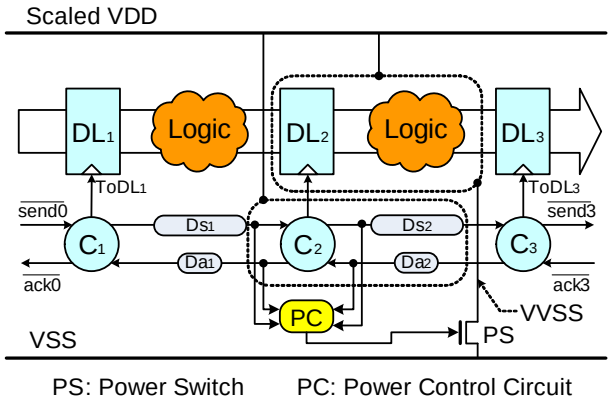

Fig. 2: Power-supply control for STP.

The ULP-STP structure makes it possible to power-down or power-off stage-by-stage, and thus the necessary power is supplied only to the processing stages having a valid data while the leakage power at other idle stages are finely cut. Therefore this power gating scheme is named runtime fine-grain power gating (RTPG) in this paper. In addition, the power gating for each core is achieved without any additional mechanism because all of the stages in an idle core are powered down as a result of the stage-by-stage power gating in each stage. Since each stage will consecutively wake up along with travelling of a newly arriving data within the STP, total rush current of the whole STP system can be temporally distributed when the PS is powered on.

2.3 Runtime voltage scaling

With the proposed structure, the DVS and the PG can be enabled independently or simultaneously. The supply voltage to the STP can be autonomously altered without adjusting the clock frequency since the STP itself is clockless. The supply voltage can be controlled based on the consumption current which is proportional to the amount of processing load in the STP system.

On scaling the supply voltage in runtime, sharp scaling may cause overshooting or undershooting the voltage and thus power noise and malfunction may be generated. On the other hand, dull scaling may bring down to degrade its prompt operation. Since the consumption current of the STP may fluctuate usually, adaptive control mechanism is necessary. Thus, we introduce the proportional-integral-derivative (PID) controller to our voltage scaling scheme to minimize the error by adjusting the process control inputs, i.e., consumption current values.

Figure 3 shows the runtime voltage scaling mechanism (RTVS) introducing the PID controller. At the I-V lookup table in the figure, the appropriate supply voltage is indexed by a sampled consumption current value. For instance, the target voltage in the I-V table may be designed to achieve the maximum throughput per power. How to optimize the

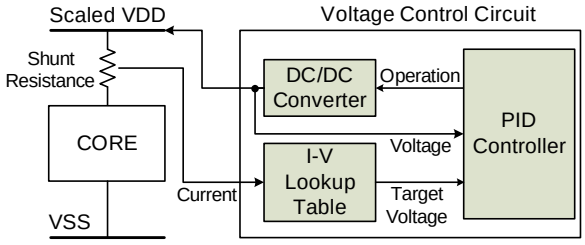

Fig. 3: Voltage controller.

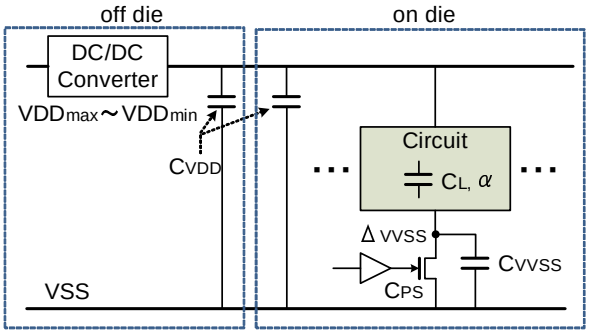

Fig. 4: Equivalent load capacitance of ULP-STP.

I-V table may depend on the low-power policy of the target application. Note that a transfer function of a target system can be simply approximated by its dead time and first-order lag. Thus, the PID parameters for our RTVS can be adjusted by using the same approximation.

Those advanced features indicate that the STP is more robust than the clocked pipeline, especially in the nanometer-scale processes with more variation in transistor performance.

3. Break-even model of the ULP-STP

Although voltage scaling and power gating can reduce the switching power and the leakage power of the transistors respectively, there are power overheads such as charge/discharge current during scaling supply voltage and switching current of the power switch transistors for the power gating, and so on. In this section, a break-even model of power reduction effect against its overhead is discussed, especially in terms of runtime and fin-grain of RTPG and RTVS.

Figure 4 illustrates a simple equivalent circuit model of the ULP-STP. With the voltage scaling, there are equivalent load capacitances C_{VDD} of on-die/off-die power lines and. With the power gating, there are some equivalent load capacitances, C_L, C_{VVSS}, and C_{PS} each of which is extracted from the target power domain circuit, the virtual ground line (VVSS), and the power switch (PS) respectively. Here, the switching energy of the PS, E_{PS}, is represented as follows:

$$E_{PS} = C_{PS} \times VDD^2 \quad (1)$$

It is assumed here that the power of ISO is negligible because the ISO can be overlapped onto the data-latch. When the power switch is powered on, the power consumption due to the rush current to the circuit, E_{rush}, can be calculated based on [7] as follows:

$$E_{rush} = \left(C_{VVSS} + \frac{1}{2} C_L \right) \times VDD \times \Delta_{VVSS} \quad (2)$$

where Δ_{VVSS} denotes the increased amount of VVSS before wake-up. Based on equations 1 and 2, the lower bound of the sleep time to get power reduction effects, BET can be represented as follows:

$$BET = \frac{C_{PS} \times VDD^2 + \left(C_{VVSS} + \frac{1}{2} C_L \right) \times VDD \times \Delta_{VVSS}}{P_{leak}} \quad (3)$$

where P_{leak} denotes the leakage power of the target power domain circuits.

As for the break-even condition related the voltage scaling, it depends on the processing load. Thus, the break-even processing load, $BEPL$ can be expressed as follows:

$$BEPL = \frac{C_{VDD}}{C_L \times \alpha} \quad (4)$$

where α denotes the average switching provability of the transistors within the target power domain circuits. Although the PID controller itself must consume the energy, it can be negligible compared to the charge/discharge energy of C_{VDD}.

The equation 3 and 4 represents the basic break-even conditions of the proposed runtime fine-grain power-supply control scheme. As represented in those equations, the break-even conditions depend on those load capacitances of the target system. In the following section, the low-power characteristics of the ULP-CUE as an actual STP system will be evaluated through the execution of a practical networking application program.

4. Power-performance evaluation

In our collaborative research project on ultra-low-power data-driven networking system (ULP-DDNS), a data-driven processor ULP-CUE based on the self-timed pipeline has been implemented by using 65 nm CMOS process. In this section, the ULP-CUE is briefly introduced and then the basic power-performance characteristics are evaluated by integrating actual measurement results of the ULP-CUE chip and SPICE simulation results. Finally, total power reduction effects of the proposed runtime fine-grain power-supply are revealed in the case the ULP-CUE executes a UDP/IP protocol handling program based on a typical traffic log of an ad hoc wireless network simulated by the network simulator[8].

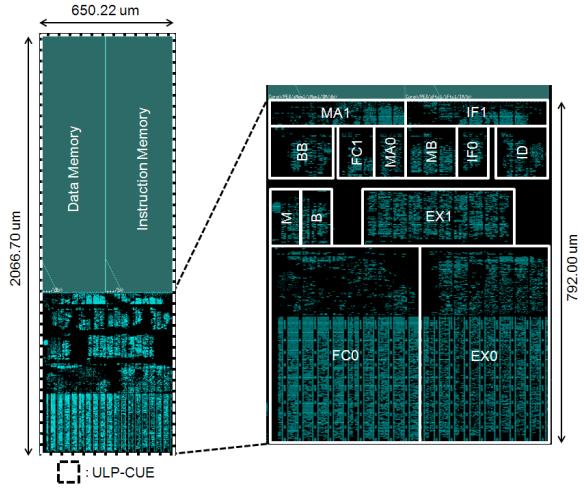

Fig. 5: Layout of the experimental ULP-CUE (65nm CMOS 7ML process).

4.1 Circuit configuration of ULP-CUE

The ULP-CUE is a 32 bit dynamic data-driven processor implemented by the 13-stages ring-shaped STP and each STP stage is composed of the following elemental functional module.

- M: merging function of input tokens and internally circulated tokens.
- FC: firing control function to detect a pair of operand tokens for its instruction execution. It is divided into two STP stages, FC0 and FC1.
- MB: merging function for tokens bypassing the FC stages.
- IF: instruction fetching function. It is divided into two stages, IF0 and IF1.
- ID: instruction decoding function.
- EX: execution function, i.e., ALU. It is divided into two stages, EX0 and EX1.
- MA: data-memory access function. It is divided into two stages, MA0 and MA1.
- BB: branch function to bypass the FC stages or not.
- B: branch function to ether output port or the circular STP.

Those stages are placed and routed on a die shown in figure 5. As shown in the figure, area of each stage is different from others so that the load capacitance of each stage is different. This means its break-even condition is different.

4.2 Evaluation procedure

Because each STP stage of the ULP-CUE is implemented as different circuits, the break-even time is different. For each stage, it is difficult to measure every parameter in equation 3. Thus, in this evaluation, PS switching energy E_{PS}, energy consumption caused by rush current E_{rush},

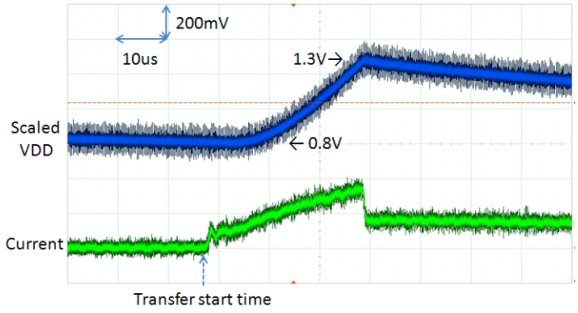

Fig. 6: An example measurement result of RTVS (25°C).

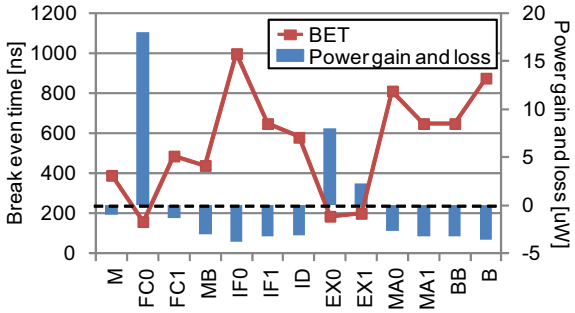

Fig. 7: Break even time of each STP stage (0.8 V, 25°C).

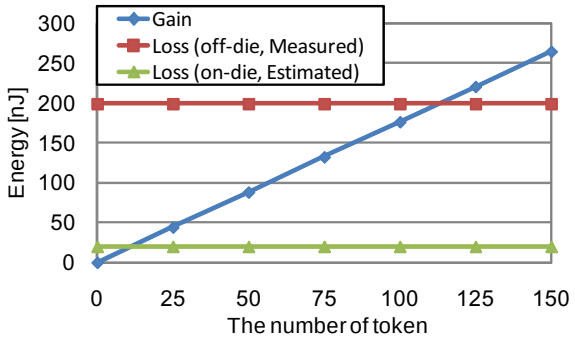

Fig. 8: Break even processing load of ULP-CUE (0.8 V 1.2 V, 25°C).

and leakage power P_{leak} are evaluated by SPICE simulation of each stage. This is because the detailed breakdown of each stage's power consumption cannot be measured on the fabricated ULP-CUE chip. Since the voltage of the VVSS depends on sleep time, the SPICE simulation is conducted in many times in the case of different sleep time. Furthermore, the gate width of the power switch NMOS transistor is designed to reduce the voltage drop to less than 5%. Wake-up delay time of the stage is hidden by asserting a power-on signal from the preceded STP stage.

As for the voltage scaling, total power of the ULP-CUE processor can be measured on the fabricated chip as shown in figure 6. This measured wave shows an example of consumption current of the ULP-CUE in the case the supply voltage VDD is changed from 0.8 V to 1.3 V by using the PID controller. This consumption current includes charge current to both C_{VDD} and C_L. Since the VDD can be forced to alter from 0.8 V to 1.3 V, only the charge current to C_{VDD} can be measured. Thus, the difference of both measurement values expresses that to C_L. As a result, the break-even processing load can be calculated based on the equation 4.

4.3 Basic evaluations on break-even model

As described in the previous subsection, the basic characteristics of power consumption in the ULP-CUE have been evaluated in the case it execute the UDP/IP protocol handling program. Figure 7 shows the break-even time and power reduction effect of each STP stage composing the ULP-CUE at 0.8 V, 25°C. The solid line shows the break-even time, and the solid bar shows the amount of power reduction when the sleep time is 250 ns. If the sleep time is longer than 250 ns, the total power reduction of the ULP-CUE can be gained by the stage-by-stage power gating.

The FC0 stage has the shortest BET, 159 ns. This is because its area is the largest in all stages. Furthermore, the gate width of the PS can be shortened because the switching probability of transistors composing the FC0 is not so high compared with other stages. The IF0 has the longest BET, 839 ns. It is about 5 times longer than the shortest one. Those results implies that it is important to introduce an adaptive power gating mechanism such as an invalidation scheme of individual power gating based on a leakage current monitor[9].

As for the voltage scaling, the break-even processing load is evaluated based on the equation 4. Figure 8 shows the break-even processing load of the ULP-CUE based on the measurement current of the chip when the supply voltage is changed from 0.8 V to 1.2 V. The diamond-shape plots indicate C_L, i.e., the denominator part of the equation 4, and the square-shape plots indicate C_{VDD}, i.e., the numerator part of that. From this result, the BEPL is about 113 tokens.

In order to estimate an acceptable voltage scaling frequency, potential performance-power characteristics of the ULP-CUE have been measured at 0.8 V to 1.3 V. Those results are shown in figure 9. From this result, the maximum performance of the ULP-CUE is 87K UDP/IP packet/sec. at 1.3 V where the length of a UDP/IP packet is 512 bytes. When the throughput of UDP/IP packets is 29K packet/sec., total power consumption at 0.8 V can be reduced to 38% compared to that of 1.2 V. Therefore, the evaluated BEPL, i.e., 113 tokens, indicates that the acceptable voltage scaling frequency is at most 32.7 KHz.

The measured chip is not equipped with the on-die DC-DC convertor. If a DC-DC convertor can be implemented on a die, the load capacitance of the power line, C_{VDD},

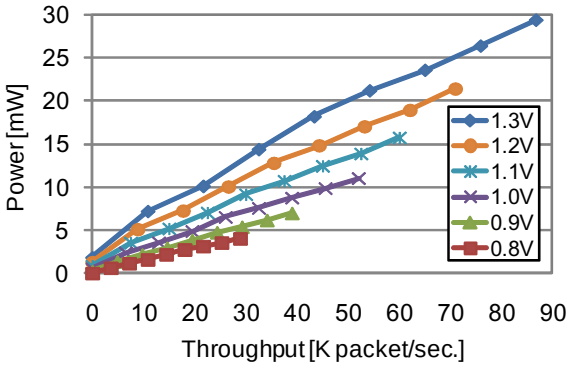

Fig. 9: Performance-power characteristics of the experimental ULP-CUE under altered supply-voltage (25°C).

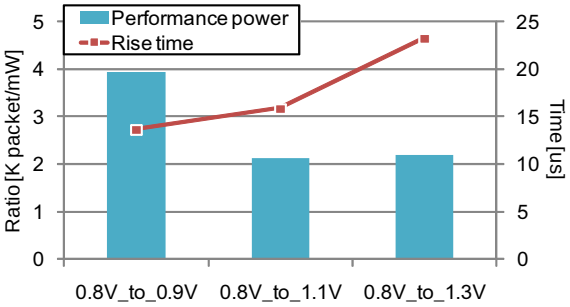

Fig. 10: Performance-power characteristics of RTVS (25°C).

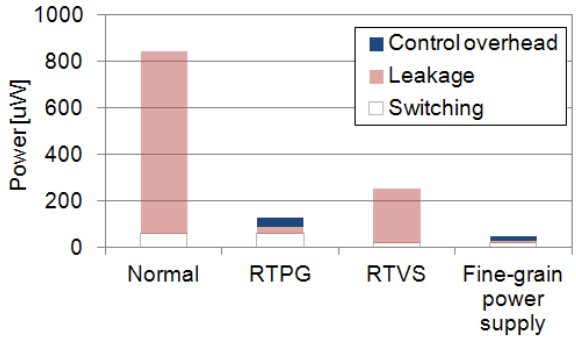

Fig. 11: Power comparisons of the ULP-CUE (54 M bit/sec., 25°C).

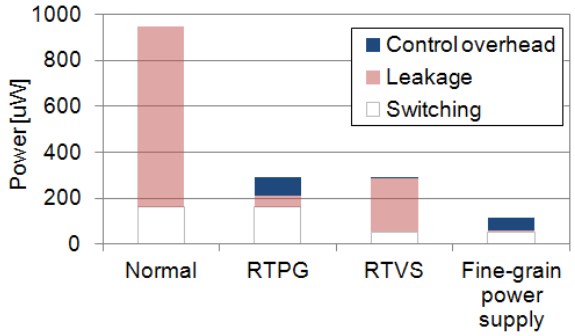

Fig. 12: Power comparisons of the ULP-CUE (162 M bit/sec., 25°C).

can be reduced to one-tenth of that. In this case, the break-even processing load can be reduced to 11 tokens. This assumption indicates that the runtime voltage scaling may be conducted at most 336 KHz.

Figure 10 shows the measured transient power-performance ratios and voltage rise times when the supply-voltage is altered from 0.8 V to 0.9 V, 1.1 V, and 1.3 V. Even during such transient time of supply-voltage, the ULP-CUE can work at reasonable power-performance ratio. Therefore, total performance-power ratio could be improved as well as better dependability against hard real-time constraints can be obtained.

4.4 Evaluations on typical network traffic

Since the ULP-CUE has been designed to implement network protocol handling efficiently, its practicality should be evaluated based on actual network traffic pattern. Therefore, we used a network simulator, OPNET, to obtain such benchmark traffic logs. In this evaluation, an ad hoc wireless network [8] is assumed and then simulated by OPNET to get traffic logs. From those traffic logs, a set of input token to the ULP-CUE is extracted and the data-driven UDP/IP program is executed on it.

In the case that the basic wireless transmission rate of this network is 54M bit/s or 162M bit/s, the power consumption of the ULP-CUE is estimated based on the above basic evaluation results. Figure 11 and 12 show the power comparison among the normal STP, the STP with RTPG, the STP with RTSV, and the STP with the proposed runtime fine-grain power-supply scheme (i.e., with both RTPG and RTSV).

In figure 12, the STP with RTPG can reduce its leakage power to 48uW. This is 6% leakage power compared to the normal STP. The STP with RTVS can reduce its switching power to 51.7uW and its leakage power to 235uW. This is 32% switching power compared to the normal STP. In the case of the STP with the proposed power-supply scheme, the ULP-CUE can reduce the total power to 13%. Because of the synergetic effects between RTPG and RTVS, the switching power of the PS in RTPG can be reduced to 68%.

5. Conclusion

In this paper, a runtime fine-grain power-supply mechanism based on the self-timed elastic pipeline (STP) was proposed to realize lower-power LSI circuits and then it was analyzed by defining a break-even model in terms of power trade-off. The proposed circuit introduced both the power gating and voltage scaling techniques so that it could utilize

the synergetic effects between them. The low-powered STP circuit was then applied to an ultra-low-power data-driven processor, ULP-CUE, and evaluated through typical UDP/IP traffic of a wireless ad hoc network. In this case, total power can be reduced to about 13% compared with the original STP-based CMP.

Since the break-even condition of the proposed scheme may change depending on the temperature and process variations, a kind of self-checking circuit of typical leakage and switching power should be introduced on a die and its monitoring result should be dealt with as a feedback to power-supply controller. Furthermore, in order to verify such on-die mechanism in terms of power consumption and performance, a microarchitecture simulator must be developed which can simulate not only architectural behavior but also transient power consumption. We are now developing such a platform simulator [10] in our collaborative research project and then we will report the comprehensive evaluation results using this simulator iin near future..

Abstract – ***Since an ad hoc network does not need a base station and can constitute a network locally, it is important for a sensor network or a temporary network in emergency. Especially at the time of a disaster, power-saving is required for a long battery life. Since the power consumption is proportional to a processing load linearly and the essential power is only consumed, ultra-low power data-driven networking system (ULP-DDNS) utilizing a passive data-driven principle is low power consumption. We consider that the feature that processing time does not change in multi-processing enables an overload condition to be avoided in advance if a content of a process is obtained. In this paper, we describe an overload-avoidance scheme for congestion-free networking system.***

Keywords: ad hoc network, Data-driven networking system, Congestion-free, Overload avoidance

1 Introduction

Wireless ad hoc network communication does not need an infrastructure such as an access point or a base station, and transmits information by a function being had in a node and hop-by-hop manner. Therefore, it attracts attention as an urgent communication tool when an infrastructure is down in a time of disaster. However, in order that a host may move, communication route changes. It is difficult to determine the communication route in that situation. A simple flooding is used as a one method to solve the problem. The simple flooding makes an unwanted traffic increase in ad hoc network, it causes increases of collision and retransmit, and it causes a congestion finally.

In order to reduce the increases in the unwanted traffic, efficient information discovery system [1] and efficient broadcast type transmission mode [2] have been proposed. Moreover, in an ad hoc network, since the certificate authority in an infrastructure cannot be used, a communication partner cannot check whether you are a partner who wants truly. Therefore, the efficient technique of attesting a communication partner from the confidential relation between nodes has been also proposed[3].

Furthermore, energy saving is required for ad hoc network node which is supplied energy by a battery in many cases in order to enable a long time communication. Especially in case of disaster, electric power may be lost in a long time, thus more energy saving is required to the network nodes. In order to satisfy these requirements, we paid our attention to a feature of a data-driven processor of which processing period is constant even for multi-processing condition required by a network processing and a self-timed elastic pipeline which consumes energy only in pipeline stages in which valid data exists. And, we have developed a data-driven processor with a self-timed elastic pipeline as hardware realization of the processor [4][5].

In order to achieve congestion-free ad hoc network communication, it is also necessary to avoid an overload condition of network nodes for preventing degradation of the communication quality. There are two reasons that congestion occurs. One is that a traffic exceeding a bandwidth of a link between nodes flows into the link. Another is that a traffic exceeding a processing performance of a node flows into the node. Because the node can control the flow when a processing load is low, the congestion can be avoided. However, when the node is overload, the node cannot also control the flow. Therefore, an overload of the node must be avoided. A processing period on ULP-DDNS is predictable as described before, and if a traffic pattern is obvious, overload avoidance can be performed in advance. There, in this paper, we considered about an overload avoidance scheme being appropriate for ULP-DDNS applied in ad hoc network.

2 Ultra-low-power data-driven Networking System: ULP-DDNS

ULP-DDNS is a networking system which can provide longer lifetime or stronger dependability under severe power budget and traffic condition. Each networking node only consumes the minimum and essential power without any runtime overhead by ultimately utilizing passive data-driven principle throughout ad hoc networking scheme, CMP platform dedicated to multiple UDP/IP processing and its self-timed VLSI realization.

2.1 ULP-DDNS node

Fig. 1 shows a block diagram of ULP-DDNS node. This ULP-DDNS node is constructed so that ad hoc networking system is executed on an application processor and UDP/IP

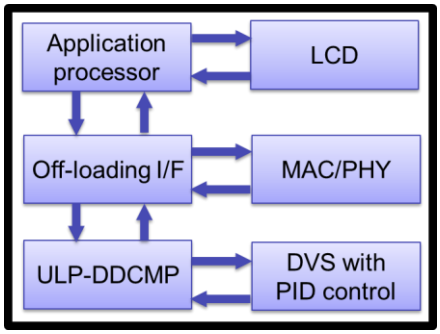

Fig. 1. Block diagram of ULP-DDNS

processing is executed by offloaded to ULP-DDCMP. Therefore, ULP-DDCMP and the application processer are embedded in ULP-DDNS. However, the architecture of ULP-DDNS is not restricted by this architecture. It is assumed that the ad hoc networking system is executed on ULP-DDCMP in future.

An electrical power for ULP-DDCMP is supplied by using dynamic voltage scaling (DVS) with PID control, a processing load of ULP-DDCMP is estimated by an observed electrical current consumption of ULP-DDCMP and electrical power is supplied by autonomously controlled voltage according to the processing load. In this way, DVS is constituted by a simple mechanism without observing an internal condition of ULP-DDCMP.

Off-loading I/F translates data received from MAC/PHY or the application processor into tokens by 4 Byte so that ULP-DDCMP is able to process them, and sends the tokens to ULP-DDCMP adequately. The I/F coordinates a timing between synchronous and asynchronous signals since ULP-DDCMP performs in asynchronous. In this paper, ULP-DDNS node is used to explain an operational timing of some kind of processes and packet sending and receiving.

2.2 Ultra-low-power data-driven chip multiprocessor: ULP-DDCMP

ULP-DDCMP is a chip multiprocessor in which four ULP-CUEs are connected by a token router. The tokens sent to ULP-DDCMP are sent to either ULP-CUE through the token router. Since an electrical current of each ULP-CUE is observed individually, a load distribution is also possible by observing electrical current varying according to processing load of each ULP-CUE.

2.3 Ultra-low-power data-driven CUE: ULP-CUE

ULP-CUE is constituted by a self-timed elastic pipeline of a circular type with short-cut path in order to shorten a turn-around-time of unary operations and to improve a processing performance. A feature of ULP-CUE is that a processing latency is constant at multi-processing condition

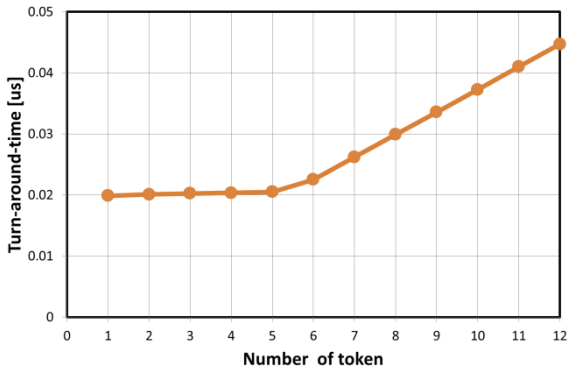

Fig. 2. Turn-around-time of ULP-CUE

unlike von Neumann processor. Since ULP-CUE is constituted by a circular pipeline, an execution time for one instruction is a turn-around-time that a token goes around the circular pipeline. The number of multi-processing is also represented by the number of tokens existing in the circular pipeline. Fig. 2 shows the experimental result of the turn-around-time of when the number of tokens in the circular pipeline is varied by repeated issuing multiply instructions. Fig. 2 shows that the turn-around-time is constant when the number of tokens is between one to five, therefore, a constant processing time is kept by five multiple process.

In this way, it is studied about overload avoidance scheme for congestion-free network of when ULP-DDNS which is appropriate for a network processing and is ultra-low power is applied to ad hoc network.

3 Urgent ad Nohoc networking system

3.1 Migration to an urgent ad hoc network

Network nodes communicating through base stations of an infrastructure when the infrastructure can be used will migrate to an ad hoc network and will try to communicate with the other nodes if the communication between the nodes and the base stations is lost by disaster etc. the nodes migrating ad hoc mode send packets to neighbor nodes by using flooding, and the neighbor nodes relay the packets as the relay nodes. The packets spread in whole ad hoc network, it increases traffic. Since the location of the relay nodes is determined in ad hoc network, traffic concentrates at a part of the relay nodes. Therefore, a collision in wireless area and traffic exceeding a processing performance of the nodes cause congestion.

To achieve an efficient ad hoc communication by solving these problems, some schemes are proposed [1][2][3]. It is explained that a discovery of a node stored any information, an authentication of the node, and obtaining data from the node which are assumed to be used in urgent ad hoc network communication

3.2 Discovery

There is a demand that it wants to know a current state of a particular place at the time of disaster etc. A method finding a network node being in this particular place and having desired information has been proposed, and the method makes an inquiry efficient. A procedure is as follows.

- A node requiring to obtain an information sends a query packet. A reply area is determined an angle a on either side of the line that connects itself with the destination.
- A node in a reply area calculates a distance of a destination node coordinate included in the query packet and a local node coordinate obtained by GPS and reply.
- The node requiring the information requests the discovery to a node which is closest to the destination
- By a repeat of these operations, a node which is closest to the destination is selected, and offers information.

In this way, the node holding necessary information is discovered efficiently.

3.3 Authentication

It is necessary to confirm whether a communication partner is correct or incorrect even if the communication uses ad hoc network. A public key certificate collection method based on a trust relationship list has been proposed. The method collects only the necessary certificate when a communication is required. Some trust relationships are created between neighbor nodes in the initial phase of constructing the network. Based on the initial trust relationship, the nodes collect the information of the trust relationship by a trust chain. In this way, the method makes authenticating a node efficient

3.4 Forwarding

As described above, since it is difficult to determine a route in ad hoc network, a communication utilizes flooding mainly. However, simple flooding causes many collisions. Information can reach only nodes of 70% in ad hoc network by the collision. Therefore, Load-aware Dynamic Counter-based Flooding (LDCF) has been proposed. LDCF forwards information efficiently by using a load state of local node.

LDCF measures a current processing load of a local node by a queue length in layer 2. LDCF judges by a queue length of to whether send or discard packets received at node. When the queue length is large, the queue length makes LDCF conscious of the high-load of a node and LDCF inhibits the forwarding packets. An inhibition of a sending packet is operated as follows.

- One or more relay nodes transmit the same packets from a same information source and the number of times same packets reception caused by above reason is counted in certain interval.
- Thresholds which allow transmission dynamically are configured for each information source and each packet, and the transmissions are canceled if the number of counts exceeds the threshold.

In this way, packets are forwarded efficiently.

4 Overload avoidance for congestion free network

4.1 Condition for avoiding overload

Generally, there are two reasons that a network go into congestion condition. One is the case that a packet is not able to send by a collision caused by attempting a packet sending of a traffic exceeding the network bandwidth. Another is the case that packet is not able to forward by receiving packets exceeding a processing performance of a network node. Former is able to give a notice to reduce a transmission rate to a packet sending host by checking a status of a packet sending. However, since latter is in overload condition, it cannot give a notice to another host to reduce a transmission rate based on a status of a packet sending. Therefore, it is necessary to consider a scheme to avoid an overload before a node becomes overload.

When ULP-DDNS is used, a constancy of processing period is kept even if processes are multiple by the feature of ULP-DDCMP and ULP-CUE as described above. Here, IEEE802.11 standard which is typical wireless communication method is described. IEEE802.11 has adopted Carrier Sense Multiple Access/Collision Avoidance (CSMA/CA) as an access control, and a data frame transmission is prohibited during a back-off control period even if wireless area is not used. 802.11 headers are also added to UDP/IP packet. These overhead decrease an actual transmission rate. For instance, in the case of IEEE802.11g, maximum wireless transmission rate is 54Mbps, however, UDP/IP transmission rate is less than 25Mbps. period when wireless area is used by sending and receiving packets depends on UDP/IP packet length. Therefore, minimum interval of sending and receiving packets depend on UDP/IP packet length. ULP-DDCMP will not be an overload if a packet process is completed in a period shorter than this minimum packet receiving interval as one view.

In this paper, as an example, Discovery (Phase 1), Authentication (Phase 2), and forwarding (Phase 3) which are needed to obtain certain information by using ad hoc network communication were considered about conditions for

overload avoidance for starters. As an ad hoc network used by this examination, we assumed that ten nodes are placed at same distance on a line. A wireless range of each node also assumes three nodes. Then, sending and receiving data frames, a receiving process (Rx), a forwarding process (Fwd), and a sending process (Tx) are considered in ULP-DDCMP at a request node, a relay node, and an information node. Moreover, UDP/IP packet lengths by using discovery, authentication, and forwarding are 100Byte, 1000Byte, and 500Byte are assumed, respectively. The packet lengths are average packet lengths in each protocol. Then, in this examination, LDCF sending packet efficiently was used since it decreases flooding in wireless range at transmission

4.2 Discovery phase

The state of packet sending and receiving and internal processing in node 1, 4, 10 is shown in Fig. 3. Node 1 requires to obtain a information, node 4 receives a request as next discovery node, and node 10 holds the required information. Moreover, Fig. 3 shows the process until an information discovery is completed. Colored rectangles represent periods that radio wave is transmitted and received in wireless area, Rx, Fwd, and Tx represent periods of a receiving process, a forwarding process, and transmitting process, respectively. Additionally, a downward arrow shows that MAC/PHY tries to transmit a packet, however, that the transmission is waited because the wireless area is used by receiving packet.

At first, node 1 sends a query packet by broadcast to discover node 10 having an information being desired by node 1. Node 2, 3, and 4 which receive the query packet from node 1 reply distances between a destination coordinate and each node according to the information discovery protocol. Node 1 sends a request packet to request next information discovery to node 4 which is nearest to node 10 in the received reply packet. Node 4 which received the request tries the information discovery similar to node 1. In Fig. 3, a processing flow of the discovery processing in node 4 is omitted because it is same as the processing flow in node 1. When the request packet is received at node 10 that is the information source, the destination coordinates are forwarded to node that transmitted this request packet. The packet replied from node 10 is sent to the node having requested the information discovery. Finally, this information discovery is completed when the reply packet arrives at node 1.

The examination that uses Fig. 3 leads following result.

- Since destination of packets received at when each node perform a transmission process is not local node, processes does not overlap in ULP-DDCMP
- If a period of packet receiving process is shorter than a packet receiving interval, processes will not overlap in ULP-DDCMP.

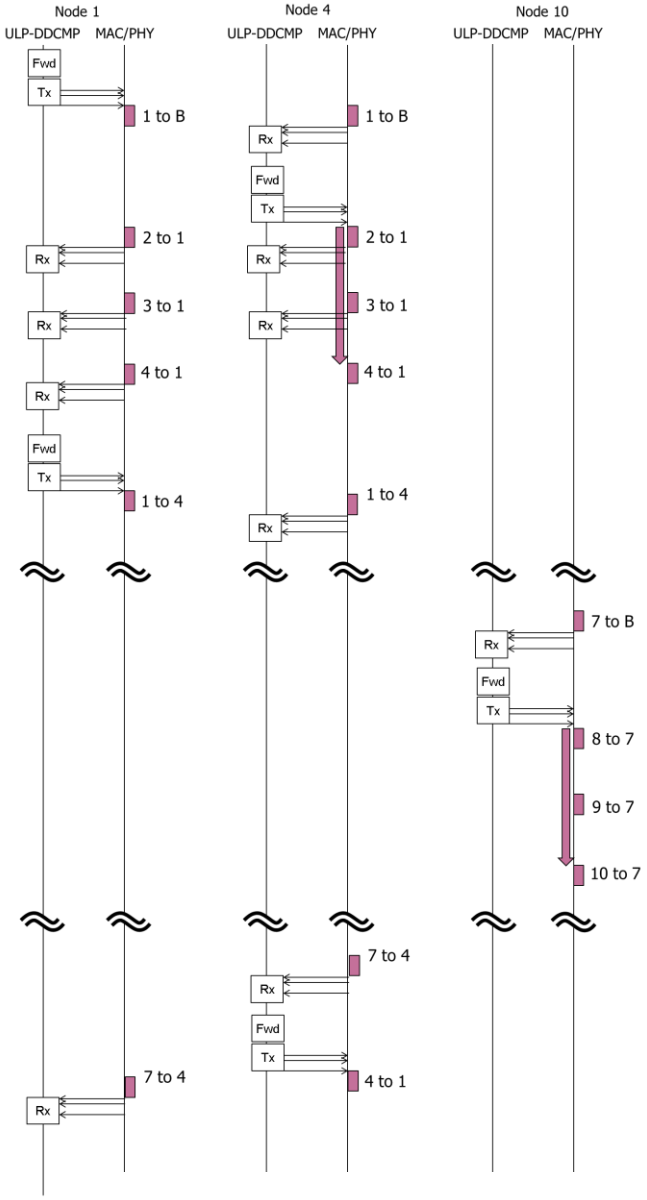

Fig. 3. Discovery phase

For these reasons, when a period of packet receiving process is shorter than a packet receiving interval, ULP-DDCMP does not enter a state of an overload.

4.3 Authentication phase

To consider packet flows, we assumed that node 1 obtains a certificate of node 5 (refer Fig. 4). And, processing flows on ULP-DDNS and sending and receiving packet at node 1, node 5, and node 2 which are relay nodes. Since node 1 and node 5 does not exist in each range of wireless access. The packets are transmitted by using LDCF. Colored rectangles represent periods of transmitted and received packets so as described above, and Rx, Fwd, Tx, and Auth represent periods of a the received packet process, the forwarding packet process, the transmitted packet process, and Authenticated process, respectively.

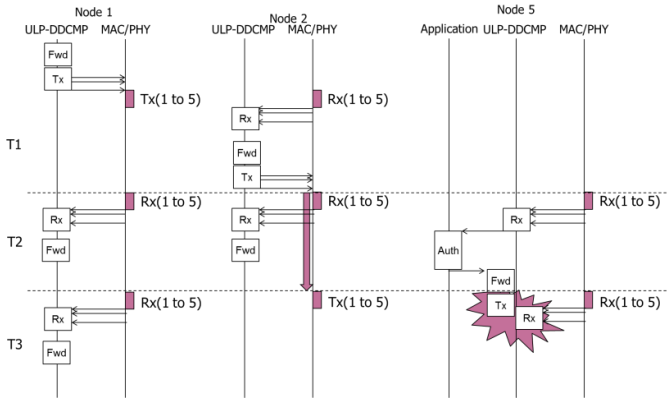

Fig. 4. Authentication phase

In T1, node1 judges that the acquisition of the certificate of node 5 is necessary from a trust relationship list, and node 1 send a packet to node 5. The packet is sent by using LDCF that is forwarding of flooding base because Node 5 is out of range of wireless area. The packet sent from node 1 is received at node2, node 3, and node 4. Node 2, node 3, and node4 judge that destination of the received packet is not local node. Each node starts a forwarding process and a transmission process to forward the packet.

In T2, node 3 that previously acquired the transmission right by CSMA/CA forwards the packet for the node 5 by using LDCF. This packet is also received at node 1, 2, 4, 5, 6. Node 2 and node 4 try to send the packet received in T1, because transmission timing was taken by node 3, the packet transmissions of node2 and node 4 are waited until next transmission timing in a MAC/PHY

Node2 that obtained transmission timing sends the packet of the node 5 addressing in T3, and the packet is received by node 1, 3, 4, and 5. In T2, node 5 which received the packet to local node has performed a process issuing the certificate. However, it is difficult to expect a processing completion time if this process is not performed with a data-driven processor. Thus, it cannot be guaranteed that a certificate issue processing, forwarding, and a transmission processing are completed by next packet reception. In the worst case, a packet might be arrived while processing forwarding or transmission. There is a possibility those processing and a packet receiving processing are executed at the same time.

When these are taken into consideration, a processing of requirement most strict in authentication phase is a process in T1 and in node 2. Thus, when a period of packet receiving process is shorter than a packet receiving interval, ULP-DDCMP does not enter a state of an overload.

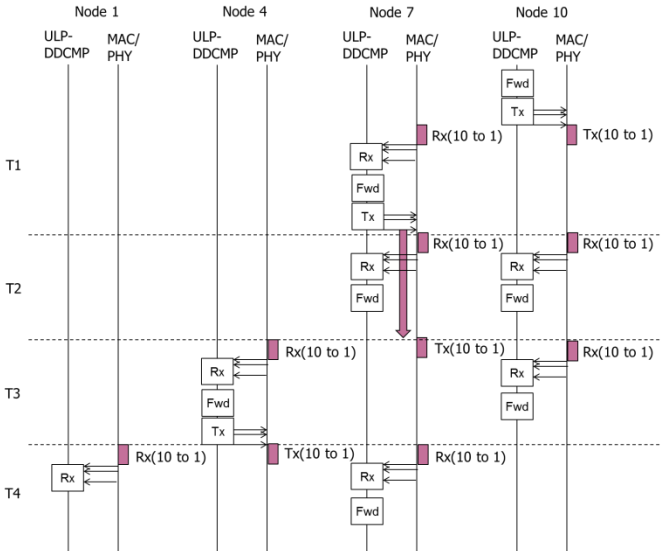

Fig. 5. Relay phase

4.4 Relay phase

A packet which is sent from node 10 is relayed in ad hoc network with LDCF and arrives in node 1. It is assumed that nodes relaying the packet are node 8, node 7, and node 4 until the packet arrives in node 1. Fig. 5 shows transmission and reception of packets and an internal processing of node 1, 4, 7, and 10. Node10 is a sender of information, node 1 is a receiver, and node 4 and node 7 are relay nodes as a representative.

At T1, a packet which will be sent from node 10 to the node 1 with flooding is received in node 7, and node 7 starts forwarding with LDCF.

At T2, node 8 sends a packet which has been received at T1 and is forwarded to node 1. Node 7 tries to send a packet, however, node 8 has sent the packet before, and the packet is stored in MAC/PHY until next transmission timing. Moreover, ULP-DDCMP has sent the packet addressed to node 1 to MAC/PHY at T1, as a packet that has already been processed. Only forwarding process is executed for the packet. A transmission process is not executed.

At T3, node 7 gets an opportunity to send the packet. Since the packet which has already been received, node 10 performs a forwarding process, however, node 10 does not perform a sending process. Node 4 starts a transmission process because node 4 received this packet for the first time. And, at T4, the node send a packet, node 1 receives the packet, and when a traffic of the packets addressed to node 1 which are flooded in ad hoc network disappears, a series of processing is completed.

Packet forwarding process according to reception of new packet similar to authentication phase is required most processing power in relay phase. Thus, when a total period of packet receiving process, forwarding process, and transmission process is shorter than a packet receiving interval, these processes does not overlap. By using ULP-DDNS, the period from start to completion of processing can be guaranteed, an overload can be avoided in advance.

5 Consideration

5.1 Overload avoidance scheme for sparse condition

Wireless communication is processed with one port generally. A sending packet and a receiving packet do not overlap unless a collision occurs. And, packet interval is also prepared. Therefore, shortest time until next packet is received can be predicted when the packet has been received. When each node works as a relay node, ULP-DDNS node executes a receiving process, a forwarding process, and a sending process and sends a packet according to following packet reception. It has been described that an overload is avoided when the receiving process, the forwarding process, and the sending process complete until next packet arrives. On the other hand, it was suggested that a receiving process and the other process may overlap in authentication phase. An overload avoidance scheme in case of a local node is source will be considered.

Basically, it cannot predict when a packet is received. Therefore, when local host sends a packet, forwarding process or transmission process and receiving process required according to packet reception might overlap. If a receiving process has started before a forwarding or transmission of which local host is source, the forwarding or transmission process can be delayed easily. In contrast, forwarding or transmission of which local host is source starts before a packet is received. Receiving process should be delayed, since refusing a receiving packet is the congestion itself. The overload avoidance scheme for an overlap of these processes is described in next sub section in detailed.

5.2 Overload avoidance scheme for dense condition

The case of one node in an ad hoc network acquiring information was examined. In actual case, since many nodes send and receive packets, a node might become in overload condition. Therefore, overload avoidance scheme in this situation was examined. If an internal process and a packet transmission process which are performed in local node delay, we can consider what is happen and can control the node. However, it is difficult to assume an influence when packet receiving and forwarding process delay. Therefore, to consider an overload avoidance scheme, the process is separated to a network process and an internal process. In this case, it is considered that the internal process can be delayed as described above, and a network processing is considered in this paper.

Table 1. Packet types

No.	Rx/Tx	Bcast/Ucast	From/To	denial	delay
1	Receive	Broad-cast	To local node	R	R
2		Broad-cast	To remote node	R	R
3		Uni-cast	To local node	R	R
4		Uni-cast	To remote node	R	R
5	Transmit	Broad-cast	From local node	R	A
6		Broad-cast	From remote node	A	R
7		Uni-cast	From local node	R	A
8		Uni-cast	From remote node	R	R

A: Allow
R: Refuse

There are two processes for network processing. One is a receiving process, and another is a transmitting process including a forwarding process. Moreover, there are a broadcast and a unicast for types of packet, and there are a local node and remote node for source and destination of a packet. These can be shown like Table. 1. A process that can be refused and a process that can be delayed are arranged for these network processing. And overload avoidance scheme is considered by refusing or delaying the process if ULP-DDNS node seems to be overload condition.

A transmitting and a receiving were examined at first in broad term. It is possible to delay or refuse the process so that a transmitting process is possible to confirm a content of a packet. However, it is impossible to delay or refuse a packet so that a receiving process cannot confirm a content of a packet until the process is completed

Next, decision from how each transmitting packet is used was tried. A packet of No. 5 is used as a source packet in a discovery phase or a source packet of LDCF forwarding. Since the packet is also used as reply for a request, it is possible to delay the packet processing. However, the processing is not permitted to be refused. A packet of No.6 is used at a relay node. Since the packet is sent to many nodes by flooding and LDCF has a mechanism to cancel a forwarding process depending on a processing load of a local node. The processing can be refused. Moreover, the delay is not permitted because there is a possibility that other nodes have already forwarded it and there is no meaning to delay processing. It is basically the same as No.5 though No.7 becomes the node is also source node in the unicast. No.8 is used for the unicast forwarding, and it is necessary to process in priority over other transmission processing because delaying this processing will greatly decrease the communication quality. Table 1 shows these summaries of the idea.

From these considerations, the transmission processing of No.6 is refused and the processing of No.5 and No.7 are delayed when the load of the node is high. In this case, because a unicast forwarding process is only performed as transmission process, an overload is not only avoided, but the increase of traffic is also avoided.

The delay and the refusal of the transmission process can be controlled by a local node. However, there is a situation that a receiving process must be delayed as described in the authentication phase. The local node cannot control a receiving packet, there is possibility that next packet cannot be processed by the delay of a receiving process. On the other hand, method controlling between nodes is proposed [6]. The method decreases a transmission rate of a remote node according to an allowable receiving rate noticed from peer node. The allowable receiving rate is obtained from an electrical current of ULP-DDCMP. When the receiving process delay occurs, an overload is avoided by a notice which lower value is less than a value obtained from current to reduce a transmission rate from a remote node temporary. The overload is avoided like this by the control of the transmission process delay in the local node and the control of the reception rate control between nodes.

6 Conclusion

scheme to avoid an overload of a network node required to achieve congestion-free ad hoc network communication was considered. Since a processing period of ULP-DDNS is constant even if multi-processing is required, it is possible to predict a period of processing. When ULP-DDNS is applied to urgent ad hoc network as an example, it was considered whether overload avoidance achieves by using the traffic pattern and packet types.

We have described an overload avoidance scheme as follows, (1) when the processing load becomes high, a transmission process is delayed before a receiving process, (2) Appropriate allowable throughput is notified to a remote node to lower the receiving packet rate when it is necessary to delay the receiving processing according to timing.

In future, we will evaluate the overload avoidance scheme and an appropriate scheme distributing tokens to each ULP-CUE will be examined.

Abstract – *The importance of the ad hoc network is paid attention in order to secure communication under emergency or disaster. Traffic control in order to avoid the network congestion and to secure communication is also paid attention for same reason. However, traffic control method of packet communication on the ad hoc network has not been well established. Ultra Low Power Data Driven Networking System (ULP-DDNS) works based on the principle of data driven processing and achieves low power consumption networking system. The ad hoc network realized by the ULP-DDNS enables simple and effective node load measurement by power consumption and throughput linearity. Efficient traffic control method with the advantage to achieve congestion-free network is proposed.*

Keywords: Ad Hoc Network, Data-Driven, Congestion, Flow Control

1 Introduction

East Japan earthquake disrupted not only the public switched telephone network (PSTN), but also the Internet, and it caused congestion. However, because of the nature, while the throughput was very low, communication connection over the Internet was more secured and relatively better communication than PSTN. Moreover short message communication such as Twitter which can exchange information with less bandwidth was found applicable for minimum level of communication. For these reasons, IP communication was considered as an important means of securing emergency communication so that IP traffic control becomes more and more important.

In the East Japan earthquake, existing network infrastructure was swept by Tsunami and lost. When the infrastructure has been lost by such disaster, IP communication over ad hoc network has been attracting attention as a means of communication in order to secure emergency communications The communication in such situation, reachability to communication party is important, and to achieve effective communication, a certain level of other quality such as throughput and packet delivery ratio must be guaranteed as well. However, in the ad hoc network employed in an event of disaster is unable to have enough network capacity because of multi-hop communication and vulnerability caused by unstable power supply and node mobility or insufficient bandwidth. On the other hand, bandwidth demand such as large size video data transmission or data access concentration to specific information on servers is increasing even under disaster situation. For example, sharing a certain remote location situation with video and sharing necessary information on a server is popularly used. Therefore, appropriate traffic control is more and more important to avoid congestion caused by traffic concentration.

Traditional telephone network has traffic control system to avoid network congestion caused by traffic concentration such as ticket reservation, inquiries on the radio and TV or telephone of safety confirmation in the event of a large scale disaster such as catastrophic disasters of large earthquake and Tsunami in east Japan. The traffic control system detects the traffic concentration to a specific number or areas, or high traffic exceeding node capacity or trunk circuit capacity. Then, it limits or stops connecting the call to prevent network congestion and affection to not-related calls. The system is independent from network and centralized control is employed. It widely monitors network resource usage and loss of calls to detect congestion and control calls. Once congestion is detected, it controls switches preventing connection of calls to a congested number or area. However, such independent control system is not only increase cost and power consumption, but also it is not suitable for the ad hoc network whose nodes have more autonomy and distributed functionality. So, network system with autonomous and distributed traffic control capability which is applicable for ad hoc network has been desired.

Authors have been studying data-driven networking system, ULP-DDNS. Applying ULP-DDNS to the emergency ad hoc network under an emergency situation like loss of infrastructure by earthquake has also been studied to utilize its advantage of low power consumption.

This paper proposes a method of applying ULP-DDNS as a node to achieve congestion free emergency ad hoc network. It is distributed flow control of ad hoc network node to avoid congestion with maximizing throughput and network resource utilization without losing ULP-DDNS advantages.

2 Congestion and flow control

In this section, various congestion controls are described and their characteristics are discussed whether they are suitable to ULP-DDNS ad hoc network.

2.1 Existing congestion control mechanism

Congestion occurs when a network or a part of network have more traffic than its performance. Existing network congestion control system is to maintain traffic amount within network performance. From a network system point of view, there are three important parameters which represents network performance.

- Trunk bandwidth
- Node throughput(bandwidth)
- Switching rate

In the PSTN, traffic control system measures these performance indexes and related resource usage. When the system detects congestion occurrence, it commands originating switches to limit number of calls to the congested numbers, switches or areas. In the ATM network, traffic flow is managed by virtual circuit or virtual path bases. A traffic flow reserves network resources based on the requested bandwidth and the traffic is shaped and polished to be within the reserved bandwidth. Different from ATM and PSTN, IP packet network like the Internet does not carry out aggressive traffic control, but it simply discards overflowed packets. Traffic control is dependent on congestion avoidance scheme of TCP/IP which is widely deployed [1] [2] [3]. Also, if a new communication flow is added to network, it is difficult to avoid congestion reoccurrence.

Congestion avoidance of emergency ad hoc network is important to reduce unnecessary traffic and help reserving battery capacity when utility power is lost. Moreover, real time communication such as voice or video over IP network uses UDP which has no flow control mechanism. So that congestion avoidance dependent on TCP is insufficient for traffic control and is unable to avoid congestion completely.

2.2 Flow control for congestion avoidance

There are two approaches of flow control for congestion avoidance. They are open loop method and closed loop method. By the open loop method, a traffic source requests necessary bandwidth and traffic characteristics at beginning of transfer and network reserves necessary network resource and if the network resource is not enough, the request is rejected by the network. The source controls its traffic throughput within the bandwidth and characteristic. If the source violates their limit, the exceeding traffic is discarded. SBR and VBR of ATM are the example of the method. With the closed loop method, network monitors resource usage and feedbacks to the traffic source or transit nodes if traffic exceeds threshold. ABR of ATM or congestion control of PSTN belongs to the method. If the network resource is known, open loop is easier to guarantee quality of service (QoS). However, in the ad hoc network, especially when it is deployed for emergency, it is hard to assume that static network configuration is known. In addition, the network configuration dynamically changes due to new participants or out such as battery exhaust. So that closed loop control is more suitable to emergency ad hoc network because it is able to reflect network condition in real time.

There is another classification of flow control approach. One is controlling traffic after congestion occurrence and the other is controlling traffic before congestion occurrence. TCP/IP approach is former one. It is assumed that packet drop is due to network congestion and the discarded packet is retransmitted with fallen down rate to resume non-congestion communication. Even the network resume normal state, the retransmission consumes network resources additionally. On the other hand, flow control has a risk of over control. The network performance can be lower than its maximum allowance when traffic is not properly limited. However, this paper focuses on the flow control because it can achieve perfect congestion free.

Traffic control within network is not sufficient to avoid congestion. A traffic source may be requested to reduce or stop traffic eventually. End terminal must be included within flow control mechanism. Accurate flow control needs enough network resource usage or traffic load information in timely manner, however measuring them also consumes a certain amount of network resource. It is necessary to consider measurement and accuracy balance for cost and energy efficient traffic control.

2.3 Flow control implementation

The ad hoc network is composed of nodes which are autonomous and distributed nodes. In case of emergency, it is hard to implement flow control system in parallel with ad hoc network. Therefore, it is requested for the each ad hoc network nodes equipped with the flow control function control as well as traffic switching and routing functions.

Controlling traffic flow is necessary to know network load. In the emergency ad hoc network, it is not suitable to know whole network load or load of entire network nodes. On the other hand, flow control without other node load information is unable to prevent the node from causing other node congestion. As a result, at minimum, adjacency node load information is necessary to prevent neighbor node congestion. Such load information must be exchanged over the ad hoc network, because of its distributed and loose coupled nature. But the information exchange increases network load. Efficient method of information exchange is necessary. To control other node traffic directly is also not suitable for ad hoc network congestion control. Such control request must be passed via network connection if necessary.

In the emergency ad hoc network, the ULP-DDNS nodes are connected via wireless network. There are two types of congestion in the case. One is congestion within ULP-DDNS node which is caused by overload of resources in the node. To control the congestion it is necessary to measure resource

usage and mechanism to reduce the load using the resource. The other is wireless network congestion. The air section for wireless network is shared with neighbor nodes so that only one node is able to send data and other nodes which have data to be sent need to wait while the air is occupied. There is a possibility of congestion if neighbors have transmission requests same time. In this case a node is able to monitor air section usage because all node are able to monitor wireless signal same time except nodes out of range

3 Congestion in ULP-DDNS node

Figure 1 describes the block diagram of ULP-DDNS [4] which is developed for evaluation purpose. It has enough functions as an ad hoc network node. Congestion within the ULP-DDNS is discussed in this section and ULP-DDCMP, Communication Device and Application Processor are point of congestion and need a control for congestion avoidance.

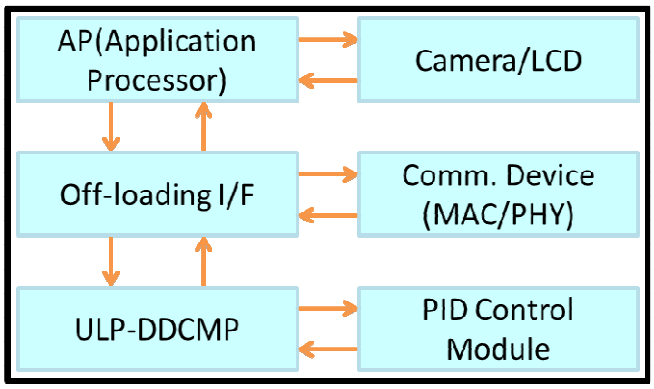

Figure 1 ULP-DDNS

3.1 Congestion in ULP-DDCMP

ULP-DDNS has an ultra-low-power data-driven chip-multi-processor: ULP-DDCMP whose block diagram is shown in Figure 2. The ULP-DDCMP functions as a network processor and an IEEE 802.11g wireless LAN interface is used as communication device. It also has an application processor, a camera and an LCD, they are usable for demonstration purpose of the ad hoc network application. The ULP-DDNS has enough functionality as an ad hoc network node.

Off-loading interface converts between tokens and data. Tokens are processed in ULP-DDCMP and data are processed in AP or transferred through communication device. With a data-driven principle, data arrives at ULP-DDCMP or in ULP-DDCMP begins to be processed when its data set is ready. After the data is processed, it leaves ULP-DDCMP and transferred to AP or communication device via off-loading interface.

ULP-DDCMP consists of 4 ULP-CUE data-driven processor cores. The ULP-CUE processes based on data-driven principle whose data and instruction sets flow in a packet format and it is called token in this paper. The tokens in the ULP-CUE are processed and sent to other ULP-CUE if necessary. Also, to communicate with outside device, Off-loading interface

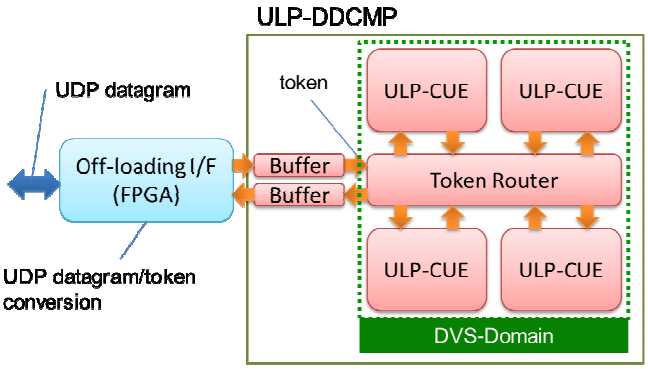

Figure 2 ULP-DDCMP

Figure 3 shows ULP-CUE block diagram which consists of pipeline of function stages. FC invokes a token which has a set of data and ready to be processed flows the circular pipeline. Instruction in a token is decoded at ID and executed at EX. The circular pipeline has a bypass circuit BB to MB for unary-operation which mating is unnecessary.

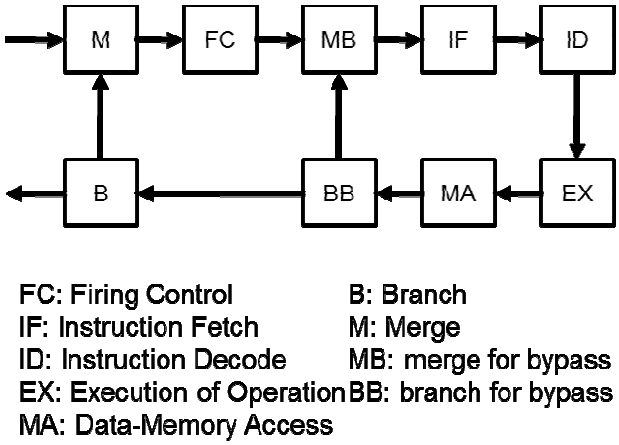

Figure 3 ULP-CUE Block Diagram

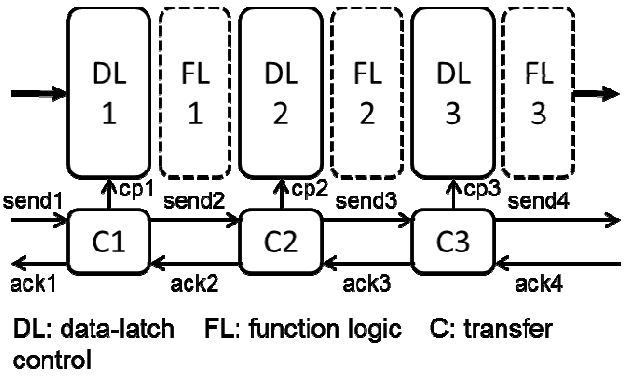

Figure 4 Self Timed Pipeline

The pipeline stages in the ULP-CUE are based on self-timed pipeline (STP) principle shown in Figure 4. A latched token is transferred to next data latch through function logic. Each latch is controlled by a transfer control which communicates with adjacency transfer control with handshake signal. Since the handshake is asynchronous and demand based, the STP realizes data driven principle. [5]

With above mentioned principle, ULP-CUE has almost flat turnaround time independent from number of threads as shown in Figure 5 and achieves scalability in throughput with number of processors. [6]

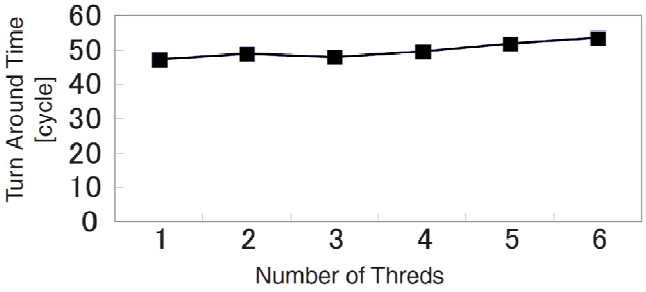

Figure 5 Number-of-Threads and TAT

With above mentioned principle, ULP-CUE has almost flat turnaround time independent from number of threads as shown in figure 5 and scalability in throughput with number of processors.

Figure 6 shows the relation between throughput and power consumption of ULP-STP. The ULP-STP has power gating (PG) function and the graph shows the relationship in three voltages. According to the result, power consumption and ULP-STP throughput relationship is almost in linear when voltage is same.

Processor load of ULP-DDCMP is measured by number of tokens processed and it is equivalent to packet throughput. Instead of counting the number of tokens in pipeline, it is able to measure processor load through power consumption with these characteristics of ULP-STP which compose ULP-DDCMP. Measuring power consumption is measuring electric current when voltage is same. Measuring current can be easily achieved without consume processing power of ULP-DDCMP. This enables easy load measurement without affecting processor performance. On the other hand, because TAT is almost flat, it is hard to assume load through TAT which is often used to measure processor load from outside.

From congestion control point of view, knowing other nodes load is necessary to control traffic. However, in the emergency ad hoc network, it is difficult to implement separate congestion control system so that nodes are requested to implement autonomous traffic control mechanism

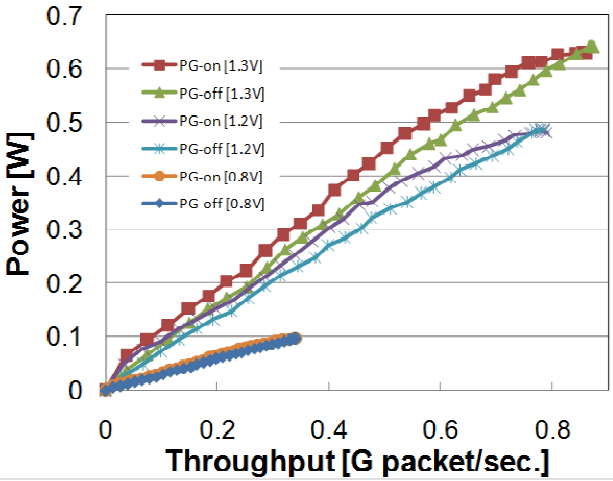

Figure 6 Throughput to Power Consumption

In this distributed traffic control implementation each node need to know load of other nodes, at least neighbor node load which the node communicates In order to know other node load, there are two strategies, measure node load from outside or announce self-measured load to other nodes. As mentioned above, TAT is useless but power consumption indicates load. However, it is difficult to measure power consumption from other nodes. Considering this, a ULP-DDNS is requested to announce its load to other nodes which is measured by its own power consumption.

3.2 Congestion of other blocks

There are other congestion of ULP-DDNS, high load of AP and communication device. AP congestion or high load and its load control are not discussed in this paper because it is an application level control and depends on the application in the AP. Although it is assumed that AP has However, the AP has to be informed available throughput of the network in order to avoid unnecessary traffic generation which can be waited or reduced resource allocation.

Another type of congestion exists in wireless network portion. The air section is shared with neighbor nodes and can be congested even the node load is low enough. If the air is busy because of the high usage, packet is queued and waiting until it is ready to be sent. If the waiting packet queue is already full, the queue will be dropped and discarded so that it is necessary to stop the packet queuing before the queue become full. The resource usage is not only immeasurable by ULP-DDCMP power consumption but also the power consumption decreases whichever the queue is implemented outside of ULP-DDCMP or within. If the queue is outside of ULP-DDCMP, its power consumption decreases when a packet leaves ULP-DDCMP. If the queue is implemented in ULP-DDCMP it means the packet related token(s) is stopped in the pipeline including FC so that power consumption of logic switching decreases. Therefore, the ULP-DDNS node

looks operating under low load when only power consumption is measured. It is necessary to implement the queue length counter for wireless network load measurement purpose.

4 Proposed flow control

4.1 Throughput margin announcement

As it is mentioned previously, ULP-DDNS node load is represented by power consumption of DDCMP and a queue length of the communication device. However, from other node point of view, the load information are useless because they do not explicitly tell the amount of data or throughput which they can transfer to the node. Although a ULP-DDCMP load may be useful for the ULP-DDNS node, the load is necessary to be converted into an index which represents available resource for other nodes. The queue length of communication device is also same. The load and queue length are different dimension but they are not completely independent. It is convenient for other nodes when these two indexes are merged into an index.

Following is the representative indexes popularly used for network system and useful for other nodes

- Available bandwidth (throughput)
- Available packet rate
- Available data size
- Available queue length

Bandwidth and packet rate are convertible when average packet size is fixed. Data size and queue length are also convertible because of same reason. Data size and bandwidth can be convertible when maximum burst rate and duration are defined as traffic characteristics. In this proposal, available bandwidth is selected as node load index because of following reason.

1. Bandwidth is physically defined and solid.
2. Packet length and necessary bandwidth depend on the protocol even if pay load data size is the same.
3. Bandwidth is popular and often used for performance index

Available network throughput $th_{avail\_ulp-ddcmp}(V,I)$ is calculated from available ULP-DDCMP throughput measured by volts and current. A conversion ratio of average UDP/IP packet size and average number of tokens is necessary. This depends on program implementation on ULP-DDCMP, its parallelism and stages.

There is another throughput margin of queue of communication device. When ULP-DDNS communicates with other node, it is via communication device and the throughput consists of the communication device throughput and air section throughput. To use the communication device, there is a queuing buffer to absorb the throughput difference. The throughput of the queue $Th_{avail\_comm.dev}(Q)$ is described as following

1. No queue: the throughput is equal to or less than network throughput and there is throughput margin to be increased.
2. The queue length is constant: the throughput is equal to network throughput and there is no throughput margin.
3. Increasing queue length: the throughput is higher than network throughput and throughput must be decreased until the queue length decreasing. Throughput margin is negative.
4. Decreasing queue length: the throughput is lower than network throughput and keep the throughput until the queue disappear. The throughput margin is 0.

In the ULP-DDNS, ULP-DDCMP and communication device are series connected as it is shown Figure 7. In the model, throughput is limited by the slowest one so that announced is throughput $th_{available}$ is

$$th_{available} = \min(th_{avail\_ulp-ddcmp}(V,I), th_{avail\_comm.dev}(Q)) \quad (1)$$

Figure 7

The ULP-DDNS ad hoc network employs wireless communication so that the throughput margin can be broadcasted to neighbor nodes within transmission range. The broadcasted announcement helps reduce time and power of node. On the other hand, nodes which can receive the announcement are requested to monitor and check it for next transfer. Otherwise, it has to wait until next announcement.

4.2 Simultaneous transmission and throughput allocation

Simple data transfer control mentioned above has a simultaneous transmission problem shown in Figure 8. If a node which receives an announcement can transfer within the announced throughput, total throughput may exceed the announced throughput. To avoid the problem, throughput allocation protocol is necessary.

For example, when Node 1 announces available throughput 1Mb/s and Node 2, Node 3 and Node 4 has 500kb/s throughput request for each. The simultaneous transfer cause overload of Node 1 because total throughput is 1.5Mb/s. To avoid the congestion, Node 1 have to permit or deny transfer request each by each or reallocate lower throughput to keep total throughput being available throughput. However, generally speaking Node 1 does not know characteristic of data transfer except it is clearly mentioned so that whether other nodes can accept lower throughput or not is not guaranteed. Considering this, ULP-DDNS node also need throughput allocation mechanism with permit or deny basis.

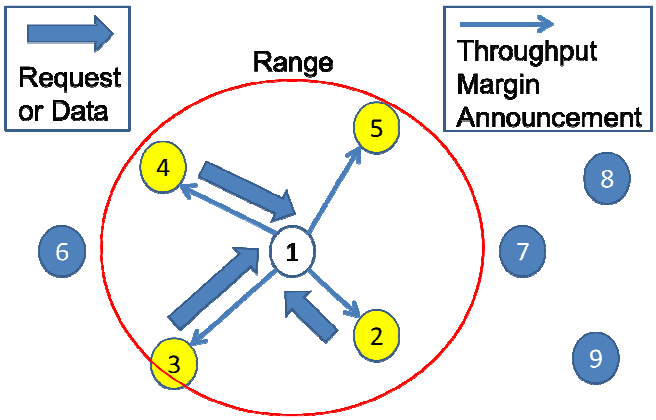

Figure 8 Simultaneous transmission

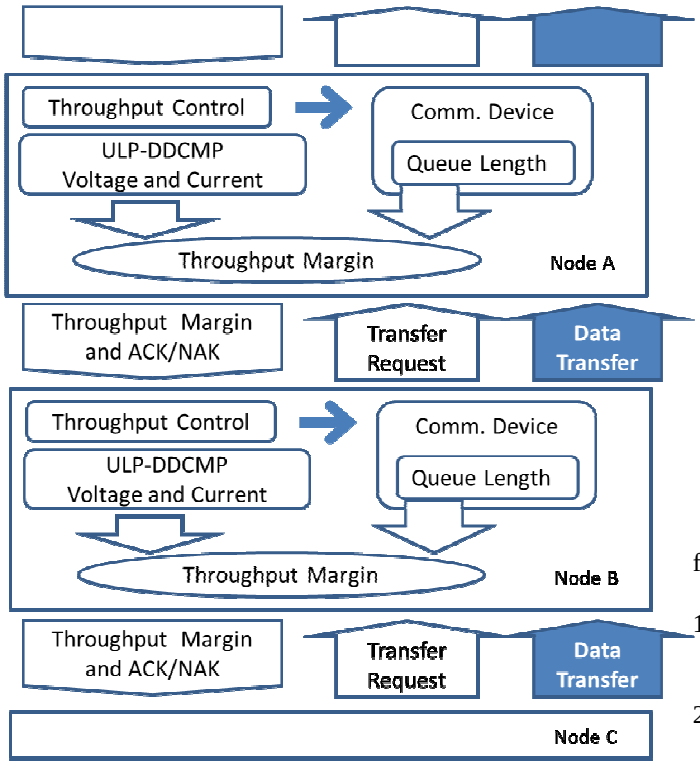

Figure 9 Proposed flow control mechanism

4.3 Flow control mechanism and protocol

In the communication, there are two type of traffic. One is not always expected to be reached. Like a broadcast, the traffic may be discarded when receiver is busy or off. The other is communication which needs a certain level of reachability and may need to know who the receiver is the later type of communication is the first priority for congestion free network. Although the broadcast type of traffic is considered as "load", flooding traffic is not described in this protocol. It is assumed that flooding traffic may not be received or discarded by node whenever a node is in high load or occupied.

Flow control functional model is shown in Figure 9 and Figure 10 describes the proposed flow control protocol sequence. Figure 9 describes relationship of nodes in series. A node may have other relationship such as a hub-spoke model

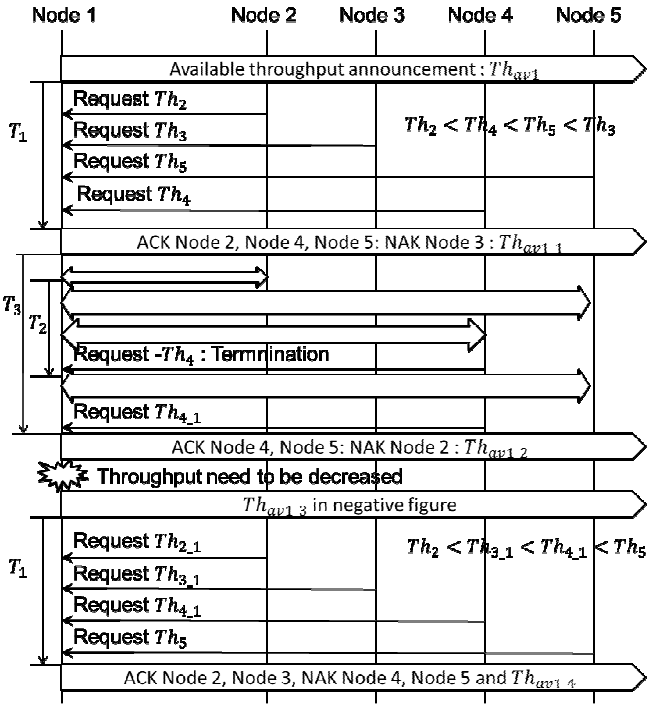

Figure 10 Proposed flow control protocol

The flow control protocol described in Figure 10 is following. Example in Figure 10 is written in brackets.

1. An ad hoc network node (Node 1) has a function to measure its throughput margin based on voltage and current of ULP-DDCMP and queue length of communication device.
2. Throughput margin is calculated from them. It is announced in broadcast (Th_{av1})
3. Among the neighbor nodes (Node 2, Node 3, Node 4 and Node 5) which have transmission request to Node 1 send transmission request with Th_n (Node 2, Node 3 and Node 4 ; $Th_2 < Th_4 < Th_5 < Th_3$) within the timer T_1.
4. If there is no request, the node (Node 1) announce again after T_3
5. The node (Node 1) accepts traffics in the order of lower to higher while $\sum Th_n$ is less than Th_{av1} and if it exceeds Th_{av1} the request is denied.(Node 2 and Node 4 are accepted and Node 5 and Node 3 are denied)
6. The node (Node 1) announces new available throughput (Th_{av_1}). The announcement is with ACK list of accepted request and NAK list of denied request (ACK Node 2, Node 4and Node 5: NAK Node 3)
7. Each node begins data transfer within the requested throughput.

8. When data transfer finishes, a node notifies termination with transfer request termination with the node throughput in negative figure (Node 4)
9. While a node continuously transfers data within T_2 it is regarded as sending request 0 (Node 5)
10. When there is no transfer within T_2 and no transfer until announcement, it is regarded as termination of transfer (Node 2).
11. A node is able to make new request even just after termination. (Node 4 with Th_{4_1}) It is also able to request to decrease throughput with negative figure.
12. After T_3 the node announces new available throughput (Th_{av1_2}) with all ACK list of accepted requests and NAK list of denied requests. (ACK Node 4 and Node 5: NAK Node 2)
12. T_2 time out flow is explicitly listed in NAK (Node 2) in order to inform termination.
13. When the node is requested to decreased due to the node internal reason, it announces available throughput in negative figure in order to request nodes to reduce
14. All nodes (Node 4 and Node 5) suspend their transfer upon negative available throughput announcement.
15. Each node decide new request referring requested throughput decrease. The new requests are expected to be decreased. The same throughput request is also acceptable although the request has higher risk of being denied.
15. "Same procedure in 3 and 4." Each nodes send transmission request with new throughput (Th_{2_1}, Th_{3_1}, Th_{4_1} *and* Th_5) within the timer T_1. If there is no request, the node (Node 1) announce again after T_3
16. "Same as procedure in 5." The node (Node 1) chooses request. (Node 2 and Node 3 are accepted, and Node 4 and Node are denied)
16. "Same procedure in 6." The node (Node 1) announces new available throughput (Th_{av1_4}). The announcement is with ACK list of accepted requests and NAK list of denied requests (ACK Node 2 and, Node 3: NAK Node 4 and Node 5)

5 Conclusion

This paper described congestion in the emergency ULP-DDNS ad hoc network and proposes a method of congestion avoidance to achieve congestion free network. The proposed flow control is based on distributed control therefore independent flow control system is unnecessary. It is proposed simple and non-load measurement with utilizing the ULP-DDCMP advantage whose load is measurable with its power consumption. It also takes in account of sending queue. The flow control protocol considering distributed implementation is also proposed.

The proposed measurement has assumption that the number of tokens in the ULP-DDCMP and UDP/IP packet traffic is in proportion. It is also assumed that communication device queue and throughput is convertible in certain ratio. Further study and experiment is needed in this area.

Throughput control described in the paper is not yet implemented. Although the traffic shaping mechanism is widely implemented in many network components, a study may be requested for data-driven shaper implementation.

6 Acknowledgements

Although it is impossible to give credit individually to all those who organized and supported the CUE project and the ULP-DDNS project, the authors would like to express sincere appreciation to all members in the project.

Abstract - *Support Vector Machines (SVM) are powerful classification and regression tools. They have been widely studied by many scholars and applied in many kinds of practical fields. But their compute and storage requirements increase rapidly with the number of training vectors, putting many problems of practical interest out of their reach. For applying SVM to large scale data mining, parallel SVM are studied and some parallel SVM methods are proposed. Most currently parallel SVM methods are based on classical MPI model. It is not easy to be used in practical, especial to large scale data-intensive data mining problems. MapReduce is an efficient distribution computing model to process large scale data mining problems. Some MapReduce software were developed, such as Hadoop, Twister and so on. In this paper, parallel SVM based on iterative MapReduce model Twister is studied. The program flow is developed. The efficiency of the method is illustrated through analyzing practical problems.*

1 Introduction

With the development of electronic and computer technology, the quantity of electronic data is in exponential growth [1]. Data deluge has become a salient problem to be solved. Scientists are overwhelmed with the increasing amount of data processing needs arising from the storm of data that is flowing through virtually every science field, such as bioinformatics [2-3], biomedical [4-5], Cheminformatics [6], web [7] and so on. Then how to take full use of these large scale data to support decision is a big problem encountered by scientists. Data mining is the process of discovering new patterns from large data sets involving methods at the intersection of artificial intelligence, machine learning, statistics and database systems. It has been studied by many scholars in all kinds of application area for many years and many data mining methods have been developed and applied to practice. But most classical data mining methods out of reach in practice in face of big data. Computation and data intensive scientific data analyses are increasingly prevalent in recent years. Efficient parallel/concurrent algorithms and implementation techniques are the key to meeting the scalability and performance requirements entailed in such large scale data mining analyses. Many parallel algorithms are implemented using different parallelization techniques such as threads, MPI, MapReduce, and mash-up or workflow technologies yielding different performance and usability characteristics [8]. MPI model is efficient in computation intensive problems, especially in simulation. But it is not easy to be used in practical. MapReduce is a cloud technology developed from the data analysis model of the information retrieval field. Several MapReduce architectures are developed now. The most famous is the Google, but the source code is not open. Hadoop is the most popular open source MapReduce software. It has been adopted by many huge IT companies, such as Yahoo, Facebook, eBay and so on. The MapReduce architecture in Hadoop doesn't support iterative Map and Reduce tasks, which is required in many data mining algorithms. Professor Fox developed an iterative MapReduce architecture software Twister. It supports not only non-iterative MapReduce applications but also an iterative MapReduce programming model. The manner of Twister MapReduce is "configure once, and run many time" [9-10]. It can be applied on cloud platform. It will be the popular MapReduce architecture in cloud computing and can be used in data intensive data mining problems.

Support Vector Machines are powerful classification and regression tools [11]. Many SVM software models have been developed, such as libSVM, lightSVM, ls-SVM and so on. LibSVM is taken as the most efficient SVM model and widely applied in practice because of its excellent property [12]. But SVM's compute and storage requirements increase rapidly with the number of training vectors, putting many problems of practical interest out of their reach. The core of an SVM is a quadratic programming problem (QP), separating support vectors from the rest of the training data. For improving the training speed of SVM, many efforts have been done. Reference [13] accelerates the QP with 'chunking', where subsets of the training data are optimized iteratively, until the global optimum is reached. Sequential Minimal Optimization (SMO) [14], which reduces the chunk size to 2 vectors, is the most popular of these algorithms. Eliminating non-support vectors early during the optimization process is another strategy that provides substantial savings in computation. Parallelization has been proposed by splitting the problem into smaller subsets and training a network to assign samples to different subsets [15]. Variations of the standard SVM algorithm, such as the Proximal SVM have been developed that are better suited for parallelization [16], but how widely they are applicable, in particular to high-

dimensional problems, remains to be seen. A parallelization scheme was proposed where the kernel matrix is approximated by a block-diagonal [17]. Most of parallel SVM are based on MPI programming model. Little research work has been done with MapReduce work.

Based on current research work of SVM and Twister MapReduce framework, the paper develops a parallel SVM model based on MapReduce. In this model, training samples are divided into subsections. Each subsection is trained with a SVM model. In this paper, libSVM is used to train each subSVM. The non-support vectors are filtered with subSVMs. The support vectors of each subSVM are taken as the input of next layer subSVM. The global SVM model will be obtained through iteration. The MapReduce based SVM model is encoded with Java language.

The following of the paper is organized as follows. LibSVM method is introduced briefly in part 2. The Twister model is introduced in part 3. MapReduce based parallel SVM model and its program flow is introduced in part 4. Two practical examples are analyzed with the proposed model in part 5. At last some conclusions are summarized.

2 LibSVM

2.1 Support Vector Machines

SVM first maps the input points into a high-dimensional feature space with a nonlinear mapping function Φ and then carries through linear classification or regression in the high-dimensional feature space. The linear regression in high-dimension feature space corresponds to the nonlinear classification or regression in low-dimensional input space. The general SVM can be described as follows.

Let l training samples be $T = \{(x_1, y_1), \cdots, (x_l, y_l)\}$, where $x_i \in R^n$, $y_i \in \{1, -1\}$ (classification) or $y_i \in R$ (regression), $i = 1, \cdots, l$. Nonlinear mapping function is $k(x_i, x_j) = \emptyset(x_i)\emptyset(x_j)$. Classification SVM can be implemented through solving the following equations.

$$\min_{w,\xi_i,b}\left\{\frac{1}{2}\|w\|^2 + C\sum_i \xi_i\right\}$$
$$s.t.\, y^i(\Phi^T(X_i)w + b) \geq 1 - \xi_i \quad \forall i = 1, \cdots, n \qquad (1)$$
$$\xi_i \geq 0 \quad \forall i = 1, \cdots, n$$

By introducing Lagrangian multipliers, the optimization problem can be transformed into its dual problem.

$$\min_{\alpha} \sum_{i,j} \alpha_i \alpha_j y_i y_j k(x_i, x_j) - \sum_{i=1}^{l} \alpha_i$$
$$s.t.\ y^T \boldsymbol{\alpha} = 0 \qquad (2)$$
$$0 \leq \alpha_i < C, i = 1, \cdots, l$$

After obtaining optimum solution a^*, b^*, the following decision function is used to determine which class the sample belongs to.

$$f(x) = sgn\left(\sum_{i=1}^{l} y_i \alpha_i^* K(x_i, x) + b^*\right) \qquad (3)$$

The classification precision of the SVM model can be calculated as

$$\text{Accuracy} = \frac{\#\text{correctly predicted data}}{\#\text{total testing data}} \times 100\%$$

2.2 libSVM

LibSVM is taken as the most efficient SVM software. It is an integrated software for support vector classification, regression, and distribution estimation. Most efficient analysis models are included. For example, C-SVC and nu-SVC classification models, epsilon-SVR and nu-SVR regression models, and one-class SVM distribution estimation. For improving the classification correct rate, cross validation is adopted. For processing unbalancing classification problem, weighted and probability models are adopted. The detail of libSVM can be found in [12]. In this paper, C-SVC libSVM model is selected to analyze the classification problems.

3 Architecture of Twister

There are many parallel algorithms with simple iterative structures. Most of them can be found in the domains such as data clustering, dimension reduction, link analysis, machine learning, and computer vision. These algorithms can be implemented with iterative MapReduce computation. Professor Fox developed the first iterative MapReduce computation model Twister. It has several components, i.e. MapReduce main job, Map job, Reduce job, and combine job. Twister's programming model can be described as in figure 1.

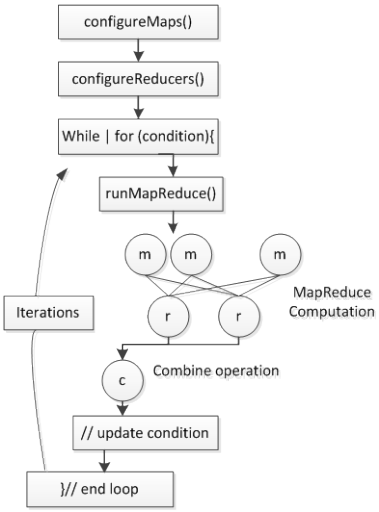

Fig. 1 Program model of Twister

MapReduce jobs are controlled by the client node through a multi-step process. During configuration, the client assigns MapReduce methods to the job, prepares KeyValue pairs and prepares static data for MapReduce tasks through the partition file if required. Between iterations, the client receives results collected by the Combine method, and, when the job is done, exits gracefully. The message communicate between job is realized with message brokers, i.e. NaradaBrokering or ActiveMQ.

Map daemons operate on computation nodes, loading the Map classes and starting them as Map workers. During initialization, Map workers load static data from the local disk according to records in the partition file and cache the data into memory. Most computation tasks defined by the users are executed in the Map workers. Twister uses static

scheduling for workers in order to take advantage of the local data cache. In this hybrid computing model, daemons communicate with the client through messages.

Reduce daemons operate on computation nodes. The number of reducers is prescribed in client configuration step. The reduce jobs depend on the computation results of Map jobs. The communication between daemons is through messages.

Combine job is to collect MapReduce results. It operates on client node. Twister uses scripts to operate on static input data and some output data on local disks in order to simulate some characteristics of distributed file systems. In these scripts, Twister parallel distributes static data to compute nodes and create partition file by invoking Java classes. For data which are output to the local disks, Twister uses scripts to gather data from all compute nodes on a single node specified by the user.

4 Parallel SVM based on Twister

4.1 Architecture of Parallel SVM

The parallel SVM is based on the cascade SVM model. The SVM training is realized through partial SVMs. Each subSVM is used as filter. This makes it straightforward to drive partial solutions towards the global optimum, while alternative techniques may optimize criteria that are not directly relevant for finding the global solution. Through the parallel SVM model, large scale data optimization problems can be divided into independent, smaller optimizations. The support vectors of the former subSVM are used as the input of later subSVMs. The subSVM can be combined into one final SVM in hierarchical fashion. The parallel SVM training process can be described as in figure 2.

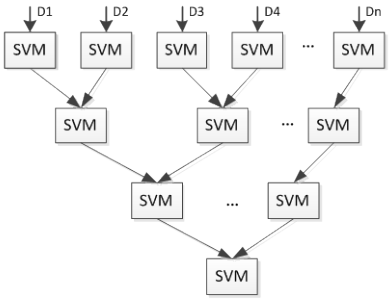

Fig. 2 training flow of parallel SVM

In the architecture, the sets of support vectors of two SVMs are combined into one set and to be input a new SVM. The process continues until only one set of vectors is left. In this architecture a single SVM never has to deal with the whole training set. If the filters in the first few layers are efficient in extracting the support vectors then the largest optimization, the one of the last layer, has to handle only a few more vectors than the number of actual support vectors. Therefore, the training sets of each sub-problems are much smaller than that of the whole problem when the support vectors are a small subset of the training vectors. In this paper, libSVM is adopted to train each subSVM.

4.2 Program flow

From the parallel SVM architecture, the pseudo program code based on Twister is as follows.

```
Preparation
    Computation environment configuration
    Data partition and distribution to the computation nodes
    Create partition file
Main class
    JobConf; //configure the MapReduce parameters and classnames
    TwisterDriver; //to initiate the MapReduce tasks
    While(condition)  //not combined to one SVM
      JobConf;  //reconfigure the MapReduce parameters;
      TwisterDriver; // initiate new MapReduce tasks, Broadcast combined
    support vectors to each computation node;
      Get feedback results;
    If(condition) break; // if one SVM obtained, program finished
End mian class
Map class
    If(the first layer SVM)
      Load data from local file system;
    else
      Read data broadcasted by Main class
    End if
    Svm_train(); //the parameters of the SVM model are transformed through
    jobConf.
    Collector;  //sent the training result to Reduce job through message.
End Map class
Reduce class
    Read data transformed from Map job;
    Combine support vectors of each two subSVM into one sample set.
    Collect; //feedback all the trained support vectors
End Reduce class
```

Firstly, computation nodes should be available. The program can be described as follows. Original large scale data D should be partitioned into smaller data sections $\{D_1, \cdots, D_n\}$. These data sections are put to computation nodes. Then create partition file according to Twister command. The partition file will be used in Twister configuration.

Based on the available computation environment, jobConf is used to configure the computation parameters, such as Map, Reduce, and Combine class names, number of Map tasks and Reduce tasks, partition file and so on. TwisterDriver will initiate the MapReduce task. Dynamic parameters will be transformed to each computation node through API interface.

In each computation node, Map tasks are operated. In the first layer of figure 2, sample data are loaded from local file system according to partition file. In the following layers, the training samples are support vectors of former layer. LibSVM is used to train each subSVM. In the LibSVM, Sequential Minimal Optimization is used to select the workset in decomposition methods for training support vector machines [14]. C-SVC model is used to train classification SVM. Trained support vectors are sent to the Reduce jobs.

In the Reduce job, all support vectors of all Map jobs are collected together and feed back to client. Through iteration, the training process will stop when all subSVM are combined to one SVM.

4.3 Computation time analysis

The time cost of SVM can be divided into following sections. The computation time complexity of libSVM is $O(n^2)$. The transformation time of data between Map and Reduce nodes is depend on the bandwidth of the connection network. The transfer time can be described as t_{trans}. The combination time cost of two SVMs is O(n). When training data set is divided into m partitions, the computation cost is calculated as follows. The layers of cascade SVM is $N = \log_2 m$. Suppose that the ratio between the number of support vectors and that of whole training sample is α ($0 < \alpha < 1$) and the ratio between support vectors and that of training sample except the first layer is $\beta(1 < \beta < 2)$, i.e. the number of the last layer in Fig. 2 is $n_N = n\alpha\beta$ and the number of training sample of the first layer is almost $n_1 = n/m$. The number of training samples of the i layer is $n_i = n\alpha\beta * \left(\frac{\beta}{2}\right)^{N-i}$. So the computation time can be calculated as follows.

$$t = O\left(\left(\frac{n}{m}\right)^2\right) + \sum_{i=N}^{2} O\left(\left(n\alpha\beta * \left(\frac{\beta}{2}\right)^{N-i}\right)^2\right) + O\left(\sum_{i=N-1}^{2} n\alpha\beta * \left(\frac{\beta}{2}\right)^{N-i} * 2^{N-i}\right) + t_{trans} \quad (4)$$

Overhead of data transfer mainly includes three parts. The first part is data transfer from Maptask nodes to Reducetask nodes. The transferred data are the support vectors obtained by Maptask nodes. The second part is data transfer from Reducetask nodes to server node. The transferred data is the support vectors also. The third part is the data transfer from server nodes to Maptask node. The transferred data is the training samples combined by two subSVM's support vectors. The overhead of data transfer depend on the bandwidth of the MapReduce cluster.

From the architecture of parallel SVM, we can find that it is hierarchal structure. The low level SVM training has to be performed when all the upper level subSVM be trained. In the last level of the architecture, all the support vectors should be included in the training samples. The sample size must be bigger than the number of support vectors. When the ratio between support vector and training sample is bigger the speed up will be less. It is the shortcoming of the cascade SVM model.

5 Examples

All examples are analyzed in India cluster node of FutureGrid. Eucalyptus platform is adopted to configure the MapReduce computation environment. Twister0.9 software is deployed in each computation nodes. ActiveMQ is used as message broker. The configuration of each virtual machine is as follows. Each node is installed Ubuntu Linux OS. The processor is 3GHz Intel Xeon with 10GB RAM.

5.1 Adult data analysis

5.1.1 Data source

The source data are downloaded from NEC laboratory American Inc. website http://ml.nec-labs.com/download/data/milde/. In the adult database, 123 attributes are labeled 2 classes. Each attribute denoted by binary variable, i.e. 0 or 1. Labels are denoted by +1 or -1. It is a binary classification problem. The database includes two files. One is used for training and the other is used for testing. The training file includes 32562 samples. The testing file includes 16282 samples. In this example, 5 computational nodes are used. Training data are partitioned into n sections randomly. Each section has roughly equal number data.

5.1.2 Training process

The problem is taken as a binary classification problem. C-SVC model is adopted. The parameter of the SVM model is set as follows. Constant C is set 1, radial basis function is taken as kernel function, and gamma is set as 0.01. Firstly, the example is analyzed with only 1 computation node, i.e. classical SVM method is used to train the SVM model. The trained model is used to predict the testing samples. The training time and classification correct rate are listed in Table 1. Secondly, the example is analyzed with the parallel SVM based on map/reduce. For comparison, the sample is partitioned into 2, 3, 4, 5 sub-samples respectively. When the sample is partitioned into 2 sub-samples, 2 computing nodes are used. The training time and classification rate of each partition form are listed in table 1. And so forth to the other partitions.

Table 1 analysis result of SVM with different partition nodes

Number of nodes	Number of SVs	Training time(s)	Classification correct rate
1	11957	490.591	84.82
2	11933	281.152	84.98
4	11908	239.914	83.06
8	11887	237.441	82.74

5.1.3 Feature selection with correlation coefficient

In the example, there are 123 attribute variables. Most variables provide minor contribution in the classification. For improve the training speed and reduce the noise effect of attribute variables, correlation coefficient is used to measure the correlation between class variable Y and attribute variable X. The attribute variables are selected according to the correlation values. The correlation coefficient is calculated as the following equation.

$$\rho_{X,Y} = \frac{cov((X,Y)}{\sigma_X \sigma_Y} = \frac{E[(x-\mu_X)(y-\mu_Y)]}{\sigma_X \sigma_Y} \quad (5)$$

where $cov((X,Y)$ is the covariance of the two variables, σ_X, σ_Y are the standard deviations of X and Y. After calculating the correlation coefficient, the pruning value is set 0.1. At last, 34 attribute variables are selected. The training result is listed in table 2.

Table 2 analysis result of SVM based on feature selection

nodes Number	Number of SVs	Training time(s)	Classification correct rate
1	11702	154.098	84.10
2	11694	94.338	84.06
4	11710	86.142	83.95
8	11692	83.57	82.99

5.1.4 Results analysis

The analysis results are shown as in Fig.3 and Fig. 4. From Fig.3 we can find that the training time can be reduced

greatly when the sample is partitioned 2 parts. But with the increase of partition number, the training time reduction will become slow. From Eq. (8), the computation cost mostly concentrate on the training calculation of each subSVM. The example was analyzed in HPC cluster. The data transfer time cost is minor. In this example, the ratio $\alpha \approx 0.35$ and $\beta \approx 1.2$. The last layer will occupy the mainly part computation time and it will not decrease with the increase of partition number. With the decrease of α, the computation time can be reduced more. With the introduction of feature selection, the computation can be reduced greatly without decreasing the correct classification rate.

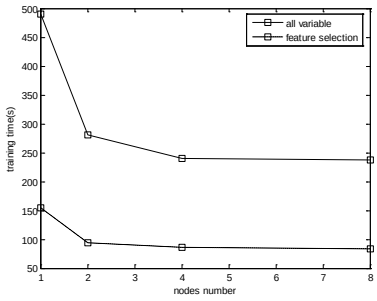

Fig. 3 Training time based on different partition nodes

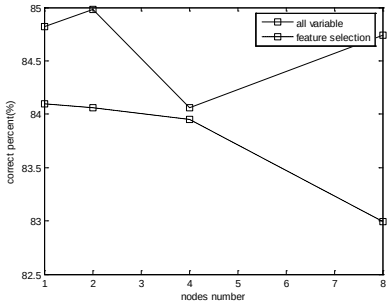

Fig. 4 Correct rate based on different partition

5.2 Forest Cover type Classification

5.2.1 Data source

The source data are downloaded from http://ftp.ics.uci.edu/pub/machine-learningdatabases/covtype/. The data is used to classify forest cover type. The original data are collected by Remote Sensing and GIS Program, Department of Forest Sciences, College of Natural Resources, Colorado State University. Natural resource managers responsible for developing ecosystem management strategies require basic descriptive information including inventory data for forested lands to support their decision-making processes. The purpose is to predict the forest cover type according to cartographic variables' values. The square of each observed section is 30 x 30 meter cell. There are 54 columns in each data item. They denote 12 variables, i.e. Elevation, Aspect, Slope,Horizontal_distance_to_hydrology,Vertical_Distance_To_Hydrology,Horizontal_Distance_To_Roadways,Hillshade_9am,Hillshade_Noon,Hillshade_3pm,Horizontal_Distance_To_Fire_Points, Wilderness_Area, and Soil_Type, where Wilderness_Area is denoted by 4 binary columns and Soil_Type is denoted by 40 binary columns. They are labeled as 7 cover types, i.e. Spruce/Fir, Lodgepole Pine, Ponderosa Pine, Cottonwood/Willow, Aspen, Douglas-fir, and Krummholz. There are 581012 samples in total. In this example, 28000 samples are taken as training samples and the left are taken as test samples.

5.2.2 Analysis preparation

In this example, 5 computational nodes are used. Training data are partitioned into n sections randomly. Each section has roughly equal number data. Each attribute is normalized according to the following equation.

Let X denote attribute variable. The maximum value of X is x_{max} and the minimum value is x_{min}. The range of normalized attribute is set [0, 1]. The normalized equation is

$$x_{norm} = \frac{x - x_{\min}}{x_{max} - x_{min}}$$

5.2.3 Training process

The problem is taken as a multi-value classification problem. Multiclass classification is realized with pairwise method, i.e. k class SVM is realized through $k(k-1)/2$ binary SVMs. The "one against one" strategy, also known as "pairwise coupling", "all pairs" or "round robin", consists in constructing one SVM for each pair of classes. Thus, for a problem with k classes, k(k-1)/2 SVMs are trained to distinguish the samples of one class from the samples of another class. Usually, classification of an unknown pattern is done according to the maximum voting, where each SVM votes for one class.

In this example, C-SVC model is adopted. The parameter of the SVM model is set as follows. Constant C is set 1, radial basis function is taken as kernel function, and gamma is set as 0.01. Firstly, the example is analyzed with only 1 computation node, i.e. classical SVM method is used to train the SVM model. The trained model is used to predict the testing samples. The training time and classification correct rate are listed in Table 2. Secondly, the example is analyzed with the parallel SVM based on map/reduce. For comparison, the sample is partitioned into 2, 3, 4, 5 sub-samples respectively. When the sample is partitioned into 2 sub-samples, 2 computing nodes are used. The training time and classification rate corresponding to each partition form are listed in table 3.

Table 3 analysis results with different partition nodes

nodes Number	Number of SVs	Training time(s)	Classification correct rate
1	22177	396.125	58.76
2	21831	297.32	58.35
4	20941	251.402	58.24
8	20139	219.346	57.96

5.2.4 Feature selection with correlation coefficient

In the example, there are 54 attribute variables. Most variables provide minor contribution in the classification, especially the Soil_Type variables. For improve the training speed and reduce the noise effect of attribute variables, correlation coefficient Eq. (9) is used to select attribute variables. After calculating the correlation coefficient, the

pruning value is set 0.1. At last, 18 attribute variables are selected. The training result is listed in table 4.

Table 4 analysis result of SVM based on feature selection

Number of nodes	Number of SVs	Training time(s)	Classification correct rate
1	14624	82.022	57.46
2	14198	58.899	57.99
4	13298	55.154	58.57
8	12207	45.029	58.65

5.2.5 Result analysis

This example is a multiclass classification problem. How to improve classification correct rate of multi-class is still a big problem. From Fig.5 we can find that the training time can be reduced greatly when the sample is partitioned 2 parts. But with the increase of partition number, the training time reduction will become slow. In this example, the ratio $\alpha \approx 0.4$ and $\beta \approx 1.2$. It is similar to the analysis problem of example 1. With the introduction of feature selection, the computation can be reduced greatly. From the analysis correct rate we can find that correct rate will not decrease too much.

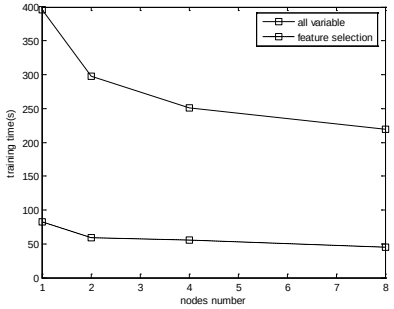

Fig. 5 training time based on different partition nodes

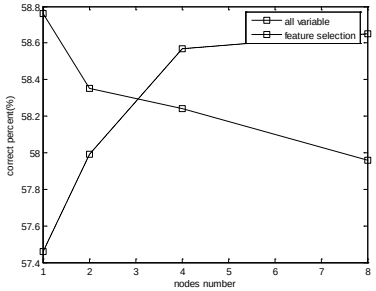

Fig. 6 Correct rate based on different partition

5.3 Heart disease classification

5.3.1 Data source

There are 270 clinic reports. Each report includes 13 factor variables. Clinic is divided into 2 classes. For testing the efficiency of the proposed cascade SVM, we replicate the data 500 times, 1000 times, and 2000 times separately. The generated data sets has 135000, 270000, 540000 samples separately. The initial data set is used to test the SVM model. The training time and correct rates based on different partition styles are listed in table 5, table 6 and table 7 respectively.

Table 5 analysis result with data replicated 500 times

Number of nodes	Number of SVs	Training time(s)	Classification correct rate
1	7585	313.755	99.629
2	7712	148.184	99.259
4	7690	87.523	98.518
8	7487	76.773	98.148

Table 6 analysis result with data replicated 1000 times

Number of nodes	Number of SVs	Training time(s)	Classification correct rate
1	8972	539.28	100
2	9055	234.49	99.63
4	8739	123.887	98.15
8	8688	86.503	97.41

Table 7 analysis result with data replicated 2000 times

Number of nodes	Number of SVs	Training time(s)	Classification correct rate
1	N/A	N/A	N/A
2	9901	578.507	100
4	9650	266.587	99.63
8	9202	158.531	99.63

The analysis result is shown as in figure 7, figure 8 and figure 9.

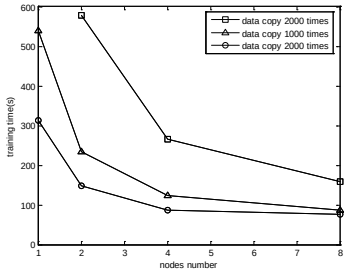

Figure 7 training time based on different partition nodes

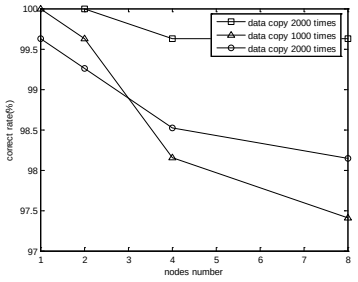

Figure 8 Correct rate based on different partition

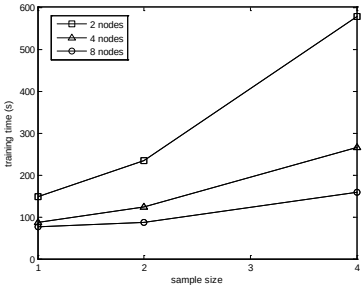

Fig. 9 training time based on different parallelism corresponding to different sample size

5.3.2 Result analysis

From the above analysis results we can find that the bigger the sample size the more obvious of the speed up.

From figure 7, we can find that when the sample size is very big, i.e. 540000 samples, it can't be processed with one single computation node. It is out of the memory. It is necessary to process big size problem with parallel style. The training time will decrease slowly when the parathion number is bigger than 8. It is because of two reasons. The first reason is that he ratio between optimum computation time and data transform overhead is less. The other reason is that the sample size of the last level can't be less than the number of support vectors. The computation cost will account a big proportion. So the computation will decrease very slowly. From fig. 9 we can find the computation time based on different partition style is approximate linear relationship to sample size.

6 Conclusions

Data-intensive data mining is still a big problems faced by computer scientist. SVM is taken as a most efficient classification and regression model. The computation cost of SVM is square proportion to the number of training data. Classical SVM model is difficult to analyze large scale practical problems. Parallel SVM can improve the computation speed greatly. In this paper, parallel SVM model based on iterative MapReduce is proposed. It is realized with Twister software. Through example analysis it shows that the proposed cascade SVM based on Twister can reduce the computation time greatly. But it doesn't mean that it is better to partition sample data into many parts. The computation time will not decrease through the analysis of the computation time. The partition number can be estimated according to the concrete problems. For increase the computation speed, the cascade SVM can be combined with other feature selection and feature extraction methods. In total, the analysis results show that the parallel SVM based on iterative MapReduce is efficient in data intensive problems.

CUERA: A generic data- and undo/redo-consistency framework for realtime interactive collaboration applications

Daniel Stolzenberg and Erika Müller
Institute of Communications Engineering, University of Rostock, Germany

Abstract— *Existing solutions for eventual consistent any-undo/redo in collaborative applications are very limited to specific domains. Thus a widely applicable framework based on entity-relationship-models is introduced. It defines generic state-focusing action types and undo/redo meta-actions. Convergence is based on a transitive precedence order and is achieved by applying a last-writer-wins scheme to an efficient scope organization of action history. Its performance scales for data and action history, but degrades regarding the number of sites.*

Keywords: CSCW, any-undo/redo, entity relationship models, eventual consistency, precedence transitivity

1. Introduction

Realtime interactive collaboration applications (RTICAs) let multiple users at different locations interact within a shared context at the same time. Since users demand high responsiveness and fluid interactivity, all data making up the shared context has to be *optimistically replicated* [1]. Consequently, the most challenging aspect of RTICAs is to ensure *eventual consistency*. That many systems developed so far are error-prone [2] or inefficient [3], highlights the severeness and importance of this consistency challenge.

Moreover, users must be able to recover from erroneous actions any user may have performed. Therefore RTICAs have to provide collaborative undo/redo features, that further complicate consistency maintenance. And since existing correct and efficient solutions for collaborative undo/redo are very limited to specific domains, consistency has to be solved independently for every non-trivial project.

To reduce complexities and efforts of this task, the generic *collaborative undoable entity-relationship-actions* (CUERA) framework is introduced. It provides a state-based solution sufficient for many RTICA projects. When better conflict resolution is needed, it can be extended to a domain specific operation-based solution. This way, developers are freed from designing a consistency solution from scratch.

But CUERA's full potential is in building the core of a data modeling, propagation and persistency platform for collaborative applications. Such an replicated model layer "out-of-the-box" would completely free developers from dealing with the intricacies of consistency maintenance: Just specify the desired data model and use derived model objects in the application's controllers and views.

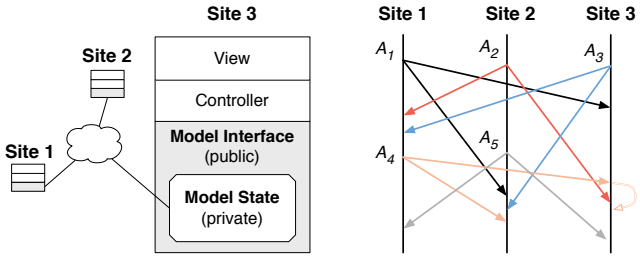

Fig. 1: Collaboration Network, Time-Space-Diagram

2. System Model and Problem Definition

2.1 Collaboration Network

The *collaboration network* is a dynamic set of *sites* S_i with equal roles. Sites can enter or leave the network at any time and any pace. Each site maintains a local *replica* of shared context data. Any local replica can be modified at any time by performing some *action* A_j. Local actions are executed immediately, assigned a unique ID_{act} and then propagated asynchronously in the network. No assumptions are made on propagation technique, time and order, but eventually all actions are received and executed at every site in the network - including late joining sites.

Each site in the network provides a graphical interface, that enables user interaction with the collaboration context. The underlying design follows the MVC pattern: The user interface elements make up the *view*, that is mediated by *controllers* to represent the current state and interaction facilities of the *model*, where replicated context data resides. Typically the view represents only a part of the model bound to the current region of interest. Moreover, the model sends *change notifications* to controllers observing this region.

In principle, the model layer is a *graph of objects*, each featuring a *private state* of encapsulated member variables and references to other objects. Based on this state, a programmatic *model interface* exposes functionality and behavior to the controllers (Figure 1). In general, all parts of this model interface, that actively update the model state, must be captured by actions propagated in the collaboration network. But since model interfaces usually provide rich and complex capabilities and are subject to regular changes, assuring consistency is a daunting task. In addition, model interfaces are highly application specific and thus cannot be generalized directly.

2.2 Consistency of RTICAs

To target consistency of user experience in RTICAs, Sun introduced the *CCI model* [4]. Its requirements depend on timings of action propagation and execution, which are commonly depicted in time-space-diagrams like Figure 1.

Causality Preservation: Users expect that semantic cause-effect-relations between actions are preserved. Since sequential timing is a necessary condition for causality, each pair of actions is determined to be either in *happened-before* ($\rightarrow$) or *concurrent* ($\|$) relation [5]. Then strict preservation of happened-before relations at all sites is sufficient to respect any potential causality. Therefore execution of an action has to be delayed, until all actions that happened-before its generation have been executed – so A_4 in Figure 1 is queued at Site 3 until A_2 from Site 2 is received and executed.

Convergence: Due to asynchronous propagation, sites can significantly differ regarding actions already executed (Figure 1) and replicas diverge temporarily. But optimistic replication assumes, that replicas converge to a consistent state, when eventually all actions are executed at all sites. But this assumption of convergence is questionable for actions that were initiated concurrently: Because they are not ordered a priori, they can and will be executed in differing sequences ($\mapsto$) (Figure 1). Since actions do *not inherently commute* in general [4], different execution orders lead to diverging states and permanent replica inconsistency. Therefore commutativity of concurrent actions has to be forced in order to achieve convergence [3].

Intention Preservation: But in order to meet intuitive expectations of users, it is not sufficient to converge to any consistent state. Rather this state has to preserve intentions of all concurrent actions [4]. The intention of an action is commonly defined as the effect of its local execution at the initiating site [4], [3]. Preserving effects of all actions is not always possible, since actions can express conflicting user intentions. As manual conflict resolution is no option in RTICAs, convergence can only be assured by coherent *automatic conflict resolution* [1]. This criterion has turned out to be quite problematic, because it is under-formalized and hard to prove [6]. Despite this criticism, intention/effect preservation has to be taken account of when designing eventually consistent RTICAs.

2.3 Undo/Redo

Supporting undo/redo is essential, even for single user applications. But research has shown that it has to be recognized as an error recovery user intention rather than a fixed system function [7]. So several undo/redo modes have been proposed, that enable users to express intentions for error recovery (Figure 2).

Meanwhile *chronological undo* has become the de facto standard, because it is powerful, yet easy to use and users can anticipate its behavior. But its simplicity also causes a major restriction: To undo an action, all subsequent actions have to be discarded as well. To overcome this limitation, *selective undo* allows users to undo/redo *any* action. But simply employing the inverse action does not always reveal the correct result for this undo mode. So achieving the correct effect is more difficult for the system and its anticipation more demanding for users.

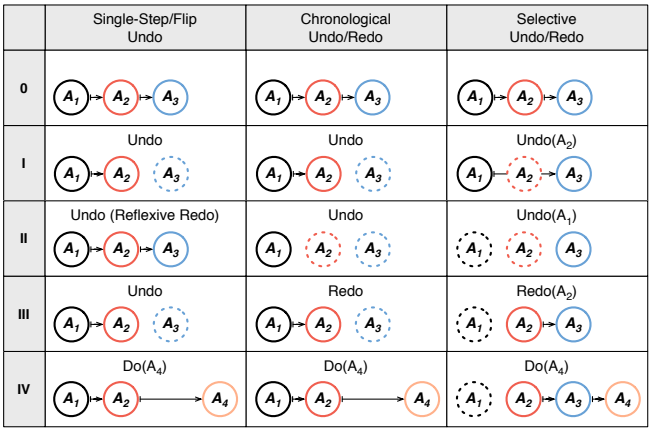

Fig. 2: Important Undo/Redo Modes

Generally, RTICAs should be compatible to features of applications, users are accustomed to [8]. But in addition, error recovery in RTICAs is of increased importance:

- Errors potentially have impact on other users' work.
- Probability of errors increases due to concurrency.
- Conflict resolution can produce unintended results.
- Fear of irreversible errors hinders explorative usage.
- Acts of vandalism are possible in open systems.

If undo/redo provides a powerful way to recover from errors caused by collaboration, it can help users managing its complexity [9]. But supporting collaborative undo/redo in a compatible way is more complex. Fortunately, undo/redo concerns can be separated into different components [8]:

A *history* component stores all actions performed in the network, including initiating site and local execution order.

The *selection* component keeps track of all information, that is needed to identify, which actions are intended to be undone/redone. The user facing details of selection depend on the current state, mode and scope (local/global) of undo/redo and are out of the focus of this paper.

The *algorithm* component has to assure, that replicated data consistently reflects the actions as specified by their undo state. Undo/redo itself underlies concurrency as well and therefore has to converge to achieve consistency. As undoing and redoing the same action is non-commutative per se, convergence control beyond actual data is needed. And even plain data convergence is influenced by undo/redo: Because concurrent actions of all users are interleaved and executed in different orders, actions may be located very differently in the history of each site. Still undoing/redoing an action has to reveal consistent data.

3. Related Work

Based on the previous section, relevant research related to the scope of this paper can be identified. Most of this is rooted in the field of collaborative text editing systems, featuring $insert$ and $delete$ operations on a linear data type. *Operational Transformation* (OT) [10] dominates research in this area and has been extended to a wide range of domains [11], [12]: Conceptually, concurrent operations are transformed against each other to let different execution orders converge. In fact, elaborating this basic idea has led to a plethora of algorithms [13], most of them failing in special situations called "puzzles" [14], [6]. Algorithms known to be correct are very complex to design in practice and computationally expensive when implemented [15], [16].

In reaction, some recent research targets convergence by commutativity of operations without transformation. In particular, Shapiro et al. [2] and Roh et al. [3] developed commutatively replicated variants of important abstract data types (Counters, Registers, Sets, Arrays and even Graphs). But none of them offers the spectrum of capabilities targeted in this paper and especially undo/redo has been neglected.

Though many OT based systems support undo/redo of any action [17][18], non-OT research on this matter is rare. Most of it is related to text editing in P2P-Wikis [19] [20]: Besides the limitation to sequential data, their counter-based undo/redo results in a user experience not suitable for realtime collaboration. The latter also holds for the XML tree editing system in [9], but XML nodes and attributes at least partly resemble the model object graph concepts identified in Section 2. Hence, some of its approaches can inspire the development of the intended CUERA framework: The history organization of operations in their respective scope and the LWW technique for attribute convergence. But most aspects of a generic data and undo/redo consistency solution are still unresolved and motivate this paper.

4. CUERA Framework

4.1 Data & Action Representation

One of the most promising and generic abstractions of data has not yet been directly considered in RTICA research. Entity-Relationship Models (ERMs) [21] formalize a domain of interest for a given project. Its constituting elements are classified into several *entity-types* (T_{ent}). Relevant properties of these elements are identified to become *attribute-types* (T_{att}). Similarly connections and dependencies of elements are represented as *relationship-types* (T_{rel}) between their corresponding entity-types, where *cardinalities* and *labels* for both directions are attached. Advanced features of ERMs are beyond the scope of this paper, but will be examined in future investigations: *Specialization/generalization* of entity-types, *aggregation/composition* of entities and inherently *ordered* relationships.

ERMs are the de facto standard in data modeling [22] and the vast majority of software projects start with some form of ERM to derive database schemas and class structures. Therefore ERMs can be assumed to be a widely applicable abstraction of common data needs. Moreover, concepts of ERMs match those of model object graphs (Section 2). Consequently, ERMs serve as the conceptual foundation for the intended collaborative data framework.

So a *replicated entity relationship graph* (RERG) data type is introduced, literally realizing an ERM: Its vertices and edges are incarnations of entity- and relationship-types. Actions on this data type are composed of an ordered set of *operations*, in order to capture user intentions involving more than one of the defined *operation-types* (Figure 3):

- $EntityOperation\ (T_{ent}, ID_{ent})$
  - $CreateEntity$
  - $DestroyEntity$
- $AttributeOperation\ (T_{att}, ID_{ent}, [Parameters])$
  - $SetAttribute\ (\ldots, Value)$
- $RelationshipOperation\ (T_{rel}, ID_{src}, ID_{dst})$
  - $AddRelationship$
  - $RemoveRelationship$

Entities are identified by unique and unambiguous ID_{ent} generated at the initiating site. In addition, entities are *non-reviving*: Once destroyed they cannot be created again. Relationships are *bidirectional* per se and unambiguousness is assured by a unique *source-destination-direction* for every type. So relationships and attributes do not need dedicated IDs, since they are identified by type and entity IDs.

In order to ensure integrity of this graph, relationships using destroyed entities are considered *invalid*. Moreover, ERM conformance implies another constraint: An entity can only be connected to a single entity for a relationship-type with singular cardinality in this direction ("To-One"). Hence such relationships are considered to be *replaced* by new relationships involving the same type and entity.

In RTICAs, these constraints have to be obeyed in face of concurrent changes. This is simplified by the RERG approach, because relationships are represented explicitly in comparison to the implicit reference representation normally used in model object graphs. Nevertheless, the familiar reference representation can be translated to and from the explicit relationship representation.

This representation of data and actions focuses on the private state underlying the model interface to the controller layer. So of any kind of interaction, only the resulting changes to the state of entities, attributes and relationships are captured. This state-based approach is the enabling factor for the generic abstraction of rich, complex and application specific model interfaces. Particularly, the amount of action-types is drastically reduced and consistency maintenance is simplified. But of course, this state-based replication also has disadvantages [1], that will be discussed in Section 5.

4.2 Convergence Control

Section 2.2 demonstrated that assuring CCI consistency is dependent on commutativity of concurrent actions. So all combinations of operation-types are analyzed for inherent commutativity in a naive implementation, that respects the aforementioned relationship invalidation and replacement. It is obvious, that concurrent actions are commutative as long as affected entities and relationships do not overlap. Within the same region of the graph, some combinations can never occur: Due to unique and non-reviving entities, strictly no action can involve an entity created concurrently. Only three of the remaining combinations do not commute inherently:

- Concurrently setting the same attribute of the same entity to different values does not commute, since the attribute always reflects the last executed operation.
- Concurrently adding and removing the same relationship does not commute, because the relationship always reflects the last executed operation.
- Concurrently adding different relationships to the same singular cardinality does not commute, because the last executed addition replaces all previous ones.

Convergence of concurrent actions, that do not commute, must be forced. This requires both a conceptual framework and a solution specific to the RERG data type. This paper makes use of the *Operation Commutativity by Precedence Transitivity* (OCbyPT) framework by Roh et al. [3], because it provides a useful guideline for the design and proof of eventually consistent systems. Conceptually, it establishes an artificial total *precedence order* of actions, that respects happened-before relations. The convergent state is then defined as the result of naively executing actions in this precedence order, thereby automatically resolving intention conflicts. Any other valid causal execution order has to reveal exactly this state by commuting actions, *as if* they were executed in precedence order. This can be achieved by keeping some metadata: Based on the knowledge of already executed actions and their precedence relations (PR) to a received action, its correct execution effect leading towards the consistent state can be inferred. Although this approach resembles serialization, *it does not restrict action execution to precedence order*.

When OCbyPT is applied to the RERG data type, it allows to utilize the simple Thomas‘ write rule (LWW - Last Writer Wins) to force convergence and resolve intention conflicts. Because of the state-based approach, only one operation is *effective* for every RERG element:

- The set-attribute with the highest precedence is effective for an attribute and defines its value.
- The addition or removal with the highest precedence is effective for a relationship and defines its existence.
- The relationship with the highest addition precedence is effective for a singular cardinality – regardless of being removed, invalidated or replaced (in "One-To-One").

To preserve semantic cause-effect-relations, precedence relations ($\rightsquigarrow$) must include and generalize happened-before relations ($\rightarrow$). So in practice, they are derived from the same distributed *clock* mechanisms needed for causality preservation anyway [3]. Thus, in addition to expressing happened-before relations, *timestamps* unambiguously order and identify actions by precedence. Although no particular technique is assumed in this paper, disadvantages related to distributed clocks in general are discussed in Section 5.

4.3 Undo/Redo Representation

The convergence control based on OCbyPT and LWW already implies the fundamental approach to undo/redo: The correct effect is defined by the result of executing only actions in precedence order, that are *active* (i.e. not undone). So it must be defined, how this state of actions is altered.

Since a closed action expressing a user intention generally involves several RERG operations, undo/redo must reflect this by restricting granularity to the action level. In addition, the same holds for undo/redo itself: Expressing an error recovery user intention generally requires to undo/redo more than one original action. And because performing undo/redo does not directly alter the RERG state, but rather the state of actions, undo/redo is represented by *meta-actions* composed of an ordered set of *meta-operations* (Figure 3):

$MetaOperation(ID_{act})$
- $UndoAction$
- $RedoAction$

Affected actions are identified by their IDs and if only original actions are targeted, undo/redo is non-reflexive: To undo an undo meta-operation, the original action has to be redone. This allows to hide the existence of meta-actions, which simplifies user experience to the state of original actions. Concurrently undoing and redoing the same action does not commute, so undo/redo convergence has to be forced as well. Thus meta-operations take part in the same LWW scheme used in RERG operations: The meta-operation with the highest precedence is effective for an action and defines its *meta-state*. Because of the many commonalities, actions and meta-actions are abstracted by *events*.

4.4 Model State Retrieval

To enable efficient model retrieval, the CUERA framework exactly reflects LWW convergence and undo/redo meta-state control at runtime. Each element references its *affecting* (meta-)operations sorted by precedence. The one with the highest precedence and active meta-state is tracked as its *effective* (meta-)operation. This *scope organization* is depicted in the *timestamp event graph* (TEG) in Figure 3.

To capture replacement at any singular cardinality, relationships additionally track their topmost preceding $AddRelationship$ operation. This allows entities to track the effective relationship at singular cardinalities. Model state retrieval is carried out based on this scope organization:

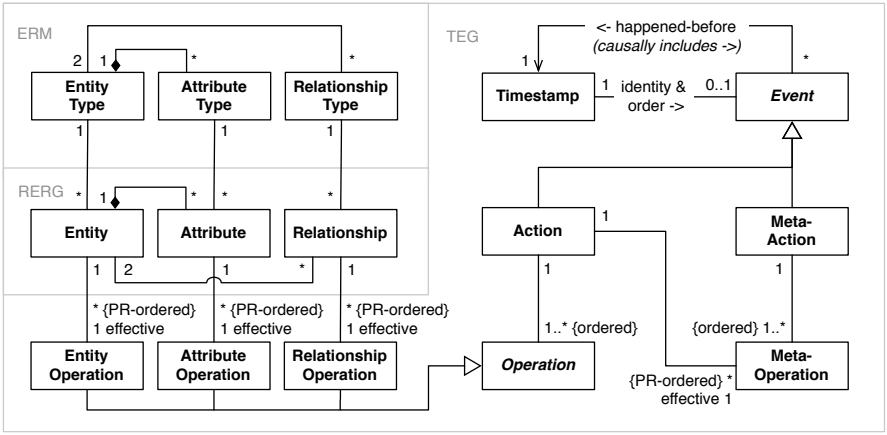

Fig. 3: CUERA Framework

- For an entity to exist, its effective operation must be of $CreateEntity$ type.
- If an attribute's surrounding entity exists, its state is defined by the effective operation's $Value$ parameter.
- To provide a familiar model interface, relationships have to be translated into a reference representation: If the entity at the origin of the retrieval exists, connected relationships of the type in question are inspected (for a singular cardinality at the origin of retrieval only the effective relationship is considered):
  - The existence of the relationship itself is checked: Its effective operation must be of $AddRelationship$ type.
  - The target entity is tested for existence.
  - In case of singular target cardinality, it is examined if the relationship is the effective one.
  - If all conditions are met, a reference to the target entity is included in the result.
- An action is only active regarding meta-state, if no $UndoAction$ operation is in effect.

4.5 Local & Remote Event Execution

Local interaction with the public model interface has to be recorded into a (meta-)action object. To assure that a local event always precedes all existing events, first the timestamps are attached to the event with the clock being incremented in between. Then the event components can be recorded:

- $Create/DestroyEntity$ operations for entities. Moreover, a fresh ID_{ent} is generated for created entities.
- $SetAttribute$ operations for attributes.
- Again, the reference representation has to be translated into relationships: From the ID_{ent} of each reference the $Add/RemoveRelationship$ operation can be build. In addition, the relationship element in the RERG has to be created if necessary.
- $Undo/RedoAction$ meta-operation for actions.

To be reflected in the private model state, each recorded (meta-)operation must be inserted into its affected elements' scope. Because of its most recent timestamp, it immediately becomes the effective operation, which in turn triggers a change notification: For example, when an $UndoAction$ meta-operation becomes effective on its affected action, the action changes to inactive meta-state. So it notifies all its contained operations, which notify their respective affected elements of becoming inactive. This process goes down the chain of dependent elements, updating the scope of each affected element and notifying all model observing controllers in the end.

Finally, the local event is encoded and propagated in the collaboration network. After reception at a remote site, the event is decoded before it can be executed. But causality constrains the execution of remote events: If happened-before relations were violated, the execution must be delayed until all these events are received and executed (Section 2.2).

When it is causally ready for execution, the remote event is integrated in the private model state representation. At first, affected elements must be retrieved or created, if they do not exist yet. Then, the same as for local events, each (meta-)operation is inserted into the scope of its affected element: Precedence of the received (meta-)operation is compared to all existing ones in this scope in top-down progression. If it becomes effective and the resulting state changes, a change notification is triggered.

4.6 Undo/Redo Selection

Any framework has to support various undo/redo selection modes, that depend on a total order of all executed actions. Thus the *perceived causal execution sequence* (pCES) is provided, that mirrors the unique history of every site by appending actions upon execution. A selection order equal for all sites is the *precedence ordered sequence* (POS), that is particular useful, since it exactly reflects convergence control and thus eases anticipation of the undo/redo effect for users.

5. Evaluation

5.1 Consistency Correctness

The CUERA framework preserves causality by delaying execution of remote events that violate happened-before relations. Convergence can be divided into two conceptual layers. The RERG and TEG representations are inherently commutative: Elements are only added and element orders are based on the globally consistent precedence definition. Thus RERG and TEG are eventually consistent. Finally, the model state is retrieved and converges by applying LWW rules theoretically backed by the OCbyPT framework.

While CUERA preserves causality and convergence, its intention preservation capabilities are limited for conceptual reasons. In general, any generic data consistency solution has to abstract application specific model interfaces. The CUERA framework accomplishes this by focusing on the model state: Syntactical results of interactions are captured, while their semantical meaning is lost. So state convergence can be achieved, whereas the full potential of conflict resolution and intention preservation cannot be tapped [1].

For example, imagine two concurrent interactions that both result in incrementing the same "counter" attribute. An application-specific solution could increment the counter twice, but the state-based RERG ignores one incrementation, since both are interpreted as setting the counter to the same value. While in this example all intentions can be preserved in theory, this is not always possible. Another interaction, e.g. resetting the counter to zero, will inherently contradict concurrent incrementations as well.

While some intentions are inherently contradicting and cannot be preserved, still a significant fraction of intentions violated by the generic RERG could be preserved by specific data types. To which extent such conflicts are caused in practice, is a really complex matter dependent on many different factors (like concurrency interval, interaction rate, number of participants, group focus, application domain, model interface, ERM design ...). If their overall probability and frequency as well as their percentage increase beyond a certain degree, the user experience is affected perceivably and becomes ineffective and distracting.

Therefore the generic state-focusing operation-types of this framework can be insufficient. In the "counter" example above, an alternative ERM design is possible: Both the counter itself and its incrementations can be refactored into connected entity-types. Using these, a "virtual" counter attribute can be derived for the public model interface.

In addition, CUERA can be enhanced with application specific operation-types. In this case, $CounterAttribute$ can be added, that accumulates effective $IncrementCounter$ operations with higher precedence than the effective $SetAttribute$. Hence CUERA still provides a valuable framework, even when the need for better conflict resolution arises.

5.2 Time Complexity

RTICA performance is dependent on time complexity regarding factors that underlie scaling. Thus model retrieval and event execution in the CUERA framework must be analyzed regarding the number of:

- sites in the network s
- events in the history $|H|$
- data elements N

Entities and actions can be retrieved in constant time using ID maps. The same holds for attributes, since they are linked to their surrounding entity. Retrieval of references involves translation of multiple relationships, entities and replacements: Still their number is independent from the above factors in practice, since only connected relationships of the type in question and their target entities are inspected. Because each element tracks its effective (meta-)operation, state retrieval performs with constant time complexity $O(1)$.

Upon execution, both local and remote events and their components are integrated in the RERG and TEG. This process involves several tasks: Element retrieval, creation and registration all perform in $O(1)$. Then (meta-)operations are inserted in the affected elements‘ scope. This is carried out in top down progression, because final locations of operations are likely to be near the top. Hence, insertion only involves precedence comparisons to operations with the same scope and higher precedence. Therefore this subset is denoted as $|h_{\rightsquigarrow}|$. In particular, it is independent from and significantly smaller than the total number of events in the history. But the amount of operations already present and of higher precedence depends on the number of sites, so $|h_{\rightsquigarrow}| \sim s$. Fortunately, distributed clock techniques allow precedence comparisons in constant time after initial computation. So insertion performs with $O(s)$.

If becoming effective, event components trigger change notification down the chain of affected elements, which is of constant size. To reflect the inserted event, each affected element has to update its current effective operation and state. This involves a number of precedence comparisons to operations in its scope, which is independent of the factors in question. So change notification performs in $O(1)$.

In summary, CUERA performs in linear time in regard to network size $O(s)$ due to precedence comparison in scope organization. As a consequence, scalability is limited in terms of participating sites. But on the other hand, performance scales perfectly in respect to data and event history, which is the benefit of operation scope organization.

5.3 Space Complexity

The CUERA framework features linear space complexity regarding events and data (including obsolete elements). In addition, events maintain timestamps and although there are efficient distributed clock mechanisms, space consumption increases with the number of sites. Thus space complexity is $O(N + s \times |H|)$.

Obviously, the space overhead in respect to the current model state is huge: Not only obsolete events in the TEG, but also unnecessary elements in the RERG must be kept to support full undo/redo of any action. But the undo/redo scope is limited in practice, since the probability of a user undoing/redoing an action rapidly decreases with its age. Furthermore, undo/redo in single user applications does not stretch beyond persisted states. How these fact can be exploited to purge the RERG and TEG is left open for future research.

6. Conclusion

To ease the development of collaborative applications, this paper has introduced the CUERA framework - a generic solution to data and undo/redo consistency. It is applicable in a wide range of domains, because data is represented in a literal realization of an entity relationship model (RERG). To provide a generic consistency solution, a set of state-focusing operation-types has been defined. In addition, non-reflexive meta-operations allow to undo/redo any action. To ensure convergence, a LWW scheme based on transitive precedence relations is employed (OCbyPT). Efficient state retrieval, event execution and notification of changes are facilitated by the precedence ordered scope organization of event components (TEG). Beyond undo selection in local execution order (pCES), the global precedence order (POS) is provided, that exactly mirrors convergence control and thus eases undo/redo effect anticipation for users.

Correctness of the CUERA framework according to CCI has been evaluated and two optimization strategies have been proposed to overcome the conceptual weakness of the generic solution regarding intention preservation. And furthermore, performance has been examined: All processes perform in $O(s)$ or better, therefore the framework does not scale well in terms of network size. But on the other hand it scales perfectly in regard to data and event history.

In summary, the CUERA framework provides a generic and efficient consistency solution for RTICAs: Developers are freed from the most complex intricacies of collaborative applications. But only if the framework is employed as the core of a distributed data platform, its full potential is unleashed: By simply specifying the desired ERM, developers can be provided with an "out-of-the-box" data layer. So the CUERA framework can potentially lead to a proliferation of realtime interactive collaboration applications.

In future research, the missing ERM features will be added to tap the full potential of this approach. Moreover, some performance experiments will be conducted to prove the scalability and efficiency claims of this paper. Finally, removal of obsolete history and data elements will be examined to reduce space overhead of unlimited undo/redo.

Increasing the Efficiency of Distributed Goal-Filling Algorithms for Self-Reconfigurable Hexagonal Metamorphic Robots

J. Bateau[1], A. Clark[1], K. McEachern[1], E. Schutze[1], and J. Walter[1]
[1]Computer Science Department, Vassar College, Poughkeepsie, NY, USA

Abstract— *The problem addressed is the distributed reconfiguration of a system of two-dimensional, hexagonal mobile robots (modules), from an initial straight chain into an arbitrary shaped, connected goal configuration that satisfies a simple admissibility condition.*

We present algorithms that improve the efficiency of the deterministic algorithms presented in [16] and [15]. In this paper, we first present a new algorithm for optimally filling a chain of cells that bisect the goal configuration. Then we present reconfiguration algorithms that combine techniques used in the goal-filling algorithm papers cited above combined with the bridging algorithms presented in [7] and [4]. We compare the performance of our new algorithms to existing goal-filling algorithms via simulation using a discrete event simulator. The results of our simulation are presented and discussed.

Keywords: Metamorphic robots, distributed reconfiguration, self-reconfiguration

1. Introduction

A *self-reconfigurable* robotic system [5] is a collection of independently controlled, mobile robots, each of which has the ability to connect, disconnect, and move around adjacent robots. *Metamorphic* robotic systems [3] are a subset of self-reconfigurable systems. In metamorphic systems, each module is identical in structure, motion constraints, and computing capabilities. The modules have a regular symmetry so that they can be assembled with no gaps between adjacent modules. In metamorphic robotic systems, robots achieve locomotion by moving over a substrate composed of one or more other robots. The mechanics of locomotion depend on the hardware and can include module deformation to crawl over neighboring modules [3], [13] or to expand and contract to slide over neighbors [14]. Alternatively, moving robots may be constrained to rigidly maintain their original shape, requiring them to roll over neighboring robots [10], [19], [20].

Shape changing in these composite systems is envisioned as a means to accomplish various tasks, such as bridge building, structural support, satellite recovery, tumor excision [13], and automated movement of two-dimensional arrays of solar collectors or shields. The complete interchangeability of the robots provides a high degree of system fault tolerance. Self-reconfiguring robotic systems may be potentially useful in environments that are not amenable to direct human observation and control (e.g., interplanetary space, undersea depths) or for tasks that are monotonous for humans.

The motion planning problem for a metamorphic robotic system is to determine a sequence of robot motions required to go from a given initial configuration (I) to a desired goal configuration (G).

Many existing motion planning strategies rely on centralized algorithms to plan and supervise the motion of the system components [3], [5], [13], [14], [18]. Others use totally distributed approaches which rely on heuristic approximations or require communication between robots in each step of the reconfiguration process [2], [10], [11], [19], [20].

We focus on a system composed of planar, hexagonal robotic modules as described by Chirikjian [3]. We present a motion planning strategy that assumes knowledge of all initial coordinates of cells in G. We start with a centralized phase in which modules match themselves to a position in G. This is followed by a distributed phase when as many robots as possible move in parallel. Our distributed approach offers the benefits of localized decision making, the potential for greater system fault tolerance, and less communication between modules than other approaches. We have previously applied this approach to the problem of reconfiguring a straight chain to an intersecting straight chain [17] and a straight chain to a goal configuration that satisfies a general "admissibility" condition [16], [15]. We modify the admissibility requirement on G in this paper.

2. Related work

Chirikjian [3] and Pamecha [13] discuss centralized algorithms for planar hexagonal modules that use the distance between all modules in I and the coordinates of each goal position to accomplish the reconfiguration of the system, moving a single module in each time step. Pamecha et al. [13] define the distance between configurations as a metric and apply this metric to system self-reconfiguration using a simulated annealing technique to drive the process towards completion. In [6], motion planning time is shown to be in $O(n)$ for n modules when particular motion

constraints are used on hexagonal metamorphic robots. They do not address the reconfiguration time as we do in this paper.

Centralized motion planning strategies for systems of two dimensional robotic modules are also examined by Nguyen et al. [12] and analysis is presented for the number of moves necessary for specific reconfigurations. A centralized motion planning strategy for three dimensional cubic robots is presented by Rus and Vona [14]. A set of distributed motion planning algorithms for a system of cubic robots is presented by Butler et al. in [2]. In another paper [1], Butler et al. present a rule set that can be run by vertical "layers" of cubic modules and a distributed control algorithm for locomotion is described that will work in any system composed of cubic modules.

Distributed approaches are taken by Murata, et al. to reconfigure a system of two dimensional hexagonal modules [10], and a system of three dimensional cubic modules [11]. Yim et al. [19] and Zhang et al. [20] present distributed algorithms to reconfigure three dimensional rhombic dodecahedral modules. In [9], Miao et al. present algorithms to reconfigure two dimensional hexagonal modules to envelop obstacles. Unlike the planning algorithms presented in this paper, these algorithms are probabilistic and require message passing between neighboring modules.

2.1 Our approach

This paper examines distributed motion planning strategies for a planar metamorphic robotic system undergoing a reconfiguration from a straight chain to a goal configuration satisfying certain simple properties. In our algorithms, robots are identical but act as independent agents making decisions based on their current position and the sensory data obtained from physical contacts with adjacent robots. We have shown that collision-free reconfiguration in certain scenarios, like those presented in our earlier papers [17], [16], [15], can be accomplished using algorithms that do not require any message passing. Our long term goal is to seek an understanding of the necessary building blocks for reconfiguration, starting with algorithms in which no algorithm messages need to be passed between participating robots during reconfiguration. Therefore, our algorithms are more communication efficient than the distributed approaches of [2], [10], [19] and [20].

Our proposed scheme uses a classification of robot types based on connected edges similar to the classification used by Murata et al. [10] for connected vertices. In the algorithms presented in this paper, each robot independently determines whether it is in a movable state based on the cell it occupies in the plane, the locations of cells in the goal configuration, and which of its sides are adjacent to occupied cells. Robots move from cell to cell and modify their states as they change position. Since the robots know the coordinates of the goal cells, we show that each of them can independently choose a motion plan that avoids module collision.

One of the contributions of this paper is the presentation of algorithms that allow modules to move with only a single space between them while also ensuring that moving modules do not come into contact in acute angle corners. To accomplish this, we use ideas developed in our earlier work on bridging algorithms [7], [4]. In these algorithms, certain modules temporarily halt during reconfiguration, forming bridges for other modules to cross. After all modules have passed over a bridge module, the bridge module resumes motion. We use a similar technique to avoid module collision in this paper.

3. System Model

The plane is partitioned into equal-sized hexagonal cells and labeled using the same coordinate system as described by Chirikjian [3].

Our model provides an abstraction of the hardware features and the interface between the hardware and the application layer.

3.1 Assumptions about modules

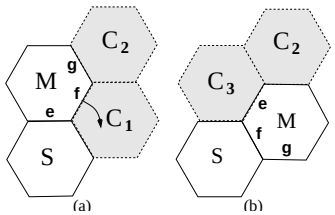

Fig. 1: Before (a) and after (b) module movement: M is moving module, S is substrate, and shaded cells are unoccupied.

- Each module is identical in computing capability and runs the same program.
- Each module is a hexagon of the same size as the cells of the plane and always occupies exactly one of the cells.
- Each module knows at all times:
  - its location (the coordinates of the cell that it currently occupies),
  - the location of the cells in G,
  - its orientation (which edge is facing in which direction), and
  - which of its neighboring cells is occupied by another module.

  Modules move according to the following rules:
  1) Modules move in lockstep rounds.
  2) In a round, a module M is capable of moving to an adjacent cell, C_1, iff (see Fig. 1 for an example)
     (a) cell C_1 is currently empty,

(b) module M has a neighbor S (called the *substrate*) that is also adjacent to cell C_1 and does not move in the round, and
(c) the neighboring cell to M on the other side of C_1 from S, C_2, is empty.

3) Only one module tries to move into a particular cell in each round.

Note that the modules may be deformable, in which case each module moves by changing joint angles to crawl over an unmoving substrate. Alternately, the modules may be rigid, using sliding movements as specified in [9] to move over the substrate.

If the algorithm does not ensure that each moving module has an immobile substrate, as specified in rule 2(b), then the results of the round are unpredictable and can lead to deadlock. Likewise, collision may result if the algorithm does not ensure rule 3.

4. Centralized Pre-processing Phase

Our objective is to design a deterministic distributed algorithm that will cause the modules to follow a collision-free plan from an initial straight chain configuration, I, to an admissible goal configuration, G. This algorithm should ensure that modules do not collide with each other, and the reconfiguration should be accomplished in the most efficient way possible (in terms of time of reconfiguration).

We assume G is oriented such that cells have flat surfaces facing north (N) and south (S). This way we can unambiguously describe the eastmost, westmost, and inner columns of G.

Definition 1: An *admissible goal configuration* is connected and has no vertical gaps within columns.

For simplicity, we require that the straight chain I consists of n modules and that it initially intersects G in one cell. The module in the cell that overlaps G does not move during reconfiguration.

In a centralized pre-processing phase, modules determine their positions in straight chain I based on their distance from the cell in I that overlaps G. Module numbering proceeds from 1 (at the greatest distance from the overlapping cell) to $n-1$ (the cell adjacent to the overlapping cell). At the start of the reconfiguration, there are $n-1$ empty cells in G.

Our previous strategy, presented in [16], to fill G while avoiding collision, was to find a contiguous path (what we call the *substrate path*, or SP) of goal cells that most evenly bisects G. After the SP cells are filled, the cells to the N and S of this path are filled in parallel, with minimal intermodule spacing. Filling the SP first guarantees that no module on the N will collide with a module on the S, allowing both segments to be filled in parallel. We designed our algorithms to further ensure that no pair of moving modules becomes adjacent throughout the reconfiguration, and for that reason, our earlier algorithms required two unoccupied spaces between each pair of modules traversing the same surface. This spacing was also applied to the modules filling the SP. Figure 2 shows the result of 2-cell versus 1-cell separation when modules move through an acute angle.

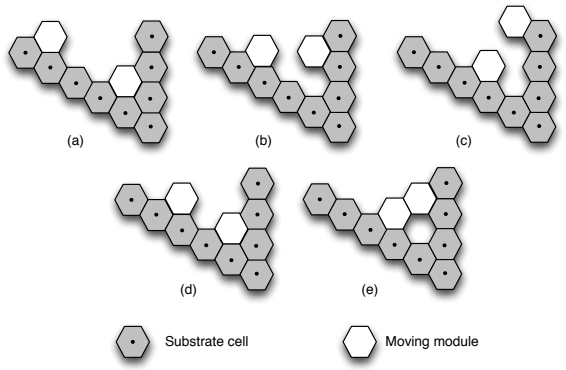

Fig. 2: Modules rotating clockwise over a substrate surface. Parts (a)-(c) show the outcome for modules with 2-cell separation. Parts (d) and (e) show how moving modules come in contact in acute angle corners if there is only 1-cell separation. In part (e), the modules are in a configuration in which the choice of substrate could jeopardize the reconfiguration if a moving module chooses another moving module as a substrate (we call this a deadlock situation).

In this paper, we place a restriction on the SP so that modules can move with a single unoccupied cell separation in both the clockwise (CW) and counter clockwise (CCW) directions.

Definition 2: An *admissible SP* is contiguous and has no vertical sections.

Our procedure for finding a SP in an admissible goal configuration is given below:

1. Find the midpoint cell in each column of the goal configuration and assign that cell to be a SP cell. If a column length is even, choose the path cell north or south (based on the distribution of cells in the next column) of where the midpoint would be if the column length was odd.
2. Check if SP found in step 1 is contiguous. If not, use algorithms presented in [16] that test every possible path in G from left to right. If any SP with no vertical segments is found, continue with reconfiguration algorithms given in this paper.
3. If the only SP found contains vertical segments, use reconfiguration algorithms described in [16] to complete reconfiguration. These algorithms use a more conservative 2 cell inter-module spacing to avoid collision and deadlock.

Since we are assuming that G is oriented in columns with cell sides normal to N and S, the slope of I (i.e., the direction from module 1 to the cell in I that overlaps

G) must be either NE or SE. If the SP has no vertical segments, there is an algorithm to fill the path using single cell spacing between each pair of moving modules. The FILLSUBSTRATEPATH algorithm is given in Fig. 4.

With one exception, to be discussed in Sect. 5, all modules in I begin moving in the round they become free, based on the cell in G to which they have been mapped. A free module is one that has one of the FREE contact patterns shown in Fig. 3. It can be seen from this figure that a FREE contact pattern is one in which a module i has at least 2 sides that are not occupied by another module and in which module i's movement (in i's local view) will not cause the system to become disconnected.

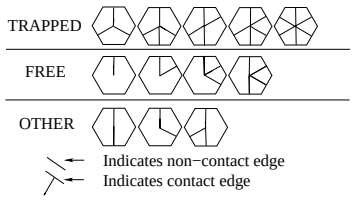

Fig. 3: Contact patterns possible in algorithm.

From Fig. 5(a) we can see that initially, the only free module in I is in position 1, furthest from G. Modules become free in order of increasing position number, with module i becoming free after the second rotation of module $i-1$.

Modules running the FILLSUBSTRATEPATH algorithm in positions i and $i+1$ (where $i \geq 1$ and $i+1 <$ length of SP) will be in the same N-S column as they move toward G. When modules move with this orientation and spacing, they are guaranteed not to collide in a contiguous SP that contains no vertical sections and that spans all columns of G. To see why, consider that exactly one of the N or S modules, x, in a moving pair of modules will always be closer, in terms of grid distance, to a particular SP cell because of the restriction on either NE or SE SP slope, and the closer modules x will therefore reach the path first.

Variables used in algorithm FILLSUBSTRATEPATH:

- *num*: Length of SP, not counting initial overlapping cell.
- *initialSlope*: Slope of I, SW to NE (called *NE* in algorithm) or NW to SE (called *SE* in algorithm).
- *lastSlope*: Slope of last two cells on SP (NE or SE).

As shown in Fig. 5, in most cases the first *num* modules fill the SP (although not always sequentially, as explained below). However, when *num* is odd and *initialSlope* $\neq$ *lastSlope*, the module in position *num*+1 reaches the SP before the module in position *num*.

Once the SP cells are calculated, the remainder of the modules are matched to positions on the N and S of the SP. Figure 5 shows the order the modules fill the SP when the length of the path is odd and the *initialSlope* $\neq$ *lastSlope*.

```
Algorithm FILLSUBSTRATEPATH()
 1. if (initialSlope == NE):
 2.       module 1 rotates CW
 3. else: // initialSlope == SE
 4.       module 1 rotates CCW
 5. if (num is even) or (lastSlope == initialSlope):
 6.       modules 2. . .num alternate directions, starting in
            direction opposite of module 1 with no delay after
            the round in which they become FREE.
 7. else: // (num is odd) and (lastSlope != initialSlope)
 8.       modules 2. . .num+1 alternate directions, starting in
            direction opposite of module 1 with no delay after
            the round in which they become FREE.
```

Fig. 4: Algorithm for modules on substrate path.

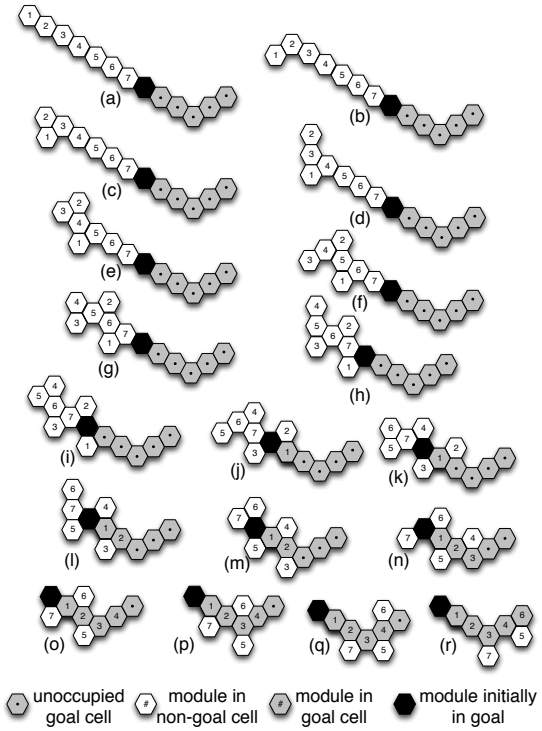

Fig. 5: Illustration of module placement when the path length is odd and *initialSlope* $\neq$ *lastSlope*. Configurations are labeled sequentially (a) through (r). Modules 5 and 7 would fill cells to the south of the SP (not shown).

To see why this algorithm works, observe in Fig. 5 how pairs of moving modules are in the same vertical column at each step. Every time the SP has a bend (which must be either to the NE or SE), the relative ordering of the module position numbers in the SP may change. So, for example, suppose the odd numbered modules start filling the path, each followed by an even numbered module. After the path bends, the even modules may begin filling the path before the odd ones.

Algorithm FILLSUBSTRATEPATH assumes the first *num* (or *num*+1) modules will be the first to enter cells on

the SP. Every obtuse bend followed by a straight chain of two or more modules in the SP changes the sequence of module positions on the path from odd/even to even/odd (and vice versa). If *num* is even, the first *num* modules will enter the path, although not necessarily in position order. If *num* is odd and the last path direction equals the initial path direction, the final module on the path (an odd numbered module) will reach the path before its even numbered counterpart.

The most complicated case is handled by lines 7–8 of FILLSUBSTRATEPATH. In this case, the final bend causes the even numbered module in position *num*+1 to reach the SP before the module in position *num*. In this case, the module in position *num* will fill a goal cell on either the N or S side of the SP (see modules 5 and 7 in Fig. 5, which will fill cells to the S).

5. Distributed Reconfiguration Phase

Each module calculates its rotation direction and delay before moving, after it determines its position in I.

Modules that will end the reconfiguration on the SP do not have to choose final goal destinations because the first module to enter a SP goal cell stops in that cell. However, the algorithm matches the remainder of the modules to goal cells on the N and S of the SP, alternating between CW and CCW rotation. Modules fill the N and S columns from right to left and from the SP northward and southward, like the algorithms presented in [15]. These modules choose their final destination from a list of goal cells that is generated by and is the same at every module.

Single-cell spacing between moving modules is the most efficient movement pattern since a module can't move into a neighboring occupied cell. However, this spacing may cause deadlock problems when the SP forms an acute angle with a goal column (see Fig. 2). To solve this problem, we use a technique like that presented in [7], [8] and [4] to either permanently or temporarily halt particular modules in areas where collision or deadlock may occur.

Each module runs a mapping algorithm in which certain goal cells are marked as WAIT-INDICATOR (WI) or STOP-INDICATOR (SI) cells. Each WI cell has an adjacent empty cell marked as a WAITCELL (WC) and each SI cell has an adjacent goal cell marked as a STOPCELL(SC). Modules mapped to SC cells choose the SC cell as their final destination. A module mapped to a WC cell temporarily halts in the WC cell when the adjacent WI cell is occupied (this only occurs once per WI per reconfiguration). The modules that temporarily stop in WC cells are matched to the extreme N or S cell in the column directly to their right. These modules temporarily stop until all cells but the extreme N or S cell in the column to the right are filled, when they resume movement.

To prevent trapping modules in WC cells, particular goal cells are marked as DELAYSET (DS). Any module mapped to a DS goal cell will delay 3 steps before it begins moving out of the initial chain after the first round in which it becomes FREE. Note that SI and WI markers are only needed when modules will collide in acute angle corners, which cannot happen if the column immediately to the right is short enough (see, for example, the 4th goal column from left side of goal configuration in Fig. 6).

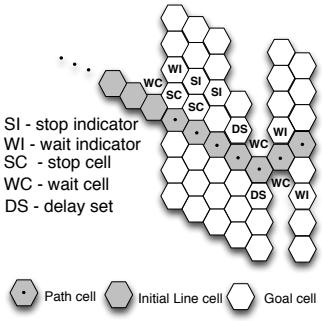

Fig. 6: Placement of markers in each module's map of G to avoid deadlock in acute angle corners.

The modules in WCs or SCs prevent moving modules from making contact in acute angle corners by filling the corner with a module, either permanently (SC) or temporarily (WC). Filling this corner cell allows the rest of the modules in the column immediately to the right to move over the corner with no deadlock.

Below we describe scenarios in which SC and WC cells are used. For the examples given in Figs. 7 and 8, we will concentrate on the columns of G on the north side of the SP (the south side is symmetric).

1) The first time a module i enters an SC in column A when there is an *occupied* adjacent SI cell in column B (as shown in Fig. 7), module i permanently stops in the SC. Column A must be non-empty in this case.
2) The first time a module i enters a WC in column A when there is an *occupied* adjacent WI cell in column B (as shown in Fig. 8), module i delays further movement until all but one goal cell in column A (the N-most cell in this case) is filled. The module in the WC then starts to move again to fill the N-most cell in column B. Column A is empty in this case. When there is a non-empty goal column to the left of empty column A with an associated WC cell, the module matched to the DS goal cell waits for 3 steps after it becomes FREE in the initial line before starting to move. Note that a goal cell may be marked as both a WI and DS.

After the proper cells are marked, each module creates a list of the goal cells, in the order they are to be filled.

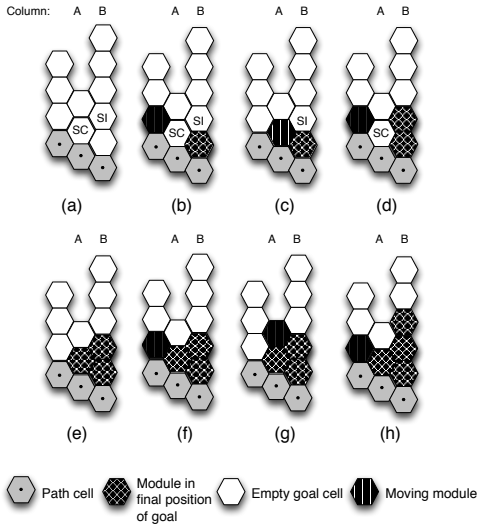

Fig. 7: Segment of N side and SP with cells marked as SI and SC. Figure (a) shows a segment of the map at each module after cells are marked initially; figures (b)–(h) show the consecutive states after modules rotating CW begin filling column B from the left in a S to N fashion. At this point, all N columns to the right of column B are filled. Once the SI cell in column B is occupied, the next module to enter the SC cell in column A stops and column B continues to be filled.

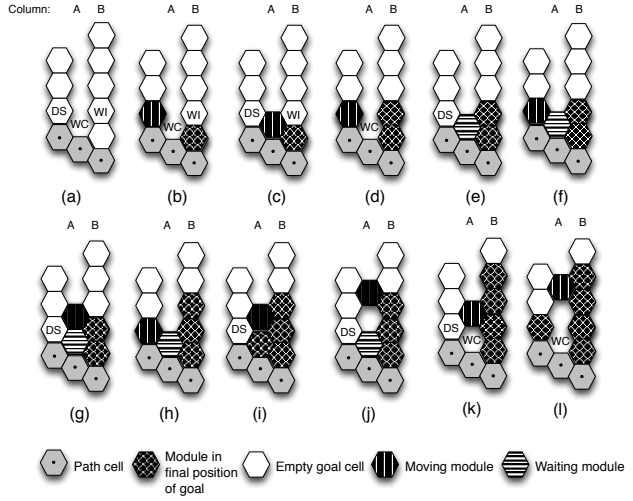

Fig. 8: Segment of N side and SP with cells marked as WI, WC, and DS. Fig. (a) shows the initial map at each module; figures (b)–(l) show the consecutive states after modules rotating CW begin filling column B from the left in a S to N fashion. At the time step shown in part (b), all N columns to the right of column B are filled. Once the WI cell in column B is occupied, the next module to enter the WC cell in column A waits until column B is filled except for the N-most cell. Then the module in the WC begins moving to the N-most cell in column B. Parts (k)–(l) show the delay between the module ending in the DS cell and the module in the WC.

Since modules know their position in I before the start of motion planning, once each module has created the list, each chooses the goal destination that corresponds to their position number. Final destinations and take-off delays are chosen prior to the distributed reconfiguration phase and the timing of temporary module halt periods are determined by each module according to its local environment during distributed reconfiguration.

6. Simulation

In this section, we briefly describe the results of running our new and old algorithms on the same configurations, both for filling the SP and for filling the rest of the goal configuration, using a discrete event simulator. The main difference between the algorithms presented in this paper and the original algorithms is the amount of inter-module spacing between moving modules. In order to avoid deadlock in acute angle corners, the original algorithm required there to be at least 2 empty spaces between moving modules. The new algorithm requires only a single space between moving modules.

We are still in the process of testing the performance of the new versus the old algorithms, but in every trial the number of rounds for the reconfiguration was lower for the new algorithms. Table 1 shows the number of rounds needed for reconfiguration on square goal configurations of increasing size (for example, see Fig. 9). For each configuration of the same size, identical SPs were used.

Table 1: Comparison of algorithms on square configurations.

Number of Modules	Number of Rounds Old	Number of Rounds New
25 (5X5)	71	53
100 (10X10)	282	222
400 (20X20)	1070	833
625 (25X25)	1616	1268

Table 2: Comparison of algorithms on comb configurations.

Number of Modules	Number of Rounds Old	Number of Rounds New
29	115	93
59	237	179
119	477	359

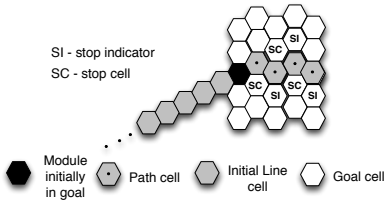

Fig. 9: Square configuration with 25 modules.

When no modules experience a temporary delay, as in the square configurations listed in Table 1, the new algorithms are more efficient than the older ones. The number of rounds used by the new algorithms remained consistent at just over twice the number of modules in the square configurations as the number of modules increased, making the running time linear in the number of modules. The number of rounds used by the old algorithms grows faster than those used by the new algorithms as the number of modules increases.

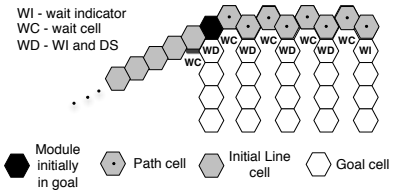

Fig. 10: Comb configuration with 29 modules. Larger combs had same length vertical columns but a longer horizontal backbone.

When some modules experience a temporary delay and the SP does not bisect the goal, as in the comb configuration shown in Fig. 10, the reconfiguration time of the new algorithms is more than double the number of modules, but is still better than the performance of the old algorithms as the number of modules increases (see Table 2).

Even though the new algorithms we present in this paper are more efficient than our previous algorithms, they do not work for as many goal configurations as do the older algorithms. Because they use the conservative two cell inter-module spacing, the older algorithms require fewer constraints on the SP. In particular, the older algorithms work as long as the SP is right-monotone. Moreover, they result in a collision and deadlock free reconfiguration even when the SP contains vertical sections, as long as the vertical sections are separated by at least 3 columns [16]. We do not feel that this difference is a major problem considering that the goal configuration can be separated into segments that end at the first vertical column in the substrate path and the new algorithms can be applied to each such segment, from right to left.

7. Conclusions and future work

We have presented algorithms for filling an arbitrary goal configuration in a column-wise fashion. These algorithms guarantee that collision and deadlock do not occur when run on an admissible goal configuration. The algorithms were shown via simulation to be more efficient (although not asymptotically so) than our older algorithms.

For future work, we are continuing to write algorithms to comprise a complete, deterministic planner for the reconfiguration of hexagonal, metamorphic robots. As part of this complete planner, we are concentrating on deterministic algorithms to reconfigure an arbitrary but admissible shape initial configuration into a straight chain.

Reducing Fragment Oscillation of Dynamic Fragment Allocation in Non-Replicated Distributed Database System

Tarun Gulyani and Pallath Paul Varghese
Pitney Bowes Software
India

Abstract— *Production and consumption of data has seen an exponential increase in recent times thus necessitating a solution which addresses the issues related to physical storage, reliability and accessing speed limits of centralized system. Distributed Database System is the solution, which overcomes these limits [1]. Designing Distributed Database System has many issues, and one of them is fragment allocation/movement. Various fragment allocation algorithms already exist in Distributed Database System. There are strengths and shortcomings of these algorithms. This paper gives the brief overview of these algorithms and proposes one new algorithm (Reduced Fragment Oscillation Algorithm). RFO algorithm moves the fragment from source node to target node by considering both the frequency of fragment access by region as well as individual nodes. It increases the overall system performance. RFO algorithm also reduces the amount of topological data required in decision making.*

1. Introduction

Distributed Database System is the Database System in which data is stored at multiple computers (node) either placed at the same physical location or spread over several geographical locations. These computers are connected to some network, via internet, intranet or extranet. Demands of Distributed databases are increasing rapidly than ever before, because it overcomes the limitations of centralized system [1]. Distributed database hides the distribution of logical and physical components of databases from users.

The prime motivation in distributed database systems are to improve performance, to increase the availability, expandability and access facility of data [8]. In Distributed database the major challenge is how to distribute the data in the best manner. If the architecture of distributed database is not perfect, then its performance will be worse in comparison to centralized database architectures.

Although distributed systems are highly desirable, the heterogeneity and lack of adherence to standards, makes it difficult to build a proper functioning system. Complexity in designing distributed database architecture is in maintaining multiple disparate systems instead of one big centralized system. Different design techniques are used to maintain the consistency in Distributed Database Architectures. Various design techniques used in Distributed Database System are replication, duplication, fragmentation, local autonomy, synchronous and asynchronous techniques etc. In case of replication technique any change in the database is replicated over all the databases stored over multiple nodes. This process is significantly time consuming and requires high network bandwidth. In duplication technique, a copy of the master database is regularly maintained in another database but it is a simple process compared to replication. In local autonomy technique, each node of distributed database can define their own policy. In asynchronous technique, a constraints of time, execution latencies and message latencies does not exist. On the other hand synchronous technique have both upper and lower bound for time constraint, execution latencies and message latencies. Depending upon the requirement for distributed databases, these technologies are used. Major concern in Distributed Database System is how to architect a good design for fragmentation of data and data allocation [2,9]. Data fragmentation as the word suggest is to distribute the data into fragments over multiple nodes either physically co-located or present at several geographical locations.

Data fragmentation technique helps increase the efficiency of data access/query performance, as it enables a mechanism to store the fragment of data at a node where it is frequently used. It increases the parallelism, because large transaction can be divided into sub transaction and all sub transaction start processing concurrently. Data fragmentation can be horizontal fragmentation, vertical fragmentation or mixed fragmentation [7]. Horizontal fragmentation can be achieved using either by range or hash fragmentation [3].

These fragmentation techniques work on static environment, in which data access pattern and/or query pattern is static. For dynamic environment, where access pattern change dynamically, static allocation decreases performance. Data fragmentation algorithms used in dynamic environment include Optimal algorithm [6], Threshold algorithm [11], NNA (Near Neighborhood Allocation) algorithm [4], BGBR algorithm [5], FNA (Fuzzy Neighborhood Allocation) algorithm [10] etc. Main objective of these algorithm is to minimize the access cost as well as data transfer cost in executing the set of queries.

A brief overview of existing algorithms is presented in the following sections and various notations/terms used in the entire paper are listed in TABLE 1.

2. Existing Algorithms

In Optimal algorithm [6], a static environment method is used to initially distribute the fragments to all nodes in the distributed network and an optimal algorithm is executed at each node. This algorithm depends highly on the frequency of access. The transfer of fragments from one node to the other is influenced by the change in frequency of access of fragments by each node. And if the frequency of access of a fragment changes frequently then there is an increase in the cost of transfer of fragment and network traffic. This would also result into significantly high oscillations of fragments between nodes. In this algorithm the access time of the fragment with highest frequency of access is significantly reduced but has a negative effect on the access time for the other nodes. The reason being the transfer of the fragment between nodes does not take the network topology into consideration.

Table 1
NOTATIONS

Node	Node is the physical locations of database, where data of distributed database stored. Each node contains multiple fragments. Number of fragments at each node can vary.
Source Node	Source node is the node, from where accessing fragment transfer to other node.
Target Node	Target node is the node, which has highest access count to fragment of source node.
Neighbor Node	Neighbor node is the node, which is in between the path of source node to target node and also nearest to source node.
Region	Group of Nodes makes Region, where each node stored data of distributed database.
Ni	Ni is known as ith Node.
F	Whole unit of database at each node is known as F, which contains more than one Fragment. F=F1 + F2 + F3...+ Fk. Value of k can vary at each node.
A	Node-Fragment Access counter matrix. Where each element a_{xy} represents, how many times fragment x access by node y.
R	Region-Fragment Access counter matrix. Where each element r_{xz} represents, how many times fragment x access by Region z.
Threshold t	Predetermined Region-Fragment access count value. Whenever Region-Fragment access count reaches to this value, fragment moves from source node.

Storage space requirement of an Optimal algorithm [6] is more as each fragment has to store the access counter value corresponding to each node. The heuristic threshold algorithm [11] addresses this drawback.

In the threshold algorithm a counter value at each fragment is initialized to 0. The counter value is incremented, whenever remote access to the fragment occurs, and its value is reset to 0 when local access to the fragment occurs. Counter value is incremented only at remote access and not at local access. When counter value of fragment exceeds the predefine threshold value, then the ownership of the fragment is transferred to the remote node that recently accessed the fragment. If the threshold value is t, then this algorithm assures that the fragment remains at the new node for at least t+1 accesses [11]. Threshold value plays a major role in this algorithm. If threshold value more, then migration of fragments at the node is less. But if threshold value is less, then migration of fragments at the node is more. Approach of this algorithm is heuristic, as the ownership of the fragment is transferred to the node which has recently accessed the fragment which may or may not be node which has highest access to the fragment. The algorithm does not use the knowledge of topology so optimal node chosen for migration may not be the globally optimal node.

Near Neighborhood Allocation (NNA) [4] algorithm is a variation of Optimal Algorithm where finding the node (say target node) to which the fragment needs to be transferred from the original node (say source node) is same as optimal algorithm. However the fragment is transferred to the nearest neighbor of the source node which is in the path between the source node and target node. Routing algorithm is used to find the nearest neighbor of the source node Here the knowledge of network topology is taken into consideration while selecting the node for transfer of fragment. NNA algorithm avoids fragment oscillation, which occur in optimal algorithm and also avoids multihop transfers. This also helps in reducing the access time from the target node. The NNA performs better than Optimal Algorithm when the size of fragment and size of network is very large. However in NNA algorithm, by moving fragment from source node to neighboring node, decreases the delay in access time for only those nodes which are in the path of between source and target nodes but for others node this may increase. If fragment access count value of the nodes, which are not in the path between target and source nodes is much more than nodes in the path then performance of system decreases. NNA algorithm avoids oscillation, so it reduces the consumption of network resources. For small fragment size, optimal algorithm is better than NNA algorithm, because cost of movement of small fragment is not more than access cost.

An improved version of NNA algorithm called FNA (Fuzzy Neighborhood Allocation) algorithm [10] is able to detect oscillation conditions and provides a solution to prevent redundant fragment migration. FNA uses a fuzzy inference engine to detect oscillations in fragment requests and ignore fragment migrations.

BGBR Algorithm [5] is an improvement on NNA algorithm. It reduces the response time and fragment migration time from source node to target node compared to NNA algorithm. BGBR algorithm requires the knowledge of the complete network topology for migrating fragment from source node to target node. It avoids fragment oscillation. Although NNA algorithm reduces oscillation by knowledge of topology but it does not use the complete knowledge of topology. In NNA algorithm for transfer of fragment from source node to neighboring node, the shortest path does not give the

assurance of best path according to global topology. BGBR performs better in both small as well as large fragment sizes however NNA performs better only when size of fragment is large. BGBR reduces fragment mobility as compared to Optimal, Threshold and NNA algorithm. BGBR algorithm shows better result, but it requires significant amount of calculations and also it requires capturing of significant amount of data about network topology.

Ulus et. al. [12] has proposed an algorithm based on Markov Chain Model where the each node autonomously decides whether to transfer the ownership of a fragment in DDS to another node or not and it depends on the past accesses of the fragment. Each fragment continuously migrates from the node where it is not accessed locally more than a certain number of past accesses, namely a threshold value.

A new dynamic fragment allocation algorithm in Non-Replicated allocation scenario proposed by Nilarun [8], incorporates access threshold time constraint of database access and most importantly the volume of data transmitted to dynamically reallocate fragments to sites at runtime in accordance with the changing access probability of nodes to fragments .

The next section discusses the proposed algorithm which addresses few drawbacks in the existing approaches of Dynamic Fragment Allocation in Non-Replicated Distributed Database System.

3. Reduced Fragment Oscillation (RFO) Algorithm

The proposed algorithm (RFO Algorithm) for dynamic allocation of data in non replicated distributed database system is designed to address the issues in the existing approaches where the movement of the fragment depends only on the node which has the highest frequency of access to a fragment. But in RFO algorithm consideration is also given to the highest fragment accessing region instead of considering the target there by reducing the access time from more than one node.

Steps of Reduced Fragment Oscillation (RFO) Algorithm are:

Step1: Group all the nodes into regions, with each region having approximately equal number of nodes subject to the constraint that the nodes are in near proximity to each other.

Figure 1 shows the layout of the regions and the access patterns of each node in the region. The steps of grouping the nodes into different regions is given below:

Step 1_a: Decide the value of m, through which whole network will divide in regions.

Step 1_b: Calculate the physical location of database in degree term by projection on map.

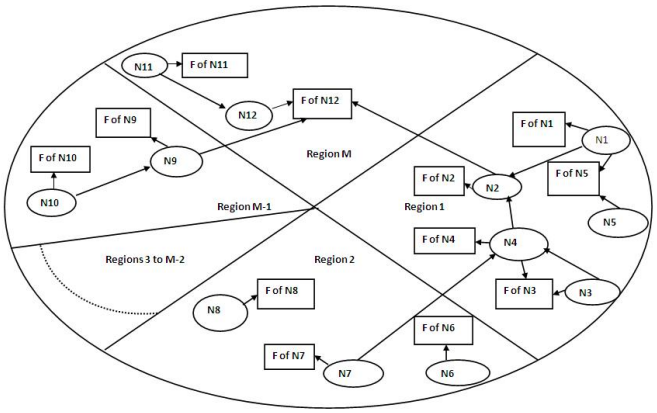

Fig. 1

DIVIDE THE WHOLE REGION OF FRAGMENT ACCESSING NODES

Step 1_c: According to value of m (Number of region), The region to which database belongs is given by: ((Degree of physical location of database / (360^0 / m)) + 1).

Number of fragments at each node can vary. Each fragment can be accessed by local node and/or global (remote) nodes. Global nodes can access the fragment at a node either directly or by more than one hop.

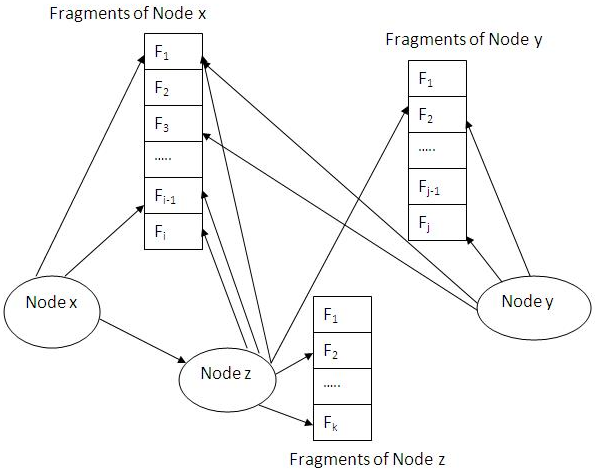

Fig. 2

FRAGMENTS INTERACTION WITH NODES.

Figure 2 shows Node x contains fragments F_1 to F_i, Node y contains F_1 to F_j and Node z contains F_1 to F_k. Number of fragments at each node can vary. Each fragment can be accessed by the local node and/or remote nodes. For example fragment F_1 of Node x is accessed locally by Node x as well as remotely accessed by Node y and Node z. A fragment can be accessed directly or indirectly by more than

one hops. Here fragment F_2 of Node y is accessed by Node x through Node z.

Step2: For each locally stored fragment initialize the Node-Fragment Access Counter matrix A as a_{xy}=0, where x is index of all fragments and y is index of all nodes.

Step3: For each locally stored fragment initialize the Region-Fragment Access Counter matrix R as r_{xz}=0, where x is index of all fragments and z is index of all regions.

Step4: Check access request for each stored fragment from both local node and remote nodes.

Step5: Fragment Access Counter matrix A, increases the access counter value for access of fragments from a node. If node y access the fragment x then a_{xy}=a_{xy}+1.

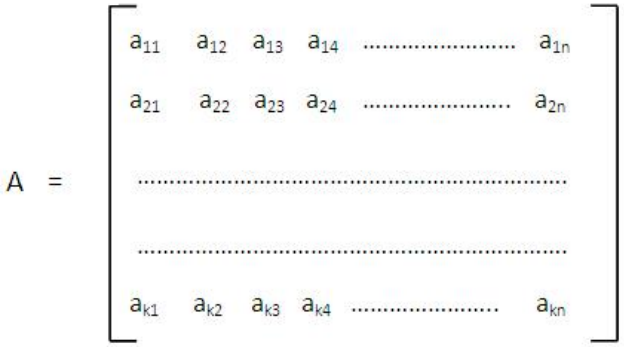

Fig. 3
NODE-FRAGMENT ACCESS COUNTER MATRIX A.

Figure 3 shows Node-Fragment Access Counter matrix A is the size of k by n, where k denote the number of fragments and n denotes the number of nodes.

Step6: Region-Fragment Access counter matrix R, increases the access counter value for accessing fragments from the regions. If region z access the fragment x then r_{xz}=r_{xz}+1.

Figure 4 shows Region-Fragment Access counter matrix R is the size of k by m, where k denotes the number of fragments and m denotes the number of regions.

Figure 5 shows Node contains local database F, which consist of more than one fragment. It contains Node-Fragments Access counter matrix A and Region-Fragment Access counter matrix R.

Step7: Migrate the fragment from source to the target in the region which has max count in R and then in that region

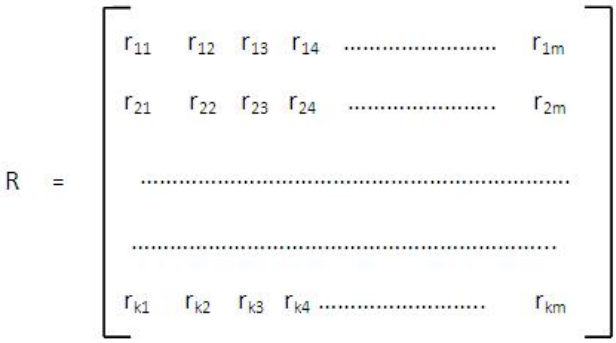

Fig. 4
REGION-FRAGMENT ACCESS COUNTER MATRIX R.

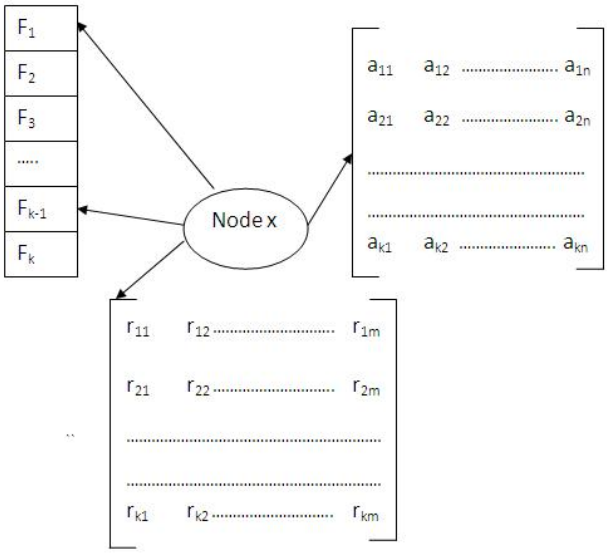

Fig. 5
INFORMATION AT EACH NODE.

move the fragment to the node in that region which has max count in A.
The algorithm only considers fragments at each node which has Region-Fragment Access counter value greater than a predefined threshold t.

Figure 6, 7 and 8 explains the process of identifying the target node for migrating the fragment.

Figure 6 shows F_k is one of the fragment of Node N13 in Region 3, which is accessed by Nodes (N1,N2,N3,N4 and N5) from Region 1,(N6,N7,N8) from Region 2, (N9,N10) from Region M-1 and (N11,N12) from Region M.

Figure-7 shows only rows of Node-Fragment and Region-Fragment Access Counter matrix of Fragment F_k according to access in Figure-6 .

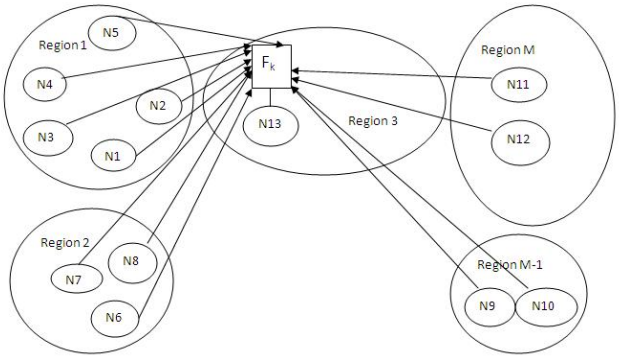

Fig. 6
FRAGMENT F_k ACCESS FROM ALL REGIONS.

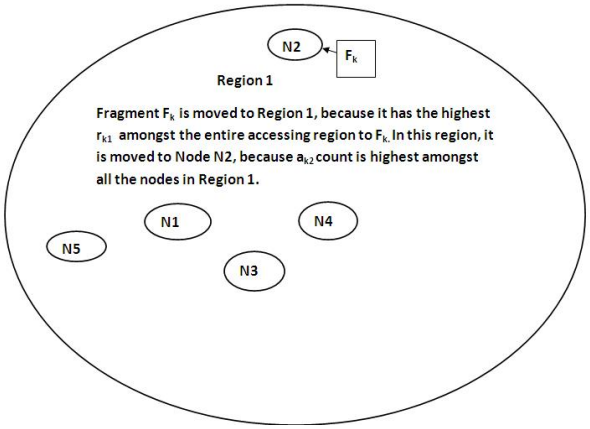

Fig. 8
FRAGMENT MOVED TO HIGHEST ACCESSING REGION.

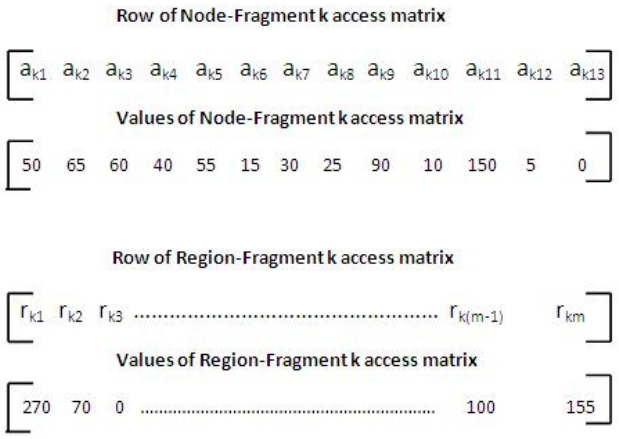

Fig. 7
ROWS OF NODE-FRAGMENT AND REGION-FRAGMENT ACCESS COUNTER MATRIX OF FRAGMENT F_k.

The Region-Fragment access count for each region is calculated. The region which has the maximum count is chosen as the region where the fragment would be moved.
Region 1 has the highest access count to Fragment F_k in comparison to other regions. Therefore Fragment F_k moved to Region 1. In Region 1 the Node-fragment access count for all the nodes is computed for the Fragment F_k.The node which has the maximum count is chosen as the target node. Therefore (in the current example Figure 8) within Region 1, Fragment F_k moved to Node N2.
If Optimal/Threshold algorithm is used instead of RFO algorithm then fragment F_k will be moved to Node N11 in Region M. Because it has the maximum Node-Fragment access count of 150, which is greater than that of all other nodes.
Transferring the Fragment F_k to Node N11 in Region M decreases the access time of node N11 for the fragment F_k, but increase the access time to all the nodes(N1,N2,N3,N4,N5) of Region 1. Resulting in decrease in total access time for the fragment F_k from Region M, which had Region-Fragment access count of 155, but increasing the access time of the fragment F_k from Region 1, which had Region-Fragment access count of 270.
RFO algorithm addresses this issue and therefore it reduces the global access time of fragment F_k by transferring the fragment F_k to node N2 instead of node N11.

4. Conclusion

Proposed algorithm decreases the migration/oscillations of fragments in comparison to optimal, and threshold algorithm using the knowledge of network topology which is not the case with both Optimal and Threshold. In comparison to NNA algorithm, RFO algorithm moves the fragment from source node to destination target node by considering both the frequency of fragment access by region as well as individual nodes, there by increasing the overall system performance. RFO algorithm also reduces the amount of topological data required in decision making in comparison to BGBR algorithm.
RFO algorithm depends on two parameters. One is the choice of threshold value which also directly impact fragment oscillation. Another parameter is division of whole network into m regions, where each region contains approximately equal nodes.
RFO Algorithm is suitable for Distributed database architectures where the access pattern to a fragment changes dynamically and distributed database is not replicated. This algorithm significantly minimizes the data transfer and also decreases the amount of complexity required in identifying a suitable target node.

Abstract—*A covering array (CA) is a combinatorial structure specified as a matrix of N rows and k columns over an alphabet on v symbols such that for each set of t columns every t-tuple of symbols is covered at least once. Given the values of t, k, and v, the optimal covering array construction problem (CAC) consists in constructing a $CA(N;t,k,v)$ with the minimum possible value of N. There are several reported methods to attend the CAC problem, among them are: direct methods, recursive methods, greedy methods, and metaheuristics methods. In this paper, three parallel approaches for simulated annealing, i.e. the independent, semi-independent and cooperative searches are applied to the CAC problem. The empirical evidence supported by statistical analysis indicate that the cooperative approach offers the best execution times and the same upper bounds than the independent and semi-independent approaches. Extensive experimentation was carried out, using 96 well-known benchmark instances, for assessing its performance with respect to the best-known bounds reported previously. The results show that cooperative approach attains 78 new bounds and equals the solutions for other 6 instances.*

Keywords: Covering Array, Simulated Annealing, Parallel Computing

1. Introduction

A covering array, denoted by $CA(N;t,k,v)$ is a matrix $\mathcal{M}$ of size $N \times k$ which takes values from the set of symbols $\{0,1,2,\ldots,v-1\}$ (called the alphabet), and every submatrix of size $N \times t$ contains each tuple of symbols of size t (or t-tuple), at least once. The value N is the number of rows of $\mathcal{M}$, k is the number of parameters, where each parameter can take v values and the interaction degree between parameters is described by the strength t. Each combination of t columns must cover all the v^t t-tuples. Given that there are $\binom{k}{t}$ sets of t columns in $\mathcal{M}$, the total number of t-tuples in $\mathcal{M}$ must be $v^t\binom{k}{t}$. When a t-tuple is missing in a specific set of t columns we will refer to it as a missing t-wise combination. Then, $\mathcal{M}$ is a covering array if the number of missing t-wise combinations is zero.

When a matrix has the minimum possible value of N to be a $CA(N;t,k,v)$, the value N is known as the Covering Array Number. The Covering Array Number is formally defined as (1):

$$CAN(t,k,v) = \min\{N : \exists\ CA(N;t,k,v)\}. \quad (1)$$

Given the values of t, k, and v, the optimal covering array construction problem (CAC) consists in constructing a $CA(N;t,k,v)$ such that the value of N is minimized.

A major application of covering arrays (CAs) arises in software interaction testing, where a covering array can be used to represent an interaction test suite as follows. In a software test we have k components or factors. Each of these has v values or levels. A test suite is an $N \times k$ array where each row is a test case. Each column represents a component and a value in the column is the particular configuration. By mapping a software test problem to a covering array of strength t we can guarantee that we have tested, at least once, all t-way combinations of component values. Thus, software testing costs can be substantially reduced by minimizing the number of test cases N in the covering array. Please observe that software interaction testing is a black-box testing technique, thus it exhibits weaknesses that should be addressed by employing white-box testing techniques. For a detailed example of the use of covering arrays in software interaction testing the reader is referred to [1].

Because of the importance of the construction of (near) optimal covering arrays, much research has been carried out in developing effective methods for construct them. There are several reported methods for constructing these combinatorial models. Among them are: direct methods [2], [3], recursive methods [4], [5], [6], greedy methods [7], [8], [9], [10], [11], and metaheuristics methods [12], [13], [14], [15], [16], [17].

In this paper, we aim to develop an improved implementation of a simulated annealing algorithm for constructing covering arrays. Simulated annealing algorithm is a general-purpose stochastic optimization technique that has proved to be an effective tool for approximating globally optimal solutions to many optimization problems. However, one of the major drawbacks of the technique is its very slow convergence. To address this drawback, we propose three parallel simulated annealing approaches to solve the

CAC problem. The objective is to find the best bounds to some ternary covering arrays by using parallelism. To our knowledge the application of parallel simulated annealing to the CAC problem has not been reported in the literature. A parallel algorithm for the verification of covering arrays is presented in [18]. The methods of parallelization of simulated annealing are discussed in [19], [20], [21], [22], [23].

Contrary to existing simulated annealing implementations [12], [13], our algorithm has the merit of improving two key features that have a great impact on its performance: an efficient heuristic to generate good quality initial solutions and a compound neighborhood function which combines two carefully designed neighborhood relations.

The remainder of this paper is organized as follows: Section 2 describes the components of our sequential annealing algorithm, in Section 3 three parallel simulated annealing approaches are discussed, Section 4 describes the experimental results, and finally, Section 5 presents the conclusions derived from the research presented in this paper.

2. Sequential simulated annealing

In this section, we briefly review simulated annealing (SA) algorithm and propose an implementation to solve the CAC problem.

SA is a randomized local search method based on the simulation of annealing of metal. The acceptance probability of a trial solution is given by (2), where T is the *temperature* of the system, $\Delta\mathcal{C}$ is the difference of the costs between the trial and the current solutions (the cost change due to the perturbation), (2) means that the trial solution is accepted by nonzero probability $e^{-\Delta\mathcal{C}/T}$ even though the solution deteriorates (*uphill move*). In this case, because the cost of the solution increases, we call this update on the solution an *uphill move*.

$$(P) = \begin{cases} 1 & if\ \Delta\mathcal{C} < 0 \\ e^{-\Delta\mathcal{C}/T} & otherwise \end{cases} \quad (2)$$

Uphill moves enable the system to escape from the local minima; without them, the system would be trapped into a local minimum. Too high of a probability for the occurrence of uphill moves, however, prevents the system from converging. In SA, the probability is controlled by temperature in such a manner that at the beginning of the procedure the temperature is sufficiently high, in which a high probability is available, and as the calculation proceeds the temperature is gradually decreased, lowering the probability [24].

In order to use the simulated annealing metaheuristic for a combinatorial optimization problem in particular, there are a number of decisions to be taken. Johnson et al. [25] classified these decisions as follows:

- *Problem-specific choices*:
  - The problem must be clearly formulated, so that the set of feasible solutions is defined.
  - The neighborhood of any solution must also be defined as well as a way of determining the value of the objective to be minimized.
  - An initial solution must also be generated.
- *Generic choices*:
  - *Initial Temperature*
  - *Cooling schedule*, a temperature function, $T(t)$, to determine how the temperature is to be changed
  - *Maximum neighboring solutions per temperature*, viz. the number of iterations, $N(t)$, to be performed at each temperature
  - *A stopping criterion to terminate the algorithm*

The following paragraphs will describe each of the components of the implementation of our SA. The description is done given the matrix representation of a covering array.

2.1 Internal representation

A covering array can be represented as a matrix M of size $N \times k$, where the columns are the parameters and the rows are the cases of the test set that is constructed. Each cell $m_{i,j}$ in the array accepts values from the set $\{1, 2, \ldots, v_j\}$ where v_j is the cardinality of the alphabet of j-th column. The size of the search space M is then given by (3):

$$|M| = v^{Nk}. \quad (3)$$

2.2 Initial solution

The *initial solution* M is constructed by generating M as a matrix with maximum Hamming distance. The Hamming distance $d(x, y)$ between two rows $x, y \in M$ is the number of elements in which they differ. Let r_i be a row of the matrix M. To generate a random matrix M of maximum Hamming distance the following steps are performed:

1) Generate the first row r_1 at random.
2) Generate s rows $c_1, c_2, \ldots, c_s$ at random, which will be candidate rows.
3) Select the candidate row c_i that maximizes the Hamming distance according to

$$g(r_i) = \sum_{s=1}^{i-1} \sum_{v=1}^{k} d(m_{s,v}, m_{i,v}),$$

$$\textbf{where } d(m_{s,v}, m_{i,v}) = \begin{cases} 1 \textbf{ if } m_{s,v} \neq m_{i,v} \\ 0 \textbf{ Otherwise} \end{cases}$$

and added to the i-th row of the matrix M.
4) Repeat from step 2 until M is completed.

An example is shown in Fig. 1. The number of symbols different between rows r_1 and c_1 are 4 and between r_2 and c_1 are 3 summing up 7. Then, the hamming distance for the candidate row c_1 is 7.

$$Rows \begin{cases} r_1 = \{\ 2 \quad 1 \quad 0 \quad 1\ \} \\ r_2 = \{\ 1 \quad 2 \quad 0 \quad 1\ \} \\ c_1 = \{\ 0 \quad 2 \quad 1 \quad 0\ \} \end{cases}$$

$$Distances \begin{cases} d(r_1, c_1) = 4 \\ d(r_2, c_1) = 3 \\ g(c_1) = 7 \end{cases}$$

Fig. 1: Example of the hamming distance between two rows r_1, r_2 that are already in the matrix $\mathcal{M}$ and a candidate row c_1.

2.3 Evaluation function

The *evaluation function* $C(M)$ is used to estimate the goodness of a candidate solution. Previously reported metaheuristic algorithms for constructing covering arrays have commonly evaluated the quality of a potential solution (covering array) as the number of combination of symbols missing in the matrix M [13], [14], [15]. Then, the expected solution will be zero missing. In the proposed SA implementation this evaluation function definition was used. Its computational complexity is equivalent to (4):

$$O\left(N\binom{k}{t}\right). \tag{4}$$

2.4 Neighborhood function

Given that SA is based on Local Search (LS) then a neighborhood function must be defined. The main objective of the neighborhood function is to identify the set of potential solutions which can be reached from the current solution in a local search (LS) algorithm. In case two or more neighborhoods present complementary characteristics, it is then possible and interesting to create more powerful compound neighborhoods. The advantage of such an approach is well documented in [26]. Following this idea, and based on the results of our preliminary experimentations, a neighborhood structure composed by two different functions is proposed for this SA algorithm implementation.

Two *neighborhood functions* were implemented to guide the local search of our SA algorithm. The neighborhood function $\mathcal{N}_1(s)$ makes a random search of a missing t-tuple, then tries by setting the j-th combination of symbols in every row of M. The neighborhood function $\mathcal{N}_2(s)$ randomly chooses a position (i, j) of the matrix M and makes all possible changes of symbol. During the search process a combination of both $\mathcal{N}_1(s)$ and $\mathcal{N}_2(s)$ neighborhood functions is employed by our SA algorithm. The former is applied with probability ρ, while the latter is employed at a $(1-\rho)$ rate. This combined neighborhood function $\mathcal{N}_3(s, x)$ is defined in (5), where x is a random number in the interval [0, 1).

$$\mathcal{N}_3(s, x) = \begin{cases} \mathcal{N}_1(s) & \text{if } x \leq \rho \\ \mathcal{N}_2(s) & \text{if } x > \rho \end{cases} \tag{5}$$

2.5 Cooling schedule

The *cooling schedule* determines the degree of uphill movement permitted during the search and is thus critical to the SA algorithm's performance. The parameters that define a cooling schedule are: an initial temperature, a final temperature or a stopping criterion, the maximum number of neighboring solutions that can be generated at each temperature, and a rule for decrementing the temperature. The literature offers a number of different cooling schedules, see for instance [19], [27]. In our SA implementation we preferred a geometrical cooling scheme mainly for its simplicity. It starts at an initial temperature T_i which is decremented at each round by a factor α using the relation shows in (6). For each temperature, the maximum number of visited neighboring solutions is L. It depends directly on the parameters (N, k, and v) of the studied covering array. This is because more moves are required for covering arrays with alphabets of greater cardinality.

$$T_k = \alpha T_{k-1} \tag{6}$$

2.6 Termination condition

The *stop criterion* for our SA is either when the current temperature reaches T_f, when it ceases to make progress, or when a valid covering array is found. In the proposed implementation a lack of progress exists if after ϕ (frozen factor) consecutive temperature decrements the best-so-far solution is not improved.

2.7 Simulated annealing pseudocode

The Algorithm 1 presents the SA heuristic as described above. The meaning of the three functions is obvious: INITIALIZE computes a start solution and initial values of the parameters T and L; GENERATE selects a solution from the neighborhood of the current solution, using the neighborhood function $\mathcal{N}_3(s, x)$; CALCULATE_CONTROL computes a new value for the parameter T (cooling schedule) and the number of consecutive temperature decrements with no improvement in the solution.

Unlike the classical method which takes as a solution to the problem, the last value obtained in the annealing chain. We memorize the best solution found during the whole annealing process (see lines 3 and 12).

In the next section, it is presented three parallel SA approaches for solving the CAC problem.

Algorithm 1 Sequential SA approach for the CAC problem.

```
1: function SA( )
2:     INITIALIZE(M, T, L)
3:     M* ← M
4:     repeat
5:         for i ← 1 to L do
6:             M_i ← GENERATE(M)
7:             ΔC ← C(M_i)-C(M)
8:             x ← random                ▷ x in the range [0,1)
9:             if ΔC < 0 or e^{-ΔC/T} > x then
10:                M ← M_i
11:                if C(M) < C(M*) then
12:                    M* ← M
13:                end if
14:            end if
15:        end for
16:        CALCULATE_CONTROL(T, φ)
17:    until stop_criterion
18: end function
```

3. Parallel simulated annealing

Parallelization is recognized like a powerful strategy to increase algorithms efficiency; however, SA parallelization is a hard task because it is essentially a sequential process.

In evaluating performance of a parallel simulated annealing (PSA), it needs to consider solution quality as well as execution speed. The execution speed may be quantified in terms of *speed-up* ($\mathcal{S}$) and *efficiency* ($\mathcal{E}$). The $\mathcal{S}$ is defined as the ratio of the execution time (on one processor) by the sequential SA to that by the PSA (on P processors) for an equivalent solution quality. In the ideal case, $\mathcal{S}$ would be equal to P. The $\mathcal{E}$ is defined as the ratio of the actual $\mathcal{S}$ to the ideal $\mathcal{S}(P)$.

Next, we propose three parallel implementations of the SA algorithm described in Section 2. For these cases, let P denote the number of processors and L the length of Markov chain.

3.1 Independent search approach

A common technique to parallelizing SA is the *independent search approach* (IS) [19], [21], [28]. In this approach each processor independently perturbs the configuration, evaluates the cost, and decides on the perturbation. The processors P_i, $i = 0, 1, \ldots, P-1$, carry out the independent annealing searches using the same initial solution and cooling schedule as in the sequential algorithm. At each temperature P_i executes $N \times k \times v^2$ annealing steps. When each processor finishes, it sends its results to processor P_0. Finally, processor P_0 chooses the final solution among the local solutions.

3.2 Semi-independent search approach

Our *semi-independent search approach* (SS) is an implementation of the *division algorithm* [19]. In the division algorithm, parallelism is obtained by dividing the effort of generating a Markov chain over the available processors. A Markov chain is divided into P sub-chains of the length $\lfloor L/P \rfloor$. In this approach, the processors exchange local information including intermediate solutions and their costs. Then, each processor restarts from the best intermediate ones.

Compared to the IS, communication overhead in this SS approach would be increased. However, each processor can utilize the information from other processors such that the decrease in computations and idle times can be greater than the increase in communication overhead. For instance, a certain processor which is trapped in an inferior solution can recognize its state by comparing it with others and may accelerate the annealing procedure. That is, processors may collectively converge to a better solution.

3.3 Cooperative search approach

In order to improve the performance of the SS approach, we propose the *cooperative search approach* (CS), it used asynchronous communication among processors accessing the global state to eliminate the idle times. Each processor follows a separate search path, accesses the global state which consists of the current best solution and its cost whenever it finished a Markov subchain and updates the state if necessary. Once a processor gets the global state, it proceeds to the next Markov subchain with any delay.

Unlike SS, CS having the following characteristics:

- Idle times can be reduced since asynchronous communications overlap a part of the computation.
- Less communication overhead, an isolated access to the global state is needed by each processor at the end of each Markov subchain.
- The probability of being trapped in a local optimum can be smaller. This is because not all the processors start from the same state in each Markov subchain.

4. Experimental results

This section presents an experimental design and results derived from testing the parallel IS, SS, and CS algorithms described in Section 3. In order to show the performance of these approaches, two experiments were developed. The first experiment had as purpose to compare the three approaches in terms of parallel execution time. Among the three approaches, the CS approach was the fastest. The second experiment evaluated the quality solutions of CS approach over a new benchmark proposed in this paper. The results were compared against the best-known solutions reported in the literature [29] to construct covering arrays. The three parallel approaches were implemented using C

language and the message passing interface (MPI) library. The implementations were run on the *Tirant supercomputer*[1]. Tirant comprises 256 JS20 compute nodes (blades) and 5 p515 servers. Every blade has two IBM Power4 processors at 2.0 GHz running Linux operating system with 4 GB of memory RAM and 36 GB of local disk storage. All the servers provide a total of nearly 10 TB of disk storage accessible from every blade through GPFS (Global Parallel File System). Tirant has in total 512 processors, 1 TB of memory RAM and 19 TB of disk storage. The networks that interconnect the Tirant are:

1) Myrinet Network: High bandwidth network used by parallel applications communications.
2) Gigabit Network: Ethernet network used by the blades to mount remotely their root file system from the servers and the network over which GPFS works.

The following parameters were used for all SA implementations:

1) Initial temperature $T_i = 4.0$
2) Final temperature $T_f = 1.0E-10$
3) Cooling factor $\alpha = 0.99$
4) Maximum neighboring solutions per temperature $L = N \times k \times v^2$
5) Frozen factor $\phi = 11$
6) The neighborhood functions $\mathcal{N}_1$ and $\mathcal{N}_2$ are applied with a probability of $p_1 = 0.3$ and $p_2 = 0.7$ respectively.

4.1 Comparison of algorithms

To test the performance of the IS, SS, and CS approaches, we propose the construction of a covering array with $N = 80$, $t = 3$, $k = 22$, and $v = 3$. Each approach was executed 31 times (for provide statistical validity to experiment) using $P = \{4, 8, 16, 32\}$.

The performance of the algorithms has been compared based on median speed-up as a function of the number of processors, the results are shown in Fig. 2.

The IS approach, had difficulty in handling the large problem instances, it does not scale. The SS approach provides reasonable results, however, because it is a synchronous algorithm, the idle and communication times are inevitable. The CS approach is who offers the best results, it reduces the execution time of the SS approach by employing asynchronous information exchange.

In the next subsection, it is presented the second experiment of this work, the purpose is to measure the performance of the CS algorithm against the best-known solutions reported in the literature.

[1]The Tirant supercomputer: http://www.uv.es/siuv/cas/zcalculo/res/informa.wiki

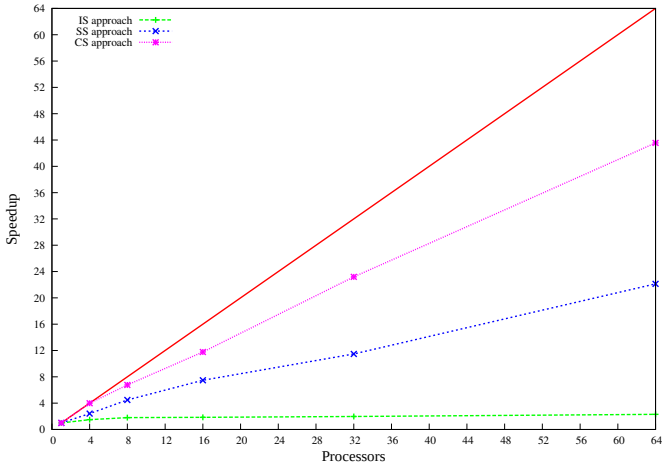

Fig. 2: Median speed-up as a function of the number of processors for the IS, SS, and CS approaches.

4.2 The cooperative search approach against the state-of-the-art procedures

The purpose of this experiment is to carry out a performance comparison of the bounds achieved by the CS approach with respect to the best-known solutions reported in the literature [29], which were produced using the following state-of-the-art procedures: orthogonal array construction, Roux type constructions, doubling constructions, algebraic constructions, Deterministic Density Algorithm (DDA), Tabu Search and IPOG-F.

For this experiment we have fixed the maximum computational time expended by our PSA for constructing a covering array to 72 hours and 50 processors. We create a new benchmark composed by 96 covering arrays with strength $t = 4$, degree $5 \leq k \leq 100$, and order $v = 3$. The detailed results produced by this experiment are listed in Table 1. The first two columns in this table indicate the strength t and the degree k of the selected instances. Next two columns show, in terms of the size N of the covering arrays, the best-known solution reported in the literature and the improved bounds produced by the CS.

The analysis of the data presented in the Table 1 lead us to the following observation. The solutions quality attained by the CS approach is very competitive with respect to that produced by the state-of-the-art procedures summarized in column 3 (ϑ). In fact, it is able to improve on 78 previous best-known solutions.

5. Conclusions

The long execution time of SA due to its sequential nature hinders its application to realistically sized problems, in this case, the CAC problem when $t > 3$, $5 \leq k \leq 100$, and $v = 3$. A more efficient way to reduce execution time and make the SA a more promising method is to parallelize

Table 1: Improved bounds on $CAN(4,k,3)$ for strength 4 and degrees $5 \leq k \leq 100$ produced by our PSA. ϑ represents the best-known solution reported in the literature [29]. β represents the best solution in terms of N produced by our PSA. Last column depicts the difference between the best result produced by our PSA and the best-known solution ($\Delta = \beta - \vartheta$).

sequential SA. It is a challenging task. In fact, there are many approaches that may be considered in parallelizing SA. However, an inappropriate strategy used will likely result in poor performance.

In this paper, we have used three different approaches to do this work. From the experimental results, we found that the IS approach is the worst performing option, it does not scale. The SS approach offers reasonable execution times; compared to the IS, communication overhead in the SS approach would be increased. However, each processor can utilize the information from other processors such that the decrease in computations and idle times can be greater than the increase in communication overhead. For instance, a certain processor which is trapped in an inferior solution can recognize its state by comparing it with others and may accelerate the annealing procedure. That is, processors may collectively converge to a better solution. The CS approach is who offers the best results, it significantly reduces the execution time of the SS approach by employing asynchronous information exchange.

The quality of the solutions attained by the CS approach is very competitive with respect to that produced by the state-of-the-art procedures, in fact, it is able to improve on 78 previous best-known solutions and equals the solutions for other 7 instances.

Finally, the covering arrays are available in CINVESTAV Covering Array Repository (CAR), which is available under request at `http://www.tamps.cinvestav.mx/~jtj/CA.php`. We have verified all covering arrays described in this paper using the tool presented in [30].

Acknowledgments

The authors thankfully acknowledge the computer resources and assistance provided by Spanish Supercomputing Network (TIRANT-UV). Exact and Approximate Median Splitting on Distributed Memory Machines

Matthieu Garrigues and Antoine Manzanera
UEI, ENSTA-ParisTech, Paris, France

Abstract— *We present in this paper a new fine grained median split algorithm which places the median on the middle index of an input array of size N. Running on P processors, the randomized version converges in $O\left(\frac{N}{P} \times (log(N) + \mu)\right)$ average time where $0 < P < \frac{N}{4}$ and μ is the time to swap a pair of elements between two nodes. At each iteration, the nodes process only its local elements and exchange part of them with another processor of the network. This makes it a decentralized parallel algorithm and offers the possibility to take advantage of massively parallel computing networks based on distributed memory systems.*

Keywords: median splitting, parallel algorithms, distributed memory machines

1. Introduction

Useful in many fields like statistics or signal processing median selection has been widely used in computer science in the last decades. Given a set of N elements from a totally ordered space, it consists in picking the element that is superior and inferior to the same number of elements. A expensive way of solving the problem would be to sort the whole input so that the median index is $\lceil \frac{N}{2} \rceil$.

Several non parallel algorithms exist. Given a pivot value p, quickSelect [1] splits the input array in two parts, places inferior elements before p and superior elements after, then recursively processes the part that contains the median. In average, it divides the problem size by a factor two after each iteration. Its average run-time is in $O(N)$ but at worst in $O(N^2)$. Median of median [1] provides a method for choosing a pivot that ensures that the run-time stays in $O(N)$ but is less efficient in practice. [2] is a randomized algorithm that successively estimates an interval that contains the median value.

Many works present algorithms that efficiently run on different PRAM models. [3] shows how median selection can map on coarse-grained computers, when the input size is an order of magnitude higher than the number of processors. It presents and benchmarks parallel implementations of [1] and [2] on the connection machine 5 (CM-5). In theses approaches, which reduce the number of elements to process after each iterations, load balancing is needed in order to feed all processors at any iteration. Randomized parallel algorithms in [4] and [5] require $O(loglog(N))$ steps for convergence. In [6], the author presents some fine grained and real-time hardware implementation of median filtering.

In this paper, we present a new fine grained distributed median randomized algorithm. In opposition to the state of the art algorithms, it is efficient on networks (See Fig. 2) containing $O(N)$ (up to $\frac{N}{4} - 1$) processing units running in parallel. Its average observed run-time is $O\left(\frac{N}{P} \times (log(N) + \mu)\right)$ where N is the input size, P the number of processors and μ the time required to swap 2 elements between two nodes. This paper is organized as follows: We first introduce the basic operators used as building blocks. Then, we present three algorithms in their sequential form, from the simpler to the most efficient one. Finally, we discuss about the parallel aspects of the final method in Sect. 5 and its convergence in Sect. 6.

2. Primitives and Notations

Let A be an array of elements drawn from some totally ordered set. $\forall i \in \{0, N-1\}, A[i]$ represents the ith element of the array.

The algorithms presented in this paper make use of the following primitives:

- $reorder(A, i, j)$ (and by extension $reorder(A, i, j, k)$) reorders the ith and jth (resp. the ith, jth, and kth) elements of A, such that $A[i] \leq A[j]$ (resp. $A[i] \leq A[j] \leq A[k]$) after the call.
- $select_{\min}(A, i, j, k)$ (resp. $select_{\max}(A, i, j, k)$) exchanges, if smaller (resp. greater), $A[i]$ with $\min(A[j], A[k])$ (resp. $\max(A[j], A[k])$).

Each instance of these operations is said *effective* and returns true if it actually modifies the input array. If not, it returns false.

3. Swap on Tree

In this section we present the basic version of our algorithm: the principle is to map the input vector A onto a binary tree, reorganizing the data such that the left half subtree is a inf-semilattice, the right half subtree is a sup-semilattice, and the median is on the root. See Fig. 1 for a graphical representation, showing the left (resp. right) part of the tree under (resp. over) the root.

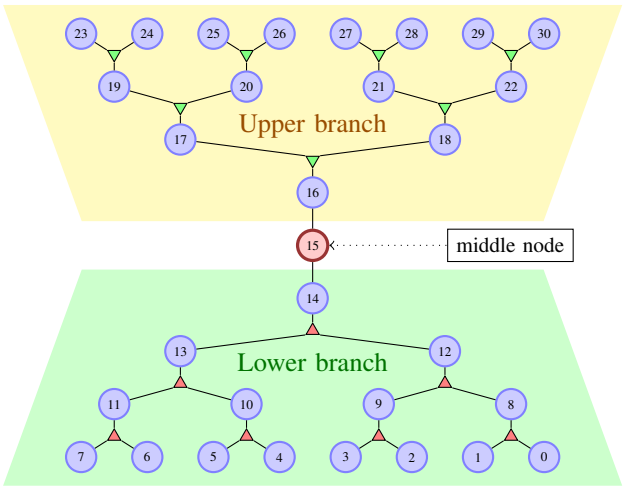

Fig. 1: A vector of 31 elements mapped on a binary tree made of an inf-semilattice (upper branch), a sup-semilattice (lower branch) and a middle node (median). Each node is labelled with its position in the array. The triangles represent the $select_{\min}$ and $select_{\max}$ operators.

The algorithm updates the input A using $select_{\min}$ (in the upper branch), $select_{\max}$ (in the lower branch), and $reorder$ (at the middle node). For simplicity we suppose that dimension $N = 2^k - 1, k > 1$.

Listing 1: Algorithm swap on tree

```
1 middle = (N-1)/2
2 repeat {
3   for (i = (middle - 1)/2; i ≥ 1; i--)
4     //lower branch
5     selectmax(A, middle-i, middle-2i, middle
          -2i-1)
6     //upper branch
7     selectmin(A, middle+i, middle+2i, middle
          +2i+1)
8   endfor
9   //middle node
10  eff = reorder(A, middle-1, middle, middle
        +1)
11 } until not eff
```

a) Complexity Analysis: Every iteration exchanges the greatest element of the lower branch with the smallest of the upper branch. Convergence occurs as soon as the *reorder* instruction (line 10) becomes uneffective, which takes at most $N/2$ iterations.

Considering the binary tree, the inputs of even levels are the output of odd levels (and *vice versa*). Then, half the tree can be processed in parallel, using $N/4$ concurrent tasks. However the number of iterations remains in $O(N)$, then the run time is $O\left(\frac{N^2}{P}\right)$ using P processors. The poor efficiency of this basic version comes from the fact that all the elements that are not placed in the good half of the array (at most $N/2$ in every half) will have to pass through the middle node, because only one element can travel from the upper branch to the lower branch at each iteration. We address this bottleneck issue in the next section.

4. Swap Inter Branches

We describe here an algorithm that improves the *connectivity* between the lower and upper branches by providing shortcuts to travel from one branch to the other.

Keeping the instructions of the *swap on tree* version, we also reorder each node of the lower branch with its counterpart in the upper branch; more precisely, $\forall i \in [0, \lfloor N/2 \rfloor - 1]$, $A[i]$ and $A[N - i - 1]$ are reordered. In a nutshell, the $select$ operators guarantees the convergence, whereas $reorder$ works as a catalyst.

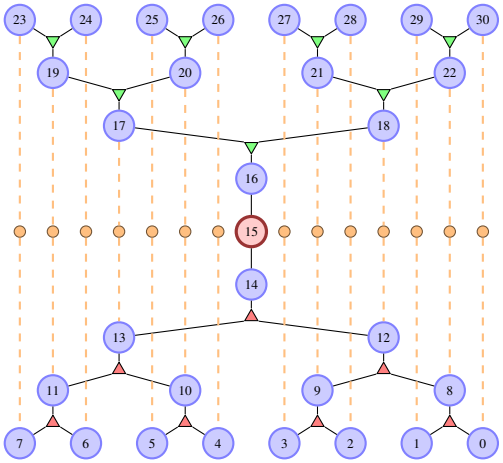

Fig. 2: Binary tree drawn on a vector of 31 elements. The circles and dashed lines show the additional $reorder$ operators of the algorithm *swap inter branches*. Each node is labelled with its position in the array.

Note that elements in the upper branch are only reordered with elements of the same level in the lower branch. The method takes advantage of the fact that at iteration i the probability of an element in the level l to be in the wrong branch is higher if l is close to the middle node. This property becomes stronger when i increases.

a) Complexity Analysis: This version keeps the high potential of parallelism, since all the instructions in the *swap inter branches* loop can be executed concurrently on $N/2$ processors.

After one iteration of *swap inter branches* instructions (line 4), there remain at most $N/4$ misplaced elements in every branch (otherwise it would mean that $k > N/4$

Listing 2: Algorithm swap inter branches

```
1 middle = (N-1)/2
2 repeat {
3   for (i = 0; i < middle; i++)//swap inter
        branches
4     reorder(A,i,N-i-1)
5   endfor
6   for (i = (middle - 1)/2; i ≥ 1; i--)
7     //lower branch
8     selectmax(A, middle-i, middle-2i, middle
          -2i-1)

9     //upper branch
10    selectmin(A, middle+i, middle+2i, middle
          +2i+1)

11  endfor
12  //middle node
13  eff = reorder(A, middle-1, middle, middle
        +1)
14 } until not eff
```

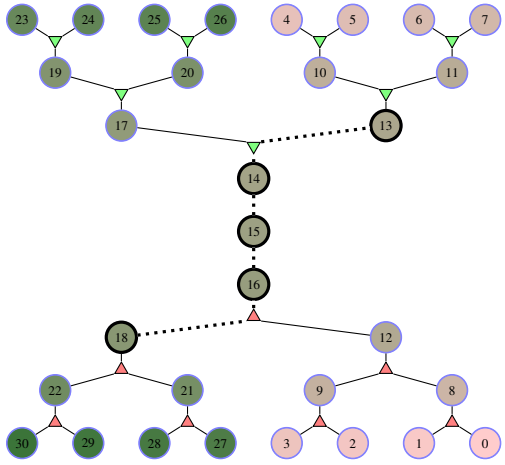

Fig. 3: Worst case for *swap inter branches*. the label and the color of a node represent the ranks of the value that it stores. The bottleneck is highlighted in dashed black.

elements smaller than the median are smaller than k other elements in the other branch and then there would be $2k > N/2$ elements smaller than the median, which is absurd). Unfortunately, the number of iterations is still $N/4$ in the worst case (see Fig. 3), so only two times faster than the *swap on tree* version. It turns out that this version still suffers from a bottleneck: in the *swap inter branches* instructions, every node is always reordered with its vertical counterpart in the other branch. Then, if some elements belonging to two diagonally opposed quarters of the tree need to be compared (like in Fig. 3), they still have to go through the middle node. Furthermore, the $select_{\min}$ and $select_{\max}$ operations (lines 8 and 10) often perform the same comparisons, since many elements do not move during one iteration (this is especially true during the last iterations). Finally, a lot of operations are not effective. In the next section we present the final version of the algorithm, adding horizontal motion at each level to improve the data mobility.

5. Final Algorithm

This section presents our final algorithm, which improves the previous version by changing at every iteration the counterpart of every node, thanks to index shifting at each level of the tree. The purpose is to minimize the bottleneck effect by allowing diagonal motion in the *swap inter branches* instructions, and to maximize the efficiency of the $select_{\min}$ and $select_{\max}$ operations, by a constant renewal of the data caused by the horizontal motion (see Fig. 4). These improvements allow to converge in $O(log(N))$ steps instead of $O(N)$ with the previous algorithm. We present the sequential version (List. 3), where RANDOM(N) is a random integer between 0 and N-1, and MOD(p,n) is the remainder of the Euclidean division of p by n, and then discuss about parallelization.

Listing 3: Final algorithm, sequential form

```
1 middle = (N-1)/2
2 repeat {
3   eff = false
4   //size of the leaf level
5   Lsize = (N+1)/4
6   //first index of the leaf level (lower
        branch)
7   Plow = Lsize-1
8   //first index of the leaf level (upper
        branch)
9   Pupp = N-Lsize
10  //shift offset of the leaf level (lower
        branch)
11  Olow_son = RANDOM(Lsize)
12  //shift offset of the leaf level (upper
        branch)
13  Oupp_son = RANDOM(Lsize)
14
15  repeat {//Processing of one level
16    Olow_dad = RANDOM(Lsize/2)
17    Oupp_dad = RANDOM(Lsize/2)
18    for (k = 0; k < Lsize/2; k++)
19      Ilow_dad = Plow + Lsize/2
20                 - MOD(k + Olow_dad, Lsize/2)
21      Iupp_dad = Pupp - Lsize/2
22                 + MOD(k + Oupp_dad, Lsize/2)
23      Ilow_child1 = Plow - MOD(2k + Olow_son,
            Lsize)
24      Ilow_child2 = Plow
25                    - MOD(2k + 1 + Olow_son,
                          Lsize)
26      Iupp_child1 = Pupp + MOD(2k + Oupp_son,
            Lsize)
27      Iupp_child2 = Pupp
28                    + MOD(2k + 1 + Oupp_son,
                          Lsize)
29      //lower branch
```

```
30        selectmax(A, Ilow_dad, Ilow_child1,
              Ilow_child2)
31        //upper branch
32        selectmin(A, Iupp_dad, Iupp_child1,
              Iupp_child2)
33        //swap inter branches
34        eff = eff || reorder(A, Ilow_dad,
              Iupp_dad)

35      endfor
36      Plow = Plow + Lsize/2
37      Pupp = Pupp - Lsize/2
38      Olow_son = Olow_dad
39      Oupp_son = Oupp_dad
40      Lsize = Lsize/2
41    } until (Lsize == 1)
42    //middle node
43    reorder(A, middle - 1, middle, middle + 1)
44  } until not eff
```

At each iteration, we scan the nodes from the leaves to the middle node using $reorder$, $select_{\max}$ and $select_{\min}$. A $select$ operation rearranges one element of a pair of nodes at level l with its parent node at level $l-1$. But, unlike *swap inter branches*, relations between levels are shifted with a random offset drawn before each iteration. Figure 4 shows the resulting relations. Arguments of $reorder$ are affected using the same method.

a) Convergence detection: The variable eff tracks whether during one iteration a $reorder$ between branches has been effective (see line 34 of listing 3). If not, we can ensure that the median is on the middle node.

b) Parallelization: At a given time, one iteration reads and writes two opposite children branch levels, and two opposite father branch levels. Since each iteration processes nodes from the leaves to the middle of the tree, we can pipeline the iterations without breaking write/read dependencies. Thus, using a pipeline of $log_2(N)/2$ stages, as many iterations can run in parallel (see Fig. 5).

c) Complexity Analysis: If we suppose that the random number generator used to compute offset always returns 0, the algorithm is equivalent to *swap and shift*. In this case, the number of iterations in the worst case is still $N/4$. Section 6 shows that this algorithm takes in average $2 \times log_2(N)$ pipeline steps to converge. Using P processors, one pipeline step runs in time $O(\frac{N}{P})$. This gives an average time complexity of $O\left(log(N) \times \frac{N}{P}\right)$. Figure 6 compares the convergence of the three presented algorithms.

6. Convergence

Let us consider the input array being re-arranged at a certain step of the algorithm. We define the event e as follows: an element drawn at random from the array is misplaced (i.e. inferior (resp. superior) to the median and located in the upper (resp. lower) branch). In this section we model the evolution of the probability $P(e)$ over the pipeline steps. First, we analyze how $P(e)$ is affected by the operators $select_{\min}$, $select_{\max}$ and $reorder$. Then we observe the average number of pipeline steps needed to place all elements.

Let a and b be two consecutive levels, a carrying the parents of nodes on level b. The event e_x (resp. f_x) occurs

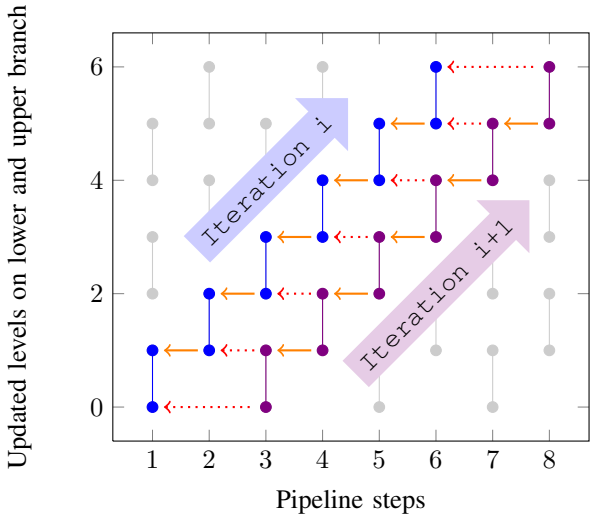

Fig. 5: Dependencies between steps of two iterations. Plain arrows show dependencies between the steps of one iteration, dependencies between iterations are dotted.

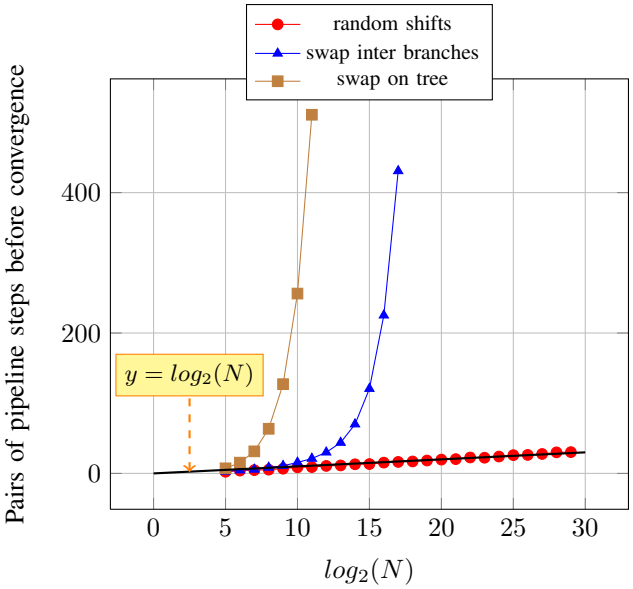

Fig. 6: Average pairs of pipeline steps before convergence on different algorithms. Means of 100 executions on random inputs.

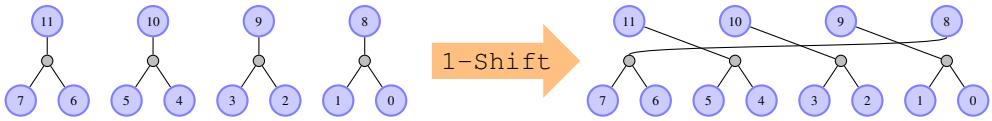

Fig. 4: Example of index shifting using an offset of size 1. Unmodified (left) and shifted (right) relations between two levels. *select* operators are shown in gray. Each nodes is labeled with its position in the array.

when an element is misplaced on level x before (resp. after) the *select* operation. On each branch, level 0 contains the root and level l contains the parents of level $l+1$. Given $p_x = P(e_x)$, we search S_p and S_l such that:

$$\begin{cases} P(f_a) & = S_p(p_a, p_b) \\ P(f_b) & = S_l(p_a, p_b) \end{cases}$$

Figure 7 shows all the possible configurations for the three operators.

$$\begin{aligned} S_p(p_a, p_b) &= \sum_{i=1}^{8} P(f_a|K_i) \times P(K_i) \\ &= 1 - P(\overline{f_a}|K_1) \times (1-p_a) \times (1-p_b)^2 \\ &= 1 - (1-p_a) \times (1-p_b)^2 \end{aligned}$$

$$\begin{aligned} S_l(p_a, p_b) &= \sum_{i=1}^{8} P(f_b|K_i) \times P(K_i) \\ &= P(f_b|K_4) \times (1-p_a) \times p_b^2 + P(f_b|K_6) \times \\ &\quad p_a \times (1-p_b) \times p_b + P(f_b|K_8) \times p_a \times p_b^2 \\ &= \frac{(1-p_a) \times p_b^2}{2} + p_a \times (1-p_b) \times p_b + p_a \times p_b^2 \\ &= p_b \times \left(\frac{p_b \times (1-p_a)}{2} + p_a \right) \end{aligned}$$

Using the same method, we model how *reorder* affects $P(e)$ on level l of lower and upper branches. The event e (resp. f) occurs when an element is misplaced on level l before (resp. after) the operation. The probability of e is noted $p = P(e)$. R defines the relation between p and $P(f)$: $P(f) = R(p)$.

$$\begin{aligned} R(p) &= \sum_{i=1}^{4} P(f|L_i) \times P(L_i) \\ &= P(f|L_1) \times (1-p)^2 + \\ &\quad \big(P(f|L_2) + P(f|L_3)\big) \times p \times (1-p) + P(f|L_4) \times p^2 \\ &= (1-p) \times p \end{aligned}$$

Let e_l^s denote the following event: an element of level l is misplaced after running the step s. It occurs with a probability $P_l^s = P(e_l^s)$. Knowing that a step is a *select* followed by a *reorder* we can build P_l^s by recurrence on s:

$$P_l^s = \begin{cases} R(S_p(P_l^{s-1}, P_{l+1}^{s-1})) & \text{if} \quad l \bmod 2 = s \bmod 2 \\ S_l(P_{l-1}^{s-1}, P_l^{s-1}) & \text{otherwise} \end{cases}$$

P_l^0 is given by the distribution of the input array. In case of all orderings of the input are equally likely, we have: $\forall l,\ P_l^0 = \frac{1}{2}$. On the root and leaf levels of each branch, the previous formula is undefined every two pipeline steps. In this special case, we have $P_l^s = P_l^{s-1}$. Figure 8 draws the convergence of P_l^s and the probability P^s that an element of the input is misplaced after step s:

$$P^s = \sum_{i=1}^{log_2(N+1)-1} \frac{2^i \times P_l^s}{N}$$

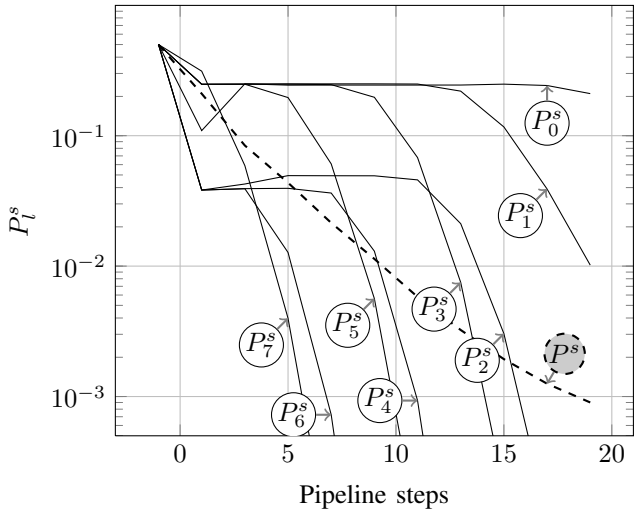

Fig. 8: Evolution of P_l^s and P^s for a input of 2^9-1 elements with $P_l^0 = \frac{1}{2}\ \forall l$. P^s shows that in average, the number of placed elements is divided by two after each pair of pipeline steps. The larger levels are the first to contain placed elements with high probability. For clarity, only values with s odd are displayed.

a) Approximation: Figure 8 shows that the probability for an element to be misplaced is reduced by a factor two every two pipeline steps. If we stop the algorithm after a given step s, we can estimate, for each level, the probability P_l^s that

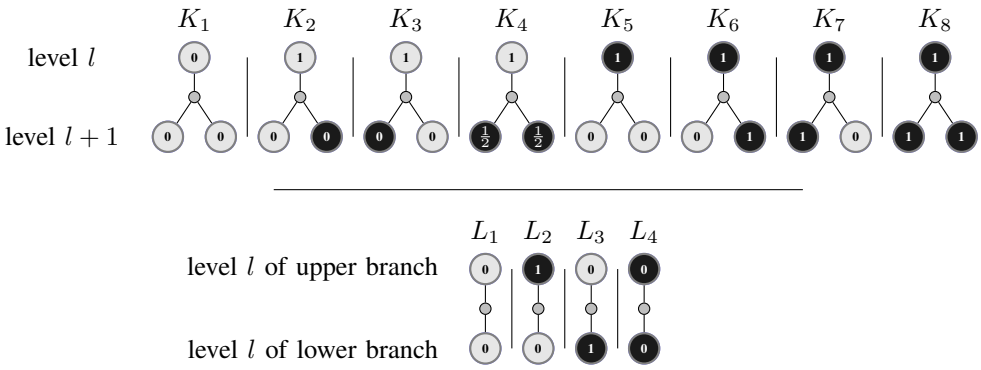

Fig. 7: All possible configurations for *reorder* and *select* operators. Misplaced elements are shown in black and placed elements are shown in gray. Each node is marked with the probability that its contains a misplaced element after the operation.

one of its elements is misplaced. Figure 9 shows the average percentage of misplaced elements after each pair of pipeline steps. For example, whatever the input size, we note that 10 pipeline steps are enough to place 99% of the elements in average.

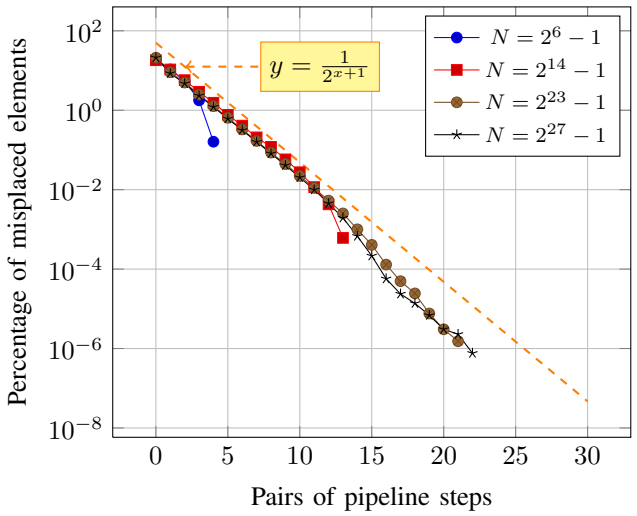

Fig. 9: Evolution of the percentage of misplaced elements over the pipeline steps. Each curve represents the mean of 10 executions of the final algorithm on random arrays.

7. Conclusion

The algorithm we presented in this paper converges to a median split of an array of N elements, placing the median at index $\frac{N}{2}$ in an observed run-time of $O\left(\frac{N}{P} \times (log(N) + \mu)\right)$ average time where μ the time to swap a pair of elements between two processors.

To make the coarse-grained parallel approaches of [3] efficient, we need to provide each processing units (PE) with enough elements, limiting their number. Because the three operators involved process locally only 2 or 3 elements without global knowledge, our approach is expected to bypass this limitation by taking advantage of architectures with a very high number of PEs (in the same order of magnitude of N). We believe that this can lead to efficient implementations on specific networks on chip with thousands of PEs.

Abstract- The **Support Vector Machine (SVM) is one of the most effective machine learning algorithms for data classification, which have a significant area of research. Since the training process of large datasets is computationally intensive, there is a need to improve its efficiency using high performance computing techniques. In this paper, we developed an efficient parallel algorithm, SMC-PBC-SVM, which combines a Parallel Binary Class with Serial Multi-class Support Vector Machines for classification. The SMC-PBC-SVM algorithm was implemented using the object-oriented C++ programming language and standard Message passing Interface (MPI) communication routines. The parallel code was executed on an ALBACORE Linux cluster, and then tested with four datasets with different sizes: Earthworm, Protein, Mnist, and Mnist8m. The results show that the SMC-PBC-SVM implementation can significantly improve the performance of data classification without the loss of accuracy. The results also demonstrated a form of proportionality between the size of the dataset and the SMC-PBC-SVM efficiency. As the dataset becomes larger, the SMC-PBC-SVM achieves a higher efficiency.**

Keywords- Classification; SVM; parallel computing.

I. INTRODUCTION

Classifying different categories among large datasets has become one of the most important computing problems. The main objective in classification is to identify patterns in a data set, which helps to analyze the data in order to make decisions. Support Vector Machines (SVMs) are a class of machine learning algorithms based on statistical learning theory, which has received wide attention for classification problems because of its accuracy and generalization property.

SVM classification involves three stages. The first one involves training the model for the classification with the training dataset. The second stage is the testing stage where the model is tested with a combination of the training data and similar unseen data. The third stage involves the actual prediction with unseen data. The training stage is the most computationally expensive process of SVMs.

The main idea behind the SVM classification algorithm is to separate two point classes of a training dataset,

$$D = \{(x_i, y_i), i = 1,2, \dots, n, \quad x_i \in R^M, \quad y_i \in \{-1,1\}\} \quad (1)$$

, with a surface that maximizes the margin between them [1]. This separating surface is obtained by solving a convex quadratic problem (QP) of the form [2]

$$\text{Min } F(\alpha) = \frac{1}{2}\alpha^T G \alpha - \sum_{i=1}^{n} \alpha_i \ , \quad (2)$$

$$\text{sub. to } \sum_{i=1}^{n} \alpha_i \, , 0 \le \alpha_i \le C, i = 1,2, \dots, n$$

, where the entries of the symmetric positive semi-definite matrix G are defined as

$$G_{ij} = y_i y_j K(x_i, x_j), i, j = 1,2, \dots, n, \quad (3)$$

where $K: R^M \times R^M \to R$ is the kernel function.

SVM has been modified to handle non-linear classification. Since the complexity of training of non-linear SVMs has been estimated to be quadratic in the number of training examples [3], it is computationally expensive when large datasets with tens of thousands of training examples are used. To reduce the training time, the optimization problem can be broken into smaller QP problems [4]. Originally, SVM was introduced for binary classification, and then it was extended for multi-class classification. It was improved by caching the kernel calculations [5]. Because of the wide use of the Internet, a large amount of data is being collected. Hence, the importance of using an efficient SVM that utilizes parallel computing facilities and multi-core processing elements for (multi-class) classification of large datasets grows even larger. Therefore, a lot of research efforts were directed to find the optimal parallel algorithm for the different kinds of datasets. For large binary classification problems, there is a need to break it down into smaller pieces, so that the smaller partitions can be computed concurrently. Research has been conducted in this area, and some progress has been made in [6], [7], and [8]. On the other hand, for large multi-class classification problems, progress has been made in [3] and [9]. Also, a lot of work has been done in [5] and [10] to develop kernel computation costs. Some other efforts have been achieved in [11], [12], [13] and [14] to optimize working set size selection. Additionally, other tries have been done in [15], and [16] to develop SVM training by quickly removing most of non-support vectors.

The LIBSVM [17] software is developed for a working set of size two, which tends to minimize the computational cost per iteration. In this case, the inner QP subproblem can be systematically solved without requiring a numerical QP solver and the updating of the objective gradient only involves the two Hessian columns corresponding to the two updated

variables. On the other hand, if few variables are updated per iteration, slow convergence is normally implied. The SVM^{light} [18] algorithm uses a more general decomposition strategy, also by common sense it can exploit working sets of sizes larger than two. By updating more variables per iteration, such an approach is more suitable for a faster convergence, but it introduces additional difficulties and costs. A generalized maximal-violating pair strategy for the working set selection and a numerical solver for the inner QP subproblems are required. Moreover, as more variables are updated per iteration, the objective gradient updating is more expensive. While SVM^{light} can run with any working set size, numerical experiences prove that it effectively faces the above difficulties only in the case of small sized working sets, $N_{sp} = O(10)$, where it often exhibits comparable performance with LIBSVM.

Following the SVM^{light} decomposition techniques, another effort to strike a balance between the convergence rate and cost per iteration was introduced in [6]. Unlike SVM^{light}, it is medium or large sized working sets, ($N_{sp} = O(10^2)$ or $N_{sp} = O(10^3)$, that allow the method to converge in a small number of iterations where the most costly tasks are. For example, subproblem solving and gradient updating can be simply and effectively distributed between the available processors. Based on this idea, a new parallel gradient projection-based decomposition technique (PGPDT) is developed and implemented in software to train support vector machines for binary classification problems in parallel as in [8].

Even though all previous results were encouraging, more research was needed to improve the performance of the process. In this paper, we introduce a new classification algorithm which merges parallel binary classification with serial multi-class classification to produce an efficient parallel algorithm for classification. We named the new algorithm SMC-PBC-SVM.

II. SMC-PBC-SVM ALGORITHM

The SMC-PBC-SVM algorithm combines Parallel Binary Class with Serial Multi Class Support Vector Machines for classification. It includes seven steps and works as follows: 1) Reads a dataset from an input file, 2) Groups samples of the same class together, 3) Collects each two classes into one task, 4) Sorts $\frac{K(K-1)}{2}$ tasks based on its size, 5) Divides processes group into two subgroups, mulgroup and bingroup, such that mulgroup is used to build $\frac{K(K-1)}{2}$ binary tasks where K is the number of classes in the dataset, and bingroup is used to solve each binary task from $\frac{K(K-1)}{2}$ tasks in parallel, 6) Builds SVM model after solving all binary tasks, and 7) Writes the SVM model into an output model file which is used to predict testing dataset file. The algorithm flowchart is illustrated in Figure 1.

Since the SMC-PBC-SVM is based on the Parallel Binary Class algorithm implemented by PGPDT, we briefly explain here the fundamental principles and decomposition technique used in [8]. We start that by stating some fundamental principles. At each decomposition iteration, the indices of the variables $\alpha_i, i = 1,2,..,n$, are split into the set B of basic variables, usually called the working set, and the set N = {1,2,…,n} \ B of nonbasic variables. In consequence, the kernel matrix G, the vectors $\alpha = (\alpha_1, \alpha_2, \dots, \alpha_n)^T$, and the vector $y = (y_1, y_2, \dots, y_n)^T$ can be arranged with respect to B and N as follows:

$$G = \begin{bmatrix} G_{BB} & G_{BN} \\ G_{NB} & G_{NN} \end{bmatrix}, \qquad \alpha = \begin{bmatrix} \alpha_B \\ \alpha_N \end{bmatrix}, \qquad y = \begin{bmatrix} y_B \\ y_N \end{bmatrix}$$

Then, suppose that N_{sp} is the size of the working set, where $N_{sp} = \#B$ and α^* is a solution of QP (2), and N_p is the number of processes which are used for solving that QP, and each of them has a local copy of the training set D (1), where the entries of G are defined by G(3). The decomposition technique used by the PGPDT falls within the general idea stated in PGPDT algorithm, which is shown in Figure 2. Label "Distributed task" in A2 and A3 of PGPDT algorithm refers to the steps where the N_p processors cooperate together to perform the required computation. In these steps, communications and synchronization are needed. In the other steps, the processors asynchronously perform the same computations on the same input data to obtain a local copy of the expected output data.

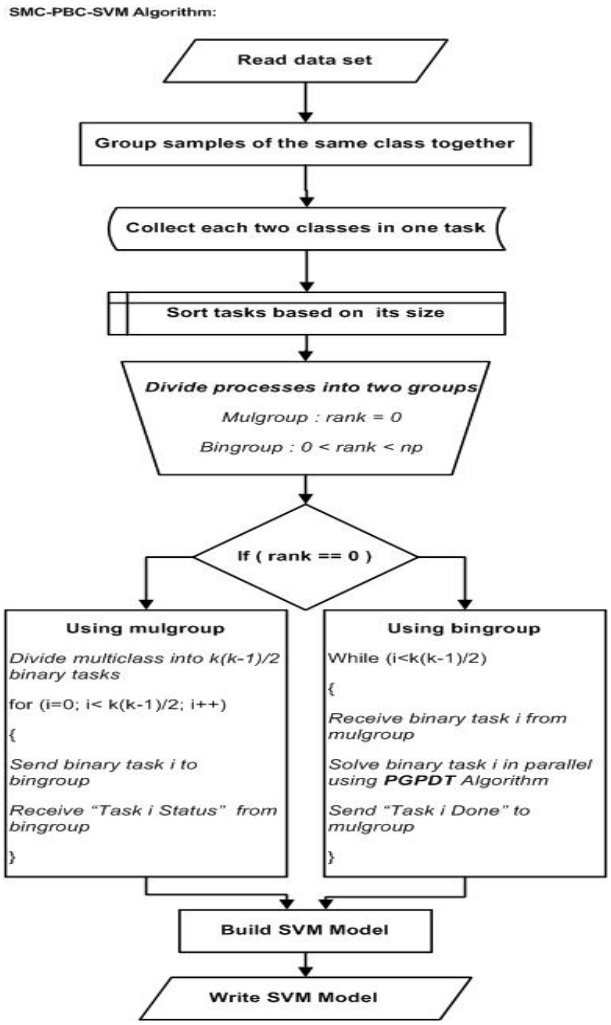

Figure 1. Serial Multi Class Parallel Binary Class Support Vector Machines

A1. *Initialization.* Set $\alpha^{(1)} = 0$ and let n_{sp} and n_c be two integer values such that $n \geq n_{sp} \geq n_c$ n_c even. Choose n_{sp} indices for the working set $\mathcal{B}$ and set $k = 1$.

A2. *QP subproblem solution.* **[Distributed task]** Compute the solution $\alpha_{\mathcal{B}}^{(k+1)}$ of

$$\begin{aligned} \min \quad & \frac{1}{2}\alpha_{\mathcal{B}}^T G_{\mathcal{B}\mathcal{B}}\alpha_{\mathcal{B}} + \left(G_{\mathcal{B}\mathcal{N}}\alpha_{\mathcal{N}}^{(k)} - 1_{\mathcal{B}}\right)^T \alpha_{\mathcal{B}} \\ \text{sub. to} \quad & \textstyle\sum_{i\in\mathcal{B}} y_i\alpha_i = -\sum_{i\in\mathcal{N}} y_i\alpha_i^{(k)}, \\ & 0 \leq \alpha_i \leq C, \quad \forall i \in \mathcal{B}, \end{aligned}$$

where $1_{\mathcal{B}}$ is the n_{sp}-vector of all one; set $\alpha^{(k+1)} = \left(\alpha_{\mathcal{B}}^{(k+1)^T}, \ \alpha_{\mathcal{N}}^{(k)^T} \right)^T$.

A3. *Gradient updating.* **[Distributed task]** Update the gradient

$$\nabla f\left(\alpha^{(k+1)}\right) = \nabla f\left(\alpha^{(k)}\right) + \begin{bmatrix} G_{\mathcal{B}\mathcal{B}} \\ G_{\mathcal{N}\mathcal{B}} \end{bmatrix} \left(\alpha_{\mathcal{B}}^{(k+1)} - \alpha_{\mathcal{B}}^{(k)}\right)$$

and terminate if $\alpha^{(k+1)}$ satisfies the KKT conditions.

A4. *Working set updating.* Update $\mathcal{B}$ by the following selection rule:

A4.1. Find the indices corresponding to the nonzero components of the solution of

$$\begin{aligned} \min \quad & \nabla f\left(\alpha^{(k+1)}\right)^T d \\ \text{sub. to} \quad & y^T d = 0, \\ & d_i \geq 0 \quad \text{for } i \text{ such that } \alpha_i^{(k+1)} = 0, \\ & d_i \leq 0 \quad \text{for } i \text{ such that } \alpha_i^{(k+1)} = C, \\ & -1 \leq d_i \leq 1, \\ & \#\{d_i \mid d_i \neq 0\} \leq n_c. \end{aligned}$$

Let $\bar{\mathcal{B}}$ be the set of these indices.

A4.2. Fill $\bar{\mathcal{B}}$ up to n_{sp} entries with indices $j \in \mathcal{B}$. Set $\mathcal{B} = \bar{\mathcal{B}}, k \leftarrow k+1$ and go to A2.

III. SMC-PBC-SVM Results Analysis

The SMC-PBC-SVM algorithm was implemented using the object-oriented C++ programming language and the standard MPI communication routines [19]. The experiments are carried out on two different parallel platforms at the Mississippi Center for Supercomputing Research (MCSR) [20], and ALBACORE Linux clusters [21]. The performance analysis was visualized using Jumpshot software [22]. The best performance was achieved with ALBACORE, which contains 12 compute nodes, each node has 2 chips, and each chip has 4 cores. Each core is an Intel(R) Xeon(R) CPU X5570 with 2.93 GHZ and 8192 KB Cache. Each node of node0 and node1 has 16 GB, and node2 to node11 has 12 GB.

The SMC_PBC_SVM has been tested using different size datasets, Earthworm, Protein, Mnist, and Mnist8m, which are small, medium, large, and very large datasets respectively. Table I includes the description of these datasets. The results show that SMC-PBC-SVM is very efficient with very large datasets as Mnist8m dataset, highly efficient with large datasets as Mnist dataset, reasonably efficient in medium datasets as Protein dataset, and less efficient with small datasets as Earthworm dataset. For more details, see Table II, which shows the training run time when number of processes 1, 2, 4, 9, 16, 25, and 36 are used.

The complexity for the multi-class classification is $O(K\,M\,N^2)$, where K is the number of classes, M is the number of features, and N is the number of training samples [3]. This serial complexity is the worst case scenario for multiclass classification using binary classifiers. But when this job is distributed among P processors, the parallel complexity becomes $O\left(\frac{K\,M\,N^2}{P} + T_c\right)$, where T_c is the complexity due to communication for task scheduling and combining the results.

We evaluate the parallel performance by the relative speedup (S), which is defined as the ratio of the time taken to solve a problem on a single processing element to the time required to solve the same problem on a parallel computer with p identical processing elements, then

$$S = \frac{T_s}{T_p} = \frac{\text{Training Time spent on a single processor}}{\text{Training Time spent on a Np processors}} \quad (4)$$

Then,

$$S = O\left(\frac{K M N^2}{\frac{K M N^2}{P} + T_c}\right) \quad (5)$$

$S \cong O(P)$, if $T_c \to 0$,
when transmitted data between processors is insignificant.

Efficiency (E) is another way to analyze the parallel implementation, which is defined as the ratio of speedup to the number of processing elements, then

$$E = \frac{S}{P} = \frac{\text{Speedup}}{\text{Processes number}} \quad (6)$$

Then,

$$E = O\left(\frac{\frac{K M N^2}{\frac{K M N^2}{P} + T_c}}{P}\right) \quad (7)$$

$S \cong O(1)$, if $T_c \to 0$,
when transmitted data between processors is insignificant.

Figures 3, 4, and 5 show the relationship between the number of processors and run time, speedup, and efficiency respectively. Also, Figures 6 and 7 show the output of Jumpshot, which is a visualization tool to study the performance of parallel programs using log files that are generated from the execution of the SMC-PBC-SVM implementation to Earthworm and Mnist datasets using 16 processors.

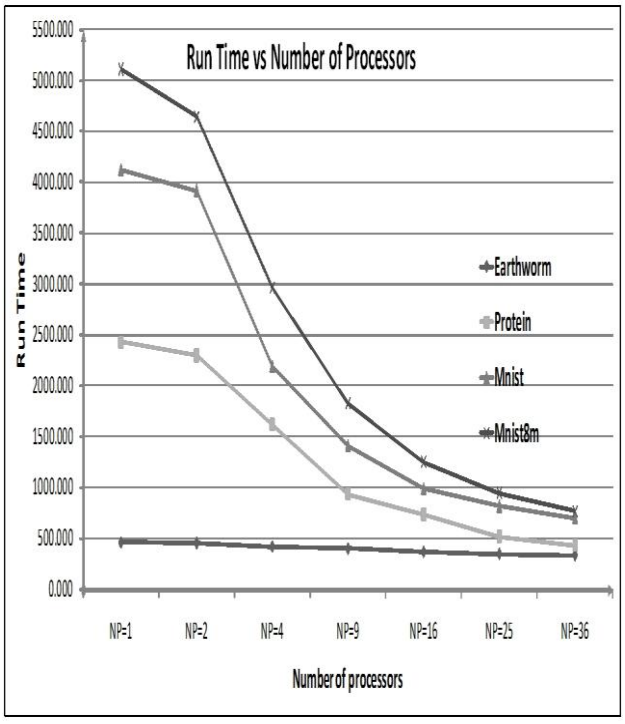

Figure 3. The relationship between Run Time and Number of Processors

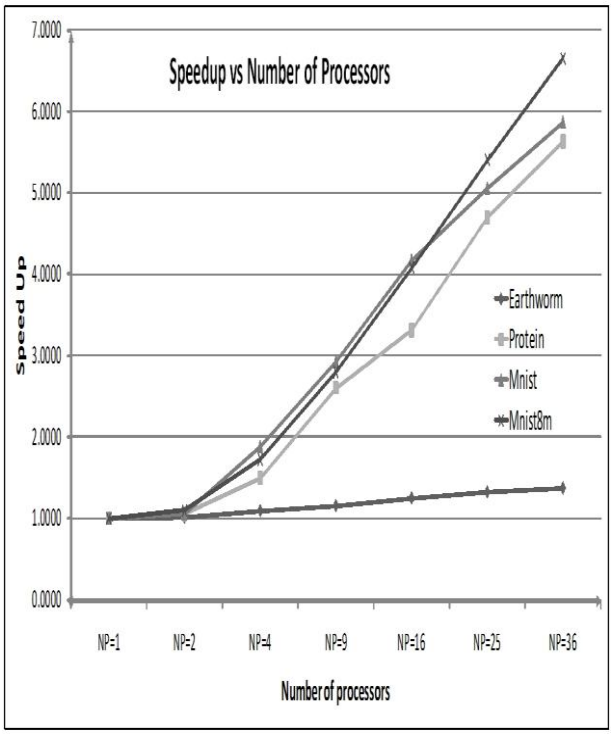

Figure 4. The relationship between Speedup and Number of Processors

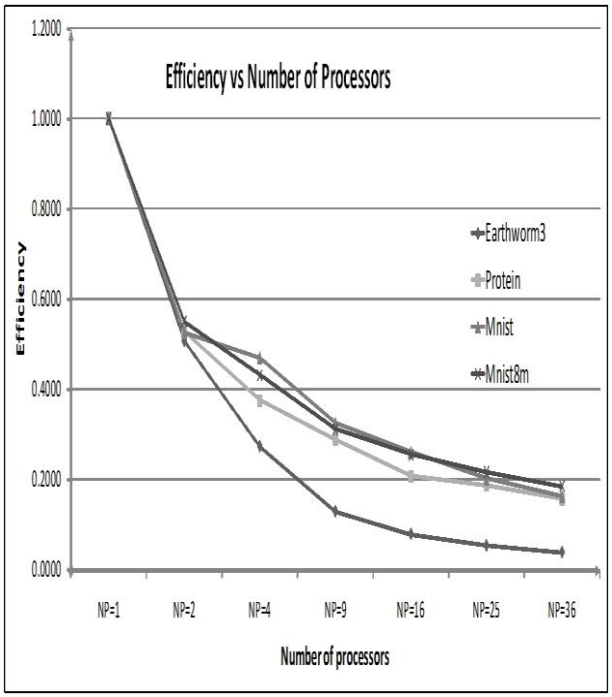

Figure 5. The relationship between Efficiency and Number of Processors

In Figure 3, we can see that the training execution time goes down as the number of processors is increased. It shows that when there is a sufficient work to be done concurrently on an increasing set of processors, there is a related improvement in performance. For small datasets, as Earthworm, there is not

enough work to be done concurrently. Therefore, there is no significant improvement in performance in that case. On the other hand, for very large datasets, as Minst8m, there is a sufficient work to be done concurrently. Therefore, there is a significant improvement in performance with very large datasets. By the same concept, the performances of medium and large datasets, such as Protein and Mnist, fell between the performances of small datasets and very large datasets. We used a Portable batch system (PBS) script which allows us to choose number of processors which are needed for job execution.

Referring to the speedup (5), we can see that, the size of datasets and the size of classes are significant factors in speedup. Therefore, it may not be possible to avoid the idling of some processes. Also, as the number of processes is increased, the speedup is less than linear, indicating idle time for few processors while waiting for other processors. In Figure 4, we can observe that the speedup is closed to linear speedup from very large dataset to small dataset.

Efficiency (7) is defined as the ratio of speedup to the number of processors. Therefore, a higher speedup ensures good efficiency, implying efficient use of the parallel resources. In Figure 5, we can see, the efficiency of SMC-PBC-SVM is gradual from a very large dataset to a small dataset.

In Figure 6, we can observe that there is a lot of lost time through idling especially with a large number of processes where the dataset size is small. Therefore, this explains the low efficiency with small datasets. While in Figure 7, we can see that there is no lost time because most time is spent in computation without idle time, where the dataset size is large. Therefore, this explains the high efficiency with large datasets.

IV. CONCLUSION AND FUTURE WORK

In this paper, the problem of solving multi-class classification using an efficient parallel support vector machine implementation was investigated. SMC-PBC-SVM is an efficient parallel algorithm, which combines Parallel Binary Class with Serial Multi-Class Support Vector Machines for classification. The SMC-PBC-SVM algorithm was implemented using the object-oriented C++ programming language and standard Message Passing Interface (MPI) communication routines. The parallel code was executed on an ALBACORE Linux cluster, and then tested with four datasets with difference sizes: Earthworm, Protein, Mnist, and Mnist8m. The results show that the SMC-PBC-SVM implementation can significantly improve the performance of data classification without loss of accuracy. As the dataset becomes larger, the SMC-PBC-SVM achieves a higher efficiency. In this paper, we used one processor in mulgroup which means SMC, and more than one processes in bingroup which means PBC.

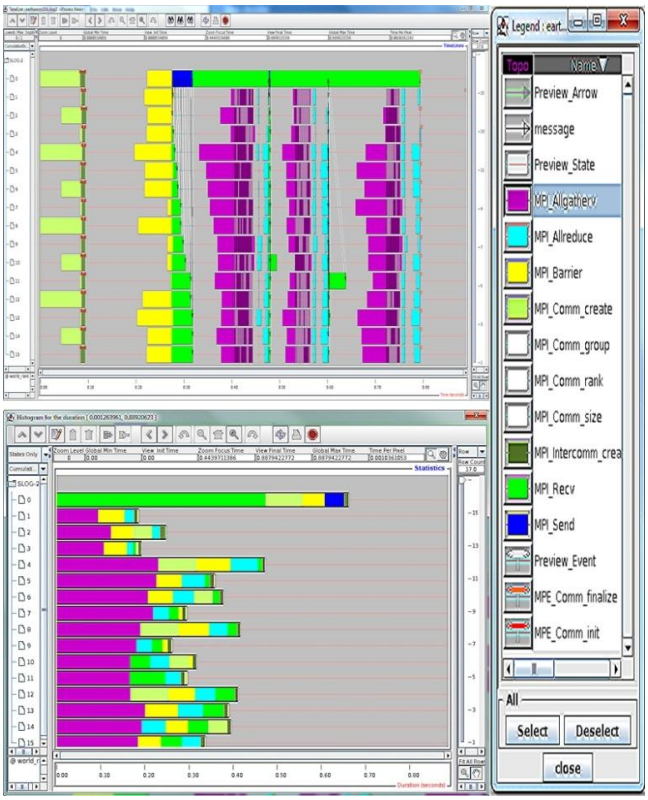

Figure 6. Jumpshot Timeline, Histogram and legend windows of Earthworm dataset using 16 processors

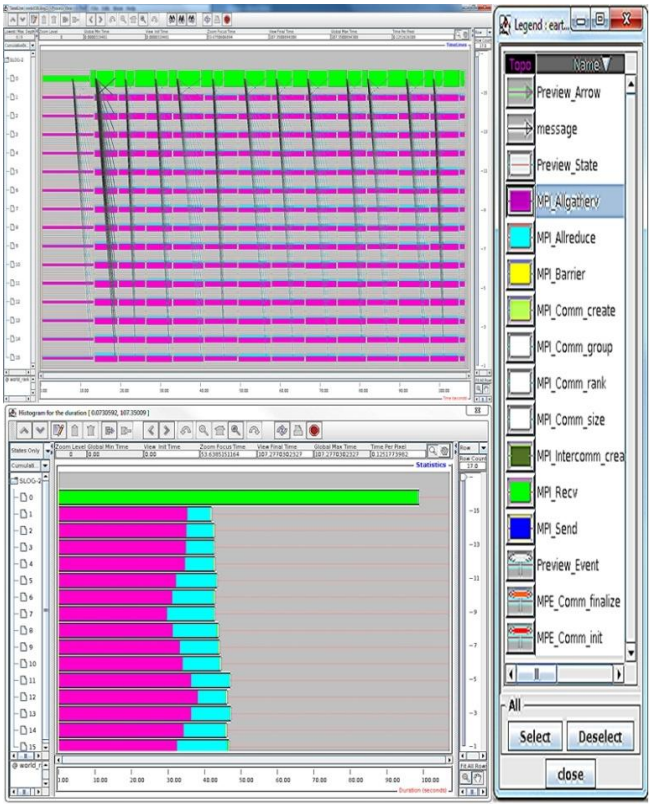

Figure 7. Jumpshot Timeline, Histogram and legend windows of Mnist dataset using 16 processors

In the future work, the scope of mulgroup will extend to include more than one processor, (Add comma) where each of which has its own bingroup. Therefore, these processes in mulgroup work in parallel, and then we will produce PMC-PBC-SVM implementation which will improve the performance and will address the limitations of SMC-PBC-SVM.

Abstract- *Horizontal and vertical partitioning are important aspects of physical design in relational database system that has a significant impact on performance and cost optimization. However, the distribution design also involves making decisions on the fragments allocation across the sites of a computer network. In this paper we address the allocation and re-allocation phases of distributed database systems by adopting an efficient algorithms that leads to a proper data allocation schemes. A new data allocation algorithm for DDBSs is presented in this work, the proposed Algorithm explores and improves some concepts used in previously developed algorithms to reallocates fragments to different sites by adopting the shortest path method to transfer fragments between the old location and the new one when migration decision is made. Experimental results proves that the proposed algorithm efficiently reduces transmission cost and speed of fragment migration over the network sites improving the overall DDBS performance.*

Keywords: Allocation, DDBMS, Partitioning, Distribution, Optimization.

1 Introduction

The allocation technique is the process of placing fragments to different sites after the database has been partitioned [13]. However, because this process plays a key role in DDBSs performance, it needs to be performed in an optimal way to reduce communication cost during query execution to achieve the proposed objectives.

There are several allocation techniques that have been employed in [2,7, 12,15,20] for dynamic allocation in distributed database systems to improve performance. They addressed dynamic environments, where sites access probabilities to fragments change over time. The objective of this paper is to design an effective allocation algorithm that guarantees minimum data transfer cost in a dynamic environment.

The allocation problem of the DDBS had been studied extensively in [6, 11] for redundant and non-redundant scenarios. In [5,2], data allocation is performed in static environment where site access probabilities to fragments never change. However, this static allocation would degrade the database performance if these access probabilities change.

A framework for dynamic data allocation was presented in [3]. A query processing cost model to evaluate the performance of the system is covered in the context of complex value databases in [10] in which a heuristic approach was proposed for performing fragmentation and allocation. In [7] a model for dynamic data allocation and redistribution was given. [4] suggested incremental allocation and reallocation based on changes in workload. SAGA approach was proposed in [1] to determine the optimal places for data fragments where data access pattern and transmission cost were used to help in specifying the optimal places.

A dynamic object allocation and replication algorithm with centralized control has been proposed in [12]. In [16] an optimal algorithm for non-replicated database systems was presented. In [15, 20] two algorithms for non-replicated distributed databases were proposed, while [20] used a threshold algorithm where the fragments are continuously reallocated according to changes in data access patterns while [15] added time constraint to reallocates data with respect to the changing data access patterns. A more comprehensive algorithm for a dynamic fragment allocation that incorporates time constraints, threshold value and the volume of data transmitted

to reallocate fragments to sites dynamically at runtime was presented in [12].

In [8] data allocation model was presented to maintain and solve DDBS problems by studying the initial allocation and post allocation problems. [9] Presented a solution for data allocation and optimization in distributed database systems that performed by means of mobile agents. A decentralized approach for dynamic table fragmentation and allocation in DDBS based on observation of the sites access patterns had been proposed in [14] that performs fragmentation, replication, and re-allocation based on recent access history. An integer programming formulation for the non-redundant version of the fragment allocation problem is presented in [13].

Our proposed algorithm is considered as an optimization to the optimal algorithm of [2], a threshold algorithm of [19, 20], TTCA algorithm of [15] and synthesis algorithm of [12]. Thus, the proposed algorithm incorporates and improves the concepts proposed in [2,12,15,19,20]. Our proposed algorithm migrates fragment (F_i) to site (S_j) only if the following conditions are satisfied: (i) Site S_j has made highest query costs for fragment F_i than all other sites, (II) The average transfer cost of fragment F_i is greater than the threshold value, and (iii) The remote access counter for fragment F_i is greater than its local access counter over several time intervals. Moreover, the proposed algorithm adopts the shortest path technique when moving fragment F_i from the old location to the new location.

1.1 The Paper Contributions

This paper contribution can be summarized in the following; first, it re-allocates data fragments according to the fragment accesses given that sites constraints are not violated. Second, it calculates and chooses the threshold value based on data transmission costs (which adopted different calculation method compared to that used in previous algorithms). Third, calculating and using the query cost QC_i^j between sites S_i and S_j, and QC_i^k between site S_i and all other sites (excluding S_i) as an alternative to the data transmission volume method used in the synthesis algorithm. Forth, it adopts the shortest path algorithm when moving fragments between the old and the new locations to minimize the transmission cost.

1.2 Paper Organization

The rest of this paper is organized as follows; Section 2 presents the proposed methodology for non-replicated dynamic data allocation. The proposed algorithm is presented in section 3. A comparison based on performance factors is given in section 4. Finally, conclusions are given in section 5.

2 The Proposed Methodology

In our proposed algorithm all the advantages of the dynamic algorithms presented in [2,19,15,20,12] will be incorporated to produce a more efficient algorithm that minimizes transmission cost given the site constraints. It is believed that this technique will prove to be a potential progress not only in reducing transfer cost but also in enhancing the overall performance of the DDBSs.

2.1 DDBS Environment

Assuming that, we have a fully connected network that consists of M sites, where each site has N fragments that initially distributed in a static way as shown in Figure1. Every fragment F_i at site S_j has two variables, the LAC_i (representing the number of local accesses to fragment F_i at site S_j) and the RAC_i (representing the number of remote accesses to fragment F_i at site S_j). And every site S_j has two constraints: Capacity C_j (indicating that no site will receive more than its capacity) and Fragment Limit FL_j (representing the maximum number of fragments each site can handle). The following migration conditions need to be satisfied for fragment F_i to be moved from S_h to site S_j.

$$S_j.F_i.RAC > S_j.F_i.LAC, \quad j = 1,2,\ldots, m \qquad (1)$$

$$\sum_{j=1}^{m} QC_h^{\,j} > \sum_{i=1}^{n} QC_h^{\,k}, \quad k,h = 1,2,\ldots, m, m <> j \qquad (2)$$

$$\sum_{j=1}^{m} QChj = DRhj * TChj \quad (3)$$

$$FTC = \left(\sum\left(\mathrm{Req_{ij}} * \mathrm{TC_{hj,}}\right),\ 1 <= \mathrm{j},\ \mathrm{h} < \mathrm{m}\right) \quad (4)$$

$$Threshold\ value = \left(\sum_{j=1}^{m}\sum_{i=1}^{n} Req_{ij} * TC_{hj} \right) / n \quad (5)$$

$$FTC > threshold\ value \quad (6)$$

Equation (1) states that the remote access counter should be greater than local access counter for fragment *(F_i)* under consideration. Equation (2) states that the average query cost between site S_h *and* site S_j should be higher than average query cost between site S_h and all other sites accessing fragment F_i (excluding site S_j). Equation (3) is used to compute the query cost between site S_h and site S_j (the same equation can be used to compute the total query cost between site S_h and all other sites). the query cost between sites S_h and S_j can be calculated by multiplying the transmission cost unit between them (TC_{hj}) by the resulted volume of data (DR_{hj}) which represents the data obtained by executing site S_j queries that require a particular data volume from fragment F_i allocated at site S_h). Equation (4) is used to give fragment transmission cost across sites S_h and S_j for fragment F_i. Equation (5) calculates the threshold value for fragment F_i. Equation (6) states that the fragment transmission cost should be greater than the threshold value.

The following constraints have to be considered throughout the allocation process.

$$\sum_{i=1}^{n} q_{ij} * Z_j < C, \qquad 1 \le j \le m \quad (7)$$

$$\sum_{i=1}^{n} q_{ij} = 1,\ 1 \le i \le n \quad (8)$$

$$\sum_{j=1}^{m} q_{ij} < FL, 1 \le i \le n \quad (9)$$

Equation (7) represents the capacity constraint which indicates that no site will receive more than its capacity. Equation (8) states that a fragment will be allocated to only one site. Equation (9) states that each site will not handle more than a given number of fragments denoted by fragment limit (*FL*). Table 1, shows the notation used in this work.

TBALE1: The Notation Used

RAC	Remote Access Counter
LAC	Local Access Counter
F	The fragments DDBSs.
S	DDBSs sites
C	Site capacity
Z	The data fragment size in DDBSs
FL	Fragment limit for each site
FI	The accessed Fragment Identifier
Q	Site query
I	Fragment index
N	Fragments number
M	Sites number
K	Query index
J	Site index
ASA	Accessing Site Address
CSA	Candidate Site Address
AC	Access Counter for each accessed site
TFA	Time of the fragment accessed
TCS	Time the candidate site address has been selected
DR_{ij}	Fragment size (in bytes) resulting from site S_i query accessing fragment F_i located at site S_j
AT	Access Time for each accessed site
QC_h^j	Average of query cost between S_h and S_j
QC_h^k	Average of query cost between S_h and any other site S_k
Req_{ij}	Equal 1, if F_i is required by S_j and 0, otherwise
RF_{ri}	Retrieval frequency of retrieval operation from site j
UF_{uj}	Update frequency of update operation from site j
QF_{ij}	Access frequency of the i^{th} query at site j
V	Volume of fragment allocation i (characters)
SC	Storage cost ($ / 5,OOO char/month)
X_{ij}	Equal 1, if F_i allocated to site S_j and 0, otherwise
TC_{ij}	Cost for site *Si* accessing a fragment located at site *Sj*

3 The Proposed Algorithm

The proposed algorithm is performed in the following three steps:

A. Determining the shortest path and their values.
B. Initializing and determining variables.
C. Running the proposed algorithm while regularly checking sites constraints.

3.1 Determining the Shortest Paths

Occasionally, after any network topology change the algorithm begins by running *Dijkstra's* algorithm of [10] in every site to obtain the shortest path from one site to every other site. This algorithm is consistently repeated until the shortest path between sites is obtained. Having a weighted directed graph *G = (V, E)*, with a weighted function *W: E → R* mapping edges of real valued weights with sites S_1, S_2, S_3 and S_4 (see Figure 1). The

shortest path matrix would look like the one in table 2.

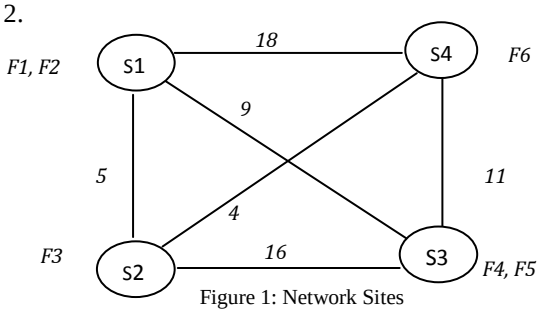

Figure 1: Network Sites

TABLE 2: Shortest Path Matrix

Source Site	Destination Site	Path	Path value
S1	S2	S1----S2	5
S1	S3	S1----S3	9
S1	S4	S1---S2---S4	9
S2	S3	S2---S1---S3	14
S2	S4	S2----S4	4
S3	S4	S3----S4	11

3.2 Threshold Calculation

Each fragment is accessed by at least one site. Accesses are represented by the Access Cost Matrix (*ACM)*. $ACM_{i,j}$ gives the number of times site S_j accesses fragment F_i. In this work, based on the Site Access Record (*SAR) shown in the paper example (table 7),* the *ACM* matrix is constructed as shown in table 3.

TABLE 3: Fragments Access Cost Matrix (ACM)

S/F	F_1	F_2	F_3	F_4	F_5	F_6
S_1	1	1	0	1	0	0
S_2	1	3	1	0	2	2
S_3	2	0	0	1	1	1
S_4	0	1	2	0	0	2

The transmission cost matrix *TCM (table 4)* gives the cost of accessing fragment F_i by site S_j. Using these matrices, the threshold value is computed based on Fragment Usage Matrix (*FUM*) which is produced by multiplying *ACM* matrix by the *TCM* matrix. Using *FUM*, we select the site whose average access cost for fragment F_i is the highest among all other sites for the same fragment. An illustrating example is given next.

TABLE 4: The Transmission Cost Matrix (TCM);

Sites	S1	S2	S3	S4
S1	0	5	9	18
S2	5	0	16	4
S3	9	16	0	11
S4	18	4	11	0

3.3 Initializing Variables

a. There are a number of *N* fragments distributed across *M* sites, where each site contains one or more fragments. Queries may access several fragments allocated at different sites. And each site has two constraints: fragment limit (*FL*) and site capacity (*C*) as shown in table5.

b. A separate data structure called Site Access Record (*SAR*) is kept for each site. The *SAR* stores information about fragments accesses at each site, denoted by SAR^k_j , indicating the. k^{th} access at site S_j, where (k = 1,2,3,…to unlimited access number, and j = 1,2,3,...m). *SAR* stores the following information for each access:

1. Accessed Fragment Identifier (*AFI)*, see *table 6*.
2. Accessing Site Address (ASA).
3. Data Record (DR) on executing a query *Q* from site S_i on fragment F_i located at site S_j (in bytes).
4. Access Time (AT) by site S_j to fragment F_i.
5. Access Counter (AC) to keep the number of access times for each accessed site.

c. Also for each site a data structure named Access Counter Record (*ACR*) is kept for every fragment in the site. The *ACR* record stores the following information about the fragment after each access:

i. Candidate Site Address (CSA): The address of the site that incurred a query cost value that is higher than that of all other sites over a time interval (*t1* to *t2*). Initially, *CSA* is set to the address of the site where the fragment is currently located.
ii. The number of local accesses to the stored fragment (*LAC)*.
iii. The number of remote accesses to the stored fragment (*RAC*).
iv. The time of the candidate site address selection (*TCS*).

For each locally stored fragment, initialize both the local and remote counters to zero (*LAC* = 0, *RAC* = 0).

3.4 Our Algorithm

After processing different site accesses to fragment F_i allocated at site S_j over time t, the following steps are performed:

```
Main {
// Enter SAR and ACR data
Enter-data ( );
// Calculate query costs
Compute- QC ( );
// Calculate threshold values
Compute-threshold (T1,T2,OCS: J, NCS: h )
// Check whether the accesses are local or remote
Checki-ASR ( );
// Make sure if the migration conditions satisfied
Migrate-data( );
}// end main

Enter-data ( ){
{for j=1 to m do
  For h = 1 to k do // Enter site data
   Read(S[j].AC,  S[j].FI,  S[j].ASA,  S[j].AT,
S[j].DTV)
End h
For i=1 to n do //Enter fragment data
  Read(S[j].F[i].CSA, S[j].F[i].DCA)
End i
End j}

Compute- QC (T1,T2, old site: J, new site h ){

4 Comparing Algorithms Based On Performance Factors

The comparison of our algorithm with the existing (Optimal, Threshold, TTCA and Synthesis) algorithms presented in [2], [19], [15,20] and [12] respectively, is clearly showed in (*Figure 3*) based on the following factors:

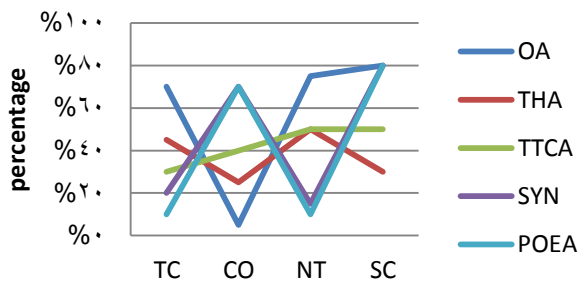
1. Fragment migration decision
2. Storage cost (*SC*).
3. Transmission cost (*TC*), Computation overhead (*CO*) and Network Traffic overhead (*NT*).

1. **Fragment migration decision**: the optimal algorithm of [2] moves fragment F_i when the counter for the remote site in the access matrix is greater than the counter of the owning site for that fragment. The threshold algorithm migrates the fragment when the counter for fragment F_i is greater than the threshold value. The TTCA algorithm migrates fragment F_i when the counter of the remote site is greater than the threshold value (t) and all the last "t+1" accesses made in a specified time (T). In synthesis algorithm of [12], the fragment is migrated to the intended site when that site has made data transfer cost that is higher than all other sites and is greater than the threshold value consistently in some recent time intervals. However, our algorithm migrates the fragment when the remote counter for fragment F_i is greater than the local counter of the owning site and the resulted query cost (*QC)* between the old site and new site is greater than the query cost between the old site and any other accessing site for that intended fragment, given that the shortest path between the old site and the new site is maintained.

2. **Storage cost factor**: it is clear from Figure 3, that the optimal algorithm of [2] consumes much storage space since it stores several access counters for each fragment. The threshold algorithm requires less storage space as compared to the optimal algorithm because it stores only one counter for each fragment. The TTCA algorithm requires more storage space as compared to optimal and threshold algorithms. The synthesis algorithm of [12] needs high storage space and thus cost because it maintains several data structures. Our algorithm requires more storage space compared to the algorithms of [2, 19, 20, 15] and almost the same space as that of [12]. This high space requirement is again because our algorithm maintains several data structures.

3. **Transmission cost and computation overhead**: Figure 3, clearly shows that the optimal algorithm sustains the highest transmission cost. This is because the basic rule of thumb that, the more access frequency acquired, the more transmission cost and network traffic overhead will be incurred. The threshold algorithm minimized the network traffic and transmission cost as a result of using the threshold factor. It also obtained less computation overhead compared to optimal algorithm. However, the TTCA algorithm used time constraint and threshold value to further decrease the network traffic and transmission cost compared to optimal and threshold algorithms. More computational overhead is produced for the synthesis algorithm of [12], due to the total volume computation for a fragment transmission to all sites accessing it within a time interval (τ). Our proposed algorithm minimizes the transfer cost for fragments migration dramatically compared to other algorithms because of the following added features: the remote counter (has to be greater than local counter for the transmitted fragment F_i). The threshold value (differently computed compared to that used in the other algorithms). Query cost (*QC*) calculation (the query cost QC_h^j between sites S_h *and* S_j and QC_h^k between site S_h and all other sites excluding site S_j) compared to data transmission volume used in synthesis algorithm, and finally the adoption of the shortest path method. According to our proposed algorithm, the fragment will stay at the owning site as long as there are site constraints violations.

Figure (2): DDBS Performance factors



4.1 A Practical Example

The following example is to test the validity of our algorithm. In this example there is a network of four sites in which six fragments are initially distributed according to a random allocation method. Our proposed re-allocation method will be tested based on the information presented in *tables (5 and 6)*.

TABLE 5: DDBS Fragments

Fragment	F_1	F_2	F_3	F_4	F_5	F_6
Identifier	1	2	3	4	5	6
Size	810B	620B	900B	660B	521B	701B

TABLE 6: DDBS Sites

Site	S_1	S_2	S_3	S_4
Capacity	2350B	1650B	2020B	3200B
Fragments Limit	3	1	3	4

First; we apply the minimum algorithm of [18] on the communication cost matrix to obtain the shortest path matrix. Then we keep the shortest paths values based on the given network graph as shown in section **III.A.**

Second; assuming that multiple accesses are performed, the site access record (*SAR*) is constructed as shown in table 7.

TABLE 7: Sites Access Records SAR_i^j

AC	SN	FI	ASA	AT	DR
1	S_1	1	1	2:10	30B
2	S_1	1	2	3:05	28B
3	S_1	1	3	3:10	27B
4	S_1	1	3	2:00	31B
5	S_1	2	1	3:10	33B
6	S_1	2	2	3:10	33B
7	S_1	2	2	3:12	12B
8	S_1	2	2	2:10	20B
9	S_1	2	4	3:00	26B
1	S_2	3	4	2:10	25B
2	S_2	3	2	3:00	25B
3	S_2	3	2	4:05	41B
1	S_3	4	1	1:50	43B
2	S_3	4	3	2:10	39B
3	S_3	5	3	3:00	28B
4	S_3	5	2	4:05	31B
5	S_3	5	2	4:50	29B
1	S_4	6	2	3:10	32B
2	S_4	6	2	3:50	34B
3	S_4	6	3	3:10	28B
4	S_4	6	4	3:10	20B
5	S_4	6	4	3:12	20B

Based on the sites access records (*SAR*), the Access Cost Matrix (*ACM*) will be constructed as mentioned earlier and shown in table 3 above.

Third: The *ACM* matrix is multiplied by *TCM* matrix to compute fragment usage matrix (*FUM = ACM * TCM*), *FUM* matrix is presented in *table 8*;

TABLE 8: Fragments Usage Matrix (FUM)

F/S	S_1	S_2	S_3	S_4
F_1	23	37	25	44
F_2	33	9	54	58
F_3	41	8	38	4
F_4	9	21	9	29
F_5	19	16	32	19
F_6	55	24	54	19

Based on *FUM* matrix, the threshold value can be calculated for fragments and sites individually when needed (*table 9*). Finally, based on threshold values and the access counter records ACR, the migration decision will be made for each fragment as shown in *table 9*.

TABLE 10: Migration Decision

F_I	Migration (Y/N)	Constraints violations (Y/N)	Threshold value	Migration Fails (F)/successes (S)
1	N	N	24, 34.6	F
2	Y	N	45,5, 32	S
3	N	N	-	F
4	N	N	-	F
5	Y	Y	24, 23.3333	Migration fails because violation of S_2 constraints
6	Y	N	36,75, 32.68	S

5 Conclusions

In this paper, we have presented a novel approach that handles data allocation problem during the design of distributed databases. A comparative study for different data allocation algorithms has been conducted to reach to the most efficient allocation scheme that leads to a better performance and less communication cost.

Our proposed algorithm is the most efficient one among all compared algorithms for dynamic data allocation as it has improved the *DDBS* performance by maintaining strict restrictions for fragment re-

allocation causing a significant reduction in the frequency of fragment migrations across sites which minimized network traffic and reduced data transmission cost by adopting the shortest path algorithm for data movement. However, the only drawback of our algorithm is that it requires more storage space relevant to some of the compared algorithms. However, this is considered as a very trivial drawback due to the dramatic fall down in the storage hardware prices.

Future work is in progress towards extending this algorithm to optimize non-replicated inter-active distributed database systems.

Design of Content-based Forwarding over Large-scale Storage Network

Zhaomeng Zhu, Gongxuan Zhang, Yongping Zhang, and Jian Guo
School of Computer Science and Technology, Nanjing University of Science and Technology, Nanjing, Jiangsu, China

Abstract - *This paper describes a design of a content-based publish/subscribe mechanism attached to large-scale storage network. The network is built as an infrastructure to support wide-area sensors network, or the Internet of Things. We want to collect the scattered computing resources of each node in a massive storage network to take up the heavy task of dissemination of a great amount of data produced by variety of sensors. Be inspired by the virtualization technology, we separate task to different functional units called bricks which can be self-tuning in large-scale network that composed by inexpensive commercial hardware. And we use Bloom filter to record algorithm status for effective forwarding. With less cost we could add more flexible data distribution mechanism to massive storage network.*

Keywords: content-based forwarding; distributed; Bloom filter; publish/subscribe

1 Introduction

During last few years, content-based publish/subscribe system has becoming more and more popular [1]. In publish/subscribe model, those who want data (be called as messages or events) from some kind of sources do not receive all the data that being produced, but only a subset for what they are interested in. Data's producers are called publisher and those who have provided sets of conditions to indicate their interests are called subscribers. The process of selecting messages for reception and processing is called filtering. In a content-based publish/subscribe system, data are only delivered to a subscriber if the attributes of those data exactly match constraints pre-registered in the system by the subscriber.

Our original propose of introducing content-based publish/subscribe mechanism to a large-scale storage network is to bring storage system the ability of supporting the wide-area sensors network [2], or the Internet of Things [3]. With a massive storage system in the cloud, data produced by wide variety of sensors can be aggregated and disseminated. The basic way of getting aggregated data is the searching service provided by underlying storage: users asking for data using a series of conditions and receiving all those data that exactly meet the conditions. The shortcoming is obvious that users must make queries by themselves. For a large scale of sensors network, there may be some sceneries like, (1) a user need to listen to some kind of sensor's data, whose time of occurrence can not be predicted, (2) some urgent data need to be delivered to users as soon as possible and can not wait for querying, and (3) continuous data should be automatically and continuously transferred to users without frequently querying. It is necessary to add a content-based publish/subscribe service to such a massive storage system for such sceneries. With this service, the only thing a user need is to register a subscription in system, and the data meeting conditions will be pushed to specified address automatically when occur.

Many distributed schemes have been proposed for content-based forwarding in wide-area sensors network [4-6], but our design focuses on some different goals. We are trying to integrate the content-based network with the storage networks. According to our observations, the massive storage network always contains a mass of computing nodes whose scale varies form thousands to millions. We try to collect these scattered computing resources so that we can design an effective content-based forwarding mechanism for massive storage system to support the sensors network.

For such a systems, there are still some constrains special. First, we should make full use of each node's limited computing resources, but do not affect the normal procedures of storage. The massive storage is designed to built using inexpensive commercial hardware whose computing power is not strong, so the additional forwarding mechanism need to undertake the enormous amount of data's forwarding tasks but only use as few resources as possible on each single node. Second, since the network's stability is built form a large of unstable components, and taking into account the natural dynamic of P2P architecture, the design must have a strong fault-tolerant ability. That's is, for example, when some of the participating peers left or crashed, the forwarding procedure should not be affected. At last, because of (1) the massive-storage will be distributed in different geographical regions as a city-wide or even world-wide infrastructure to support the wide-area sensors network, (2) the traffic caused by procedures and the contents of data may vary over time, and (3) not all data produced by sensors need to be delivered immediately using content-based information, content-based forwarding mechanism should have the capacity of self-tuning to meet such demands. In this paper, we introduce a architectural design of building a robust content-based forwarding mechanism above the large-scale storage network.

2 Background

2.1 P2P Massive Storage

More and more massive systems are built using peer-to-peer technology now [7-11]. Each node has the same functionality in a P2P storage network. The benefits of using P2P architecture includes, (1) system has a naturally highly scalability and there is no single node will became the bottleneck of performance since there is no any master node, (2) deleting and adding node is simpler since all node is same in functionality, and (3) few nodes' failure can not endanger the whole storage system. With these advantages of a P2P massive storage, we build our storage system which designed to support wide-area sensors network on a P2P overlay network referenced to existing systems like OceanStore [11] and BitVault [8].

For now, the main problem of a P2P storage network is the conflict between the reliability and persistence needed by storage applications and the dynamics of a P2P network [12]. But we assume that our storage network is deployed in a controlled and relatively fixed environment since we will build such a storage system as a public infrastructure, therefore, by using p2p technology we can make full use of the advantages while eliminating its shortcomings.

2.2 Bloom Filter

A Bloom filter [13] is a space-efficient probabilistic data structure that is used to test whether an element is a member of a set. An empty Bloom filter is a bit array of m bits, all set to 0. There must also be k different hash functions defined, each of which maps or hashes some set element to one of the m array positions with a uniform random distribution. To add an element, feed it to each of the k hash functions to get k array positions. Set the bits at all these positions to 1. And to query for an element (test whether it is in the set), feed it to each of the k hash functions to get k array positions. If any of the bits at these positions are 0, the element is definitely not in the set – if it were, then all the bits would have been set to 1 when it was inserted. If all are 1, then either the element is in the set, or the bits have by chance been set to 1 during the insertion of other elements, resulting in a false positive (but with a very small probability). While risking false positives, Bloom filters have a strong space advantage over other data structures for representing sets. On the other hand, an interesting property for Bloom filter is that union and intersection of Bloom filters with the same size and set of hash functions can be implemented with bitwise OR and AND operations, respectively.

3 Preliminary

3.1 Design Goals

Though the forwarding algorithm should be designed as quickly as possible, the performance of the massive storage network is more related to the storage procedures. For example, if one node can process only a few hundred objects pre second, an advanced content-based forwarding algorithm which is capable of processing thousands of objects but need more resources including CPU clocks and memory spaces maybe not significant better than a slower one. So what we mostly focus is not the speed or the total time used to finish all steps of algorithm, but the usability of the storage system, i.e. the attached content-based forwarding services should not affect the other aspects of a good storage system. At the same time, we think separating task to several sub-tasks and distributed them to different nodes is better than doing all by one node. Because by this way we can drop the average CPU load per node, that is, building a massive storage network using less total cost and lower power consumption.

Resisting to the instability of system is another thing we must pay much attention to. Our storage network has been designed to build from a mass of inexpensive commodity components, such as normal PC, or even embedded system attaching large storage devices that need lower power consumption to work. The failures of component will be inevitably frequent. That is said, we cannot presume that each node involved in always works just as we want. Our design must include some mechanism to ensure the algorithm's enforcement.

3.2 Terminologies

An *object* contains the data producer want to store and some information to describe data. For instance, a camera may take photos and send them to the storage. The photos will be preprocessed to attach some information to indicate the time and location. Such kind of descriptive information is called *metadata*, and is usually arranged in a form of *key-value pairs*. We call keys in key-value pairs the object's *attributes*.

Subscriptions are the information registered in the storage system by users who want data. A subscription contains a *disjunction* of *conjunctions* of *predicates* [14] and a forwarding *address*. A conjunction is also called a *filter*. For instance, subscription {{"Location" = "A5" ∧ "Time" > 20 ∨ "Type" = "image" ∧ "Producer" IN {"Camera-30A4", "Camera-30A5"}}, address = user0@example.com} has two filters, {"Location" = "A5" ∧ "Time" > 20} and {"Type" = "image" ∧ "Producer" in {"Camera-30A4", "Camera-30A5"}}, and every object that make all filters true will be sent to user0@example.com.

Predicates are pairs of *constrains* and its related attribute's name. For example, ["Location" = "A5"] is a predicate with a constrain of ["=", "A5"] and an attribute with name "Location". *Constrains* are atom units for checking and each contains a value and an *operation*. Different types have different operations. Every operation need two operands and produces a Boolean value. We call one value *satisfy* a one constrain if the result is *True* by feeding the attribute's value (in left) and the value in constrains (in right) to its operation.

For purpose of this paper, we consider two common types of data: *number* and *string*. We do not discuss *Boolean* since it can be represented by integer. We assume attribute name is a string. In this paper, we consider '<', '=' and '>' for number and on string we defined '=', '*prefix of*' (shorten it to '*PF*'), and "*IN*". An "IN" operation finds out if one string is in a set of strings.

Update the Bloom filter "a" with "b" is to add items in b into a since a bloom filter represents a set. This can be done by a bitwise OR operation.

4 Design

4.1 Overview

When an object arrives, the metadata will be picked out and assign an id. An id is a unique key generated by storage to identify an object. We only use this information but no actual data to reduce network traffic. After whole algorithm, we will get a set of forwarding addresses and send object's id to those addresses. Users can then use id to fetch data. By this way the storing procedure and the forwarding procedure can be handled separately and executed in parallel.

In a massive storage network, the first node that receives an object from outside always plays an important role in storing procedure, which includes routing, generating id and many other computing that need more resources. We do not start testing on this node because we still have enormous amount of nodes in our large-scale storage network. On the contrary, we just push the metadata identified by id to other ones with lower load. Note that we will use request to describe these information the algorithm need.

Actually, the request is send to functional bricks but not the nodes. We use functional bricks to build our system and each brick perform a certain part of the forwarding procedure. One physical node may host more than one functional bricks in parallel. There are two types of functional bricks: checking bricks and matching bricks. A checking brick can only handle a certain part of constrains assigned to a certain attribute and a matching brick can match the merged result produced by participating bricks with subscriptions. A request containing metadata and id will be send to several checking bricks one by one. Every checking brick checks if there is any attribute in metadata can be checked by self and send the remaining message to next brick. If such attribute exists, all related constrains will be calculated and produce a set of passed constrains, represented by some kind of Bloom filter. The result will be merged with those produced by other functional bricks. At last the final result will be send to a matching brick where the real forwarding addresses will be calculated.

4.2 Functional Brick

Functional bricks are basic computing units in our design.

4.2.1 Brick or node

First, limited to the scale of storage, one node may need to host several bricks to enforce our mechanism, though this should rarely happen since we are talking about large scale storage network.

Second, One physical node may have the capacity of hosting several functional bricks. For example, modern computing devices often contain several computing units in boxed, such as one or more GPUs and as well as multicore processors. It is likely to have the capacity of running several functional bricks at the same time.

Third, the functional brick actually defines the minimal size of computing that can be performed in parallel: different attributes can be handled at the same time and constrains share same attribute should be checked without being separated since many constrains are in partial order and most computing can be eliminated.

At last, another critical factor driving us to introduce the brick is that we can dynamically adjust the number of bricks to satisfy the fluctuant needs for computing resource and implement the system's self-tuning property.

4.2.2 A brick as a virtual machine

The idea of functional brick is inspired by system virtualization [15,16] and the architecture of Cloud Computing [17,18]. A functional brick is some kind of function-limited, lightweight virtual machine. Just like a virtual machine host in the cloud, a functional brick can be lunched from an image stored somewhere.

In our design, functional bricks are lunched using an executable functional image (FI), and a virtual storage image (SI) would be attached to it after launching. Both those images are stored in storage system just like other objects and can be fetched using their id. There are only several kinds of read-only standard functional images providing designed functions and many different storage images to store different runtime data. A functional image for checking brick provides programs to perform checking on a certain kind of data type while a functional image for matching brick provides binaries mapping the set of satisfied constrains to real world addresses. For example, a checking brick's functional image may be launched to a checking brick to perform all string constrains related to a certain attribute while an matching brick launched by a matching functional image can find out if there are any filter in the set being exactly satisfied and take out assigned addresses related to those filters in a subscription. Additional, the implement of function-specific functional image do not need to be unique in one storage system, there are maybe more than one implements to satisfy varying environment and a node can choose one of them to launch a new functional brick. A storage image contains information related to specific attribute, such as, a binary search tree contains all strings occurred in constrains related to attribute "producer".

With the combination of different functional image and storage image, a functional brick can act as different role. For example, a checking brick lunched from an functional image of handling strings and attaching a storage image which storing all constrains related to attribute "name" can check all predicates for attribute "name". When new subscription registers in system, new constrains will be merged into related virtual storage images.

Specific storage image usually have many copies to fasten the lunching time of functional bricks, but that may need additional mechanism to ensure the consistency of all copies on the other hand. Our suggestion is keeping few copies since the time used to launch is not so important and copying data to host's memory periodically to shorten the access time. The different copies using storage's duplicate mechanism to sync.

4.2.3 Self-tuning

An excellent advantage of using bricks is to make system self-tuning. For example, when too many forwarding requests occur in the storage network, more bricks can be launched to fit the need, and when fewer objects need forwarding we can terminate some of them to lighten system's load (then to reduce power consumption), or save resources to other tasks.

When a functional brick receives a request, first it will check whether it can handle such request, if not, it passes the request to other. Every request in the storage network with hold a number "hops" to record how many functional bricks have passed without being processed. If its "hops" reached a limited maximum value, a host can choose to launch a new corresponding functional brick for processing this request, if the physical host has resource to host another brick. If for a long predefined time a functional brick do not process any request, the brick will be terminated. Every functional brick keeps a queue for buffering and the queue's size should be carefully selected to trade-off the cost of transmission and the benefits of distribution.

4.3 Checking Constrains

A checking brick only handles predicates with a certain attribute, which calls its "target attribute", or "target string" since all attributes have type of string. Although checking bricks launched from different functional bricks have different behaviors, they still share some pattern in common. First, when received a message containing metadata, every checking brick need to find out if there any attribute can be test by self. Second, every checking brick enforce same mechanism to send remaining metadata to other checking bricks, to monitor subsequent checking bricks and merge self's result with others.

First, such a brick check if the request is a checking request. If not, the brick will pass it to another brick. Then it will find out if its target attribute is in the set of metadata's attributes. If not, the brick also pass it to another.

Second, the brick delete own target attribute and its value from metadata, and send remaining metadata to another brick at the same time. After this the brick set another thread to wait for the response.

Third, a brick use specific algorithm to calculate the result set (the result would be a Bloom filter to represent the set), which indicate those constrains satisfied by target attribute's value.

At last, when receives response from other brick, the brick update owns just calculated result with the received one and send response with new updated result to previous brick following the request's path. If not receiving the response for a limited time, the brick will send the remaining metadata to another neighbor.

4.3.1 Target attribute

When a request receives, one needs to quickly find out if there is any attribute that can be processed and pass the others to next. We use ternary search tree [19] to arrange the metadata. It takes O(logh) times to such in the tree, where h is the height of tree. Since all attributes are known when building the tree, we can build an optimal tree by, for example, sorting attributes and building by bisection method. Such a Tree performs much quicker for failed searching, and most of the searching would fail according to the relatively small size of the set of attributes for single object, so this should be quite fast.

4.3.2 Remote Bloom filter update

Bloom filters can effectively represents a set of all constrains that satisfied by an object. But the size is still too big to transmit. The simple method we used is to only transmit the non-0 bits. Although the total scale of the set containing all constrains is quite large, they are divided into different attributes and the number of constrains one object satisfied would not be too big. A functional brick holds self's Bloom filter and receives another Bloom filter with its non-0 bit, and set them to 1 on self's filter. We call this a method a remote bloom filter update. We use a general concept here since we are still seeking for a better algorithm.

4.3.3 Checking brick for numbers

For number attributes, we describe a quick checking algorithm as below.

For each attribute, we maintain an Lx4 table, where L is the total number of different values in all constrains related to this attribute. First column in the table records all values occurred in constrains, and the table has been sorted by this row. Every cell in Second to fourth column records a Bloom filter representing a set containing all constrains that would be

Number	>	<	=
-45.64	{5647, 7898}	{3611, 5564, 6617, 7118, 7130, 9142}	0
-38.26	{5647, 7898}	{3611, 5564, 6617, 7118, 7130, 9142}	0
-33.90	{2633, 5647, 6297, 7898}	{3611, 5564, 7118, 7130}	0
-26.93	{2632, 3005, 5010, 5647, 6297, 7898}	{3611, 5564, 7118, 7130}	{3540, 8132}
-17.08	{2632, 3005, 5010, 5647, 6297, 7898}	{3611, 5564, 7118, 7130}	0
-13.59	{2023, 2632, 3005, 5010, 5647, 6297, 7631, 7898}	{5564, 7130}	0
5.99	{2023, 2632, 3005, 5010, 5647, 6297, 7631, 7898}	{5564, 7130}	{3912, 8907}
14.50	{2023, 2632, 3005, 5010, 5647, 6297, 7631, 7898}	0	{2843, 8407}
20.93	{2023, 2632, 3005, 4189, 5010, 5647, 6297, 7631, 7898, 9473}	0	0
37.58	0	0	{8133, 9543}

Constrains	Bloom filter
{“>”, -45.64}	{5647 , 7898}
{“<”, -38.26}	{6617 , 9142}
{“>”, -33.90}	{2632 , 6297}
{“>”, -26.93}	{3005 , 5010}
{“=”, -26.93}	{3540 , 8132}
{“<”, -17.08}	{3611 , 7118}
{“>”, -13.59}	{2023 , 7631}
{“<”, 5.99}	{5564 , 7130}
{“=”, 5.99}	{3912 , 8907}
{“=”, 14.50}	{2843 , 8407}
{“>”, -20.93}	{4189 , 9473}
{“=”, -37.58}	{8133 , 9543}

Figure 1. Example of an Lx4 table maintained by numbers checking brick.

satisfied if this constrain is satisfied. We use F(i, op) to indicate the Bloom filter assigned constrain {op, v} in this table, where v is value in i-th row first column, and f(i, op) to indicate original Bloom filter of that constrain. Notes f(i, op) is all-0-Bloom filter if no such constrain exists. We fill the table using below rules,

$$F(i, \text{‘=’}) = f(i, \text{‘=’}), \quad (1)$$
$$F(0, \text{‘>’}) = f(0, \text{‘>’}), \quad (2)$$
$$F(i, \text{‘>’}) = F(i\text{-}1, \text{‘>’}) \text{ OR } f(i, \text{‘>’}), \quad (3)$$
$$F(L, \text{‘<‘}) = b(L, \text{‘<‘}), \quad (4)$$
$$F(i, \text{‘<‘}) = F(i+1, \text{‘<‘}) \text{ OR } f(i, \text{‘<‘}). \quad (5)$$

Take an example shown in Fig. 1, if we get a value 0.5. We could easily find the value −13.59 and 5.99, and the value in (5.99, <) indicates all satisfied constrain with an operation of “<” while the value in (-13.59, >) indicates those satisfied constrains of “<”. After applying bitwise OR operation on these values, we get Bloom filter {2023, 2632, 3005, 5010, 5564, 5647, 6297, 7130, 7631, 7898}. Such a Bloom filter represents a set of {{“>”, −13.59}, {“>”, −33.90}, {“>”, −26.93}, {“<”, 5.99}, {“>”, − 45.64}}, which is the set containing all constrains value 0.5 satisfied.

4.3.4 Checking brick for strings

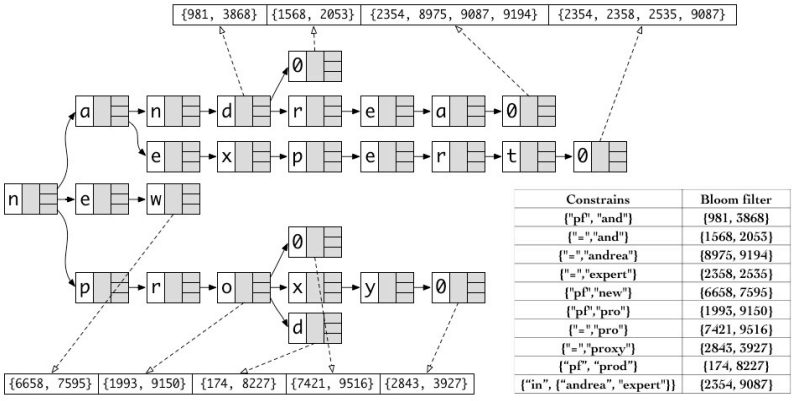
To keep simplicity, we only consider checking constrains of ‘=’, ‘PF’ and ‘IN’ operations, which can also be tested together.

For each attribute, we maintain a ternary search tree (TST) containing Bloom filters, whose each node represents a prefix of stored strings. All strings in the middle sub tree of a node start with that prefix. The string stored in TST contains the ending 0 which indicates the end of a string. If arrives in a node with the character ‘\0’, we would have matched a string exactly the same with the string it represented. For explanation, we call such a node 0 node, and others non-0 nodes. Each node in TST stores a character as well as an assigned Bloom filter. For 0 node the Bloom filter is the result of applying OR operations on constrain with “=” operation and all constrains with ‘in’ operations which string list contains this node’s represented string. On the other hand, for non-0 node, the Bloom filter represents constrain of ‘PF’ operation (0 if no such constrain).

When searching, the algorithm follows the path and update a Bloom filter whose bits are all 0 at first with each matched node’s Bloom filter. When finished, the final Bloom filter would already contain all constrains satisfied. Take the example shown in the Fig. 2 (Bloom filter of all bits are 0 is hided), if we get a string “andrea”, we can get the filter {981, 3868} and {2354, 8975, 9087, 9194} following searching path. And the final Bloom filter is {981, 2354, 3868, 8975, 9087, 9194}, or, the set of constrains {{“pf”, “and”}, {“in”, {“andrea”, “expert”}}, {“=”,”andrea”}}.

4.3.5 Monitoring chain

In our original design, we just send request to another node after finishing own computing on target string, containing the result this brick have just produced. After that,



Constrains	Bloom filter
{"pf", "and"}	{981, 3868}
{"=","and"}	{1568, 2053}
{"=","andrea"}	{8975, 9194}
{"=","expert"}	{2358, 2535}
{"pf","new"}	{6658, 7595}
{"pf","pro"}	{1993, 9150}
{"=","pro"}	{7421, 9516}
{"=","proxy"}	{2843, 3927}
{“pf”, “prod”}	{174, 8227}
{“in”, {“andrea”, "expert"}}	{2354, 9087}

Figure 2. Example of a ternary search tree contains Bloom filters

previous node does not care about anything about this object. When building the prototype, we found the problem soon. Our forwarding mechanism will be built on the massive storage network constituting large number of inexpensive commodity components. Due to the instability of such components, a message one node pushed to another may lose during the transmission, or the receiving node may crash and fail to finish the procedure. To resist the instability of components, we use monitoring chain to supervise the bricks involved. After pushing metadata to anther brick, the brick does not be terminated immediately, but remains a thread to wait for the response. This waiting uses few computing resources. If there is no response for a pre-set limited time. This brick will choose another brick to send request again. Now the question is: when to send the question?

One scheme is after processing. When having produced result, sending the metadata as well as the current checking result will reduce the network traffic since the response just need to contain a simple signal of having finished its work. By this way the last checking brick can also immediately send current result which is merged following path to matching brick and then push id to matched subscribers. But the disadvantage is inevitable: it may make users receive the id more then one times. For instance shown in Fig, when checking brick C2 not having received a response from C3, it does not know whether C3 have done its work and forwarded the request yet or not. So C2 may send request to another brick, said C5. If C3 has already finished its work and passed the remaining metadata to C4, C4 will continue the process since it does not know anything of previous bricks. For now there are two processes in whole system and those related subscribers would be likely to receive the id twice.

Another scheme is, on the contrary, sending the remaining metadata, if exists, to another brick before starting computing and waiting for response containing subsequent result. When receives, own result will be updated with the received Bloom filter and be send to previous brick after updating. Each brick only handle the first reply and ignore the others. By this way, we can ensure the id be sent to user only once. Fig. 4 shows the example.

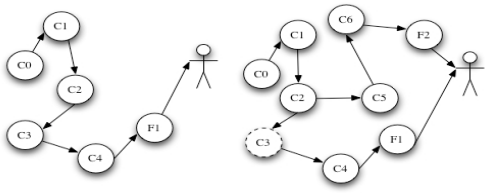


Figure 3. Failure example in scheme of no monitoring chains

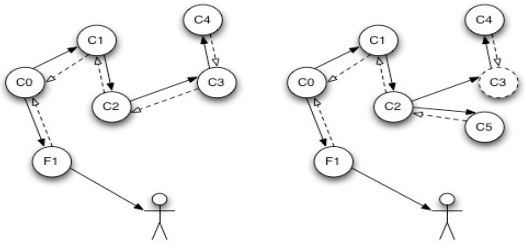

Figure 4. Failure example in scheme of no monitoring chain

We do not consider the situation that the head of monitoring chain fails because this brick hosted on the node that plays an important role in the storage procedure and failure occurred in this node may interrupt the storage procedure. Without having stored available copy of object, the forwarding result is senseless. So we leave such failure at chain's head to the underlay storage network.

4.4 Matching subscriptions

When a Bloom filter representing all satisfied constrains be produced, which would finally arrive the first brick started the algorithm, the Bloom filter and its id will be send to a matching brick for matching with all (or part of) subscriptions and find out the addresses the id should be send to. We say A matches B when A AND B equals to B, where AND is bitwise AND operation. The final matching procedure accepts a Bloom filter and a one-to-one list of addresses and its related Bloom filters and output the addresses that the id should be send to.

4.4.1 Subscription's Bloom filter

A subscription's Bloom filter represents a set containing all constrains that that subscription contains. That is, the result of feeding all constrains' Bloom filters to bitwise OR operation. For example, a subscription containing constrains which assigned Bloom filters are {1345, 7892}, {2363, 4654} and {2363, 9988} will be assign a Bloom filter {1345, 2363, 4654, 7892, 9988}, and Bloom filter {876, 1345, 1424, 2363, 4654, 7892, 9988, 9999} will match it.

4.4.2 Quick matching

We can check if A matches B using (NOT ((A AND B) XOR B)), where NOT, AND and XOR are bitwise operations. We do not use the bftree or sbstree used by Jerzak [20], because we think that (1) in our sceneries, there are many different subscriptions' Bloom filters can be matched. If we arrange these subscriptions into a tree, we need complex data structures and operations to travel among the nodes again and again. (2) This part of computing can be the most time-consuming part of whole procedure, but at the some time, is highly independent for each other and simple enough for just some bitwise operations. We can play a trick here: push this tasks to GPU, which can do these in parallel. We keep all subscriptions' Bloom filters in video memory to reduce the low-speed host to device copying and just send non-1 bit to GPU every time and output a list of wanted address's indexes.

4.5 Register subscriptions

The first thing for a subscribe/publish system is to register a subscription. The procedure is as below:

1) A subscription containing disjunction of conjunctions of elementary predicates will be separated to several

subscriptions containing only one filter (conjunction of predicates) with same target address.

2) For each one-filter-subscription, a Bloom filter will be assigned to every constrains in it, and the subscription's Bloom filter will be calculated as well.

3) New subscription's Bloom filter and its target address will be added to the list hosted by matching brick and will be merged into its storage image. And all constrains and their Bloom filters will be merged into corresponding attribute's structures in storage images.

5 Conclusion

It's necessary for a massive storage system to provide a content-based publish/subscribe service to support wide-area sensors network. Using this flexible object forwarding mechanism, data produced by wide variety of sensors can be aggregated and disseminated more effectively. By carefully using the limited computing resources of nodes in massive storage network, we proposed a scheme for this heavy task. Inspired by the development of system virtualization and the Cloud Computing, we introduced a concept of "brick" to dynamic schedule resources and tasks. Different functional bricks can be created from images to handle different attributes in a object, and at the same time they can be launched and terminated by actual demands and the resource situations of their host. We also provided same sample implements for checking brick of Integers and Strings. For every type of attribute, we have shown a fast constrains checking algorithm

Parallel Algorithm for Building Extraction from LiDAR Data

Hyo Jong Lee
Div. of Computer Science and Engineering
Center for Advanced Image and Information Technology
Chonbuk National University, Jeonju, Korea

Abstract - *The data presented by Light Detection and Ranging (LiDAR) systems are in a dense and accurate three dimensional pattern without point classification, such as trees, roads, and buildings. Extraction of boundary points is essential for recognizing buildings. However, it is complicated to process the LiDAR data due to its irregularity and a large number of collected data points. In order to find boundary points in a quick and accurate way from a huge number of data points, a parallel algorithm for building extraction is proposed. In this paper, every processor reads the LiDAR data points and builds a quadtree respectively. Thus, a quadtree is built and shared through a network file system. Later, a breadth first search (BFS) is applied on every processor. The position of a node in the quadtree, in which has the number of children smaller than a predefined grain size, is stored in an array called as BFSArray. Process farming paradigm has been applied to process each nodes using MPI. In our primary experiment, results show significant speedup for multiple processors compared to a sequential algorithm.*

Keywords: Boundary point, process farming, MPI, LiDAR

1 Introduction

Recently *Light Detection And Ranging* (LiDAR) has become a reliable technique for 3D data collection [1]. The LiDAR system consists of three data collection tools: a laser scanner, Global Position System (GPS) for sensor position information, and an Inertial Measuring Unit (IMU) for orientation information. The laser scanner transmits and detects infrared signals to measure ranges.

LiDAR offers many advantages over traditional photo-grammetric methods for collecting elevation data. These include high vertical accuracy, fast data collection and processing, robust data sets with many possible products, and the ability to collect data in a wide range of conditions [2]. Therefore, LiDAR system has been introduced as a new tool that efficiently provides accurate data collection from extensive areas.

In LiDAR processing there are two completely different possible approaches for processing images. One is using 2-D images. The advantages of 2-D images are less time required for processing and less cost. However, images in 2-D format are inadequate for accurate modeling and for defining road boundaries and other building boundaries due to their lack of high resolutions [3]. Accordingly, recent demand and utilization of 3-D terrain information has been increased in various field and researchers have already investigated 3-D extraction methods of geographical features, buildings, and road networks [4].

Obviously more time is required for processing 3-D images. In order to find boundary point in a 3-D images format in a quick and accurate pattern, parallel computing algorithm is one option. In our paper, parallel computing algorithm is applied. Firstly, all LiDAR points are built in a quadtree structure in every processor. Hence, a shared quadtree is accomplished. Secondly, BFS search is used on every processor for finding all nodes, in which the number of children is smaller than a predefined grain size. Experiment results show that building a quadtree and BFS searching take only a small amount of time compared to finding boundary point. At this point, all preparation work for our parallel computing algorithm is finished. Afterwards processor farming is performed for distributing tasks to processors. Messages Passing Interface (MPI) is employed as a communication tool during the whole process. Details description will be presented later.

The rest of the paper is organized as follows. Section II introduces quadtree representation of LiDAR data and the concepts of processor farming model. In Section III we discuss the detail operation of our algorithm. Experiment results and discussion are described in Section IV. Conclusion is drawn in the last section.

2 Quadtrees and processor farming model

2.1 Quadtree and its properties

In the field of image processing, computer graphics, and remote sensing two dimensional point and ranging data are often indexed using quadtrees[5]. A quadtree is a tree data structure in which each internal node has up to four children. All data information are stored only in the leaf nodes. Data in a quadtree is often collected in point format, for example, a height measurement is made at that location, and represented by an (x,y,z) triplet with x and y representing coordinates and z representing a measurement at that location. Nevertheless, a parent node only has the information of the number of children and the area range of its all leaf nodes locate in.

Quadtrees are most often used as a representation of a regular partitioning of space where regions are split recursively into quadrants until there is only one point in each quadrant. In other words, each quadtree block (also referred to as a cell, or node) only contains one particle. In Fig. 1, the region is recursively divided into four parts if more than one particle exists inside a single block.

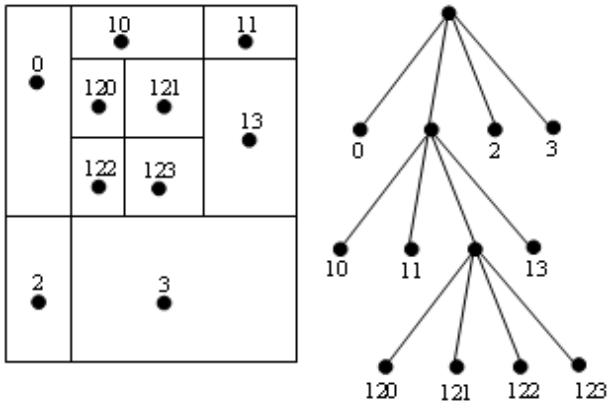

Figure 1. Quadtree structure

Quadtree-based spatial domain decomposition algorithm is designed for general use, and it can produce scalable geographical workload [6]. As we mentioned previously, LiDAR points are in a dense pattern, it is necessary to reduce the size of quadtree first before extracting boundary point. A quadtree with either a threshold or a maximum-depth limit allows us to reduce the size of tree at the cost of prediction accuracy, as it is no longer an exact copy of the original data. Setting the accurate threshold helps smooth the experimental data [7]. In this paper, a threshold value of height was set to compress a quadtree. A threshold means a criterion to merge any adjacent blocks as a single block if the height difference for the adjacent blocks is smaller than the predefined threshold.

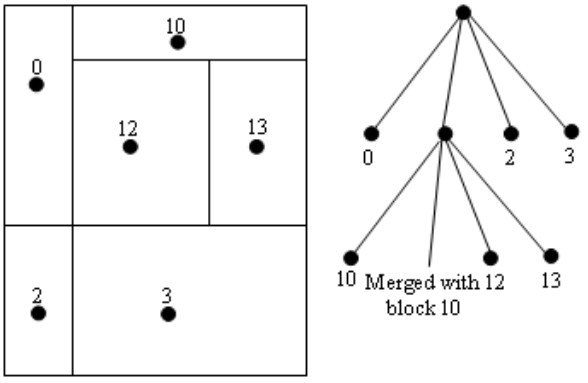

Figure 2. Reduced quadtree structure

Assuming the different height values in block 120, 121, 122, 123 in the Fig. 1 fall into the threshold, we can consider them as a single block and merge them. Equally, we assume the difference of height in block 10 and 11 is smaller than the threshold and the different height values in remaining blocks are bigger than the threshold. Therefore, block 10 and block 11 can be taken as a single block. After two block are merged, we use the average height as a new value to represent the height information in such block. Fig. 2 illustrates the reduced quadtree structure from Fig. 1 based on our assumption.

In this paper, the parallel computing algorithm is mainly focused. Therefore, finding the optimized threshold value for merging is out of scope of our problem. Adjusting the different threshold values will produce a more precise image.

2.2 Processor farming

The processor farming model works well even in a condition where pipeline structure cannot balance tasks or there are not enough buffers. Cok[8] also stated that efficient parallel algorithms could be implemented with processor farming.

Processor farming is defined as a group of independent tasks. The processors consist of a master processor and a number of worker processors [9]. A master processor controls the whole parallel processing. Our quadtree is not well balanced, that is, some nodes contain a little number of children, while other nodes contain a large number of children in BFSArray. It degrades the efficiency of algorithm if a master only sends one index of BFSArray to a worker processor at each time.

To solve the problem, we define a *lower bound* as grain size - α, and a *upper bound* as grain size + α at first. The α has been chosen to be equal to approximately 10% of the predefined grain size. When parallel computing algorithm begins, a master processor starts from the first index of the array. We call it a *start index*. If the number of children of a target node is smaller than a lower bound, then we move the pointer to the next index of array, until the total number of children of all nodes reaches lower bound or exceeds upper bound. Now, we mark the position of current pointer as an *end index*. If the second situation happens, we prefer to move the pointer back by one index. Surely, if the total number of children for all rest of nodes in BFArray is smaller than lower bound, then master sends the *start* index and the *last index* of BFSArray to a worker processor and broadcasts a "finish" signal to all worker processors. Worker processors stop receiving tasks as long as a "finish" signal received from master processor.

Likewise, a "finish" signal is sent back by a worker processor to the master processor as soon as it finished the assigned task, then the master processor repeats the previous procedure and sends *start* and *end* index to that worker processor until no more tasks are available in BFSArray.

Fig. 3 illustrates the first 13 elements of a hypothetical BFArray when grain size is defined as 40,000. The smaller number denotes the index of array. The number in the array box presents the number of children the node has. Actually, BFSArray is a pointer array and stores the address of those nodes and each node contains the information of number of children it has.

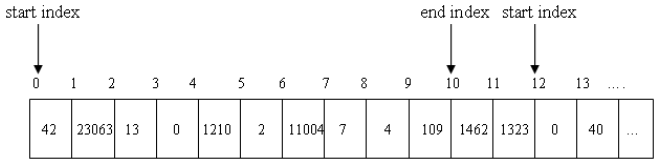

Figure 3. BFS array

When a grain size is 40,000, the lower bound and upper bound of grain size is 36,000 and 44,000, respectively. Consequently, a master processor stops moving a pointer to next index value if total number of children either falls between a lower bound and a upper bound or is beyond the upper bound scope.

The first element of BFSArray only has 42 children, and then master processor moves the index pointer to next one and calculates the summation of number of children. The index pointer stops at the index 10. Because the accumulated of children of the first eleven elements is 36916 $\in$ [*lowerbound; upperbound*]. After that, a master processor sends *start index* 0 and *end index* 10 to a worker processor. A master processor repeats this procedure until all tasks are assigned to each worker.

In next section, a detail operation for how the boundary points is generated by a proposal parallel computing algorithm will be discussed and our parallel computing algorithm will be presented.

3 Parallel Monotone Chain algorithm

Andrew's Monotone Chain algorithm [10] is implemented for extracting boundary points in this paper. The "Monotone Chain" algorithm computes upper and lower hulls of a monotone chain of points. It runs in O(*n*log *n*) time due to the sort time. After that, it only takes O(n) time to compute the hull, a hull has the same meaning of boundary point in our paper.

As we have introduced the LiDAR data previously, an object, such as a roof or a road, is represented by a set of dense data points. In order to extract the boundary points for an building, a reduction on quadtree size is preferred at first. Finding a group of neighbor points is a priori for extracting boundary points of an building. Without reducing the size of quadtree, it increases the computation time of finding groups of neighbor points. A group of neighbor points could be an object or multiple adjacent objects and the computation time for determining a group of neighbor points is $O(n^2)$. Because every point has to look for all other points for one time and the final neighbor points are determined. In our experiment, we find out reducing a quadtree does not take too much time. In contrast, looking for a group of neighbor points at the same height consumes most of computation time. Thus, reducing quadtree size is essential for speeding up the whole process.

Each index in BFSArray points to a node, in which has less number of children than a grain size. When a worker processor receives a *start* and *end* index of BFSArray, reducing each sub-quadtree according received index information. It starts to reduce the sub-quadtree, which is pointed by *start* index, and finishes until the sub-quadtree that is pointed by *end* index is compressed. After that, processor collects all the remaining data points in each sub-quadtree and sorts them by their height values.

Andrew's Monotone Chain is designed for 2D-image. In order to apply Andrew's Monotone Chain in 3D-image, we have to extract 3D-image points at different height level. Therefore, a reasonable threshold of 0.1 meter is used. When height threshold is used, all points with the height difference is smaller than the height threshold are considered on the same plane. With all the data points that a worker processor collects from reduced sub-quadtrees, a worker processor classifies all these data points. It starts from the data with the lowest height value and finds all other data points which are on the same plane. Afterwards, processors look for group of neighbor points on this plane. Finally, boundary points of each group of neighbor points can be found at this height level. After that, worker processor moves to next height level and find boundary point until all data points from reduced sub-quadtrees are searched.

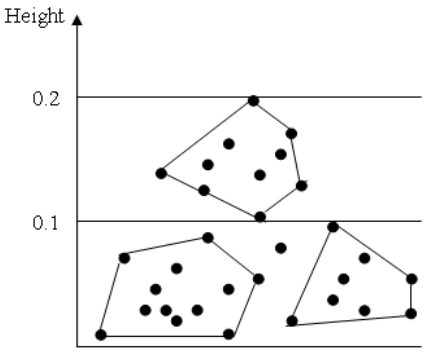

Figure 4. Finding boundary points

Suppose all the points in Fig. 4 are the remaining points after a processor performed a sub-quadtree reduction. Since all data points are sorted by height value, we know the data point whose height is the lowest. In Fig. 4, all height values have subtracted the lowest height value. Hence, the value of height starts from 0 in our example. Basically, we use the divide and conquer method to speed up the whole process. Instead of allowing one processor to find all groups of neighbor data points and then extract boundary point from each group of neighbor data points, we first store all LiDAR data points in a quadtree tree and master sends the index of BFSArray to processors, which can be considered as sending a small number of data in a small area each time to processors. With small amount of data points, worker processors finish the task much faster, since a huge amount of time on finding neighbor data points is saved. A master processor sends another task to a worker processor as soon as the worker processor finished previous assigned task.

Worker processors store the boundary point into a buffer and send the list of boundary points back to a master processor if buffer is full. We have not proved the optimal buffer size; however, the performance is acceptable in the

experiment when the buffer size is chosen as 4 or 5 times of grain size. When a master processor receives a boundary point list from a worker processor, then it resorts the all the boundary points and extracts a new list of boundary point as the same way as worker processor does.

Processor farming plays a key role in our parallel computing algorithm for extracting boundary point list. Fig. 5 presents the processor farming model of our parallel computing algorithm and the parallel computing algorithm for extracting boundary point is presented in Fig. 6.

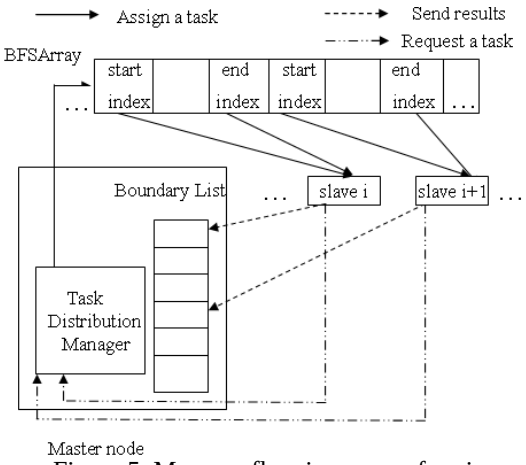

Figure 5. Message flow in process farming

Algorithm 1: Parallel Extraction of Boundary Points

***Master part*;**

Build a quadtree and creates a BFSArray;

Distribute a new task as soon as a worker finished an assigned task;

if *the buffer is full in a worker* **then**

Receives the list of boundary point in the buffer and resort all boundary points ;

end

Collect all boundary point list from workers when no available task in BFSArray;

Produce the final boundary point list;

***Worker part*;**

Build a quadtree and creates a BFSArray;

Receive a task and compresses sub-quadtrees;

Extract boundary point of buildings;

if *buffer is full* **then**

Sends a list of boundary points back to master;

end

Send the list of boundary points when all assigned tasks were finished;

Figure 6. Parallel algorithm for boundary extraction

4 Experiment results

The implemented parallel computing algorithm for abstracting boundary point was experimented on a clustering system, which has a master processor and 17 worker nodes. the master processor is Intel Xeon 2.8GHZ and each worker processor is Pentium 4 630, 3GHz. The parallel library is MPI 2.0 which was released by the MPI Forum [11]. The total number of data set is over four millions, which were collected by LiDAR from urban area.

Fig. 7 shows a sample LiDAR data and corresponding buildings extracted. Since LiDAR data are a set of coordinates with its height, the height values have been visualized as shown in Fig. 7 (a) using a rainbow bar. The extracted buildings were outlined connecting points from the Andrew's Monotone Chain algorithm. We confirmed visually that every building has been extracted correctly with an aerial photograph.

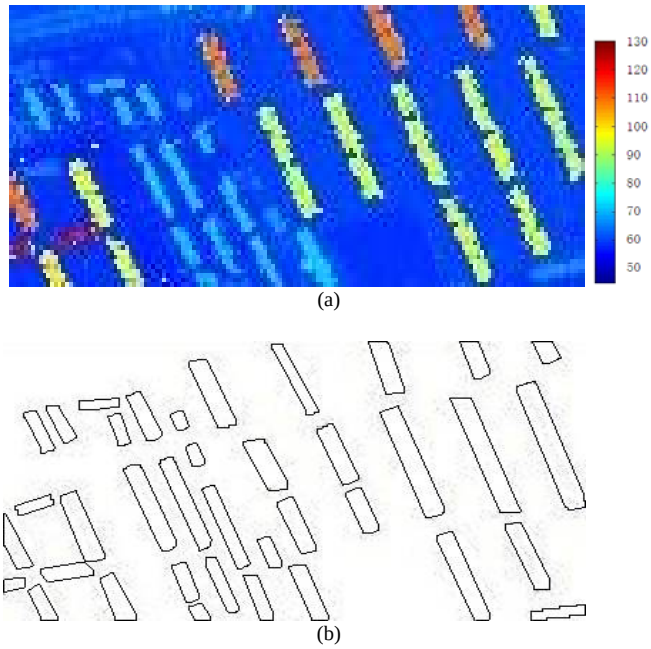

Figure 7. (a)Visualized sample LiDAR data (b) Corresponding buildings extracted

During the experiment, we tested the time for extracting boundary point with three different grain sizes. With over 4 million test data in this experiment, we chose the grain size 4,000, 40,000 and 400,000 respectively, and execution time is plotted in Fig. 8.

From Fig. 8, the performance is the best when the grain size is defined as 400,000, which is around 10% of all test data. When the grain size is small, the communication overheads increase. In our algorithm, worker processor takes much less time to finish an assigned task when the grain size is small. The reason is the complexity for finding neighbor points is $O(n^2)$. With less number of data points, the time for extraction of boundary points is much less. However, a master processor

takes more time for computation boundary point list from receiving worker processors and communication overheads were increased sharply.

From Fig. 8, it also indicates that scalability fails earlier when a very small grain size is applied. In our case, the scalability fails only after 3 processors involve, when grain size is chosen as 4,000, which is only 1/1000 of our test data. This issue should be taken care of in further study.

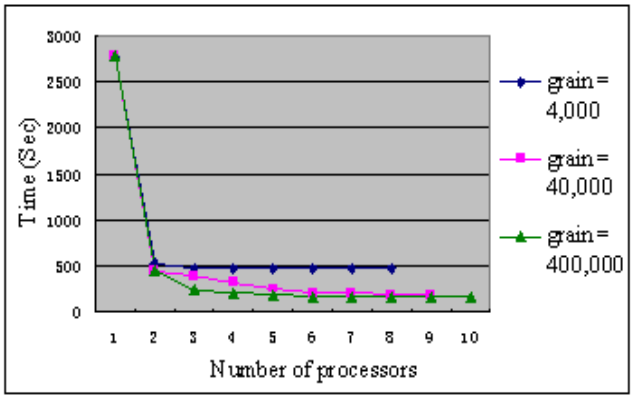

Figure 8. Excution time for extracting boundary points

5 Conclusions

Extraction of buildings from 3-D LiDAR data requires heavy computational processing. A parallel computing algorithm with processor farming model is proposed in this paper to reduce the processing time. Our algorithm is starting with building a quadtree on every processor and performs a BFS search. A BFSArray stores all the position of nodes, in which has less number of children than a predefine grain size. Processor farming distributes the indices of BFSArray to worker processors. The worker that completes a task first always asks for another task from the master. Boundary points only are sent among workers and master when the buffer is full in the workers or workers have finished all tasks in order to reduce the communication overheads. Grain size affects the performance of our parallel computing algorithm. With a small grain size, the scalability fails earlier and load balancing becomes an issue, since a master is busy at most time with extracting boundary points. The experiment results show our parallel computing algorithm improves the processing time six times faster than a sequential approach, which only one processor works.

In this paper, we do not focus on the accuracy of boundary points. However, with adjusting threshold or applying more sophisticated building extraction algorithms will generate more precise buildings. During the experiments, it proves that our parallel computing algorithm with a processor farming model works well for a large number of data set. Therefore, it is suitable for a vast range of parallel computing applications.

Abstract - *A novel method for fault diagnosis in analog circuits using S-transform (ST) as a preprocessor and Particle Swarm Optimization (PSO) based neural network (NN) identifier for classification is proposed in the paper. ST provides a frequency-dependent resolution and the features obtained from the ST are distinct, and easy to understand. The identifier, evolving with PSO, is a promising method to train NNs. It is faster and gets better results, and avoids some problems of conventional backpropagation (BP) algorithms. The comparison between the ST-based method and the wavelet-transform based method, and comparison between the ST and PSO method and the traditional NN method for analog fault diagnosis is provided. Simulation results show that the proposed method is effective in enhancing the efficiency of the training phase and the performance of the fault diagnostic system. The results clearly indicate higher correct classification of fault classes in the example circuits of similar faults.*

Keywords: analog fault diagnosis, PSO, S-transform, mixed-signal test, neural networks

1 Introduction

Analog circuit fault diagnosis has been an active area of research since the mid-1970s with significant work carried out at the system, board, and chip level [1]–[10]. A survey of the research conducted in this area clearly indicates that analog systems are among the most unreliable and least testable systems due to poor fault models, component tolerances, and nonlinearities compared with digital circuits [3-7]. This makes application of neural networks to this area very appealing since no mathematical model or comprehensive examination of these effects is required. The work in [2] is a pioneering effort, directly feeding samples of the impulse response of the linear circuits to the NNs as their inputs without any preprocessing. Nonlinear circuits are considered [3] in the frequency domain at different frequencies. Reference [4] presents a global parametric method, whose features are calculated from time domain response to a voltage step. It is executed with the use of an NN supplied with extracted features. The authors in [5] present a NN based method without preprocessing. The method requires a significant number of inputs even for a small circuit. Literature [7] presents a NN based system for linear circuit diagnosis, with preprocessing by wavelet decomposition, principal component analysis (PCA), and normalization to generate features for NNs. This technique is extended to actual circuits in [8]. References [9-10] deal with soft and multiple faults based on the parameter method. A wavelet NN method is presented in [11]. A method of designing specialized a-periodic excitation signal in time domain is described in [13], where single parametric faults are investigated by applying wavelet transform and genetic algorithms for further improvement.

Some outputs of a circuit are similar because of various factors such as element tolerance. In some cases, the outputs are so similar or even overlapped in their input space that we cannot successfully classify them. So they are often considered as ambiguous sets, which is not beneficial to real diagnosis applications. Therefore it is necessary to distinguish among fault classes with similar feature values, which always lead to a significant overlap. The work in [7] reveals that R6⇑ , R7⇓ , and R9⇑ (⇑ and ⇓ here indicate values higher and lower than the nominal values respectively in Fig.2) are similar faults, and a wavelet based method can successfully identify the faults of the circuit only if these similar faults are placed into one fault class [7]. Thus they are ambiguous sets. Otherwise, NNs cannot convergent at all.

The ST, as a hybrid of short-time Fourier transform (STFT) and wavelet transform (WT), has the similar form of STFT except its window width changing with frequency. So the progressive resolution can be provided by ST, just similar to WT. Moreover, ST interprets more straightforward frequency information than WT because a time-frequency axis is used in ST rather than a time-scale axis in WT. Hence ST provides a frequency-dependent resolution and the features obtained from ST are distinct, and immune to noise.

In this paper, we propose a S-transform based approach to analog fault diagnosis that overcomes the shortcomings of conventional methods. In this approach, we use ST as a processor to extract fault features. The outputs of a circuit under test are preprocessed by ST decomposition, PCA, and normalization to generate features. We adopt a PSO based NN identifier, which doesnot involve the gradient descent method and usually has fewer and less sensitive NN parameters than BP. This suggests that the PSO based NN identifier may be more robust.

2 S-Transform

Time-frequency analysis [13-16], as a tool of analyzing signals in both time and frequency domains simultaneously, is

very powerful in signal processing. Among the various proposed time-frequency analysis methods, STFT and WT are the most well-known and widely used linear transforms, which have the advantage of high efficiency and flexibility in the time-frequency filters. The progressive resolution can be provided by ST with its window width changing with frequency. And the ST, with a time-frequency axis is used rather than a time-scale axis in WT, is a more straightforward interpretation of frequency information than WT. So ST is a novel frequency-dependent resolution and the features extracted from ST are distinct and immune to noise.

The S-transform [13-16], is a powerful linear time-frequency representation. The filters in S-transform may consist of data adaptive weighting window with higher values for signal and lower for noise. The ST of x(t) [13] is

$$s(\tau, f) = \int_{-\infty}^{\infty} x(t) w(t-\tau, f) e^{-i2\pi ft} dt \tag{1}$$

Where *f*, *t* and τ are frequency, time and the center of the Gaussian window, ***w(t)***. ***w(t)*** is defined as

$$w(t-\tau, f) = \frac{|f|}{k\sqrt{2\pi}} e^{-\frac{f^2(t-\tau)^2}{2k^2}}, k > 0 \tag{2}$$

Where k is the dilation (window width) parameter, which determines the time frequency resolution. Unlike STFT, the width of window varies with frequency in S-transform. The S-spectrum of *x(t)* $\left(t \in [-\infty, \infty]\right)$ can be written as

$$\int_{-\infty}^{\infty} s(\tau, f) d\tau = \int_{-\infty}^{\infty} x(t) \int_{-\infty}^{\infty} w(t-\tau, f) d\tau e^{-i2\pi ft} dt \tag{3}$$

Letting T be the sample interval, the discrete realization of the ST can be calculated by taking the fast Fourier transform (FFT) and the convolution theorem:

$$s\left(jT, \frac{n}{NT}\right) = \sum_{p=0}^{N-1} X\left(\frac{m+n}{NT}\right) e^{-\frac{2\pi^2 m^2}{n^2}} e^{i\frac{2\pi m}{N} j} dt \tag{4}$$

Where $j, m, n = 0, 1, 2, \cdots N-1$ and N is the number of sampling points. $s(jT, n/NT)$ is available once the Fourier spectrum of $x(t)$ are obtained. And then compute the localizing Gaussian for the required frequency. We can get the S-spectrum by repeating the steps until all the rows of $s(n, j)$ to every frequency n have been obtained.

3 PSO based NN classifier

Conventional NNs have been widely used as trainable classifiers because of their generalization ability and function approximation [l8-21]. NN has the ability to form arbitrary nonlinear surfaces, and to respond consistently to data that are not trained with. However, the NNs use sharp decision boundaries to partition the feature space so their ability to estimate is limited. They are unable to correctly estimate class membership of data belonging to regions of the feature space if there is overlapping between the classes.

Particle Swarm Optimization (PSO) algorithm is a method for function optimization [18-20] based on social-psychological principles and provides insights into social behavior. The particles, which are a swarm of individuals, explore a multidimensional search space. The velocity vector is adjusted according to which particle goes through the search space. Therefore prior personal successful positions and the best position are found within a specific neighbourhood and act as attractors.

In PSO, a swarm of particles moves through a multi-dimensional search space [18-20]. A particle is defined by its current position *x* and velocity *v*. Each particle remembers the location y at which it has found the so far best solution to. The updating of velocity is

$$v(t+1) = wv(t) + c_1 r_1 (y - x) + c_2 r_2 (\hat{y} - x) \tag{5}$$

Where r_1 and r_2 are uniformly distributed random numbers from [0 1]. w is the inertia neural network weights, y is the personal best attraction potential. $\hat{y}$, the neighbourhood best position, is varied with the respective weights c_1 and c_2. The position $\hat{y}$ is either the best position of all particles (gbest) or the best positions within a local neighbourhood of the particle. The local neighbourhood (lbest) is to number the particles from 0 to $m-1$ and the neighbourhood of particle *i* consists of particle *i* itself and the two particles $i-1 \bmod m$. After the velocity has been updated, all particles move one step with their newly determined velocity as

$$x(t+1) = x(t) + v(t+1). \tag{6}$$

4 S-Transform and PSO based NN for Analog Fault Diagnosis

In this approach, the responses of the circuit under test (CUT) are simulated under the pre-assumed faults. And the sampled responses are processed by S-transform. The outputs of the ST are the so-called fault features. The features are applied to a BP neural network during the training phase. A unique code is given to a certain number of fault classes in advance. All the features and the associated fault codes are presented to a neural network as input–output pairs, when the BPNN is trained to its balance state after adjusting its weights and bias parameters. In the testing phase, we measure the responses of CUT stimulated by the same sources. Then the outputs of the ST are the features as input to the trained NN.

To investigate the effectiveness of the proposed approach in our fault diagnostic system, we use two circuits. The first real circuit is the Sallen–Key bandpass filter with a center frequency of 25 kHz [7], as shown in Fig.1.The nominal values for the components are also shown in Fig. 1. The tolerances of

the resistors and capacitors are assumed to be 5% and 10%, respectively. The faulty responses of the circuit are obtained when any of the components R3, C2, R2, and C1 is higher or lower than its nominal value by 50%, with the other three components varying within their tolerances. We consider the following fault classes: R3⇑ , R3⇓ , C2⇑ , C2⇑ , R2⇑ , R2⇑ , C1⇑ , and C1⇑ . The input source is an pulse of 5V peak and 10μs duration.

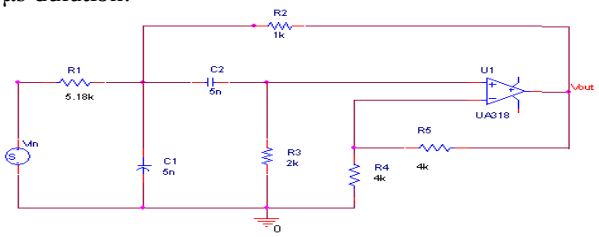

Fig. 1 25kHz Sallen–Key bandpass filter

The second circuit is a two-stage four operational amplifier (op-amp) biquad low-pass filter [7], shown in Fig.2. The authors in [7] pointed out that R6⇑ , R7⇓ , and R9⇑ are similar faults, and traditional fault diagnostic systems can successfully identify the sampled faults of the circuit only if these similar faults are placed together into one class of fault sets [7]. Otherwise, a neural network cannot be trained to distinguish among all the faults in [7].

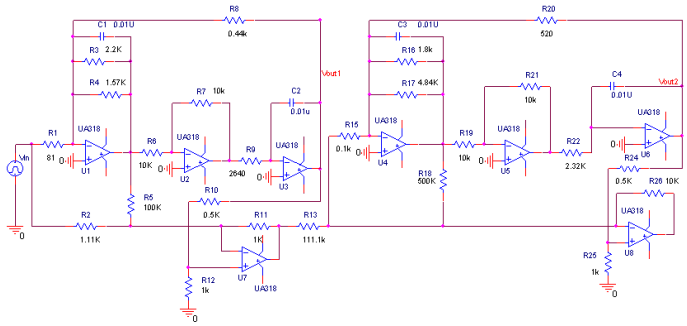

Fig.2. Two-stage 4-opamp biquad low-pass filter

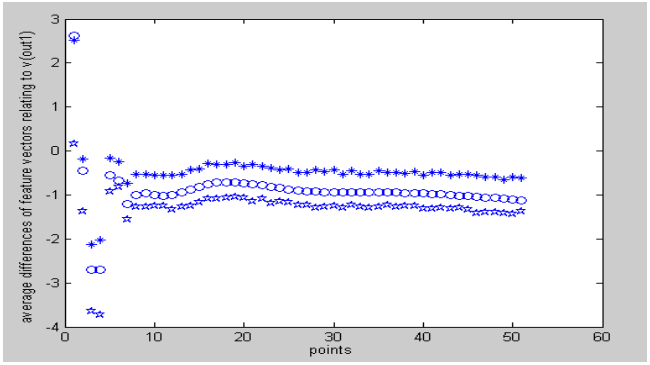
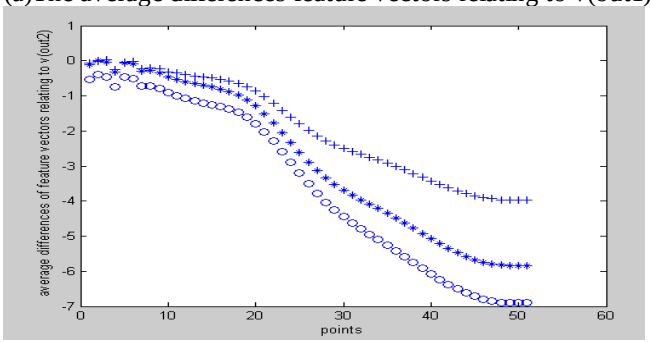
Using our proposed approach, we can successfully classify all the faults, including the similar faults as mentioned above. By using ST processor, the difference of the contours for different faults becomes distinct. The features are obtained by principal component analysis and data normalization, after the S-transform of the responses of the circuits is available. The features are applied to NN and its outputs indicate the fault classes. The average difference feature vectors of 500 Monte-Carlo runs when considering the three faults R6⇑ , R7 ⇓ , and R9⇑ are presented in Fig.3, which shows that the differences are distinct.



(a)The average differences feature vectors relating to v(out1)



(b)The average differences feature vectors relating to v(out2)

Fig.3. The average differences of feature vectors of 500 Monte-Carlo runs when considering the three faults R6⇑ , R7 ⇓ , and R9⇑

(*: the average differences of feature vectors between R6⇑ and fault free

(o: the average differences of feature vectors between R7⇓ and fault free

(+: the average differences of feature vectors between R9⇑ and fault free)

To perform diagnosis for Fig.1, the work requires a two-layer BP network with 15 inputs, 10 neurons in layer 1, and 3 neurons in the output layer. The network was able to properly classify 100% of the test patterns.

The BP network for Fig.2 is with 50 inputs, 36 neurons in layer 1, and 5 neurons in the output layer. We put R6⇑ , R7⇓ , and R9⇑ in three different ambiguity groups. We input the feature vectors to the NN after sampling the circuit response, running S-transform, calculating the amplitude of the ST output, and conducting PCA and data normalization. Training and testing data for fault free are randomly generated using Monte-Carlo method. The data for fault free is obtained by varying the circuit components to their nominal values within their tolerances, and the data for fault classes are obtained by varying the circuit components to their faulty values respectively. For each fault pattern, we run Monte-Carlo analysis 1000 times, 500 for training data and the rest for testing data. Binary outputs are adopted here to classify the fault sets. The transfer functions of neural networks are a sigmoid function. The population size is 25, $c_1 = c_2 = 2$, the maximum value of $v(t)$ is 0.9, the minimum error is 0.0001,the range of inertia weights is [0.9,0.4], the ranges of NN weights

and bias for search are [-100,100] and [-8,8], respectively. We compare the proposed method with the conventional WT and BPNN method for analog fault diagnosis in the paper. The NNs are with the same structure and parameters. The results are shown in Table 1.

Table 1: comparison of the proposed technique and WT techniques

circuit	Accuracy based on WT(%)		Accuracy based on ST (%)	
	BPNN	PSO	BPNN	PSO
Fig.1	94.72	95.13	95.03	95.22
Fig.2 (case1)	training failure	training failure	89.54	91.47
Fig.2 (case2)	92.76	94.01	93.01	96.82

case1: R6⇑ , R7⇓ , and R9⇑ is considered as a fault set
case2: R6⇑ , R7⇓ , and R9⇑ is considered as three fault sets

Table 1 shows that the performance of our proposed technique is better than the wavelet based technique ([7]) for both circuits, especially for the circuit in Fig.2. We can correctly identify the faults R6⇑ , R7⇓ , and R9⇑ . However, the wavelet based technique cannot be trained to separate all the faults shown in Table I. The proposed approach leads to a higher correct classification of the test data for all circuits even when R6⇑ , R7⇓ , and R9⇑ are considered as three different fault sets.

5 Conclusions

We have developed a ST preprocessor and PSO based neural network identifier based analog fault diagnostic method. The ST, as a combination of STFT and WT, has the similar form of STFT with more straightforward frequency information than WT because a time-frequency axis is used in ST rather than a time-scale axis in WT. All the features are extracted from the output of ST. The method significantly enhances the efficiency of the training phase and the performance of the fault diagnostic system. Our results clearly demonstrate the superiority of the method, which leads to higher correct classification of fault classes in example circuits in the presence of similar faults. The PSO based NN identifier leads to higher correct classification.

Multi-way Partitioning of Very Large Integrated Circuits

Jae Young Park, Soongyu Kwon, Kyu Han Kim, Hyeong Geon Lee, Jong Kang Park, and Jong Tae Kim
School of information communication engineering,
Sungkyunkwan University, Suwon, GyeongGi-Do, South Korea

Abstract *– This paper considers the problem of finding a minimum cost partitioning of a large logic circuit which is a collection of sub-circuits implementable with chips selected from a given library. Each chip in the library has a different price, area, and I/O pin. We propose a multi-way partitioning algorithm based on a simulated-annealing bi-partitioning. Chip set selection algorithm finds the sorted list of chip sets from minimum cost to maximum cost. Using the minimum cost chip set by chosen chip set selection algorithm, a multi-way partitioning algorithm will find a solution satisfied with area and pin constraints. We used MCNC benchmark circuits and the results satisfy the constrain conditions.*

Keywords: integrated circuit, MCNC benchmark, multi-way partitioning, simulated-annealing.

1 Introduction

As semiconductor's integration is increased, we can integrate many modules into only one circuit. However, it may not integrate into one circuit in real case because of size, cost or chip complexity. Therefore, we sometimes face with the situation that we must partition to several chips from one chip. In this reason, multi-way partitioning problem has become very important for many years ago. Goals for the partitioning are to make chip's partition satisfy area constraint and minimize interconnection between each chip. The reason to minimize interconnection between chips is that if the number of interconnections is increased, numbers of required pins are increased in each chip. This increases the size of entire system and degrades system efficiency.

Most of the previous partitioning algorithm has concentrated on heuristic method [1]. Partitioning algorithms using heuristic method need a proper initial solution, because heuristic methods start with temporary solution [2]. Having a better initial solution can make the final solution better. In this paper, we used low cost chip set selection algorithm that we proposed for initial solution and partitioning problem is proposed when variety of chips of different sizes are given in a library. We solved the multi-way partitioning problem using the simulated annealing bi-partitioning heuristic algorithm repeatedly with the low cost chip set selection algorithm [3].

In Chapter 2, we define basic definitions and explain the algorithm to find most suitable chip set. In Chapter 3, we explain multi-way partitioning algorithm. Next, Chapter 4 analyzes the results of the experiment. Finally, Chapter 5 is the conclusion.

2 Lowest Cost Chip Set Selection

This experiment defines partition size beforehand and process multi-way partitioning of different size. Here, we consider chip's cost according to its size so we decide on each block's size to materialize in a lowest cost.

Therefore, within greatest partition number, we find chip set with lowest cost. Then according to chips that makes up that chip set, multi-way partitioning is processed to get final partitioning result that satisfies each chip's pin limitation.

2.1 Basic Definition

(Definition 1): k number of partitioning, Pk = {C1, C2, … , Ck}, is done by k's clusters, C1, C2, … , Ck. At that instant, it gets relationship of $C1 \cup C2 \cup \ldots \cup Ck = V$. If k is 2, it becomes Bipartition problem.

(Definition 2)signal net, or net: A collection of pins which must be electrically connected [4].

Fig. 1 is an example of partitioning. If a netlist of n module V = {v1, v2, …, vn} are given, partitioning is set by already defined k number of clusters that each module is assigned [5]. Minimized objective function is defined as F(Pk) and this is partitioning result's cost function. Each cluster is assumed to be mutually exclusive.

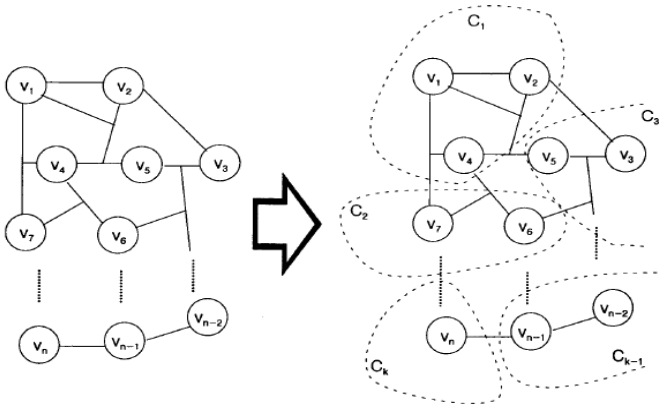

Figure 1 Example of partition to cluster

To express circuit's netlist in most regular way is hyper graph, H(V, E). Here, E = {e1, e2, … , em} is collection of signal net. Each e is collection of modules that connects this net. In all graphs, it is assumed that $e \in E$, $|e| \geq 2$. Weight function $w:V \rightarrow R$ is used in each module's area. If it is expanded to clusters, it becomes $W(C) = \Sigma v \in c w(v)$ and another weight function, $w':E \rightarrow R$ can be defined by net.

(Definition 3): For each module v, nets that are adjacent to v are $N(v) = \{e \in E | v \in e\}$, and collection of modules neighboring v is expressed as $M(v) = \{w \in V | \exists e\ v, w \in e, v \neq w\}$.

(Definition 4): Each signal net e is created by one source module S(e) and collection of destination modules D(e). This allows knowledge of direction of the signal.

(Definition 5): Collection of Hyper-edge Cut due to cluster c is expressed as in next formula. $E(c) = \{e \in E$ s.t $0 < |e \cap C| < |e|\}$. Here, at minimum, if some of pins in net e are in cluster c, relationship, $e \in E(c)$, is formed.

2.2 Problem Definition

Table 1 shows costs according to chip's area. As shown in Table 1, as chip's area increases, cost also increases greatly. Especially, when area is increased from 1(cm2) to 1.56(cm2), die cost and packaging cost in greatly increased so that it becomes noticeable. System made with 1.56(cm2) can be made with two 1(cm2) chips so looking at Table 1, system can be made with lower cost.

Most of the previous partitioning algorithm has concentrated on heuristic method [1]. Partitioning algorithms using heuristic method need a proper initial solution, because heuristic methods start with temporary solution [2]. Having a better initial solution can make the final solution better.

Table 1 Number of chipset according to partition

Maximum Partitioning Number	Number of Chipset
N=1	8
N=2	36
N=3	120
N=4	330
N=5	792
N=6	1716
…	…

2.3 Most Suitable Chip Set

There can be many chip sets depending on number of types of chips and number of chips that consist chip set. According to Table 2, if there can be 8 types of chips, number of chip sets available as much as greatest number of partition are collection that are with some duplication. Here, n is number of greatest partition.

As n gets larger, number of available collection increases. As n gets larger, system speed will get lower so n must be kept in reasonable value. This value made to be determined by the user's discretion. Next are assumptions for algorithms for selecting chip set. In net list, all cell's area is 1.

① Area between each chip's connection is ignored.

② Chip's decrease in speed is ignored from greatest partition number input from chip.tec file.

Each chip's factors, according to change in technology, like each chip's area, number of pins, and cost, are input from chip.tec file to get correct result. As situation changes, contents can be altered so we can get results from latest data. Greatest partition number is chosen by the user. This was done so that user can pick degree of system's decrease in speed due to partition.

Table 2 Cost for several die size[6]

Area (sq. cm)	Die /Wafer	Die yield /wafer	Cost of die	Cost to test die	Packaging costs
0.06	2778	79.72%	$0.25	$0.63	$5.25
0.25	656	57.60%	$1.46	$0.87	$5.25
0.56	274	36.86%	$5.45	$1.36	$5.25
1.00	143	22.50%	$17.09	$2.22	$5.25
1.56	84	13.71%	$47.76	$3.65	$52.25
2.25	53	8.52%	$121.80	$5.87	$52.25
3.06	35	5.45%	$288.34	$9.17	$52.25
4.00	23	3.60%	$664.25	$13.89	$52.25

2.4 Lowest Cost Chip Set Selection Algorithm

① All chip set $(d_j=(A_j,P_j,U_j)\ j=1,2,\ldots,m)$ are put in array – $D_{set}=\{d_1,d_2,d_3,\ldots,d_m\}$

② Eliminate all chip sets that has less area than Input circuit's area (A_{input}) from D_{set}.

③ Among remaining chip set $(d_j=\{ c_1,c_2,\ldots,c_k\})$, where k is 4. minimum, find lowest chip set's cost (U_{min}).

④ Eliminate all chip sets (d_j) from D_{set} where $U_{min} < ¼\ U_j$.

⑤ All remaining chip sets in D_{set} are arranged by cost.

⑥ Select lowest cost chipset (d_{min}) to be multi-way partition. When - $d_{min}= \{ c_1,c_2,\ldots,c_k\})$, all chips get condition $c_j=(a_j,p_j,u_j),\ (j=1,2,\ldots,k)$

While satisfying limitation of greatest partition number, to find lowest cost chip set, all chip sets that satisfies this condition have to get cost calculated (first step). For all the chip sets that are acquired through this, we get area (A) and cost (U). In second step, chip sets that have smaller area than input netlist get ignored. In third step, we find chip set that can materialize input netlist fastest that can use smallest partition. Its cost should be considered one of highest cost that can materialize input netlist. In fourth step, remaining chip sets are sorted by cost. Chip sets that are with higher cost than given cost are eliminated. Through this way, remaining chip sets are considered for materialization. In sixth step, chip set with lowest cost is applied multi-way partitioning algorithm to find partition that satisfies pin limitation. If it can't be found,

next lowest chip set is applied multi-way partitioning algorithm.

3 Multi-Way Partitioning Algorithm

In this thesis, problem that must be solved is multi-way partitioning problem. This problem must accept input of chips comprising of those satisfying given input netlist. It requires mostly at least three partitions. So we suggest algorithm that is altered appropriately from bi-partitioning algorithm to partitioning into number we want it to be partitioned.

3.1 Initial Partitioning

Basically, SA algorithm starts with temporary solution then finds best solution [7]. For this, initial solution is necessary. Information that needs to be input are partition number, each partition's greatest area, and each partition's greatest number of pins. Conditions for initial solution are partition number and each partition's area limitation. To satisfy these minimum conditions, given netlist is voluntarily partitioned. It can be formed into two ways like Fig. 2 depending how each block's cells are placed.

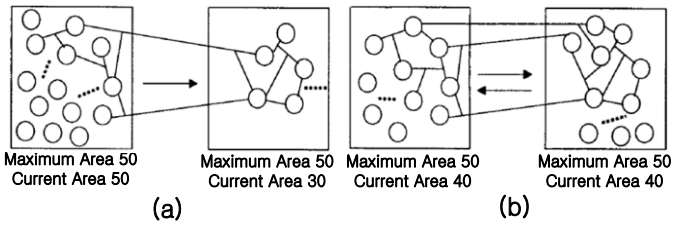

Figure 2 Initial partition

If given netlist's area is 80, and chips are partitioned into two chips with area of 50, like Fig. 2 (a), it can be partitioned so that most of cells can be in one block, or like (b), it can proportionally placed according to each chip's greatest area. In case of (a), in the beginning, cell's movement is limited but in case of (b), it's possible for easier movement. In case of (a), one side at greatest area limitation and the other is at lowest area limitation. Therefore, if cell from smaller side tries to move into larger side, it is limited. In this paper, for more free movement of cells, we applied method (b) for processing initial partitioning.

3.2 Selection of New Solution

After initial partition, each block that was partitioned must satisfy minimum and maximum area condition by moving one cell for new solution. Here, one cell is voluntarily chosen. However, in case if k partition, it can be moved to k-1 blocks. Here, requirements for new solution are lower number of cut set and high temperature even if number is high. Requirement for temperature may get lower as time passes but requirement for low number of cut set is in category of important condition. Therefore, selection of new solution is in direction where one cell moving through k-1 blocks with most reduction in cut sets. This would give increase in chance of accepting new solution in early stage in SA algorithm and lowers solution space that is created for multi-way partitioning. From each cell's movement point, k-1 movement direction's cost is each calculated and decide to go to most advantageous one. However, this decision does not guarantee that new solution is going to result in better results. Blocks that are earned when netlist is partitioned into k, each blocked is called A1, A2, A3, ..., Ak. If one cell from A1 group is moving to different group, it's direction is becomes A2, A3, ..., Ak. Here, cost change is defined as below. Here, cost is rise in cut set number.

$cel_{A1, A2}$: cost of A_1's cell is moving to group A_2

$cel_{A1, A3}$: cost of A_1's cell is moving to group A_3

$net_{A1, B1}$: rise of net B_1's cut set when one of A_1's cell is moving

3.3 Limitations That Final Solution Must Satisfy

Partitioning result that used SA algorithm have goal of reducing number of cut set (pin number) so final result would be a solution that have lowest number of cut set. However, if the result does not satisfy chip.tec file's pin limitation condition, we would not find solution that meets our demands. In this case, it comes to conclusion that it is impossible to find partition that fits input demands.

Since algorithm's goal is to minimize total number of pins, even if each partition satisfies pin limitation, it can move to solution that has smaller pin number but it does not satisfy pin limitation in partial blocks. So this means that in the end, it can reach solution that does not satisfy pin limitation.

Like Fig. 3, if netlist of area 758 is initially partitioned into two, pin number is each 634 and 357. While partitioning is continued, it meets solution that meets input requirements and pin limitation in the middle. However, partitioning still goes on so that at the end, it does not satisfy conditions. Of course, in total, it is possible to get a case with required pin number is 14, which is small, but it does not satisfy pin limitation of each chip. This thesis will solve this problem by continuously remembering solution with minimum number of pins that satisfies pin limitation during partitioning process. If final result does not satisfy pin limitation, output will be the solution that was memorized, which satisfies pin limitation. This case can be shown in result like Table 3 using t2 netlist.

This case can be shown in result like Table 3 using t2 netlist. As shown in Table 3, final result's block 4 exceeds pin limit of 120. Therefore, it is impossible to be materialized. However, result in the middle satisfies pin limitation. Program will maintain such result in the middle so when final result does not satisfy pin limitation, output will be the result in the middle.

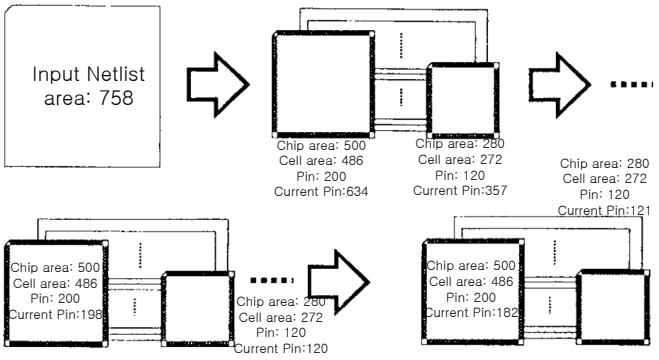

Figure 3 The relationship of the final solution with the final result

Table 3 Number of chipset according to partition

Block	Maximum Pin	Initial Pin	Middle of Process	Final result
Blk 0	200	891	93	93
Blk 1	120	633	88	86
Blk 2	120	672	34	34
Blk 3	120	614	50	51
Blk 4	120	696	120	121
		dissatisfaction	satisfaction	dissatisfaction

3.4 Simulated Annealing Algorithm

$$c(V_1, V_2) = |\{\{u,v\} \in E : u \in V_1 \ \& \ v \in V_2\}| + \alpha(|V_1|-|V_2|)^2 \quad (1)$$

$$c(V_1, V_2) = |\{\{u,v\} \in E : u \in V_1 \ \& \ v \in V_2\}| + \alpha * \sum f_i \quad (2)$$

Cost function applied to partitioning in SA[8], is equal to (1). Using this formula, during partition, as each block's area gets bigger, cost will get bigger. This would limit cell's free movement so it will downgrade solution's quality. In more improved version, SA[9], tried to fix this by making cost function to be (2). By making cell to freely move possible in between each block's area's Min and Max, final partitioning result becomes better. Fig. 4 is multi-way partitioning algorithm using simulated annealing. The most suitable chip set which is selected in previous level is partitioned to another chip set using the Fig. 4 algorithm.

4 Experimental Results

Program is written in C and circuit that was applied for this experiment is MCNC Benchmark circuits. Table 4 shows circuits that were used in the experiment. Most of circuits output results with first selected chip set but in case of industry2, it could not find satisfactory results from many chip sets.

Table 5 shows result when same information is used with maximum partitioning number of 4 and 6. Basically, as number increases, arrangement can be created with lower cost. Especially in case of t5.net, as greatest partitioning number is increased, cost is greatly reduced. However, as partitioning number is increased, circuit speed would decrease so it must be selected appropriately.

In case of industry2.net, selected chip set could not be partitioned so, many multi-way partitioning attempts occurred so this number would affect program process time. So when partitioning number is 6, unlike other cases, it would take less processing time.

1. Get a chip set .
2. Get an initial partition S .
3. Get an initial temperature T > 0 .
4. While not yet frozen do the following
   4.1 Perform the following loop L times.
      4.1.1 Pick a random neighbor S′ of S.
      4.1.2 Let $\Delta = cost(S') - cost(S)$
      4.1.3 If $\Delta \leq 0$ (downhill move)
            Set S = S′
      4.1.4 If S is satisfied with pin constraints
            Set S_{store} = S
      4.1.5 If $\Delta > 0$ (uphill move)
            Set S = S′ with probability $e^{-\Delta/T}$
   4.2 Set T=rT (reduce temperature)
5. If S is unsatisfied with pin constraints and S_{store} is satisfied with pin constraints
      Set S = S_{store} .
6. Return S .

Parameters :
L = the number of nodes * 16
cost = the number of crossing nets + size penalty
size penalty = $\alpha \times (|V_1| - |V_2|)^2$
$\alpha = 0.05$ $r = 0.95$

Figure 4 Simulated annealing algorithm[5]

5 Conclusion

The proposed algorithm is verified by C language with MCNC benchmark circuit. The C program is comprised of two big parts. First part is the algorithm that finds lowest cost chip set. Second part is algorithm that uses SA algorithm to do multi-way partitioning. In algorithm, input are net list file and library file. Outputs are each chip's area and result of partitioning that satisfies each chip's area and pin limitation. User inputs currently possible type of chip information through library to let program get information of each chip's size, pin number, and cost in given library. Program would find chip set with lowest cost with given information. That chip set would be input into multi-way partitioning algorithm. Multi-way partitioning used SA algorithm through new

neighbor structure. In process of multi-way partitioning, there could be result that satisfies pin limitation. It would be memorized so when final result does not satisfy pin limitation, even if it has more pins, result that satisfies pin limitation would be chosen as output. From partitioning algorithm, if result does not satisfy pin limitation, it is decided that given chip set cannot partitioned. Next lowest cost chip set would be then chosen for partition. It would repeat until chip set that satisfies pin limitation to get final result. Through experiment results, most got output that all chips' limitation is satisfied from first set of chip set. This result is partitioned system with lowest cost.

Study on Parallel Compressed Sensing for Mass Data in Internet of Things

Yongping Zhang, Gongxuan Zhang, Yongli Wang, Zhaomeng Zhu, and Wei Zhang
School of Computer Science and Technology, Nanjing University of Science and Technology, Nanjing, Jiangsu, China, 210094

Abstract - *Internet of Things is the network of interconnection between people and things, and between things themselves by embedding additional gadgets, such as sensors, RFID tags. Mass data are usually collected, transmitted, processed and stored in Internet of Things. In this paper, a novel sampling method, i.e. compressed sensing, is used in processing mass data in Internet of Things. Compressed sensing can significantly lower the network communication burden by reducing sampling rates of sensors, but it is nonadaptive and its algorithm is high computational complexity. For this reason, we introduce redundant dictionary into compressed sensing for increasing the flexibility and put forward the idea that is parallel processing of compressed sensing algorithm in order to improve computing speed in this paper. In the latter part of this paper, we describe the framework of parallel compressed sensing algorithm and point out our current experimental results and future work.*

Keywords: Internet of Things; compressed sensing; parallel processing; optimal recovery; adaptive

1 Introduction

The term Internet of Things (IoT), also known as Web of Things, was first used in 1999 [1]. In 2005, *The Internet of Things* [2] of ITU reported that: the Internet of Things is "*any time, any place, and any things connection*" and "*ubiquitous networks, ubiquitous computing*". In brief, Internet of Things is the Internet of things to things by embedding intellisense system, such as RFID [3], sensor technologies. In Internet of Things, at first, the information about things are acquired by intellisense system; and then the data will be sent to data processing server through a variety of transmission networks; the next, these data are processed in the data processing server; as a result, the interactions of Human to Human, Human to Thing and Thing to Thing will be implemented [2]. This is similar to wireless sensor network (WSN) [4], and somebody think that Internet of things is wireless sensor network, but they are different, such as network architecture [5], [6].

Generally, the wireless sensor network protocol consists of five layers: application layer, transport layer, network layer, data-link layer, and physical layer; but the structure of Internet of Things can be classified into three layers [7] as shown in Figure 1. Perception layer can identify and acquire information of things; the primary function of transport layer is data transmission by various communication networks; and sundry different applications can be achieve in application layer.

Application Layer	Industrial Monitoring	Smart Home	Traffic Monitoring
	Mine Safety	Environmental Monitoring	… …
Transport Layer	Internet	Information Center of IoT	Private Network
	Mobile Network	Management Center of IoT	… …
Perception Layer	Bar Code Reader	Sensors	Intelligent Terminal
	RFID Sensors	Access Network	… …

Figure 1. The structure of Internet of Things

Internet of Things is a popular scientific and technical terminology and it has been classified as national key technology in many countries. Internet of Things can be used for various application areas, such as mine safety, smart home, forest fire detection, traffic monitoring and logistics monitoring. Figure 2 shows the examples of application areas of Internet of Things.

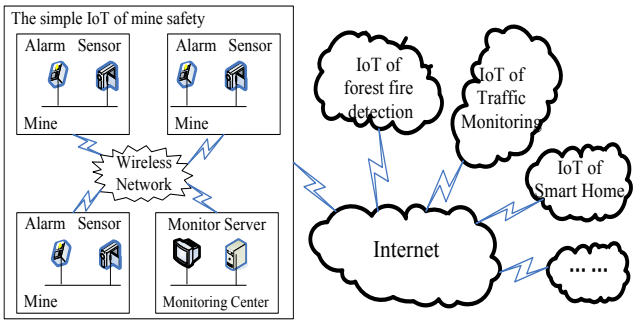

Figure 2. The applications of Internet of Things

There are usually mass data in Internet of Things. For example, a large-scale intelligent traffic or real-time ecological monitoring system, the amount of data generated can be achieved TB every day and PB each year. The existence of mass data would seriously affect sensors life,

Internet of Things coverage, and data processing and storage capacity of Internet of Things. To reduce the amount of data in Internet of Things, compressed sensing that proposed by Donoho [8], [9] and Candès [10], [11] is a good choice. Compressed sensing can significantly lower the network communication burden by reducing sampling rates of sensors, but it is nonadaptive and its algorithm is high computational complexity. So, it is necessary that parallel computing [12], [13] of compressed sensing algorithm for improving computing speed and redundant dictionary be introduced into compressed sensing for increasing the flexibility.

The remainder of this paper is organized as follows: In Section 2, we introduce compressed sensing theory. A new compressed sensing algorithm framework is the subject of Section 3. In the end, the conclusions and future study are given in Section 4.

2 Compressed sensing

Compressed sensing or compressive sampling (CS) is a new sampling mean that data sampling and compressing can be done simultaneously. Compressed sensing goes against the common principle (i.e. Nyquist density sampling theory), and it can sample at a low rate and later reconstruct the full-length signal based on numerical optimization algorithm [11], [14].

2.1 Compressed sensing theory

We suppose that there are an one-dimensional linear vector $X_{N\times 1}$ (which can be signal, image, etc) and a sparse transformation basis $\Psi_{N\times N}=[\psi_i,\ i=1,\ 2,\ldots,\ N]$. The transformation basis are assumed to be orthonormal basis at the beginning of compressed sensing be proposed. Then, we can obtain the conversion coefficient Θ about vector X based on transformation basis Ψ:

$$\Theta=\Psi^T X \qquad (1)$$

where $\Theta= [\theta_i=<X,\ \psi_i>=\psi_i^T X,\ i=1,\ 2,\ldots,\ N]$ is sparse. Here, the sparse means that the vast majority entries of Θ are zero [15].

The design of measurement matrix $\Phi_{M\times N}$ $(M<<N)$ is the next work. Φ must be independent of the transformation basis Ψ. Observation data Y about vector X would be obtained from the following equations:

$$Y=\Phi\Theta=\Phi\Psi^T X \qquad (2)$$

where Y is the compressed data. Matrix representation of the equations *(2)* is shown in Figure 3.

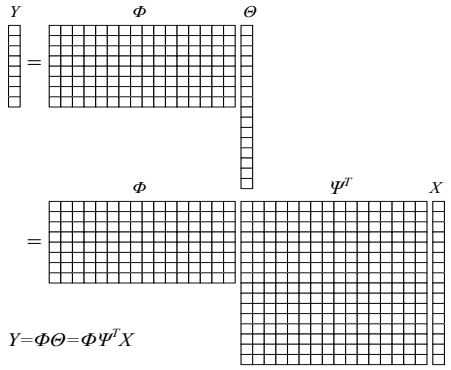

Figure 3. Matrix representation of observation vector

According to compressed sensing theory, we can reconstruct original signal X from the observation data Y via solving the 0-norm optimization problem:

$$\min \|\Theta\|_0 \qquad (3)$$
$$\text{s.t. } \Phi\Theta=\Phi\Psi^T X= Y$$

where $\|\Theta\|_0$ is the number of nonzero entries in Θ.

The computing process of compressed sensing is shown in Figure 4:

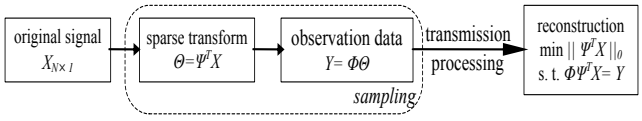

Figure 4. Theoretical framework of compressed sensing

2.2 Critical issue

The compressed sensing theory involves three key issues [16], [17]:

2.2.1 Sparse representation

Sparse representations of signal can be attributed to design of transformation basis. The transformation basis is orthonormal basis at the beginning of compressed sensing be proposed and it is nonadaptive. Peyré expand the requirement of transformation basis to orthogonal basis dictionary [18] that is formed by multiple orthogonal bases, and it can be adaptive to find an optimal orthogonal basis even unknown any information about signal in the dictionary.

2.2.2 Measurement matrix

The equations *(2)* are underdetermined and generally we cannot solve it. But if we suppose that $\Phi\Psi^T$ obey the restricted isometry property (RIP) [19], the equations *(2)* can be solved either exactly or accurately. The necessary and sufficient condition of RIP is transformation basis Ψ independent of measurement matrix Φ.

Gaussian stochastic matrix [20] is independent of most of matrix composed of orthogonal basis and it can act

as measurement matrix. In addition to Gaussian stochastic matrix, Noiselet matrix [21] and Rademacher stochastic matrix [22] obey the RIP too. But now, any measurement matrix can not guarantee 100% accurate reconstruction signal, the design of measurement matrix is still a hot topic of research.

2.2.3 Reconstruction

Accurate and exact reconstruction signal, looking for exact or approximate object $\hat{X}$ having coefficients with smallest 0-norm from the expression *(3)*, is a nonlinear optimization problem. We almost can not solve it because its solution is NP-hard [20]. However, a new theory was proposed by Donoho, Chen and Saunders [23]: when measurement matrix Φ was independent of transformation basis Ψ, we can solve the expression *(4)* instead of considering the expression of *(3)*:

$$\min \| \Theta \|_1 \quad \text{s.t. } \Phi\Theta=\Phi\Psi^T X= Y \qquad (4)$$

where the expression of *(4)* is a convex optimization problem and we can solve it as a linear programming problem.

2.3 Reconstruction algorithm

Currently, the compressed sensing reconstruction algorithms can be grouped under three categories [24]: greedy algorithm, convex relaxation method, combination algorithm.

2.3.1 Greedy algorithm

Greedy algorithm is iterative algorithm. It can gradually approache the original signal by selecting a local optimal solution in each iteration. This family of greedy algorithm includes Matching Pursuit (MP) [25], Orthogonal Matching Pursuit (OMP) [26], Stagewise Orthogonal Matching Pursuit (StOMP) [27] and Regularized Orthogonal Matching Pursuit (ROMP) [28], etc.

2.3.2 Convex relaxation method

Convex relaxation method is linear programming method for minimization 1-norm and it can solve original signal by transforming non-convex problem into a convex problem. This family of convex relaxation method includes Basis Pursuit (BP) [23], Gradient Projection for Sparse Reconstruction (GPSR) [29], Iterative Thresholding (IT) [30], Bregman Iterative (BI) [31], etc.

2.3.3 Combination algorithm

Combination algorithm can quickly reconstruct original signal by group testing. This family of Combination algorithm includes Fourier representations [32], Chaining Pursuit (CP) [33], Heavy Hitters on Steroids Pursuit (HHSP) [34], etc.

3 Parallel compressed sensing

In this section, we will describe a new compressed sensing algorithm framework and its technical details.

3.1 Parallel compressed sensing algorithm framework

Compressed sensing is a sampling method to achieve data compression while data is sampled, and the method can significantly reduce the amount of sample data in Internet of Things. However, everything has two sides; compressed sensing algorithm has also many inadequacies. For example, the transformation basis is nonadaptive, it cannot adapt the change of the signal types; compressed sensing algorithm is high computational complexity, especially the reconstruction algorithm. Such as BP algorithm, when length of signals is 8192, calculation scale of reconstruction is equivalent to solving linear programming problem with 8192×262144 [23].

According to our study, we propose an improved algorithm framework as shown in Figure 5:

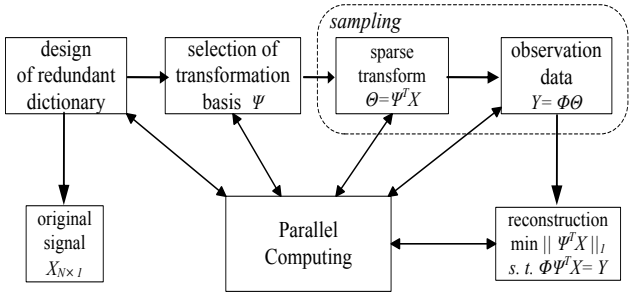

Figure 5. Theoretical framework of parallel compressed sensing

Compared with original compressed sensing algorithm, the new algorithm adds tow steps of redundant dictionary construction and transformation basis selection, and parallel computing is introduced into the new algorithm framework. In the section 3.2, we will further describe the parallel algorithm framework in detail.

3.2 Detailed description of parallel algorithm framework

3.2.1 Parallel computing of compressed sensing

Parallel computing [35] is a form of computation and carries out many calculations simultaneously. The principle of parallel computing is that many large problems can be divided into smaller parts. High-performance computing [35] is often regarded as parallel computing, because it cannot do without the support of parallel processing. Now, parallel computing has become the dominant paradigm in computer architecture, mainly in the form of multicore processors. In general, multicore parallel processing can select CPU programming or GPU programming [13].

Recently, the development of hybrid systems on the CPU and GPU is attracting our more and more attention.

Compressed sensing theory involves a large number of matrix operations, such as selection of transformation basis, sparse representation of signal, data compression and reconstruction signal. This facilitates the parallel processing of compressed sensing algorithm. And compressed sensing algorithm is high computational complexity, especially the reconstruction algorithm. So, parallel processing of compressed sensing algorithm is necessary and our study will focus on it. Parallel processing can involve in all the operations of compressed sensing algorithm, such as redundant dictionary construction, transformation basis selection, sparse representations, observation data obtainment, and reconstruction, would be implemented in the parallel algorithm framework.

3.2.2 Redundant dictionary

Sparse representation of signal is premise and base of the compressed sensing applications and it is determined by the transformation basis. We hope that the representation can adapt the change of the signal types but orthonormal basis is nonadaptive in original compressed sensing algorithm and the orthogonal basis dictionary cannot solve the problem.

Our selection about transformation basis is redundant dictionary in the parallel algorithm framework. Sparse representations that are based on redundant dictionary [36] are new theory of signal representation. In redundant dictionary, traditional orthogonal basis functions are replaced by over-complete redundancy function system. The use of redundant dictionary increases the flexibility of signal sparse representation, and we can choose transformation basis depending on the different needs. Now, we are studying the construction algorithm of redundant dictionary to fit sensors. In general, the design of redundant dictionary needs to spend a lot of computing and its parallel processing would be study.

3.2.3 Measurement matrix and observation data

According to Section Ⅱ, Ψ must be independent of Φ in compressed sensing. Stochastic matrix, such as Gaussian stochastic matrix, Rademacher stochastic matrix, is widely used as measurement matrix Φ. However, in practice, it is difficult to apply in large-scale problems because of the high computational complexity of stochastic matrix.

In compressed sensing theory, data compression is to calculate the observation data Y by the equations *(2)*. In order to fast to process mass data, it is important to construct adaptive measurement matrix based on sampling mechanism of sensor and design fast calculation method of the equations *(2)*. Parallel processing, clearly, can provide support for these.

3.2.4 Reconstruction algorithm

All compressed sensing reconstruction algorithms can be grouped under three categories: greedy algorithm, convex relaxation, combination algorithm. Parallel processing of the reconstruction algorithm can improve the calculation speed, reduce the execution time, and enhance real-time. In our experiments, under the same conditions, the reconstruction algorithm used dual-core CPU than single-core CPU can save the execution time of approximately 40% and 4-core CPU than single-core CPU can save the execution time more than 70% (shown in Figure 6), then we think that parallel reconstruction algorithm is feasible. The experiments of GPU parallel computing have not been completed and we are working on it. In addition, the hybrid systems on the CPU and GPU and cloud computing platform are also worth trying.

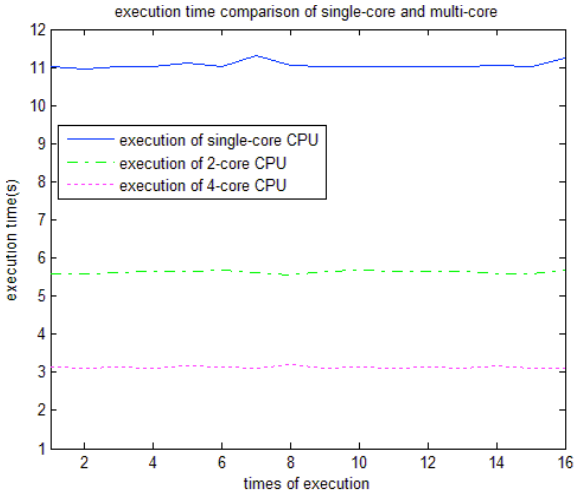

Figure 6. Execution time of OMP algorithm

According to our experience and studies, combination algorithms are more suitable for parallel computing in the three families of algorithms. The next work, we will focus on studying the mainstream combination algorithms, finding suitable algorithms to handle mass data and improving appropriately these algorithms. In the last, one of the most appropriate algorithms will be selected and achieved parallel processing.

3.2.5 Sensors

In our parallel algorithm framework, the terminal sensors were not concerned. As the basic data acquisition equipment, improving sensors performance will greatly promote the development of Internet of Things because the computing power and storage capacity of sensors are so limited. We have two ideas to improve the end of data collection:

1) Compressed sensing sensors: The compressed sensing sensors can be classified according to the application environment. Different sensors configure different simple redundant dictionary, and these redundant

dictionary can only adapt to limited choices. Sensors can compress sample data by compressed sensing system and send compressed data to backend server. Backend server can support parallel computing and any compressed sensing algorithms about all redundant dictionaries. In this way, the data transmission burden can reduced and computing speed can be improved.

2) Other sensors: Data processing platform of compressed sensing is added near the sensors. Each data processing platform can receive sample data from its neighboring multiple sensors. The sample data are compressed on data processing platform, and then transferred to the backend server. The server can support parallel computing and any compressed sensing algorithms about all redundant dictionaries, too.

4 Conclusions

In this paper, we try to process mass data in Internet of Things by using the compressed sensing theory, and propose a new idea that parallel computing of compressed sensing algorithm. In order to improve the adaptability of compressed sensing, redundant dictionary is added in the parallel compressed sensing algorithm framework. But we have not implemented a complete algorithm, which will be our next study work. In addition, it is a good research that compressed sensing algorithm be done on cloud computing platform and we will try it.

Parallel Random Search Algorithm for Large-Scale Constrained Pseudo-Boolean Optimization Problems

L.A. Kazakovtsev
Department of Information Technologies, Siberian State Aerospace University, Krasnoyarsk, Russia

Abstract - *Random search methods are successfully implemented for variety of discrete optimization NP-hard problems when any exact solution approaches cannot be implemented due to large computational demands. Initially designed for unconstrained optimization, the probability changing method gives an approximate solution for various linear and non-linear pseudo-Boolean optimization problems with constraints. Although, in case of large-scale problems, the computational demands are also significant and the precision of the result depends on the spent time. For constrained optimization, the search of any feasible solution may take significant computational resources.*

In this paper, we consider an approach to developing parallel versions of the algorithms based on the modified probability changing method for constrained pseudo-Boolean optimization. Optimization algorithms are adapted for the systems with shared memory (OpenMP) and cluster systems (MPI). The parallel efficiency is estimated for the large-scale non-linear pseudo-Boolean optimization problems with linear constraints and travelling salesman problem.

Keywords: Discrete optimization, parallel computing, MPI

1 Large-scale pseudo-Boolean optimization problem

Most exact solution approaches to the problem of discrete (combinatorial) optimization (knapsack problem, the traveling salesman problem etc.) are based on branch-and-bound method (tree search) [1,2,5]. Unfortunately, most of such problems are in the complexity class NP-hard and require searching a tree of the exponential size and even parallelized versions of such algorithms do not allow us to solve some large-scale pseudo-Boolean optimization problems in acceptable time without significant simplification of the initial problem.

The heuristic random search methods do not guarantee any exact solution but random search methods are statistically optimal. I.e. the percent of the problems solved "almost optimal" grows with the increase of the problem dimension [1].

Let's consider the problem:

$$F(X)=\left(\sum_{i=1}^{N\cdot V} a_i x_i\right)\left(\sum_{i=1}^{N\cdot V} c_i x_i\right)\rightarrow max; \qquad (1)$$

$$\sum_{i=1}^{N\cdot V} b_{ik} x_i \le B_k \;\forall\; 1\le k\le N_{constr} \qquad (2)$$

$$\sum_{i=l\cdot(V-1)+1}^{l\cdot V+1} x_i \le 1 \;\forall\; 1\le l\le N; \; . \qquad (3)$$

Here, $a_i, c_i, b_i \; (1\le i\le N\cdot V)$ are some constants, $x_i \; (1\le i\le N)$ are Boolean variables. The objective function is non-linear.

The real large-scale problems have sometimes millions of variables. For example, the problem of assortment planning of the retail trade company [6] may include thousands goods names to be selected which can be shipped from hundreds suppliers and have 3-10 variants of retail price. In general, problems of such kind can be solved only with random search algorithms.

Being initially designed to solve the unconstrained optimization problems, the probability changing method (MIVER) is a random search method organized by the following common scheme [1,2].

1. k=0, the starting values of the probabilities P_k={p_{k1}, p_{k2}, ... , p_{kN}} are assigned where $p_{kj}=P\{x_j=1\}$. Correct setting of the the starting probabilities is a very significant question for the constrained optimization problems.
2. With probability distributions defined by the vector P_k, we generate a set of the independent random points X_{ki}.
3. The function values in these points are calculated: $F(X_{ki})$.
4. Some function values from the set $F(X_{ki})$ and corresponding points X_{ki} are picked out (for example, point with maximum and minimum values).
5. On the basis of results in item 4, vector P_k is modified.
6. k=k+1, if k<R then go to 2. This stop condition may differ.
7. Otherwise, stop.

To be implemented for the problems like (1-3), this method has to be modified. The modified version of the variant probability method, offered in [6,7] allows us to solve large-scale problems with dimensions up to millions of Boolean variables.

In case of the large-scale problems, even the calculation of the linear objective function takes significant computational resources. The number of constrains usually also grows with the increase of the problem dimension. So, the calculation of the objective function and the constraints is a very large computational problem if it is repeated lot of times.

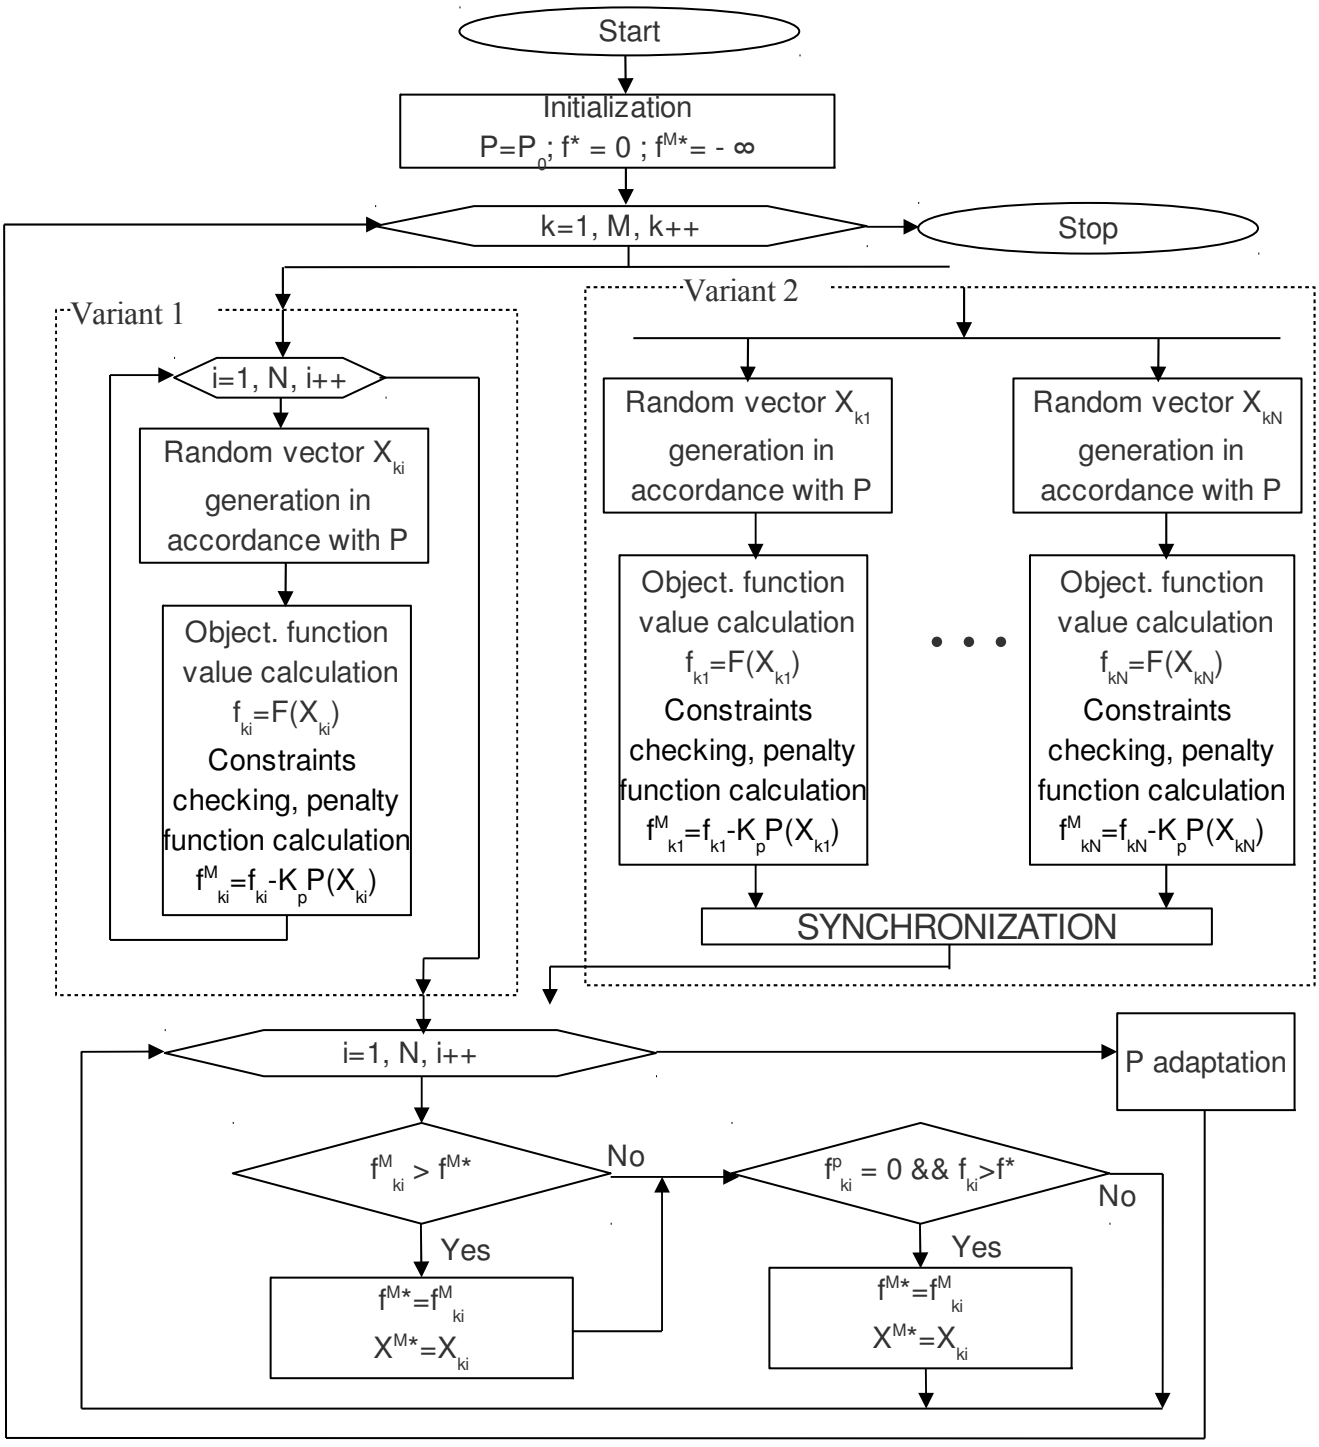

Figure 1. Parallel algorithm for systems with shared memory

That is why, the distribution of the computational tasks between the parallel processors or cluster nodes is very important.

In this paper, we do not consider greedy search algorithms (which are deterministic or also randomized [8, 10]) though they are often used to improve the results of the random search methods as the final step of them.

Also, we do not consider the parallel genetic algorithms [11] though some approaches offered for genetic algorithms may be implemented for random search algorithms parallelization.

Here, we offer an approach of adaptation of the existing programs realizing the random search methods of constrained pseudo-Boolean optimization to be implemented in the parallel systems.

2 Serial version of the algorithm and its parallelization with OpenMP

The scheme of the algorithm for the serial systems is shown in Figure 1, variant 1.

At the step of initialization, all the variables p (components of the probability vector P) are set to their initial values ($0<p_i<1 \quad \forall \quad p_i \in P$). Since our algorithm realizes the method of constrained optimization, the initial value of the probability variables is sometimes very important. Then, we generate the vectors X of optimized boolean variables. In our case of constrained problem of knapsack type, the large values of vector P components generate the values of X which are out of the feasible solutions area due to the constraints (9,10). Due to the constraints (3), the optimal initial values of the vector P components do not exceed $1/(L+1)$ [7].

We set the initial values of the vector P to $1/(L+1)$ but we have to reduce this value if several starts of our algorithm give us no results in feasible solutions area. This process is not illustrated in the Figure 1 for the simplicity.

Instead of maximum number of steps (M in Figure 1), we can use the maximum run time as the stop condition. In some cases, it is reasonable to use the maximum number of steps which do not give us the result better than previous ones as the stop condition.

In the cycle (i=1,N), we generate the set of N vectors X_{ki} in accordance with the probability vector P. Then, the objective function is calculated for each X_{ki}. Also, we calculate the values of the left parts of our constraints, and introduce the second objective function f^p (penalty function):

$$f_{ki} = F_P(X) = C_{PENALTY} \sum_{k=1}^{N_{CONSTR}} F_{Pk}(X); \quad (4)$$

$$f_{ki}^P = F_{Pk}(X) = \begin{cases} 0, \sum_{i=1}^{N \cdot V} b_{ik} \le B_k; \\ \dfrac{\sum_{i=1}^{N \cdot V} b_{ik}}{B_k}, \sum_{i=1}^{N \cdot V} b_{ik} > B_k. \end{cases} \quad (5)$$

Here, $C_{PENALTY}$ is some coefficient. If some estimation of the maximum value of the objective function is available, we can use it as the value of the coefficient $C_{PENALTY}$. For linear objective functions:

$$C_{PENALTY} = \sum_{i=1}^{N \cdot V} |a_i| . \quad (6)$$

The modified objective function f^M is the sum of the objective function and penalty.

When all the values of f_{ki} and f^M_{ki} are calculated, we choose the best (maximum) value for f^M_{ki} and, if there were the variants of the vector X_{ki} which satisfy all the constraints (f^p_{ki}=0) then we choose the maximum value of the objective function f_{ki} for that variants of the vector X_{ki}.

In case of the constrained optimization, we have to use a special method of adaptation of the vector P. The solution of different practical tasks shows the best result if we use the multiplicative adaptation with rollback procedure [2,6]. In this case, the components of the vector P are never set to the value of 0 or 1 which may cause that all the further generations of the X vector have the same value of the corresponding component which does not give the feasible solution due to constrains (3).

$$p_{k,j} = \begin{cases} p_{(k-1),j} \cdot d, & x_{kj}^{max} = 1 \wedge x_{kj}^{min} = 0 \wedge p_{(k-1),j} < 0.5, \\ 1 - \dfrac{1 - p_{(k-1),j}}{d}, & x_{kj}^{max} = 1 \wedge x_{kj}^{min} = 0 \wedge p_{(k-1),j} \ge 0.5, \\ \dfrac{p_{(k-1),j}}{d}, & x_{kj}^{max} = 0 \wedge x_{kj}^{min} = 1 \wedge p_{(k-1),j} < 0.5, \\ 1 - \left(1 - p_{(k-1),j}\right) \cdot d, & x_{kj}^{max} = 0 \wedge x_{kj}^{min} = 1 \wedge p_{(k-1),j} \ge 0.5, \\ p_{(k-1),j}, & x_{kj}^{max} = x_{kj}^{min}. \end{cases} \quad (7)$$

Here, d is the adaptation coefficient. In case of multiplicative adaptation, it does not depend on the step number k. In this case, the absolute value of adaptation step depends on the corresponding value of p_{kj}.

After several steps, the values of P vector elements are close to 0 or 1 and the decrease of the adaptation step (d) results in generation of the similar vector X exemplars which correspond to some local maximum. The rollback procedure is helpful to avoid that situation. It sets the values of P vector and its adaptation step d_k to initial (or other) values. In simplest case, rollback is performed after several steps which do not improve the best objective function value.

The best results are demonstrated with methods of partial rollback procedure which change some part of P vector components or change all the components so that their new values depend on previous results. We can use the following rollback formula:

$$p_{kj} = (p_{k-1\,j} + q_k p_0)/(1+q_k), \text{ if } p_{k-1\,j} < p_0. \quad (8)$$

Here, p_0 is the initial value of the probability. The coefficient q_k may be constant or vary depending on the results of previous steps. For example, it may depend on the quantity of the steps which do not improve the maximum result (s_m).

$$q_k = w / s_m. \quad (9)$$

The weight coefficient w has to be chosen experimentally.

In case of constrained optimization, the choice of the initial value p_0 can be very important. In some cases, the incorrect initial value causes the generation of X vector sets that lay out of the feasible solutions area. After several steps, the penalty function minimization process results in adaptation of P vector which allows to generate X vector exemplars that satisfy our constraint conditions. But the rollback procedure returns the probability vector to its initial (usually incorrect) value. Let's consider a simplest example. Let our problem have only one constraint like that:

$$b_1x_1 + b_2x_2 + b_3x_3 + \ldots + b_Dx_D < B. \quad (10)$$

Here, D is the dimension of our problem (D=N V).

The elements of the vector X at the first steps are generated so that it is set to the value of 1 with probability p_0. The expectation of the left part of (10) is

$$M = p_0 b_1 + p_0 b_2 + p_0 b_3 + \ldots + p_0 b_D = (b_1 + b_2 + b_3 + \ldots + b_D)\, p_0. \quad (11)$$

The maximum values of the objective function are usually achieved at the points where the condition is barely satisfied ($b_1x_1+b_2x_2+b_3x_3 + \ldots + b_Dx_D \sim= B$ in our case). Therefore, the optimal value of the initial probability is

$$p_0 = B/(b_1+b_2+b_3 + \ldots + b_D). \quad (12)$$

The negative effect of the rollback procedure can be reduced by adaptation of the initial value of p_0:

$$p_{0k} = (p_{1\,k-1}+p_{2\,k-1}+\ldots+p_{D\,k-1})/D. \quad (13)$$

This version of rollback procedure is most actual in case of partial rollback which performed at each step of our algorithm. The implementation of this kind of adaptation&rollback procedure is described below for the parallel version of the optimization algorithm for systems with no-remote memory access (clusters).

The adaptation of our algorithm for multiprocessor systems with shared memory can be performed by the parallel generation of the exemplars of the X vector and their estimation. The scheme of that version of our algorithm is shown in Figure 1, variant 2. If our system has N_P processors, the cycle of generation of N exemplars of the vector X can be divided between the processors. Each processor has to generate N/Np exemplars of the vector X and calculate the value of the objective function, left parts of the constraint conditions and calculate the modified objective function values.

Organizing of the parallel thread takes significant computational expenses. In [14], they estimate that expenses as 1000 operations of real number division. The experiments at 4-processor system with linear 100-dimension problem (105 constraints) show that the parallel version runs 2.8 times faster than the serial one.

3 Version for clusters

Our experiments [6,7] with adaptation of random search discrete optimization algorithms [1,2] for parallel execution gave us rather effective results with use of multiprocessor systems with shared memory and OpenMP [14]. But the intensive data interchange in running mechanisms of MPI reduce the efficiency of the realization of the same algorithms for PVM and MPI clusters when the number of the nodes increases. That issue makes the usage of the computing cluster ineffective even in comparison with low-cost multi-core systems.

For testing purposes, we used the following form of the objective function and constraints:

$$F(X) = \left(\sum_{i=1}^{N\cdot V}\sum_{j=1}^{V} a_{ij}x_{ij}\right)\sum_{i=1}^{N}\left(1 - c_i x \sum_{j=1}^{V} x_{ij}\right) \to max; \quad (14)$$

with constraints:

$$\begin{cases} \sum_{i=1}^{N}\sum_{j=1}^{V} b_{ij1}x_{ij} \le B_1; \\ \sum_{i=1}^{N}\sum_{j=1}^{V} b_{ij2}x_{ij} \le B_2; \\ \ldots \\ \sum_{i=1}^{N}\sum_{j=1}^{V} b_{ijN_{Constr}}x_{ij} \le B_{N_{Constr}}; \end{cases} \quad (15)$$

$$\sum_{j=1}^{V} x_{ij} \le 1 \;\forall\; 1 \le i \le N. \quad (16)$$

The coefficients in the constrains in the test set are generated so that the feasible solutions set is 1000-1000000 smaller than 2^N (depends on N and randomly selected values). The algorithm replaces the whole set of constraints with penalty function [2, 6, 7].Problem of a traveling salesman [1, 2, 11]:

$$F(X) = -\sum_{i=1}^{N} a_{ij}x_{ij} \to max; \quad (17)$$

The only constraint in this case is that the matrix of Boolean variables X must describe the adjacency matrix of Hamiltonian graph. This cycle must be the only path in that graph. Here, a_{ij} is the distance (cost, time, etc.) between i-th and j-th places (cities), $a_{ii} = 0\ \forall\ i$, $aij = a_{ji}\ \forall\ i,j$.If $x_{ij}=1$ then it means that the salesman must go from i-th place to the j-th one.

We tried to solve the optimization problems in Argo cluster (SISSA, Trieste, Italy). The program code was adapted for MPI running. Algorithm designed for OpenMP parallelizing (see Figure1, variant 2) was implemented for paralellizing via MPI. MPI synchronizing procedure was used at the step "Synchronization". Following this flowchart gave negative results in comparison even with a single node (8 nodes, 2 processes per node, 50 variants of X sets in each generation on each node, 10000 Boolean variables, 11000 constraints).

Analysis of the problem showed that at the step of synchronization, each node spent approximately 12% of time waiting for the other nodes to finish the calculation, data interchange between nodes in this case is rather intensive (10000 Boolean variables had to be sent from each node, then, each one had to receive 10000 real numbers of the probability vector after each step).

Reconstruction of the algorithm so that each node performs N steps (100-500 for that scale of the problem) separately, and comparing the results after the N-th step, choosing the best ones by master nodes and broadcasting new probability vector gave much better results. But, in this case, each node had to spend up to 43% of time (!) waiting for the others to complete their calculations.

Another way to organize the parallel execution of the search processes with the maximum independence from each other is to organize multiple starts of the algorithm at all the nodes. The algorithm starts at the nodes with the same or different initial parameters (for example, different initial values of the probability vector elements).These

multiple simultaneous starts are performed instead of the rollback procedure in the serial version of the optimization algorithm. Each node starts the cycle of the random X vector generation with probability vector adaptation. If the algorithm does not improve the best objective function value during several steps, the rollback procedure is performed. When all the nodes reach the stop condition, the results of all the nodes are compared to figure out the best one as the final result of the optimization problem.

In its simplest form, the above approach does not need any modification of the implemented software. The serial version of the algorithm runs at all the nodes simultaneously and the results of the nodes are then compared by the operator or by the special node.

The simultaneous execution of the serial version of the algorithm improves the results of the calculations insignificantly due to the similar behavior of the algorithm at all the nodes. The comparison of the P vector values from different nodes after several steps shows that the difference between them is reduced with each following step and the nodes generate the new exemplars of the X vectors in the very close area. In case of the algorithm with no average probability adaptation, the simultaneous execution of the serial version of the algorithm with different initial probability value gives the results much better than the serial algorithm executed at the single node. But in most cases, the version of the optimization algorithm with the average probability adaptation executed at the single node shows even better results. So, our approach must support the average probability adaptation for the optimization algorithms executed at different nodes (13).

a) Initialization (at each node), **MPI_INIT**
b) Generating N random sets of variables X, estimating F(X) and constraints (at each node)
c) Choosing the best and the worst X sets, adaptation of the probability vector P (at each node separately)
d) if I am the master node then:
d1) check if any data transfer started at the previous steps has been completed
d1.1) if so, then if it was the maximum result reached by the k-th node, check if this result is better than the global result
d1.1.1) if so, send message "OK" to the k-th node
d1.1.2) if not so, send "NOT OK" to the k-th node and send the actual global maximum and the corresponding X vector to the k-th vector
d1.2) if the completed data transfer contains the best vector X
d1.2.1) then recaclulate F(X) and if it is better than the global maximum, assume that this is the new global maximum
d2) if there are any messages from the other nodes waiting to be received and no receiving processes are in progress, start receiving (non-blocking, continue processing)
d3) check if the stop conditions are reached. **If so, send "STOP" message to all the processes, wait for all of them to receive it and then MPI_FINALIZE, stop**
e) if I am not the master node and I have already started any sending process then
e1) check if this process has been completed
e2) if so, start receiving of the answer from the master node
f) if I am not the master node and I am waiting for a response from the master then
f1) check if the master node has started sending anything
f2) if so, start receiving (non-blocking)
g) if I am not the master node and I have already started receiving smth. from the master node then
g1) if the receiving has been completed then
g1.1) if it was "OK" message, start sending my best X vector (non-blocking)
g1.2) if it was "NOT OK" message, start receiving global best X vector (non blocking)
g1.3) if it was the global best X vector, recalculate F(X) and, if it is better than my own maximum, partially restart local process to perform further search around the global maximum
g1.4) if it was the "STOP" message, then stop, MPI_FINALIZE
h) Checking for the restart conditions (at each node separately), algorithm has to be restarted if it hasn't improved the best results during several last steps
i) if the restart conditions are reached then
e1) if I am not the master node, start sending the best F(X) value
e2) reset probability vector
j) go to step b

Figure 2. Parallel algorithm description

The algorithm was re-written (Figure 2) so that all the data transfer was performed at the step of checking of the restart conditions (text in bold used for the steps performing message passing). If the algorithm does not improve the local maximum values of the objective functions after c_{max} generations, the process tries to communicate to the other processes to check if any other node has improved the previous global maximum. If so, the process receives that value and the corresponding X vector values. If the local maximum value is better than the received one then we report our values as the new global maximums.

In our algorithm, we do not send P vector values which are rather long. The vector P for the problem with 10000 variables needs 40000 bytes to be sent. The node having achieved global optimum sends this value and the values of the vector X_G^* (1250 bytes in case of 10000 Boolean variables). The values of the new probability vector are calculated as

$$p_i = \frac{(C_{corr} + (1 - 2C_{corr}) x^*_{Gi}) p_G^{AVG}}{C_{corr} + (1 - 2C_{corr}) p_G^{AVG}} \quad . \qquad (18)$$

Here, $x^*_{G\,i}$ is the i-th element of the received vector X_G^*, D is the dimension of the problem (number of the elements of X_G^*), C_{corr} is some small real value, p_G^{AVG} is the average value of the probability vector generated the vector X_G^*. If the received message does not contain it then the node which has received the message evaluates it:

$$p_G^{AVG} \approx \frac{\sum_{i=1}^{D} x^*_{Gi}}{D} \quad . \qquad (19)$$

Taking into consideration the constraints (3) if they exist, the value of the constant C_{corr} can be calculated as $0.5/V$.

The last version of the algorithm, though it is rather efficient, has very low data interchange between nodes (log shows that there was only 31-152 data transfer sessions for each node during 1 hour). So, with this intensity of data traffic, there is no need to implement any expensive network to build an efficient MPI cluster for random search problems solution.

4 Results

In case of the problem (14), the results achieved by the program working on 8 nodes separately with comparison of the best result after the last step (4 nodes, 2 processes per node, 10000 Boolean variables, 11000 constraints, non-linear objective function) this version of the algorithm achieves in half time (2 hours for the separately working nodes and 63 minutes for this version of the algorithm).

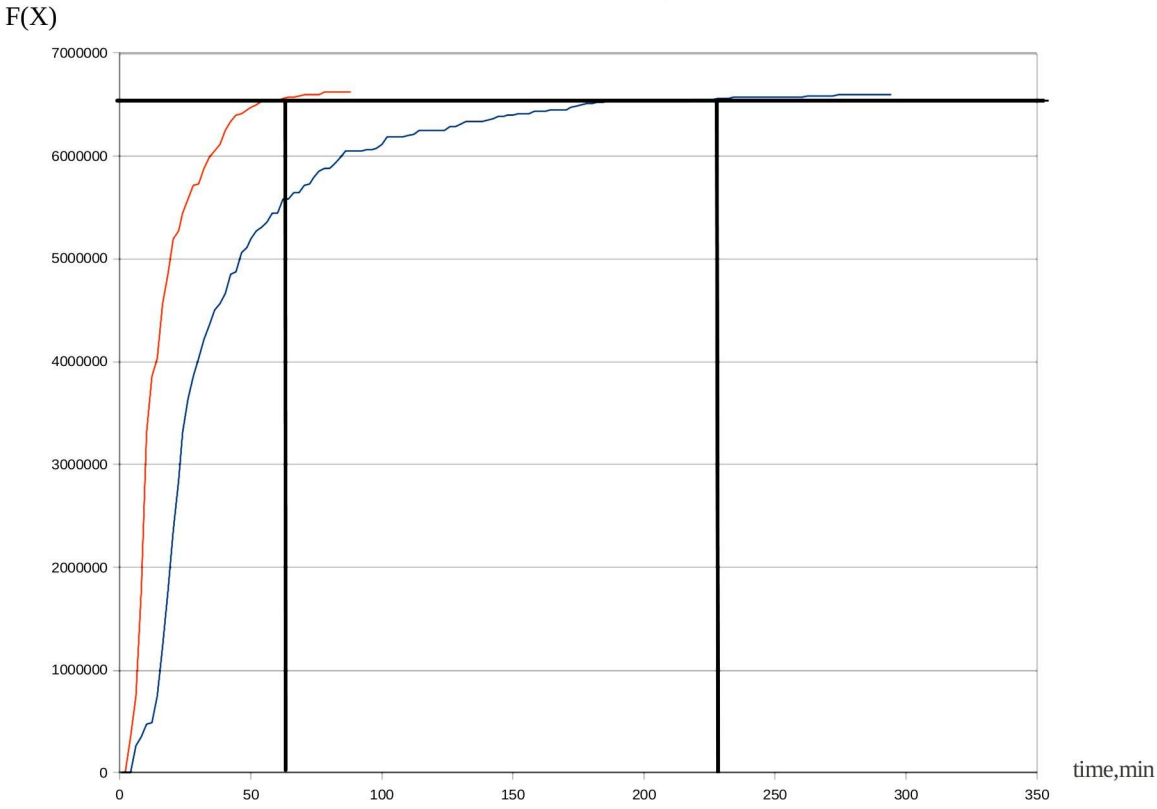

Figure 3. Comparison of the results of serial and parallel versions of the algorithm

Traveling salesman problem with 1000 points (1000000 Boolean variables) after 4 hours of calculation on 4 nodes had not given the exact results, the results were still improving at the last steps, problem with 500 points (250000 variables) after 4 hours of calculation gave rather good result, very close to the optimal solution.

The parallel efficiency for the cluster system of 6 nodes is 0.81. An example (Figure 3) shows the results of

running of the algorithm on cluster and on a single computer which is a part of that cluster. To build this diagram, we included in our algorithm special block which stores the maximum objective function value reached by the algorithm and the current time after each 10 steps to a special array. The horizontal line shows when the algorithm achieves the control value (65015.17). To reach this control value, the serial version of the algorithm has spent 229 minutes (13748 seconds), the parallel version has spent 59 minutes (3556 seconds).

The average value of the parallel efficiency (0.81) is calculated as the average speed-up coefficient after 10 runs for 5 different objective functions. It is interesting, that at the very first steps, the parallel efficiency coefficient is less than at the following steps. The possible reason of this fact is the process of parameters tuning which is performed by each node at the first steps and the intensive message passing.

5 Conclusions

- Blocking MPI operations give negative results in comparison with non-blocking ones for the random search problems. In case of fine granularity parallelization [12, 13], results are negative even in comparison with a single node;

- Though the realization of the simplest protocol with 6 kinds of messages is rather a complicated problem, non-blocking operations work fine, their implementation gives significant (2x) speedup in comparison with the simultaneous running of the same code at separate nodes;

- Using the high-performance clusters increases the maximum scale of the problems solved;

- To build the MPI cluster for random search problems, expensive high-performance network is not needed because of very low intensity of data traffic;

- Implementation of MPI does not decrease the productivity of a single node, OpenMP still gives perfect results in comparison with serial code.

The discussion of energy conservation of data center from the evaporative cooling technology of HPC

Ruan, Lin*, Li Zhenguo
Institute of Electrical Engineering, Chinese Academy of Sciences, Beijing P.R.China 100190

Abstract - *The IT industry is developing fast and more and more large scale data center and supercomputing center were built or in building, which improve scientific research and data service also bring about huge energy consumption. This paper aims to make a discussion of energy conservation of data center from the evaporative cooling technology of HPC. Firstly, the developing tendency of data center and the traditional cooling technology are introduced; secondly, much more concentration were put on the newly high performance evaporative cooling technology for HPC and we showed a prototype of the spray evaporative cooling HPC developed by IEECAS, finally, a prospective blueprint was drawn up for the future construction of data center with evaporative cooling HPC.*

Keywords: Energy conservation; Evaporative cooling technology; Data center; HPC

1. Perface

During more than one hundred years since the industrial revolution, the people's demand for the energy is dramatically increasing, which gives much more pressure to the supply of the energy and also bring about the serious environmental crisis.

With the deepening of the informationization development, the super computer or high performance computer (HPC) is developed quickly and being extensively applied in many fields.

Data center provided with lots of IT equipments especially HPC makes great contribution to the scientific researches especially in the field like astronomy and meteorology relating to a lot of data processing and computing.

Whereas, with the continuously improvement of the data processing capability, computing speed and storing ability, the data center will consume a huge amount of electricity during its daily operation and at the same time brings about serious energy consumption problem to the society.

Besides the energy consumption of the hardware in the data center, in order to secure the normal and safety operation of the IT equipment, an additional electrical energy must be used to dissipate the heat. The cooling problem of the IT equipment shows up and becomes a big challenge for the cooling technology. Among that, the energy consumption of HPC is predominant.

Aiming at the HPC cooling, the traditional method include air cooling, water cooling and heat pipe cooling etc. Water cooling and heat pipe are belong to closed loop cooling method, the manufacture technology is a little bit complex and the cost is relatively higher than others. The most important is the water cooling has the potential of leakage which will lead to an electrical accident. Air cooling is easiest and has been widely used in HPC. But the disadvantage is that is the noise is big and the cooling capability is limited. Due to its usage of air conditioner, the energy cost is very high. According to the statistic, in a nowadays air cooling data center , the minimum of 50% average carbon exhaust come from the cooling system rather that the IT equipment itself.

Recently, the research of high effective cooling technology is becoming the hot point globally and promoting the energy efficiency is a huge challenge. Evaporative cooling technology takes advantage of phase change to realize the cooling effect of the object. Its

cooling capability is far larger than the other heat transfer method using specific heat.

This cooling technology has been successfully used to the large electrical machine in china and we have priority of intellectual property right. The recent application of this technology to the large electrical machine is the world famous Three Gorges hydropower project. It's the largest hydropower plant in the world. There are two sets of 840MVA hydrogenerators using this kind of cooling technology designed by IEECAS.

The characteristic of this cooling technology include: high efficiency for the heat transfer, high safety and most important low energy cost or zero energy cost from the cooling system itself. All of these characteristics show cases it will be very suitable for the HPC and data center.

2. The development and challenge of the modern data center

Pushed forward by the explosive increase of demand for the data services and rapidly development of IT technology, the data center has experienced a tremendous development and the increase tendency will be lasting, the annual growth rate will be no less than 10%. Whereas, the energy cost of data center becomes un-neglecting.

With the increase of demand for the computing capability, more IT equipment and more density of the equipment in the data center will be needed. The general tendency of the development of data center is limited space with as many as cabinet, high integration level, small sized chips and high density, which means more energy consumption per unit space.

According to statistics, the electricity consumption of data center is increasing annually at the rate of 15-20%, the price for the energy is soaring at the same time. So the maintaining cost for a data center is very high. It was said that the biggest single cost for Google is for the electricity. That is why they want to arrange their data center near a hydropower plant. .

The energy consumption of data center has its specialties, the verity of energy consuming IT equipment is much and the construction is very complicated. In general, the energy consumption of data center mainly covers the following aspects: high performance IT equipment itself (including CPU, RAMS, CHIPSET and external appliances), power supply equipment (power losses during the conversion of power sources) and cooling system. The typical power flow is introduced in the following Fig.1.

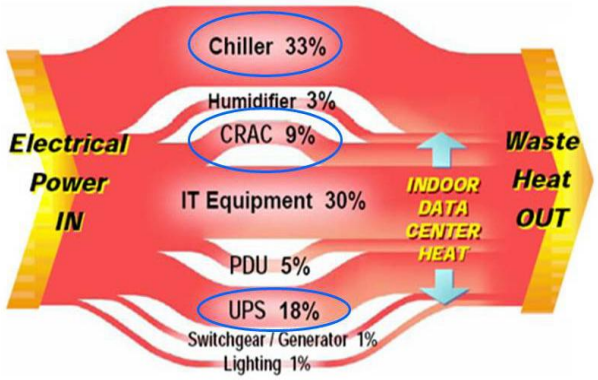

Fig.1 Power flow in a typical data center

Among that, cooling system for data center should not be belittled and it has very close relation with the cooling technology and cooling structure.

The recently built data center and supercomputing center has more concern about the energy saving, but it's still in a high level. Take ShangHai supercomputing center for example, since the Dawning "4000A" super computer system put into operation in August 2004, its stable load rate is relatively high, and the main CPU usage is retaining about 85%, it has a lot of consideration about the arrangement of the rack shelf and the ventilating passage design. Analysis on the basis of statistic of mean quarter operating data of whole supercomputing system showed the energy consumption in the following table1. From this table, we can see that the energy consumption of the cooling system account for more than 50% of that of IT equipment itself. See from this point of view, focusing on the energy saving of the cooling system will be obviously productive for decreasing the energy consumption of data center.

Table1. Energy consumption of "4000A"

Cooling method	Real cases	IT hardware electricity consumption	Cooling system account for

Air cooling	"4000A"	285kW	54.4%

3. The traditional cooling method for the HPC

Recently, the cooling technology is becoming newly researching hot point of HPC, improving the energy efficiency of the computing system and data center is a huge challenge. There are many cooling method for tackle with the heat dissipation of HPC, but from the point of view of putting into commercial use, the most traditional or easiest realizing method is air cooling and water cooling has the potential to show up due to it high performance of heat transfer

3.1 Air cooling

Air cooling is the most-easily-realized cooling method, but it needs the use of CRWC and its cooling effect rely more on the surrounding temperature and its cooling capacity has utmost. Theoretically, the design value for the cooling capacity is 1500w/m2 that means the unit computer cabinet is 6kW, the utmost is 8kW.

The most serious problem relating to the air cooling method is the fan noise and the huge energy consumption. The cooling effect and the noise of the fan is a big contradiction seems cannot be easily solved. This cooling method conform to the convective heat transfer, in order to promote the cooling effect, we must increase the speed of wind flow, so the increase of numbers of fans and the rotating speed of fans is inevitable (normally, the speed for the CPU is above 5000rpm), which lead to big noisy pollution. If for an open air cooling atmosphere, the air flow also arouse the dust flow inside the mainboard and deposited on that, bring about the decrease of safety and maintenance inconvenience.

For air cooling data center, the arrangement of the cabinets and the design for the ventilation passage is very complex, even the design is theoretically practical, and in real application, the operator of data center found that the cooling effect of different cabinet differs a lot from each other, there will appear local high temperature area and in some extreme circumstance, a few cabinet cannot working due to high temperature.

In reality, in air cooling data center and supercomputing center, up to 50% energy cost is not for computation, but for the necessary cooling system, if we concern more about the energy efficiency of the data center, this cooling method is far beyond our desire. And such problem will become more serious with the development of the chip capacity and IT cabinet integration. Lot of giant company such as IBM is struggling to solve this energy problem caused by cooling demand.

3.2 Water cooling

Due to the thermal load limit of the traditional air cooling and some other problem, the alternative is necessary. So, for large processor or supercomputing system, the water cooling method shows up the practical significant. Water is a good fluid having bigger specific heat than air, so the cooling effect can be promoted a lot. Google is programming its largest super computer with two 4-layer building used for cooling system. K-computer with water cooling system (Fig.2 and Fig.3) ranked No 1 in the last year's world top 500 in the supercomputer field.

For cooling method itself, there is no technique knowhow and easy to be extended. But higher safety risk (water is of electrical conductivity and water leakage cannot be easily avoided due to high flowing pressure), higher manufacturing cost (technology is complex and hard to assembly and maintain) and having no positive contribution to the energy saving make it commercial prospective not very well.

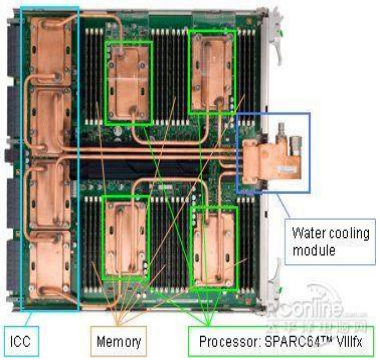

Fig.2 Cooling main board of K computer

Fig.3 K computer cabinet

4. The application of the evaporative Cooling technology to the HPC

The evaporative cooling takes advantage of the physical process of phase change to take away heat losses when an appropriate liquid-phase coolant becomes gas-phase coolant. The evaporative cooling technology is kinds of liquid cooling method combined with specific cooling structure design which can avoid the fatal disadvantages of the water cooling completely due to it adopt some special coolant with high insulation.

The Institute of Electrical Engineering, Chinese Academy of Sciences (IEECAS) has been doing the evaporative cooling research since 1958. During more than 50 years' developing process, the evaporative cooling technology has experienced some stage of innovation and has been used to various electrical equipments, such as turbogenerators, hydrogenerators, electrical power transformers and power electronic component equipment etc.

Due to the urgent demand of high efficiency cooling technology for HPC, we try to use it to the HPC on the basis of our experiences on applying of it to the power electronic component equipment. Its application to the HPC not only can solve the heat dissipation problem but can obtain the goal of energy saving.

Phase change heat transfer is of high efficiency, it can realize the good cooling effect for the HPC, at the same time the stability and safety of HPC can be guaranteed due to the selection of the evaporative coolant. The evaporative coolants are all liquid material with proper boiling temperature best matched with the cooling target. It is primarily environmental protected, is of high insulation, it has on toxicity, no liable to inflame and good chemical and physical stability.

As to energy conservation, for different cooling structure, the energy saving level varies. The following will introduce two kinds of evaporative cooling HPC design. The energy saving target is different.

4.1 Spray evaporative cooling HPC

We have developed a kind of spray evaporative cooling super computer with the cooling medium directly contact with the heated chips, during the phase-changing procedure, the large amount of latent heat will be absorbed by the coolant from the heated chip without increase its temperature, so it very fit for the high density computer cabinet cooling, the cooling effect is better than air cooling at the same thermal load level, and most important effect is that the coolant circulation just need a little momentum provided by the pump, the energy consumption for this kind of cooing system is just for the energy cost of pump.

When the HPC start working, the liquid phase evaporative coolant sprayed out from the nozzle and have a direct contact with the heated chips distributed in the HPC cabinets, part of them vaporizes when absorbing heat and gas phase coolant rise to the condenser. The pump provides the momentum for the coolant circulating in the closed loop. In the equipment, the nozzle is located near the mainboard and spays liquid coolant toward the main heated chips shown in Fig.4.

We have built a prototype of spray evaporative cooling super computer in our lab (Fig.5), it unit cabinet thermal capacity is 50kW, but the max energy cost for the pump is just 3.06 kW accounting for only 6.12%. If a group of computer cabinets operate parallel, the proportion of pump energy cost will decrease due to the power of pump is non-linearly increased. So, for a data center with many hundreds of cabinet, the energy saving effect is more in evidence.

4.2 Self-circulating evaporative cooling HPC

For more energy saving cooling system, we come up with the self-circulating evaporative cooling system for

HPC, which have some thin liquid boxes attach to the heated chips and all these boxes can be connect together or form circulation branches separately.

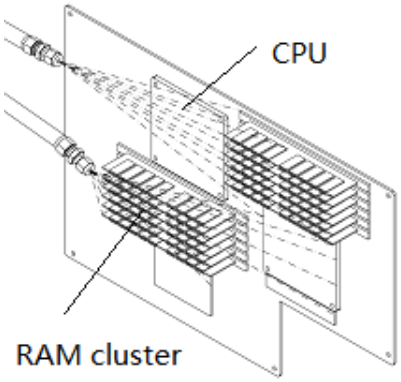

Fig. 4 Spry of coolant to the heated chips

Fig.5 Prototype of spray evaporative cooling HPC

The self-circulating evaporative cooling HPC consists of blade units, blade cases, cabinet, condenser, liquid boxes and some connecting tubes. The principle diagram is shown in the fig.6. the liquid box shown in Fig.7 is fill with the evaporative coolant with the boiling temperature of 40-50℃. When the chip heated, it will transfer the heat to the box attached on it, the coolant inside the box absorb the heat, part of them boiling and liquid coolant becomes gas phase coolant and flow upward along the gas tube due to the density difference and flow back along the liquid tube after it is cooled into liquid phase in the condenser. So, the whole circulation system is closed loop, and the coolant flow momentum is aroused from the density difference between liquid phase and gas phase coolant, there is no need of external forcing momentum. So, there is no energy consumption at all.

The use of thin box brings about additional contact thermal resistance and a thermal conductive link along the direction of box wall thickness. For improve it, some researches on surface conductive and convective enhancement methods are underway in our lab.

In a long run, this kind of cooling system for HPC is the best choice for the data center and supercomputing center. The prototype is under construction in our lab. The cooling system itself can completely realize zero energy consumption and is self-circulating, no fan or pump noise, self-adaptive and safety. The only problem is a little higher primary investment for the fabrication of liquid box due to its odd-shaped. When it can be standardization and realize mass production, the initial investment will not be a problem anymore.

5. The prospect for the construction of the future low energy consumption data center

For the next generation of HPC, air cooling cannot be satisfying and water cooling was hampered by the high cost, safety and maintenance. So, introducing the high efficiency evaporative cooling technology to the IT equipment, especially the data center with centralized use of IT equipment is a good resolution for high cooling effect and lower energy consumption.

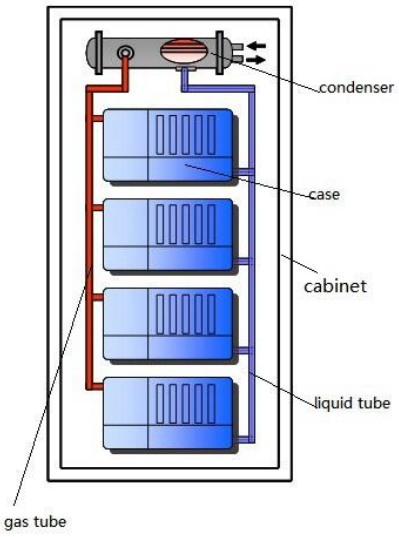

Fig.6 The diagram of self-circulating evaporative cooling HPC

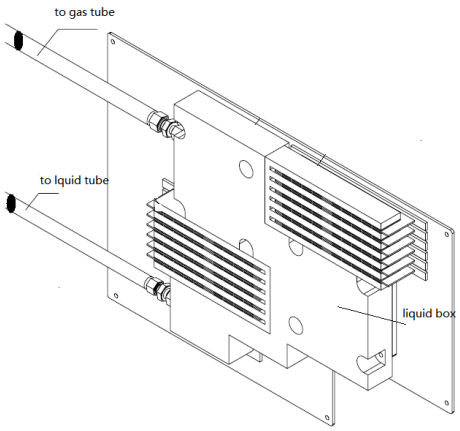

Fig.7 Liquid box with connecting tube

The evaporative cooling system is closed loop and has direct cooling effect to the heated chip, so there is no need of installation of CRWC, it can eliminate to the maximum the noisy pollution aroused form the fan of air cooling in the data center and can save a lot of money for the electricity usage relating to the cooling system. It can provide a clean, high capacity, quiet environment for the future scientific research and large scale numerical calculation. By adopt micro-force circulation and self-circulation system to realize the high-performance of cooling system, it provide more rooms for increase the density of single chip; it can also increase the density of cabinet or data center; it has more flexibility to get a good use of space of data center. Due to its low or zero energy cost, it will have a great contribution to push forward the energy conservation of data center and with no doubt will play a positive influence on the sustainable development of IT industry.

Furthermore, lower power consumption or zero power consumption evaporative cooling technology combined with the architecture energy-saving and the reasonable usage of afterheat should attract more attention when sketching the future construction of data center and some auxiliary facilities.

A Parallel Algorithm Development Model for the GPU Architecture

J. Steven Kirtzic, **Ovidiu Daescu**
Department of Computer Science
University of Texas at Dallas
Richardson, TX USA
{jsk061000, daescu}@utdallas.edu

Abstract— *Parallel computing has been in use for decades, and throughout many researchers have sought to define a model for algorithm design for such a platform. Valiant developed a model for parallel computing, which was later extended to later include multi-core processors, but it still may not be best suited for the unique GPU architecture. With the current advances in high performance computing, it is easy to see the role that GPUs can play, and even easier to see the need for a model for GPU algorithm development. Here we propose a parallel GPU model which offers both a general design and a fine-grained approach, intended to accommodate nearly any GPU architecture. We show how our model can result in significant increases in performance when algorithms are designed based on its principles.*

Keywords: GPU, parallel processing, algorithm design

1. Introduction

The rapid advancement of the Graphics Processing Unit, or *GPU*, over the last few years has opened up a new world of possibilities for high-speed computation, ranging from biomedical to computer vision applications. Recent examples include [1], [2], and [3]. However, the GPU architecture is unlike that of any other, and designing algorithms to fully harness the capabilities of a GPU is not an easy task, especially when one considers the advantages and disadvantages of the various resources that a GPU has available to it. In this paper we introduce a parallel algorithm design model for the GPU architecture which addresses these issues. In Section 2 we discuss related work; in Section 3 we present a brief overview of the GPU architecture, focusing on NVIDIA's CUDA architecture; in Section 4 we present the model in its entirety; in Section 5 we illustrate the use of our model as we apply it to template and shape matching algorithms; in Section 6 we discuss the results of our model as applied to these template and shape matching algorithms; and finally in Section 7 we conclude and remark on future work.

1.1 Contribution

We believe that our main contribution with this work is to provide an easily accessible parallel algorithm design model for the GPU architecture. Our model addresses the limitations of other parallel models in that it accounts for the unique architecture of the GPU, in particular the various types of memory that the GPU possesses and their individual attributes. Our model is also designed to include single or multi-core CPUs as part of the system, if the designer chooses to do so. Finally, our model is intended to be easily accessible for a wide variety of reseachers from all scientific fields interested in GPU algorithm design, ranging from the novice to the experienced.

2. Related work

We present the following parallel model designs in succession to demonstrate the evolution of our Parallel GPU Model (PGM) and give it proper context.

2.1 The PRAM model

The PRAM model is generally regarded as one of the original parallel algorithm design models. The main shortcoming of the PRAM model lies in its unrealistic assumptions of zero communication overhead and instruction-level synchronization. Another drawback of with the PRAM model is that the time complexity of a PRAM algorithm is often expressed in big-O notation, which is often misleading because the machine size n is usually small in existing parallel computers. Consequently, the PRAM model is generally not used as a machine model for real-life parallel computers.

2.2 The BSP model

The BSP, or bulk-synchronous parallel model, was proposed by Leslie Valiant [4] to overcome the limitations of the PRAM model [5], while maintaining its simplicity. In the BSP model, a BSP computer consists of a set of n processor/memory pairs (nodes) that are interconnected by a communication network. The BPS model is *Multiple Instruction Multiple Data* (MIMD) in nature, and uses the concept of a *superstep*, which is comprised of a computation step, a communication step, and a synchronization step. The BSP model is also variable grained, loosely synchronous, has non-zero overhead, and uses message passing or shared variables for communication.

The program executes as a strict sequence of supersteps. In each superstep, a process executes the computation operations in at most w cycles, a communication operation that

takes gh cycles, and a barrier synchronization that takes l cycles. Note that in the communication overhead gh, g is the proportional coefficient for realizing a h relation. The value of g is platform-dependent, but independent of the communication pattern. In other words, gh is the time that it takes to execute the most time-consuming h relation.

Within a superstep, each computation operation uses only data in its local memory. This data is put into the local memory, either at the program start-up time or by the communication operations of previous supersteps. Therefore, the communication operations of a process are independent of other processes.

The BSP model is more realistic than the PRAM model because it accounts for all overheads except for the parallelism overhead for process management. The time for a superstep is estimated by the sum

$$w + gh + l \tag{1}$$

This model is highly regarded and has formed the basis for other parallel models, such as the parallel phase model [5], which we will briefly discuss next. However, its generality is its shortcoming when one attempts to apply it to more specific architectures, such as that of the GPU. Valiant recently extended his model to include multi-core CPUs [6]. While this model is much more akin to the architectural nature of the GPU, it still does not take into consideration the complexities of the typical GPU architecture, in particular the various types of memory, which as we will demonstrate in later sections have a tremendous impact on the performance of a given GPU algorithm.

2.3 The parallel phase model

Kai Hwang and Zhiwei Xu [7] proposed a phase parallel model for parallel computation that is further refined from the above two abstract models. This model is similar to the BSP model with the following distinctions: a parallel program is executed as a sequence of phases: the parallelism phase, the computation phase, and the interaction phase. The total execution time of the superstep on n processors is expressed by

$$\begin{aligned} T_n &= T_{comp} + T_{interact} + T_{par} \\ &= (w + \sigma\sqrt{2logn})t_f + t_0(n) + \alpha * w * t_c(n) + t_p(n) \end{aligned} \tag{2}$$

where w is the number of cycles, as with the BSP model, α is the *communication-to-communication ratio* (CCR) of each superstep, and t_f is the average time to execute a flop by a processor.

Improved from the PRAM and the BSP models, the phase parallel model is closer to covering real machine/program behavior. In this model, all types of overheads are accounted for, as shown in Eq. (2): the load imbalance overheads, the interaction overhead (t_0 and t_c terms), and the parallelism overhead (t_p term).

While these models represent the evolution of parallel algorithm design in general terms, they are limited in scope as they ultimately fall short when applied to the unique architecture of the modern GPU. The need for a model suited to this architecture was vocalized in a paper from MIT [8] in which the authors identify that official documentation for CUDA from NVIDIA was rather sparse, the forums required a lot of searching to find an answer to a particular problem, and the trade-offs between various programming options were difficult to discern. We attempt to address these issues by providing a model which was designed to not only include the more general models identified above, but to also take into consideration the unique nature of the GPU architecture, as it differs considerably from the CPU architecture.

3. GPU architecture

In this paper we will often refer to the machine containing the GPU as the "host" and the GPU itself as the "device". The NVIDIA GeForce 8800 series is an example of a typical GPGPU (General Purpose GPU) device, which utilizes NVIDIA's CUDA (*Compute Unified Device Architecture* GPU design. The GeForce 8800 contains 16 multiprocessors, each containing 8 semi-independent cores for a total of 128 processing units. Each of the 128 processors can run as many as 96 threads concurrently, for a maximum of 12,288 threads executing in parallel. The computing model is SIMD (*Single Instruction Multiple Data*), and the memory model is NUMA (*Non-Uniform Memory Access*) with a semi-shared address space. This stands in contrast to a modern CPU, which is typically either SISD (*Single Instruction Single Data*) or MIMD, in the case of a multi-processor or multi-core machine. Additionally, from the perspective of the programmer, all memory is explicitly shared (in multi-threading environments) or explicitly separate (in multi-processing environments) on a desktop machine.

3.1 GPU instruction throughput versus memory access

The GPU architecture is much more optimized for performing calculations than for memory accesses. Therefore, considering the multiple types of memory that the GPU architecture typically includes, it is important to keep this in mind when accessing these types of memory, particularly the slower, off-chip ones such as the GPU's global and the host's main memory. The most costly memory access is by far the host-to-device (CPU to GPU) data transfer, and reducing that transfer can have a tremendous impact on the overall performance of any algorithm that is implemented in part or fully on a GPU.

As an example of our research, we present the case of a typical Full Search Method of template matching, which is otherwise known as a "brute force" method. A naïve GPU

implementation of this algorithm is relatively easy, as the underlying architecture (such as CUDA) will handle most of the scheduling, thread allocation, memory management, etc. for you. In this case, a naïve, straightforward GPU implementation should run in *O(mn/p + log m)* time, where *p* is the number of processors, assuming that $1 \ll n$. We present the results of the implementation of this naïve GPU algorithm using several different types of GPU memory (discussed below) versus the serial implementation in Table 1.

Table 1: Run time for Full Search Method template matching for a 512x512 image and a 64x64 template. Times are in ms.

	Run Time	Copy Time
CPU	23290	N/A
GPU	3042	217.7
GPU Shared Memory	200.68	217.7
GPU Texture Memory	107.38	2.361

Table 2: Average results over 1000 trials of basic CUDA memory operations. The first column refers to the amount of data used for this experiment, in bytes. "malloc" and "malloc 2D" refer to allocating an array and a byte aligned 2 dimensional array on the GPU, respectively. "copy" and "copy 2D" refer to copying data from the CPU's global memory to the GPU's global memory. All times are in ms.

size	malloc	copy	malloc 2D	copy 2D
$4 * 10^3$	0.067567	0.005253	0.116700	0.014929
$4 * 10^5$	0.118616	0.291486	0.122187	0.296680
$4 * 10^6$	0.141160	2.576290	0.180513	2.713126
$4 * 10^7$	0.241793	23.344471	0.629537	24.801236

Given the considerable differences in architecture between the GPU and CPU, one can see that the ratio of overall run-times of the CPU to naïve GPU implementation (which we define as "speedup", *S*) is only 23290/3042 = 7.66. Given the number of processing cores *p* in our GPU is 128, this is clearly not an optimal solution, as it yields an efficiency of .060 (we define ''efficiency" as *E = S/p*). The majority of this is due to communication overhead (data transfer), as global memory on the GPU is uncached. Experimentation confirms that the instruction throughput is only .034, indicating that 96.6%≈97% of the total run time was due to host-device data transfer.

In addition to the host-device memory read/write, there are several other types of memory that a GPU may have and access, either on-chip or as part of the graphics card, including (in order of typical size) global memory, L2 cache memory, texture memory, shared (local) memory, and the processor registers. The type of memory that a programmer uses for a particular operation depends upon the size and nature of the data structures to be used, whether or not these data structures can be broken up (and if so how), and whether they are read/write data or simply read-only. In Table 2 we present the results of our experimentation with host-device data transfer times for different sizes of data to illustrate the importance of proper data partitioning.

4. Parallel Algorithm Design Procedure for GPUs

As discussed earlier, Valiant's multi-core parallel algorithm model falls short when one attempts to apply it to many-core GPUs. In designing our Parallel GPU Model, we opted to refer back to Valiant's original BSP model as a basis, and build out our model from there.

4.1 General model

GPU Superstep:

$$max_{i=1}^{p} w_i + max_{i=1}^{p}(h_i * g) + l \tag{3}$$

where p = number of processors (cores) on the GPU

w_i = cost of local computation in process *i*

h_i = number of messages sent and received and/or variables accessed by process *i*

l = cost of synchronization

g = message speed (bandwidth)

Algorithm total cost:

$$\begin{aligned} \mathrm{C}_{GPU} &= \sum_{i=1}^{S} superstep_i \\ &= W + H * g + S * l \\ &= \sum_{s=1}^{S} w * s + (\sum_{s=1}^{S} h_s)g + S * l \end{aligned} \tag{4}$$

where *S* = number of supersteps

W = total cost of local computations in all processes

H = total number of messages sent and received and/or variables accessed by all processes

CPU Superstep:

The CPU component of this general model is very similar to the GPU component above, with the exception that the variables apply to the CPU (i.e. *p* applies to the number of CPU cores, processes are executed on the CPU cores, etc.)

Total

$$C_{total} = \sum_{i=1}^{n} C_{GPU_i} + \sum_{i=1}^{n} C_{CPU_i} + (\sum_{i=1}^{m} T_i)b \tag{5}$$

where C = cost

n = number of algorithms or parts of algorithms executed

m = number of data transfers between CPU and GPU (usually an even number)

T = one-way data transfer

b = CPU to GPU data transfer bandwidth

In the simplest, single algorithm situation, this can be represented as:

$$C_{total} = C_{GPU} + C_{CPU} + 2 * T * b \quad (6)$$

Reducing the number of *T*s along with the size of *T*(the amount of data transferred) are two coarse-grained methods of reducing an algorithm's overall run time and thereby increasing performance.

4.2 Fine-grained model for parallel GPU algorithm design

If the algorithm designer is experienced in parallel algorithm design principles, they can typically skip to Step 3 below, otherwise they should continue with the following steps.

Step 1: Once a serial implementation of a given algorithm has been either acquired or originally designed, the first consideration is what types of instructions (operations) are to be performed on the given data set or sets of the algorithm. This will help in determining data dependency (as discussed below), as well as to help determine what operations must be performed on which processor.

Step 2: The goal is to reduce the total data transfer time as much as possible, meaning reducing the amount of data that is transferred back and forth between the host and device. Furthermore, this round trip may be performed multiple times for one algorithm depending on the structure of the algorithm and/or the size of the data sets. The various types of GPU memory are of varying sizes, but are all generally very small compared to modern host main memory. Therefore, in some parallel applications a data set may have to be broken up and sent to the GPU for computation through several round-trips. Consequently, as discussed briefly in Section 3.1, sending large amounts of data to and from the GPU unnecessarily may lead to a longer run time than the original serial algorithm (especially if it is optimized and/or implemented on a multi-core CPU).

With this type of trade-off of data and operations between the CPU and GPU, the most important aspect in determining what should be transferred to the GPU is *data dependency*. This essentially refers to identifying what operations require the data that is the result of previous operations. If an operation must wait for the resulting data from a previous operation, then these operations must be performed serially. They can still be performed serially on the GPU, but that would defeat the purpose of using the GPU and would require unnecessary data transfers. Furthermore, in most cases the CPU would be able to complete these serial operations faster than a GPU would, even without taking into consideration the costly host-device transfer time.

At this point, more experienced parallel GPU algorithm designers can proceed to Step 4 where we discuss optimizations specific to the GPU architecture. Otherwise it is recommended to take the following step of designing and implementing a naïve parallel algorithm before continuing to the optimization step.

Step 3: Implementing a naïve parallel GPU algorithm is a relatively straight-forward task. Most GPU architectures, such as CUDA, include a thread scheduler which will automatically distribute computations to threads and handle other high level functions of the GPU for you. What this results in is a simple port of a serial algorithm to a GPU with little or no consideration for the various aspects of a GPU's architecture that can be leveraged to create an optimal parallel algorithm. While a naïve parallel implementation can be accomplished rather quickly and easily resulting in a notable speedup of the algorithm's performance, this speedup will not be as great as it could be when the GPU architecture optimizations are performed, as discussed below.

Once the data dependencies within the algorithm have been identified, the designer is then able to break the up algorithm into the various parts that have to be done in serial and the parts that can be done in parallel. From that point, the designer can implement the serial parts on the CPU using typical CPU code (i.e. C/C++, Java, etc.) and implement the parallel parts using GPU code (i.e., C for CUDA, Brook+, etc.). With architectures such as CUDA, you can implement the CPU and GPU code in the same program, with the GPU code written simply as individual kernels that are called from within the CPU code, which simplifies the writing of the code a great deal. Also, recently many CPU and GPU manufacturers have adopted a language known as OpenCL, which allows algorithms to be implemented in a single language that can run on both the CPU and GPU, eliminating the need for separate languages for each architecture [9].

As far as GPU memory manipulation goes, with a naïve implementation it is usually easy to simply load the data set (or as much as possible at one time) into the GPU's global memory. The GPU will handle transferring the data from the host's RAM into the GPU's memory whenever a kernel is invoked. The designer just specifies, in the case of CUDA for example, which memory type is being used for which kernel when the kernel is defined in the code. The global memory, while being the largest type of memory and read-write capable, is also the slowest memory. Therefore it is one of the first areas to avoid, if possible, when performing algorithm optimizations, as is described in the next step.

To achieve optimal or near-optimal performance, we must take into consideration the unique architecture of the GPU and exploit this architecture to its fullest. It may take even the most experienced GPU algorithm designer several attempts to achieve optimal results, as often time optimality is best determined through experimentation. But careful analysis of the algorithm along with the GPU architecture can help to greatly reduce the need for experimentation to achieve optimality.

One basic yet effective step toward optimality is to eliminate unnecessary computations. As discussed above, naïve brute force parallel algorithms simply perform the same computation on an entire data set in one step (or several steps depending upon the size of the data set and the number of available threads). Our implementation of a naïve template matching algorithm searched the entire image for a match to the template, which required the transfer of the entire image data from the host's main memory to the GPU's global memory, a very costly operation. However, by redesigning our algorithm to first perform a "pruning step", we were able to reduce the overall runtime by as much as 99%, depending upon the amount of noise in the original image [12]. This is an example of placing "smart" bounds on the dataset to greatly reduce the amount of data that has to be transferred from the host to the device.

The next step in creating optimal parallel algorithms for the GPU is to determine what type and size of data structures your algorithm will use. These considerations are closely associated with what types of memory the algorithm will utilize, both within and outside of the GPU. As discussed in Section 3.1, the GPU architecture is unique in its design and varies considerably from that of a CPU. Indeed, it's fair to say that a GPU is analogous to being "a computer within a computer". Thus the various types of memory that a GPU contains and has access to certainly complicates considerations when designing parallel GPU algorithms. Following, we will discuss the various types of CPU/GPU accessible memory and their advantages/disadvantages.

4.2.1 GPU memory considerations

We denote a system's RAM as M, and note that it has the following attributes: it is read/write capable, is the largest sized memory overall (typically in the order of GB by current standards), its transfer speed (host to device) is the slowest by far, and it is not directly accessible by kernel threads. Global memory, which we denote with G has the following attributes: it is read/write capable, is the largest GPU (on card) memory, its transfer speed is the slowest for a given GPU and graphics card, and it is accessible by all threads. The L2 cache, denoted by L, is an example of a high capacity, high speed component that may or may not be available on a particular GPU, depending upon the model that one is using, such as in the case of the Fermi architecture (see [10]). The texture memory, which we denote as x, has the following attributes: it is read only, is smaller than global memory, but larger than shared memory, it is much faster than global memory but not as fast as shared memory, and is accessible by all kernel threads. The next type of memory is the shared local memory/L1 cache (in the cases where shared local memory also includes an L1 cache [10]). Shared local memory has the following attributes: it is read/write capable; is much smaller than texture memory but larger than the registers; and is somewhat faster than texture

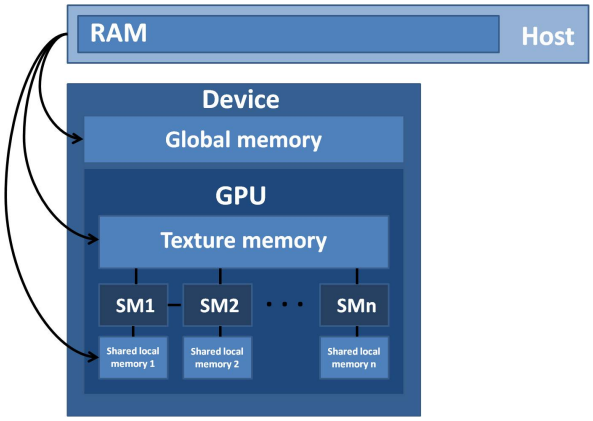

Fig. 1: The host(CPU)-device(GPU) memory hierarchy available to programmers (note that registers are excluded as they are not directly addressable by GPU programmers). We can see how the GPU must go through the host to load data from the RAM into the GPU's global, texture, or shared memories, the latter of which can communicate through SMs (Streaming Multiprocessors).

memory, but is accessible only by threads on a Streaming Multiprocessor (SM). Finally, we denote the register usage by$r$, where registers have the following attributes: they are read/write capable, they are the smallest and fastest of all memory types, and they are typically one register per core. We illustrate the various types of memory available to the GPU programmer with their relative sizes in Figure 1.

With this in mind, however, we will omit the following terms from the final PGM for the following reasons: the RAM transfer time (i.e. host-to-device) is accounted for by the term Tb in Equation (1). Further, we consider the fact that the registers are simply used by the cores as "scratch pads" to temporarily hold the data to be used by the processors and thus are not able to be directly manipulated by the programmer. Therefore, with the exception of bank conflict concerns, the register use should not be of consequence to the designer, and can then be eliminated from consideration.

Naturally, we wish to use the fastest type of memory available in all occasions. However, due to limitations imposed by the size and nature (i.e. read only or read/write) of the data structures that we use for a given algorithm, along with the sizes of the various types of memory as discussed above, a designer may choose different types of memory for various data structures. For example, with our template matching algorithm, we chose to use the texture memory to load our initial query image into, due to the fact that the texture memory is large, fast, and the image does not require write capabilities [12].

Obviously, with the goal being to take as much advantage of the fastest types of memory as possible, a designer's data structures may need to be altered to adhere to the size

limitations of certain forms of memory. As an example, if image data can be streamed into the shared memory blocks at a faster rate than transferring the entire image into global or even texture memory, (without disrupting the computation being performed in those blocks) then using the faster shared local memory is preferable.

Once the algorithm designer has an understanding of the various types of memory that the GPU provides, they can proceed to design the data structures that their parallel algorithm utilizes accordingly. This includes deciding how to break up the data itself, so that the size and the nature of the data structures allow them to be grouped into logical blocks that can be mapped into thread blocks of one, two, or three dimensions, where the threads can maximize their intercommunication through variable sharing within the SM's shared local memory. With our GPU template matching algorithm (discussed in Section 5), we demonstrate the advantages of not only breaking up of the data into logical blocks, (or "strips" in this case) but also the smart use of the GPU's texture memory instead of the GPU global memory, with the former being much faster.

It is important at this point to reinforce that the naïve parallel implementation will typically be subject to the underlying system's automatic (typically non-optimal) scheduling system, which will typically distribute threads on a first-come-first-serve basis, which is generally not optimal.

Another important technique toward achieving optimality with a given parallel GPU algorithm is identifying and reducing (or even eliminating) algorithm execution bottlenecks. As we have discussed above, the execution bottlenecks primarily are memory transfers, in particular the host to device transfer. This issue is being addressed with the new generation of CUDA architecture (Fermi [10]), but for the present the average algorithm designer and implementer dealing with commodity GPUs needs to consider the massive host-device bottleneck.

Above we discussed several ways to reduce the amount of data transfer between the host and device, as well as ways to design your data structures to fully take advantage of common GPU architectures. Following we shall formally define our Parallel GPU Model based upon the above considerations.

Previously, we defined a GPU operation in the following manner:

$$\begin{aligned} C_{GPU} &= \sum_{i=1}^{S} \text{superstep}_i \\ &= W + H * g + S * l \\ &= \sum_{s=1}^{S} w_s + (\sum_{s=1}^{S} h_s)g + S * l \end{aligned} \tag{7}$$

where S = number of supersteps, W = total cost of local computations in all processes, H = total number of messages sent and received and/or variables accessed by all processes, w_s = cost of local computation in process s, h_s = number of messages sent and received and/or variables accessed by process s, l = cost of synchronization, and g = message speed (bandwidth)

Generally parallel algorithms work toward computing a result from a large number of simpler calculations performed in parallel on the various processors/cores in the system. This requires a reduction step, which as discussed above typically runs in O(log *m)* time. We represent this step as R and add it to Equation (7), which gives us:

$$\sum_{s=1}^{S} w_s + (\sum_{s=1}^{S} h_s)g + S * l + R \tag{8}$$

The PGM is essentially an extension/adaptation of existing parallel algorithm models, including the PRAM, BSP, and Parallel Phase Model. However, our model is focused on the GPU architecture, which requires the redefinition of certain terms from the original BSP/Parallel Phase Model. In our model, we equate a BSP/Parallel Phase Model superstep with the execution of a GPU "kernel", which is essentially a GPU function or method which handles the importing of the data set, the computations to be performed on said data set, and the exporting of the resulting data to the CPU (i. e. RAM). Therefore we shall now denote a kernel/superstep as k, with the total number of kernels executed as K. This gives us an updated version of Equation (8) as:

$$\sum_{k=1}^{K} w_k + (\sum_{k=1}^{K} h_k)g + S * l + R \tag{9}$$

4.2.2 Message/variable passing

The term $(\sum_{k=1}^{K} h_k)g$, which describes the total number of messages and/or variables transmitted multiplied by the bandwidth of the transfer medium, is perhaps the most important of the terms and deserves more consideration. As we expand this term to include the various types of memory that a GPU can read from and write to, we get

$$\begin{aligned} (\sum_{k=1}^{K} h_k)g =& (\sum_{a=1}^{A} h_a)G + (\sum_{b=1}^{B} h_b)L \\ &+ (\sum_{c=1}^{C} h_c)x + (\sum_{d=1}^{D} h_d)y \end{aligned} \tag{10}$$

where a = an individual global memory read/write
A = the total global memory reads/writes
b = an individual L2 cache memory read/write
B = the total L2 cache reads/writes
c = an individual texture memory read/write
C = the total texture memory reads/writes
d = an individual shared memory read/write
D = the total shared memory reads/writes

When we substitute this more accurate representation of memory reads/writes into Equation (2), we get:

$$\sum_{k=1}^{K} w_k + (\sum_{a=1}^{A} h_a)G + (\sum_{b=1}^{B} h_b)L + (\sum_{c=1}^{C} h_c)x + (\sum_{d=1}^{D} h_d)y) + S * l + R \quad (11)$$

It should be noted that with memory transfers we do not take into consideration the size of a word for the particular system, so we are utilizing the *uniform cost criterion*, as is commonly done with parallel algorithm design and analysis [11]. Also, based upon the ratios of run times between the global, texture, and shared local memories, we can calculate coefficients to represent the approximate cost of using each type of memory and add these coefficients to Equation (5). Normalized with respect to global memory we get ratios of 0.035 and 0.066 for the texture and shared memories, respectively. Note that these two values are roughly in a ratio of 1 to 2 in relation to each other. Applying this to Equation (5) then gives us the following:

$$\sum_{k=1}^{K} w_k + (\sum_{a=1}^{A} h_a)G + (\sum_{b=1}^{B} h_b)L + 0.035(\sum_{c=1}^{C} h_c)x + 0.066(\sum_{d=1}^{D} h_d)y + S * l + R \quad (12)$$

Which can be generalized to:

$$\sum_{k=1}^{K} w_k + (\sum_{a=1}^{A} h_a)G + (\sum_{b=1}^{B} h_b)L + \frac{1}{32}(\sum_{c=1}^{C} h_c)x + \frac{1}{16}(\sum_{d=1}^{D} h_d)y + S * l + R \quad (13)$$

Thus, with the above equation we can see the relative costs of using various types of memory addressable by the GPU programmer. This model is intended to be applicable to most, if not all GPU architectures: indeed, if a particular architectural feature is not available with the model of GPU being employed (i.e. L2 cache memory), then that term is simply zeroed out or removed from the above equation.

Step 5:The last step of this Parallel GPU Model design procedure is more advanced and involves a more intimate knowledge of the specifics of the architecture of the particular GPU the algorithm is designed for. It should be noted that this step is not necessary to achieve near-optimality, as that can typically be achieved by adhering to the above steps. However, for the designer desiring as much optimality as possible, they should identify and understand several physical aspects of the particular device. These physical aspects include the following: the number of processors/cores that the GPU has; the number of SMs the GPU has; the number of processors/cores per SM; the amount of global, texture, and shared local memory the GPU has; the type and speed of the connection between the host and the device (i.e. PCI, PCIe, etc.); the availability and size of the L1 and the L2 caches (as with Fermi GPUs); whether or not the particular GPU architecture supports IEEE 754-2008 (which includes full double precision support); the nature of the GPU's warp scheduler (i. e. whether or not it is a single or dual warp scheduler); whether or not the device has Error Correcting Code (ECC) memory support; whether the device is 32 or 64 bit-based; and what programming languages the device supports, such as C/C++ for CUDA, OpenCL, etc. (and to what degree).

By knowing hardware-specific details, such as the number of processors/cores in the particular GPU, we can augment our abbreviated PGM with the above substitution, which yields the following version of the PGM:

$$\sum_{k=1}^{K} \frac{mn}{p} + (\sum_{k=1}^{K} h_k)g + S * l + R \quad (14)$$

where *mn/p* = w_k
m = number of computations to perform
n = number of data elements
p = number of processors/cores

5. Applications of the PGM

We first applied our GPM to the field of template matching in [12]. Here we developed a GPU-accelerated template matching algorithm from the ground up based upon the PGM. Template matching essentially involves searching an image *I* attempting to find the match for a template *x* among all possible candidates y_i in a sort of "sliding window" fashion. The searches are independent of each other and therefore are highly subject to parallel processing on the GPU. Furthermore, we employed a pruning step to eliminate unnecessary data transfer to the GPU, as discussed in Step 3 of Section 4 above.

In our second application of the PGM, we chose to apply it to a shape matching algorithm that we had developed [13] previously. In this case, a 3D shape is given a unique "signature" which is calculated by computing the distances between each vertex of the shape and every other vertex, as long as that vertex is "visible" to the original vertex. The result is a large number of calculations which are then formulated into a histogram, which then forms the shape's unique signature. Obviously, these calculations are completely independent of each other and therefore this algorithm is also a very good candidate for parallel processing on the GPU.

6. Results and discussion

The experimental design for our template matching algorithm consisted of averaging the results of running our algorithm over a number of trials with a variety of images of different sizes and resolutions, which yielded the following performance results: when comparing the performance of our template matching algorithm to the Full Search Method discussed earlier on small images (512x512) at zero to low noise levels, our algorithm has better performance than the Full Search Method. When comparing our algorithm's performance to that of a standard brute-force Full Search Method implemented serially on the CPU on medium to large images one can see the tremendous performance increase of our algorithm. With an image size of 1024x1024 and a template size of 256x256, our algorithm experiences a 8700x performance increase over the Full Search Method. Further, when we implemented the Full Search Method in a naïve parallel manner on the GPU, our optimized algorithm performed 39x faster.

Similarly we observed a considerable speedup in run-time in our shape matching algorithm when applying the PGM to it. Serially, this algorithm has a run-time of:

$$O(n^2\ \lambda(n)log(n/\epsilon)/\epsilon^4 + n^2\ log(np)\ log(n\ log\ p)$$

However, with the application of the PGM, we observe the following: if the number of data items equals n and the number of processors equals p, then the total computation time for the above shape matching algorithm is:

$$n/p + logn \tag{15}$$

where *log n* is the reduction step. This is assuming that at each timestep a processor p is calculating the distance from a query point to another point. The reduction step results in the shortest distance from the query point to the signature point. Therefore, this algorithm could perform in near-linear time, depending upon the number processors in the parallel system.

In comparison with other parallel design models, we observe the following: the PRAM model, while being a fundamental and an "all-encompassing" parallel design model, is rather inadequate when applied to modern GPGPU design, due to its generality. Valiant's BSP model is a MIMD model consisting of node/memory pairs interconnected through a network. This is not very analogous to modern GPU architectures. The parallel phase model attempts to make up for this shortcoming by accounting for all overhead costs, but is still based on a model which does not account for the various types of memory that the GPU possesses, nor their individual advantages and disadvantages. Valiant's more recent multi-core model is much more akin to the many-core GPU architecture, however it still falls short when one considers the various types of GPU memory, including their attributes and design concerns. We believe that our model is well-suited to the GPU architecture by accounting for all possible types of memory and their associated costs that a GPU can access, both with current commodity GPUs and new, more advanced architectures. Furthermore, we provide a thorough analysis of the various considerations that one must keep in mind when designing algorithms for any GPU architecture, and we believe that our model provides an opportunity to do so that other models don't.

7. Conclusion and future work

Overall, we believe that our parallel GPU method is very effective in allowing parallel GPU algorithm designers, ranging from the novice to the expert, to design and implement optimal (or nearly optimal) algorithms that take advantage of the GPU architecture. We noted that while previous models have been adequate for general parallel architectures (which can vary considerably), they fall short when addressing the unique architecture of GPUs. Indeed, the degree of performance that can be achieved with the application of other parallel models, such as the BSP and phase parallel model, is not optimal for the GPU architecture, and we showed how the PGM can achieve a greater degree of optimality. Therefore, depending upon the degree of optimality desired, our model seems superior to other existing parallel models when applied to the GPU architecture.

Future work with our model will include applying it to simulations involving radiation therapy, such as Volume Modulated Arc Therapy (VMAT) and Intensity Modulated Radiation Therapy (IMRT). In such simulations, various computations need to be made in real-time or near real-time and the use of GPUs would certainly be a great advantage. Also, more practical experience with a Fermi GPU would allow for the implementation of various algorithms to quantitatively measure the speedup that a particular architecture allows over other parallel and serial architectures. Finally, the development of software which employs an "automated" version of this model would make it accessible to even more researchers by aiding them in making more informed with their algorithm designs, thereby producing even more optimal results.

A GPU Support for Large Scale Quantum Chemistry Applications

Selva Kumar Sengottaiyan[1], **Fang Liu**[1], **Masha Sosonkina**[1]
[1] Ames Laboratory, Iowa State University

Abstract— *GPU/GPGPU computing has been used widely in scientific simulation to improve the performance on hybrid architectures. The quantum chemistry field has benefited greatly from using GPUs, including tasks such as visualization of molecular orbitals and computation of electronic structures. To gain significant success in using GPUs, a large amount of code rewriting and restructuring is required, which is done primarily by those who understand the algorithm in great detail. In this paper, two widely used quantum chemistry packages are investigated to identify the hot spots that can benefit most from GPUs, as well as be the least intrusive to the existing code base. The paper uses an experimental approach to integrate GPU capability without restructuring the application. Experimental results show that the bottleneck is in CPU–GPU data transmission. Additionally, a GPU-based DFTFOCK method is implemented in GAMESS/NWChem and a GPU-based eigensolver is integrated with NWChem successfully. Further performance tuning is ongoing.*

Keywords: GPU Computing, Eigensolver, Quantum Chemistry, GAMESS, NWChem

1. Introduction

Graphics processing unit (GPU) computing or general-purpose computing on graphics processing units (GPGPU) is the use of a GPU to do general purpose scientific and engineering computing. The model for GPU computing is to use a central processing unit (CPU) and GPU together in a heterogeneous co-processing computing model. While one part of the application runs on the CPU, another computationally intensive part can be accelerated by the GPU. GPUs are an excellent accelerator for data-parallel applications. From the user's perspective, the application just runs faster because it is using the high performance of the GPU to boost performance. Large gains in performance have been achieved through GPUs in recent years and GPUs have become ubiquitous in handhelds, laptops, desktops, and supercomputer clusters. The power of GPUs has been incorporated into simulations or experiments and shows a large benefit. However, a large amount of code rewriting and restructuring is often required. GPU computing has recently begun to be adopted in the quantum chemistry domain [7] from visualization of molecular orbitals to computation of electronic structures.

The General Atomic and Molecular Electronic Structure System (GAMESS) is a widely used computational chemistry package [3], [8] for *ab initio* molecular quantum chemistry. Using GAMESS, a variety of molecular properties, ranging from simple dipole moments to frequency dependent hyperpolarizabilities may be computed. GAMESS is capable of a very broad range of electronic structure theory calculations and is therefore very widely used, with an estimated user base of $150,000$ in more than 100 countries.

NWChem [12] is a high-performance computational chemistry software package that focuses on providing new and essential scientific capabilities to its users in the areas of the kinetics and dynamics of chemical transformations. Initially, the problems of interest focused on environmental issues, but recently NWChem has been applied to the examination of metal clusters, biological systems, nanostructures, and materials. Both GAMESS and NWChem offer a multitude of highly correlated methods, density functional theory (DFT) with many exchange correlation functionals. Additionally, NWChem provides plane-wave DFT with exact exchange and Car-Parrinello simulations, molecular dynamics with the AMBER and CHARMM force fields, and combinations of these methods.

GPU and CPU hybrid platform have become widely used during the past few years. Well designed algorithms can fully take advantage of the performance of GPUs. Since quantum chemistry applications such as GAMESS and NWChem have always been at the forefront of improving time to solution for platforms from desktops to supercomputers, it is natural for these codes to use the computing power of GPUs.

In this paper, after briefly introducing the GPU computing model, two GPU eigensolver packages are compared. Next, details of the integration work are given, followed by the experimental results, related work and conclusions.

2. GPU computing model

The success of GPGPUs in the past few years has been due in part to the ease of programming of the associated CUDA parallel programming model. In this programming model, the application developers modify their application to take the compute-intensive kernels and map them to the GPU. The rest of the application remains on the CPU. Mapping a function to the GPU involves extensively rewriting the function, usually in C or C++, to expose the parallelism in the function and adding keywords to move data to and from the GPU. The developer is tasked with launching $10s$ to $1000s$ of threads simultaneously. The GPU hardware manages the threads and does thread scheduling.

Figure 1 shows the GPU computing model in which the GPU is a compute device which serves as a co-processor for the host CPU. The GPU architecture consists of a scalable number of streaming multiprocessor (SM)s, a multi threaded instruction fetch and issue unit, and a read-only constant

cache. A SM consists of Scalar Processor (SP) cores, special function units for transcendentals, a multi threaded instruction unit, and on-chip shared memory. The SM creates, manages, and executes concurrent threads in hardware with zero scheduling overhead. To manage hundreds of threads running several different programs, it employs a new architecture single-instruction, multiple-thread (SIMT). The SIMT unit creates, manages, schedules, and executes threads in groups of 32 parallel threads called warps.

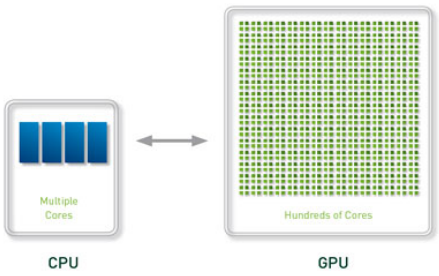

Fig. 1: GPU computing model

a) Threads: For GPU acceleration, a program must be decomposed into a large number of concurrently schedulable units so that groups of threads can execute the same code parallel to each other or suffer poor performance. In GPUs these groups, known as warps, consist of 32 threads. If threads within a warp diverge on a branch, the full warp is serially executed on each branch path, with threads converging into a single execution path only after the divergent branch is finished. CUDA also requires the organization of warps into larger units called blocks. Threads are assigned in units of blocks and can only communicate directly with other threads in the same block. Communication across blocks requires termination of the GPU kernel and data transfer into CPU memory where the required data manipulation can be performed. These issues limit the applicability of GPUs primarily to data parallel applications.

b) Memory hierarchy: Each thread has a private local memory. Each thread block has a shared memory visible to all threads of the block and with the same lifetime as the block. All threads have access to the same global GPU memory. The memory model gives the developer the freedom to choose global or local memory, which may affect the performance.

3. GPU eigenvalue computing packages

There are some eigensolver packages with GPU support which are publicly available. The GPU-accelerated linear algebra libraries (CULA) and Matrix Algebra on GPU and Multicore Architectures (MAGMA) packages utilize the NVIDIA CUDA parallel computing architecture to dramatically improve the computational speed of sophisticated mathematics.

CULA[1] is a high-performance linear algebra library that executes in a unified CPU/GPU hybrid environment. CULA provides easy interfaces through which an application can be integrated without extensive GPU programming experience. CULA can provide significant speedups over existing packages and supports both dense and sparse linear algebra. CULA features a wide variety of linear algebra functions, including but not limited to, least squares solvers (constrained and unconstrained), system solvers (general and symmetric positive definite), eigensolvers (general and symmetric), singular value decompositions, and many useful factorizations (QR, Hessenberg, etc.). All such routines are presented in four standard data types in the Linear Algebra PACKage (LAPACK) computations: single precision real (S), double precision real (D), single precision complex (C), and double precision complex (Z).

The **MAGMA** project[2] aims to develop a dense linear algebra library similar to LAPACK but for heterogeneous/hybrid architectures, starting with current "Multicore+GPU" systems. MAGMA provides linear algebra algorithms, designs and frameworks for hybrid many core and GPU systems that can enable applications to fully exploit the power that each of the hybrid components offer. This package also aims to solve a nonsymmetric linear system of equations by increasing speed for the price of relaxed accuracy.

a) Comparison between the two packages: CULA supports both dense and sparse linear algebra while MAGMA mainly supports dense linear algebra. CULA supports both single and double precision mathematics, and MAGMA supports only single precision. The eigensolver routine in CULA is a commercial code, while MAGMA is free. Both packages have multi-GPU support.

Based on requirement in NWChem,where single precision is sufficient. We have chosen MAGMA for our first stage of integration.

4. Integration of GPU support

The DFT algorithms in GAMESS and NWChem are integrated with GPU support, while the GPU-based eigensolver, MAGMA, is linked to NWChem. The experimental work examined these two well-known packages and identified the hot spots for GPU integration.

4.1 DFT integration

a) GAMESS DFT with GPU: In GAMESS, the typical DFT approach solves the Kohn-Sham equation [6] in which the total energy of the molecular system is a function of the positions of the atoms and one-particle densities. The approach in DFT is to assume an initial charge density and obtain successively better approximations of the density and energy. When the total energy is minimized with respect to the variational parameters, the resulting one-particle

[1]CULA tools `http://www.culatools.com`
[2]MAGMA `http://icl.cs.utk.edu/magma/index.html`

equations are exactly the same as the Hartree-Fock method except for the handling of the exchange terms and the way the electron exchange correlation is incorporated. DFT methods can yield results similar to those obtained with *ab initio* methods such as MP2, but at a substantially reduced computational effort.

The major hot spot in a GAMESS DFT energy and gradient calculation is in a routine called 'GRDDFT' which calculates the correlation correction to Self-Consistent Field (SCF) with an arbitrary set of density functionals. The calculation of 'GRDDFT' takes 94% of the total DFT calculation time. The routine consists of four parts:

1) Memory allocation
2) Geometry and symmetry setting (DFTSET).
3) Calculating the exchange correlation energy (DMATD).
4) Calculating the exchange correlation energy gradient (DFTGRAD).

The calculation of the energy exchange correlation matrix takes almost 99% of the total GRDDFT execution time. The function DMATD calculates the exchange correlation energy by looping over radial grids which in turn loop over the angular grids surrounding atoms. The looping over radial grids and angular grids takes almost 99% of the total DMATD execution time. Inside the loop over grid points, DFTFOCK (which adds the DFT exchange/correlation contribution to the Fock matrix) takes the largest amount (72%)of the execution time. Thus DFTFOCK is chosen as the routine to be executed on the GPU. Other reasons are that the data dependency of DFTFOCK as compared to other subroutines is minimal and the amount of parallelism inside the function is high.

Figure 2 shows the integration of the CPU Fortran code with the GPU Fortran code in GAMESS. Inside the GAMESS Fortran code, the application code that has a high degree of parallelism and that takes most of the CPU time is identified. Then the identified code is transfered into CUDA Fortran. In the above case, the DFTFOCK subroutine is identified as a hot spot and converted into CUDA Fortran. Then the changed code is compiled using the CUDA Fortran compiler (PGFortran). The compiled code is linked with GAMESS and the CUDA libraries.

b) NWChem DFT with GPU: NWChem contains a parallel implementation of the Hohenberg-Kohn-Sham formalism [4] of DFT which differs significantly from other *ab initio* methods in the treatment of the exchange-correlation term used in building the Fock matrix. The computationally intensive components of a DFT calculation include the fitting of the charge density, construction of the Coulomb potential, construction of the exchange correlation potential, and the subsequent diagonalization of the resulting equations. The GPU accleration of DFT in NWChem concentrates getting exchange-correlation contribution to the gradient and adding the Bonacic-Fantucci repulsive term [6].

Figure 2 shows the integration of the CPU Fortran code with GPU Fortran code in NWChem. As with the GAMESS integration, the application code that has a high degree of parallelism and that takes most of the CPU time is identified. Then the identified code is changed into CUDA Fortran. The NWChem GPU kernel is similar to GAMESS GPU kernel (Figure 2) as in both cases the GPU kernel uses the CUDA runtime API and CUDA libraries. During integration of the GPU kernel in DFT for both NWChem and GAMESS, the GPU kernel implementation requires only minimum code rewriting as using the existing code is one of objectives of this GPU acceleration implementation.

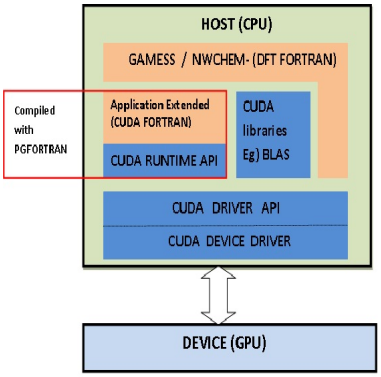

Fig. 2: GAMESS/NWChem DFT-GPU Programming

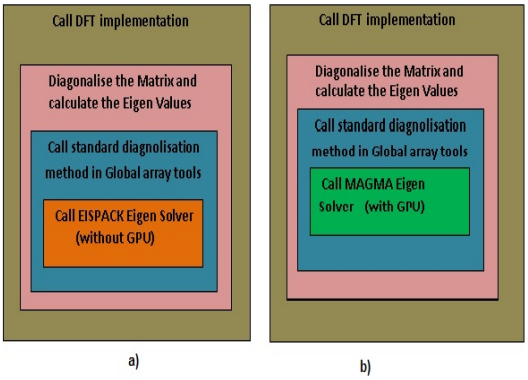

Fig. 3: Function calls inside the NWChem eigensolver implementation without and with GPU implementation

4.2 Integration of NWChem DFT eigensolver with MAGMA

Figure 3a shows the order of function calls inside the NWChem the DFT eigensolver DFT implementation without GPU implementation. Figure 3b shows the changed order of function calls inside the NWChem DFT eigensolver implementation with GPU implementation. Figure 4 shows the integration of the CPU Fortran code with GPU Fortran code (MAGMA eigenvalue package) in NWChem. The calculation of eigenvalues and eigenvectors is a time consuming part in the Fock matrix updating procedure. The MAGMA library of C functions offers two LAPACK-style interfaces, referred to as the GPU interface and the

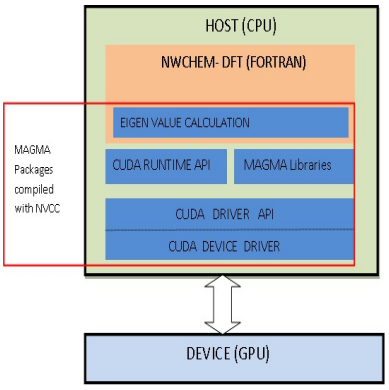

Fig. 4: NWChem-GPU MAGMA Interface

CPU interface. The GPU interface takes input and produces results in the GPU's memory, whereas the CPU interface produces results in the CPU's memory. The GPU and CPU interfaces, although similar, are not derivatives of each other, but instead have different communication patterns. The GPU function returns or sets the logical flag indicating whether the GPU interface is to be used for calculations involving the specified MAGMA matrix. NWChem normally calculates the eigenvalue by using the EISPACK available with the GA tool.

Global Array eigenvalue calculation

The Global Array diagnolization subroutine calls a sequence of subroutines from the eigensystem subroutine package (EISPACK) [10] to find the eigenvalues and eigenvectors (optional) of a real symmetric matrix. In NWChem for serial execution, the eigensolver 'rs' from EISPACK is used. (The eigensolver in ScaLAPACK [1] is called only for parallel execution.)

In order to demonstrate the GPU version eigensolver can benefit NWChem, the EISPACK eigenvector calculation in NWChem will be replaced by the MAGMA GPU solvers. Since NWChem invokes the 'rs' solver through the Global Array interface, the Global Array diagonalization subroutine EISPACK calls are replaced by MAGMA calls. The MAGMA eigensolver routine is Magma_dsyev which is very similar to the analogous LAPACK routine. The major difference between the 'rs' subroutine and Magma_dsyevd is that 'rs' uses the whole real symmetric matrix whereas Magma_dsyev uses the lower or upper triangular matrix. By switching from the 'rs' routine to the Magma_dsyevd, the matrix needs to be converted to a new format.

5. Experiments

All the tests are conducted at the US Department of Energy Ames Laboratory GPU computing cluster - Exalted, which consists of 26 nodes, each having six 2.66 GHz Intel Xeon processors, 8 nodes have 4 NVIDIA Tesla C2070 GPUs and 18 nodes have 2 NVIDIA Tesla C2070 GPUs. The nodes are connected via Mellanox QDR InfiniBand and each node has 24GB of RAM. Despite having two GPUs per node available, we focused on using only a single GPU per node. The speedup here is defined as the ratio of the existing sequential algorithm execution to the parallel execution time.

5.1 GPU implementation of DFT in GAMESS

This experiment on the DFT method in GAMESS focuses on performance improvement of the algorithm in terms of speed up. As explained in Section 4.1, the DFTFOCK routine is separated from the existing application and is tested with various problem sizes (Fock matrix sizes) to find the actual performance gain in terms of speed up. Various scenarios with different optimization techniques are tested and results are explained below.

Scenario 1: The GPU CUDA memory model comprises various memory spaces, which differ enormously in latency times, availability of caches, etc. Particularly important features are global and shared memories, the former being an off-chip memory and thus featuring high-access latency; the latter being on-chip memory and thus having reduced latency. This scenario tests the global and shared memory usage inside the GPU. The experiment results with problems of various matrix size are shown in Table 3. Results are after optimization for the number of threads and blocks based on the problem size. In order to find the break point where DFTFOCK can start to take advantage of the GPU, the matrix size is continually increased. The GPU implementation shows better timings for problems with matrix size of 10,000 or more (Table3). For the problem size of 20,000, there is not much difference in performance between CPU implementation and CPU-GPU implementation using global memory, but the CPU-GPU implementation using shared memory increases the speed up from the CPU implementation (Table 3, columns 1&3) 2 times and the CPU-GPU shared memory implementation also increases the speed up from the global memory implementation (columns 2&3) by about 2 times. The experimental results prove that the GPU implementation should involve less kernel calls and memory allocations for better performance. Shared memory is exploiting the availability of on-chip shared memory by enabling kernels to load all needed field components, including the components corresponding to adjacent blocks and provides huge performance gains in terms of GPU and CPU execution time. Such gains are due both to the high efficiency of shared-memory access, and due to the limited number of separate memory transaction issued for each thread i.e., reducing the effective number of memory read operations for each thread. GPU speed up can be increased more if memory usage is optimized. Hence it is necessary to carefully design and implement kernel codes in order to minimize the number of global-memory reads, by making use of the other available kinds of memory.

Scenario 2: In this scenario, we used various Fock matrix sizes to explain the factors affecting CPU-GPU implementation. An experiment (CASE A) is built with 50 outer loops and 12525 inner loop iterations. This computation takes about 20 microseconds in the CPU implementation. The total execution time for the CPU-GPU implementation is 70

Table 1: **Comparison of CPU, global memory GPU and shared memory GPU times in seconds (s)**

Size of Matrix	Total CPU execution time(s)	CPU+GPU execution time(Global)(s)	CPU+GPU execution time (Shared (s)
50	$20*10^{-6}$	$70 *10^{-3}$	$70*10^{-3}$
500	$100*10^{-6}$	$74 *10^{-3}$	$74*10^{-3}$
1000	$2.145237*10^{-3}$	4.213462	2.561576
5000	1.80	27.8	17.4
10000	211.2	277.0	173.6
20000	1732.1	1687.1	973.2

milliseconds. As expected, the GPU time is much greater than the CPU execution time. The breakdown of execution time for the CPU-GPU implementation (Table 2) shows that memory allocation time in the CPU-GPU code far exceeds the total CPU execution time. So experiments (B,C,D,E) are built with a problem size of 500 outer loops and 125250 inner loop iterations and execute with various GPU-CPU implementation/optimization techniques. The results are shown in Table 2. For all cases (B,C,D,E), each GPU block has 512 threads and the warp size is 32.

CASE B : Implementation of inner loop (DFTFOCK) in the GPU kernel, allocating the memory outside the kernel call. In this case, a small kernel size and large number of threads and memory allocation calls are needed in the GPU.
CASE C : Implementation of inner loop (DFTFOCK) in the GPU and allocating the memory inside the CUDA kernel.
CASE D : Implementation of outer loop (DFTFOCK) in the GPU kernel, allocation of memory outside the outer loop with a single kernel. In this case, the kernel size is increased but the number of threads inside the problem is decreased.
CASE E : Implementation of outer loop (DFTFOCK) in the GPU kernel, allocation of memory outside the outer loop and splitting the GPU kernel into two parts. In this case, the kernel size needed for implementation is increased and the number of threads inside the problem is decreased.

From Table 2, CASE A shows that the kernel call in a loop is the bottleneck as each kernel initialization takes a lot of time. Cases B, C, D and E also demonstrate that allocation takes more time than kernel execution, and therefore GPU implementation should involve less kernel calls and memory allocations.Kernel execution time is in micro seconds range where as total execution time is in milliseconds range. The best execution time is from the results of CASE D (i.e., the implementation involves less GPU memory allocations and less number of kernel calls irrespective of kernel size). Test case D has increased kernel size (i.e., more functions) compared to the kernels in other test cases, irrespective of which it almost takes same time as the other test cases. Thus, for GPUs, global inter-thread synchronization from kernel calls is very costly, because it involves a kernel termination and a new kernel call overhead from the host. The application specific software optimization is critical to fully utilize compute/bandwidth resources for both CPUs and GPU.

5.2 DFT acceleration using GPU in NWChem

The experiment on the DFT-FOCK method in GAMESS focuses on performance improvement of the algorithm in terms of speed. As explained in Section 4.1, the DFT GPU implemention is also done in the NWChem package. The problem size is determined by the number of atoms used in the input to the DFT NWChem package. The number of GPU threads inside each block is 512 and the warp size is 32. Table 3 shows the speedup in DFT using the GPU for various problem sizes. With the increase in problem size, the speedup increases. Due to data transfer latency, the benefit of using the GPU appears only if the problem size is increased to more than 2000 atoms. The size of the kernel is also very important in determing the speedup in the GPU.

Figure5, shows the running time for different numbers of threads for a problem size of 10000 atoms. Figure5 explains performance of GPU in terms of number of threads per block. The decrease in time with an increase in GPU occupancy (threads) shows that more performance gain is possible. A more occupancy indicates that the application fully exploits available processing units. Unfortunately, the amount of shared memory and registers used by each thread block limits the occupancy value. The size of thread blocks and/or shared-memory and registers usage must be designed with care in order to maximize the occupancy. The speedup increases with the increase in problem size but is greatly limited by data transfer between the CPU and GPU. The limitation in speedup highlights the importance of software optimizations (memory and GPU occupancy), and an application driven design methodology. s

5.3 MAGMA with eigensolver

The MAGMA package is integrated with NWChem package and the eigensolver of EISPACK available with the GA tool is replaced with MAGMA eigensolver. We tested the integration for various input molecules like Ozone, Cr_2. Since the input molecules available for testing have relatively small matrix size, we separated the Global Array eigensolver from the NWChem calculation and ran the tests separately from the NWChem execution. This allowed us to experiment with larger matrix sizes in the MAGMA-based eigensolver. Specifically, the test case uses the Global Array tools (which NWChem also calls to calculate the eigenvalues) where the existing EISPACK sequential eigenvalue solver is replaced with the GPU eigenvalue solver from the MAGMA package.

Table 2: **Time comparisons for various DFTFOCK CUDA implementations**

Experiment	Total execution time(Milli s)	Memory allocation time(Milli s)	Total Kernel execution time(Micro s)
A	70	70	87
B	3.8 $*10^3$	73	270
C	76	73	270
D	74	73	87
E	75	73	110

Table 3: **Comparison between CPU and GPU implementation times of DFT in NWChem**

Size of Matrix	Total CPU execution time(s)	CPU+GPU execution time (Shared)(s)	Speed up
10	0.000	4.3954	Nil
100	$1.326*10^{-3}$	7.8526	Nil
1000	15.1234	17.2368	Nil
2000	38.3678	27.8459	1.3
5000	228.398	80.2697	3
10000	876.679	158.9643	5

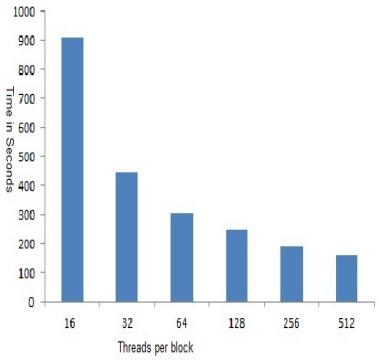

Fig. 5: Timings in DFT calculations using various number of threads in NWChem

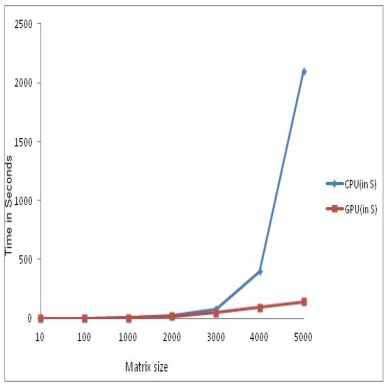

Fig. 6: Speedup in eigenvalues calculation using MAGMA

Table 4 shows the speedup with various matrix sizes. If the matrix size is less than 2000 there is no speed up. So a GPU implementation for the eigenvalues can be effective if the size of the matrix is around 2000. The speedup increases with increase in matrix size.

Figure 6 shows execution time for various matrix sizes on CPU and GPU respectively. The speedup starts to show when the matrix size reaches 2000. To summarize, it is advisable to keep data on the GPU memory, coalesce global memory accesses to reduce latency of data transfer, take advantage of shared memory, and to use hybrid code with double-precision applications.

6. Related work

Several other quantum chemistry applications have been implemented on GPU to exploit the greater level of parallelism. The strategy and optimization techniques for back porting an optimized GPU kernel to a multi-core CPU platform for the application TeraChem - a quantum chemistry code that was developed from the ground up to run on NVIDIA GPUs - is discussed in [13]. For this study, one of TeraChem's largest and most complex GPU kernels is considered. This kernel is used to calculate the electron repulsion integrals involving d-functions. It also investigates which CPU-specific optimizations can be applied to improve performance of the backported kernel. The exploitation of Quantum Monte Carlo algorithms with multiple forms of parallelism and its package simulation code portability to the NVIDIA CUDA GPU platform are discussed in [2]. The restructuring of the CPU algorithms to express additional parallelism, minimize GPU-CPU communication, and efficiently utilize the GPU memory hierarchy is important in porting the CPU code to GPU [2]. The restricted Hartree-Fock method is implemented on a multi-GPU system (a conventional cluster outfitted with GPUs) and its effectiveness is demonstrated [9]. According to [11], GPUs can significantly

Table 4: **Speedup in eigenvalues calculation using MAGMA**

Size of Matrix	Total CPU execution time(s)	GPU execution time(s)	SpeedUp
10	0.00001	0.001300	Nil
100	0.00399	0.399	Nil
1000	2.4650	2.4550	Nil
2000	22.91551	19.17751	1.2
3000	80.09583	50.1824	2
4000	400.1783	95.3697	4.19
5000	2100.7624	143.2457	15

outpace commodity CPUs in the central bottleneck of most quantum chemistry problems. It also explains the method to separate memory bound operations by modifying the algorithm and the memory scheme. It also demonstrates speedups are readily achievable for chemical systems of practical interest, and the inherent high level of parallelism results in complete elimination of inter-block communication. Due to the relative number of single and double precision cores, the best performance for GPU accelerated code is achieved when performing operations at single precision. It also discusses various issues that come with GPU implementations like memory transfer, accuracy, and thread consistency [5].

7. Conclusion and future work

In this work, a GPU integration for two widely used quantum chemistry packages, GAMESS and NWChem, is successfully performed. The exploration of two applications gives insights into GPU needs, and the experiments results demonstrate that there is a trade-off between performance gains and the ease of integration. This work focuses mainly on the experimental exploration of two large code bases: it pinpoints the most time consuming part in the DFT algorithm and links the GPU based eigensolver for NWChem. The intention was to integrate the GPU support without much source code changes. To accomplish this goal, the standalone units are identified, such as the eigensolver in the DFT algorithm. However, in order to fully exploit the available GPU, several software strategies have to be carefully designed and implemented. Currently, the performance bottleneck is in the data transfer between CPU and GPU. Performance tuning and further investigation of adapting GPU to more complex algorithms used in computational chemistry is ongoing.

Abstract - *Power consumption has become a chief impediment in the advancement of digital computing. To improve performance amid power limitations, accelerators are being applied to everyday systems. In particular, due to the mix of popularity and raw computational power, graphics processing units (GPUs) have extended the applicability of digital computing in a multitude of sectors from ubiquitous smartphones to environmentally responsible supercomputing. Operating within the mobile power constraint, the usefulness of a high performance graphics processor system in a tactical environment is explored in this study. A line-of-sight optimization algorithm serves as a compute-intensive application with characteristics relating to a tactical scenario. Power-efficient hardware options and achievable parallel computing capabilities are analyzed for assisting tactical operations.*

Keywords: GPGPU, line-of-sight, mobile HPC

1 Introduction

Computing power continues to increase as new generations of processors are released to consumers. Following Moore's Law, where the number of transistors double every 18 months, computing elements within processing units have grown exponentially since the birth of digital computing. By common logic, higher transistor count translates into higher performance potential. The TOP500 maintains statistical lists of supercomputers around the world. High performance systems are ranked according to the performance outcome of the Linpack benchmark, which tests the ability to solve a dense system of linear equations. In a nutshell, the benchmark algorithm evaluates the compute speed of double-precision arithmetic on a given system [1]. The TOP500 table is released biannually and includes technical details such as processor type, number of processors, theoretical peak performance, and maximum Linpack performance. Since 2008, detail on power has been included as part of the statistical fields, a hint of the important role power will play in future systems as computing field advances to reach exascale performance.

The U.S. Army Research Laboratory (ARL) Department of Defense Supercomputing Resource Center (DSRC) supports and maintains high performance computing (HPC) resources. The ARL DSRC provides state-of-the-art computational solutions for the DoD research and development community. Among the systems available at ARL is Harold system, which consists of 10,752 cores with the processing capability of 120 trillion floating-point operations per second (TFLOPS). A predecessor, JVN system, decommissioned in 2009, had 2048 cores with the theoretical peak of 14.7 TFLOPS. Shifting the focus to single-precision, the peak processing power for the Harold system is 240 TFLOPS and 29.5 TFLOPS for the JVN system. Given that a single graphics card, Radeon HD 6990, is rated at 5.1 TFLOPS for peak single-precision arithmetic, this means a single video card is equivalent to roughly 1/6 of the JVN's theoretical compute power. In other words, networking six AMD Radeon HD 6990 PCI-E boards can provide a combined peak performance exceeding that of the available 32-bit floating-point power in JVN, albeit single-precision. A graph showing peak performance values for GPUs and their relationship to ARL's previous-generation supercomputers is presented in Figure 1. The peak comparison figure reflects the current state of raw compute abilities offered by common GPU cards and systems, which rival decommissioned yet once TOP500 ranked systems. Moreover, an equivalently powerful system using accelerators built today requires less space, power, and cost to operate. This is the motivation behind leveraging GPU accelerators to enhance power-constrained tactical computing.

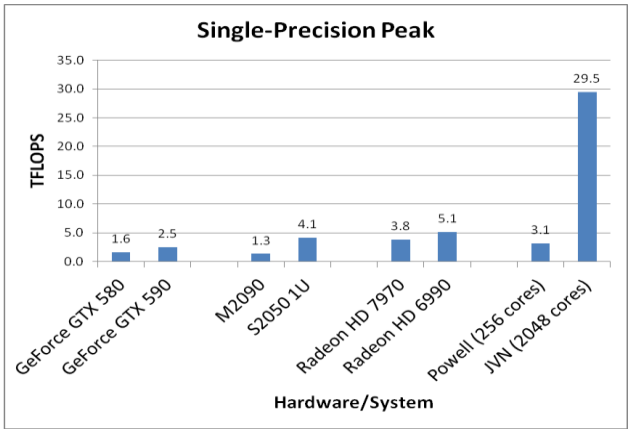

Figure 1. Single-precision comparison of GPU devices with previous-generation supercomputers at ARL

Originally designed to drive displays, GPU cards have become quite powerful in executing single-precision calculations to account for the parallel nature of drawing graphics on a screen. Since 2007, general purpose computing on graphics processors has introduced CUDA and OpenCL languages to support general C-based algorithms to access the underlying parallel hardware. This effectively and seamlessly boosted performance in systems, which most likely had graphics processors installed. In this respect, the GPU approach is an affordable and readily available consumer product with some programming effort since its characteristics are similar to C language. The result of continuing advancement of consumer-grade GPUs has made HPC available to the masses.

2 Influenced by Power

Examples of power influencing design can be observed at multiple levels of computing hierarchy, starting from supercomputing centers to transistor designs. Topics relating to power issues in computing market are summarized in this section where multitudes of options for reducing power consumption are briefly visited.

The cost to power and cool a system is usually one of the limiting factors and is a challenge for hosting large scale HPC systems. The average electrical power consumption for petaflop systems in the TOP500 in November 2010 was 3.3 MW, which translates to $2.89 million per year, assuming $0.10/KWh. As the supercomputing community strives to achieve exascale computing, efficiently managing energy and power will be one of the major challenges. The emphasis on power is evident on the ubiquitous HPC DARPA project soliciting for a prototype of a petaflop-class rack system drawing 57 KW by year 2014 [2].

The shift toward multiple cores in semiconductor giant Intel and AMD is another example of how power and heat have affected central processor architecture design. In order to avoid producing more heat per square centimeter than the surface of the sun, while continuing to improve performance, multicore was introduced as a solution. Yet, the clock frequency did not advance during this period, but rather relied solely on the resource parallelism for performance gain. Additional attention to power is manifested via Intel Sandy Bridge's implementation of on-die power meters that can measure power use on the chip and can dynamically distribute power [3]. Intel's 3D transistor gate is another technique for power reduction. Novel vertical fins of the semiconductor substrate mean more energy efficiency resulting from lower voltage operation and lower leakage [4]. Moving forward, the largest transistor allocation inside an Intel Nehalem die relates to cache. Distributed L1 and L2 cache inside each core and the shared L3 cache clearly dominate the transistor usage. This implies that the majority power is dissipated in the cache circuitry of the CPU. Coupled with the energy required to transfer data from main memory, data movement seems to impact power consumption at a multiple memory hierarchy.

Similarly, features to optimize power consumption are evident in graphics architecture. For example, advanced power management techniques available in Nvidia include multiple levels of clock gating, dynamic voltage scaling, and adaptive clocking. Clock gating shuts off clocks during idle conditions, voltage scaling drops voltage levels during idle states, and adaptive clocking automatically adjusts core and memory frequency to save power. Scientists and engineers at ARL have collaborated with researchers at University of Texas El Paso in looking at selected use of double-precision functions for Nvidia compute resources to reduce energy consumption. In order to analyze accurate measurement of power usage, probing equipments are installed to capture voltage and current signals. Power efficient computing is addressed from a software perspective in [5].

Field-programmable gate arrays (FPGAs) are an option for application-tailored, low-power processing. Altera's Stratix V FPGAs are a low-power option that supports floating-point implementations with a variable-precision DSP architecture. A white paper by Altera's describes that the single-precision multiplier density in Stratix V has increased to 4096, which calculates to floating-point processing rates in excess of 1 teraflops [6]. In terms of the metric flops per watt, this equates to 10 GFLOPS/W. Yet, the programming model and development processes are not as friendly to those familiar with working in C.

In the fourth quarter of 2010, sales of ARM-based smartphones exceeded the sales of personal computers [7]. ARM has historically emphasized the metric of power efficiency due to having evolved in a low-power, battery-operated environment. ARM processors have gained dominance in the segment of the mobile market. Additionally, ARM is looking to enter the server market as the efforts are underway by companies like Calxeda to implement large-scale ARM powered servers. Current Calxeda products offer server nodes operating at 5 W using Cortex-A9 cores [8]. For hosting and servicing web applications, ARM processor's low power consumption offers promising alternative to the traditional server platforms.

3 Hardware for Tactical Computing

Workstation footprint system is a manageable-sized PC augmented with high-end graphics processors. This concept of HPC in a box to aid on-field computations was investigated from two angles. First, the upper limit as to how much computing power can be packed into a workstation

form factor was explored. Secondly, development software and algorithms were analyzed for feasibility and possibilities. Initial attempts at the asymmetric workstation system involved switching heat sinks and fans with custom fitted water blocks for GPU cards to populate the system with seven Radeon HD 4870X2 cards. Since Radeon HD 4870X2 cards contain dual graphics engines, it is equivalent to having 14 GPU devices inside a single workstation. Additionally, liquid cooling allowed for overclocking the reference clocks to achieve extra performance. The target goal was to reach 20 TFLOPS mark for single-precision operations. In regards to software development environment, both CUDA and OpenCL frameworks, which extend the power of the GPUs beyond graphics, were evaluated for parallel computing. CUDA is proprietary and thus specifically supports Nvidia GPU architectures. CUDA was made public in 2007 and was originally based on Open64 C compiler until the recent switch to low level virtual machine (LLVM) for CUDA release 4.1. Nvidia's earlier start has served to acquire initial momentum within the GPGPU community extending to Matlab, Python, and Fortran, to name a few. OpenCL, on the other hand, is vendor agnostic that can target x86 processors, AMD GPUs, and Nvidia GPUs. In both frameworks, a language is provided for writing kernels representing core functions and application programming interfaces (APIs) that are used to manage the platforms. Ongoing translation research continues for compiling OpenCL programs to run on FPGAs and ARM processors.

More recently acquired test bed systems at ARL include a Nvidia GeForce 580 system and an AMD Radeon HD 6970 GPU system. The configuration for the 4U workstation platforms are dual-socket Hex-core Xeon system, 24 GB DDR3 memory, double-width PCIe slots for holding four GPU cards, a solid-state drive, and 1400 W power supply. The goal is for this system to target compute-intensive calculations inside a mobile platform. Typically, an average alternator in a vehicle is rated at 100 A at 12 V, which computes to 1200 W. Thus, the power requirement of the four GPUs workstation seems to be within an achievable range for an automobile operation.

ARM powered devices are explored for integrating with the GPU workstation platforms for a tactical computing scenario. One of the purposes for mobile ARM products would be to serve as an end user interface to display supercomputing calculated results. For instance, iPhone can request ray-tracing calculations to a nearby GPU-enhanced workstation to achieve near real-time computation. To learn the development process and the compute capabilities of an ARM processor, PandaBoard ES was procured for evaluation and its possible role in mobile HPC. PandaBoard ES has the OMAP 4460 processor that is designed by Texas Instruments, which is a combination of the ARM architecture series Cortex-A9 and an Imagination Technologies POWERVR graphics core. Once a Linux operating system is loaded on a PandaBoard, Army applications written in C can be benchmarked. Currently, OpenCL support for ARM is still in its initial stage and a STDCL support is under development. Linux distributions, Angstrom and Ubuntu, were successfully tested on a PandaBoard. A noticeable slow behavior was observed in the GUI mode of Ubuntu. Currently in process of examination is the open source Android operating system that has quickly gained popularity in smartphones and tablets. Although, still relatively immature, Android has a potential to be Microsoft Windows for the next decade.

4 Army-centric Application

An algorithm for ballistic field calculation based on first-hit ray-tracing method was developed using OpenCL. The ray-tracing method allows for the calculation of line-of-sight ballistic threat locations within a specified area. A three-dimensional representation of a small part of town was selected for testing the ballistic hit probability field calculations. The input for the algorithm is a triangle data format describing a three-dimensional surface and layout. For user interaction and displaying of results, functionalities were leveraged and added to the World Wind program. World Wind was developed by NASA and is an open-source interactive world viewer. Figure 2 shows the World Wind interface window with loaded elevation map and the ballistic hit probability field, denoted by red shaded overlay on the surface. In the figure, the end user can insert entities, which are color coded to designate red as a shooter, green as an observation point, and blue as a watcher. A shooter was placed on top of a roof and an observation point was set near the front wall of the building to represent a door of interest. Executing the ballistic threat minimization algorithm generates the optimal locations for a watcher that minimize threat level while maintaining line-of-sight to the observation point.

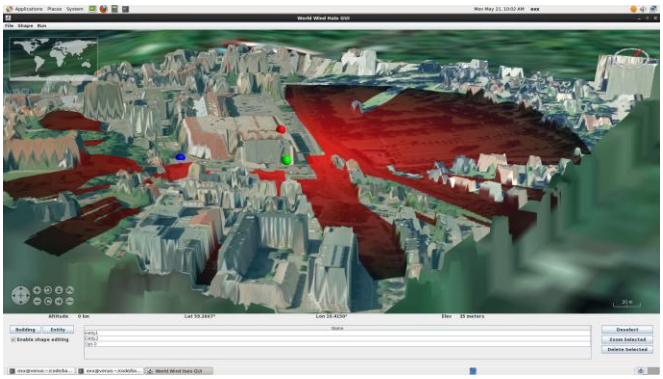

Figure 2. Interface to ballistic threat minimization

The example case consisting of two shooters and two observation points was benchmarked on a single Nvidia GPU machine and an AMD multi-GPU workstation. The Nvidia

system contained Tesla C2050 graphics card and the multi-GPU workstation had four Radeon HD 6970 cards. The code was written to support multi-GPU execution, but to avoid serialization between GPUs; an older version of AMD graphics driver was required for CentOS Linux operating system. Timing results for ballistic threat calculation and placement optimization are presented in Figure 3. Written in OpenCL, the algorithm is portable to x86 processors as well. The calculation on a dual-core Xeon 5160 completed in 25 minutes.

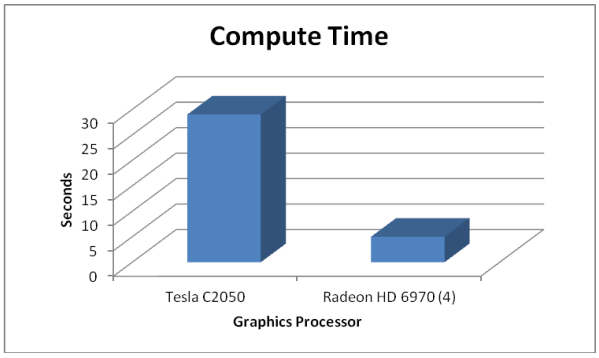

Figure 3. Timing measurements for ballistic threat minimization

5 Conclusion

Armed with mass-marketed processors, Army applications are targeted for enhancement with heterogeneous computing solutions. With the assistance of GPUs, computationally powerful systems can be placed closer to field operations in a small form factor and can handle processing requirements onboard. Furthermore, ARM-based devices with portability and low-power characteristics are naturally appropriate interface in tactical operations. A GPU workstation will be responsible for complex and time-consuming computations of algorithms while an ARM product will provide an intuitive interface and abstraction. Future work for ARM development boards would be to assess and analyze ARM systems in a networked configuration, running cloud computing software.

This research investigated the applicability of asymmetric core computing in a battlefield environment. Across computing disciplines, power related issues play a dominant role in architecture, design, and systems. This work hopes to complement and facilitate the transition of heterogeneous computing to battlefield operating systems.

A Parallel Algorithm for Constructing Obstacle-Avoiding Rectilinear Steiner Minimal Trees on Multi-Core Systems

Cheng-Yuan Chang and I-Lun Tseng
Department of Computer Science and Engineering
Yuan Ze University, Taiwan

Abstract - *In the field of integrated circuit physical design automation, the problem of obstacle-avoiding rectilinear Steiner minimal tree (OARSMT) construction is a fundamental problem and has attracted a lot of research attention. In this paper, a parallel algorithm for constructing OARSMTs is proposed. The algorithm is based on maze routing and double front-wave expansion. Experimental results show that our algorithm not only generates very short wires, but also performs efficiently on shared-memory multi-core computer systems. Compared with the sequential execution of our parallel program that has been implemented, the program can achieve 23% speed-up on average while running on a multi-core workstation.*

Keywords: VLSI Physical Design Automation, Routing, Parallel Programming, Multi-Core, Algorithm

1 Introduction

As the semiconductor process technology advances, transistor feature sizes have been shrinking. As a result, an integrated circuit can accommodate many transistors and building blocks. To implement an integrated circuit containing complex functions, a number of building blocks are usually required. Since each building block performs a specific set of functions (e.g., inverter, NAND, NOR, shift register, memory, and ALU), we can combine many building blocks and make proper connections between their terminals in order to build a larger circuit. Routing algorithms, which are capable of making connections between building blocks, play a crucial role, especially when the design is large or complex.

In the field of integrated circuit physical design automation [5, 6], many routing algorithms require the function of constructing *rectilinear Steiner minimal tree*s (RSMTs). That is because most integrated circuit layouts use rectilinear wires. Also, by minimizing the total wire length of an integrated circuit, the signal propagation delay, the power consumption, and the die size can all be reduced. Since an integrated circuit layout can contain building blocks and pre-routed nets, it is desirable to consider regions that cannot be passed through by a net (or wire) as obstacles. Consequently, developing efficient algorithms for solving the *obstacle-avoiding rectilinear Steiner minimal tree* (OARSMT) problem is important and has thus received a lot of research attention [1-4, 7-10].

Although many algorithms have been proposed in order to solve the OARSMT problem, most of these algorithms are sequential, rather than parallel. As inexpensive multi-core processors and computer systems have become widely available, developing parallel algorithms allows us to exploit the computational power from these shared-memory multi-core systems.

This article presents a parallel algorithm for constructing OARSMTs. The algorithm is based on Watanabe's Steiner tree construction algorithm [12], but there are differences between these two approaches. First, our algorithm is suitable for use on a shared-memory multi-core computer system, whereas Watanabe's algorithm is suitable for use on a computer system containing a two-dimensional array processor. Specifically, an array processor can have as many as tens of thousands of processing elements, while a shared-memory multi-core computer may have less than ten processor cores. Second, our algorithm adopts two parallelized procedures, namely PARALLEL-CONNECT() and PARALLEL-CLEANUP(), and these two procedures can efficiently reduce the program execution time. The parallel algorithm proposed in this article has been implemented in C++ with the use of OpenMP [13]. Experimental results show that the implemented parallel program performs efficiently on a shared-memory multi-core workstation.

The remainder of this article is organized as follows. In Section 2, we formulate the OARSMT problem. Our parallel algorithm for constructing OARSMTs is presented in Section 3. Experimental results are given in Section 4. Finally, conclusions are drawn in Section 5.

2 Problem Formulation

In the *xy* plane, let $T = \{t_1, t_2, \ldots, t_m\}$ be a set of m terminals which are to be connected by a net (or wire), and let $O = \{o_1, o_2, \ldots, o_n\}$ be a set of n rectilinear obstacles. A terminal can exist on the boundary or on a corner of an obstacle, but cannot exist within an obstacle. In Fig. 1(a), for example, t_2 is a valid terminal since it is on the boundary of an obstacle, whereas t_3 is an invalid terminal since it is located

This research was supported in part by the National Science Council of Taiwan under grants NSC-98-2221-E-155-053 and NSC-99-2221-E-155-088.

within the obstacle. Invalid terminals cannot appear in an instance of the OARSMT problem. For the figures in this article, obstacles are denoted by light-gray regions.

With regard to physical positions of line segments of a wire, a line segment can overlap with the boundary of an obstacle as shown in Fig. 1 (b), but cannot pass through the interior of an obstacle as shown in Fig. 1 (c). Since a wire is composed of rectilinear line segments, the *total wire length* of a routing result is computed as the sum of the lengths of all line segments. Fig. 1 (d) illustrates a valid routing result and its total wire length is 8. The OARSMT problem is defined below.

Definition 1 (The OARSMT Problem):

Given a set T of terminals and a set O of rectilinear obstacles in the xy plane, we are requested to construct a net (or wire) which consists of rectilinear line segments and connects all the terminals in T, while possibly through some Steiner points. In addition, line segments of the net cannot pass through the interior of each obstacle in O, and the total wire length of the routing result must be minimal.

3 The Algorithm

Our approach for constructing an OARSMT is based on Watanabe's algorithm [12], which mainly consists of two repetitive phases (known as *double front-wave expansion*). The first phase is called the *first front-wave propagation*; a set of start points P_S is selected, and then we propagate from these points in order to find another terminal $t_t \in T$, which is the closest to P_S. During the propagation process, in addition, the propagation wave cannot pass through the interior of each obstacle. Also, the shortest distance between a point in P_S and each visited grid point must be recorded; the numbers representing these distances are called *distance numbers*.

The second phase of Watanabe's algorithm is named the *second front-wave propagation*; another propagation wave starts from the terminal t_t to reach either a point or points in P_S. An overlapping region between the first and the second phases can thus be found. Moreover, Steiner points can also be determined. Therefore, an OARSMT can be obtained after connecting all the Steiner points and terminals.

Our parallel algorithm for constructing an OARSMT from given sets of T and O is described in Fig. 2. First, a start terminal (t_s) must be selected from T. Although an arbitrary terminal can be selected from T as the start terminal, our implementation of the algorithm selects the terminal which has the least value in terms of the sum of x and y coordinates. The set V is used for storing all the terminals that have been visited during double front-wave expansion. Since the algorithm starts by propagating from the start terminal t_s, it is assigned to V in line 2. The set S, which can be implemented as a task queue, is used for storing grid points from which the next iteration of double front-wave expansion will start; these grid points may include terminals and/or Steiner points.

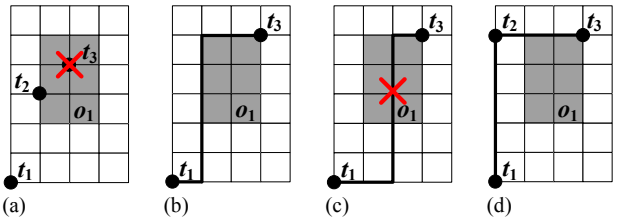

Figure 1. Valid and invalid OARSMT examples and routing results.

Algorithm PARALLEL-OARSMT-CONSTRUCTION(T, O)

Input: T /* all the terminals which are to be connected */
O /* all the rectilinear obstacles */

Output: An OARSMT which connects all the terminals in T using only horizontal and/or vertical line segments while these line segments cannot pass through the interior of each obstacle.

1. $t_s \leftarrow$ select a start terminal from set T
2. $V \leftarrow t_s$
3. $S \leftarrow t_s$
4. **while** ($|V| < |T|$) {
5. $t_i \leftarrow$ PROPAGATE_1ST(S)
6. $p \leftarrow$ PROPAGATE_2ND(t_i)
7. $R \leftarrow$ the intersection region between the first and the second front-wave propagation phases.
8. Insert t_i into V.
9. **if** ($p \neq$ NULL **AND** $p \notin T$)
10. PARALLEL-CONNECT()
11. PARALLEL-CLEANUP()
12. $S \leftarrow \phi$
13. $S \leftarrow$ all the grid points from which the first front-wave propagation in the next iteration will start.
14. }
15. FINAL-CONNECT()
16. **return** the completed OARSMT

Figure 2. The proposed parallel algorithm for OARSMT construction.

The **while** loop in line 4 checks whether all the terminals have been visited or not. Lines 5–13 will be executed if at least one terminal in T has not been visited. The first front-wave propagation phase is implemented in the procedure PROPAGATE_1ST(); the procedure returns a terminal (t_i) which is the terminal found in the phase and is the closest terminal to grid points in S. Note that distance numbers increase as the propagation proceeds during this phase.

The second front-wave propagation phase is implemented in the procedure PROPAGATE_2ND(). The procedure returns p, which is either a newly found Steiner point or NULL. Note that distance numbers decrease as the propagation proceeds during this phase. In line 7, a region R, which is the intersection of regions between the first and the second propagation phases, can be obtained. In line 8, the terminal that has just been discovered during the first front-wave propagation phase is inserted into V.

In lines 9–10, if Steiner point p exists and it is not an element in T, the wire connections between p and terminals in a region which was formed previously will be made. We have found that the connection process can be parallelized; it has been implemented in the procedure PARALLEL-CONNECT(). The procedure can efficiently speed up the connection process and will be described in detail in subsection 3.1.

Since distance numbers are recorded during double front-wave expansion, parts of these numbers must be cleared in preparation for the next double-wave expansion iteration. Because the process of clearing distance numbers does not have any data dependency, the process can be parallelized; the parallelized process has been implemented in the procedure PARALLEL-CLEANUP() and will be described in detail in subsection 3.2.

In lines 12–14 of our parallel algorithm, the set S is reset and then its content is updated in preparation for the next iteration of double-wave expansion. After all iterations of double-wave expansion have been completed, there can still exist terminals that remain unconnected. The procedure FINAL-CONNECT() will complete the routing for these unconnected terminals.

Fig. 3 illustrates an example of constructing an OARSMT by using our algorithm. As shown in Fig. 3(a), an instance of the OARSMT problem, which is to be solved, contains four terminals and three obstacles. If t_1 is the start terminal, the first front-wave propagation phase will generate distance numbers, as shown in Fig. 3(b), after t_2 is reached. The second front-wave propagation phase, which starts from t_2 and then reaches t_1, will generate the result as illustrated in Fig. 3(c). Note that the second propagation phase will only visit grid points that have been visited previously in the first propagation phase. Therefore, the overlapping region (region A) between the first and the second front-wave propagation phases can be obtained, as shown in Fig. 3(d). After the first iteration of the **while** loop finishes, set S contains all the grid points which are on the boundary of region A; these points include terminals t_1 and t_2. During the second iteration of the **while** loop, terminal t_4 will be visited and then region B will be generated. A Steiner point, which is at the intersection between regions A and B, can be obtained; the point is named p_1 in Fig. 3(e). The procedure PARALLEL-CONNECT() can then be invoked to connect p_1 and t_1 as well as to connect p_1 and t_2, as illustrated in Fig. 3(f). After that, the third iteration of the **while** loop will visit t_3, and region C in Fig. 3(g) will be formed. Next, Steiner point p_2 will be obtained, and it can then be connected to p_1 and t_4. Finally, the unconnected terminals (i.e., t_3 only in this example) can be connected after invoking the procedure FINAL-CONNECT(). The final routing result is shown in Fig. 3(h).

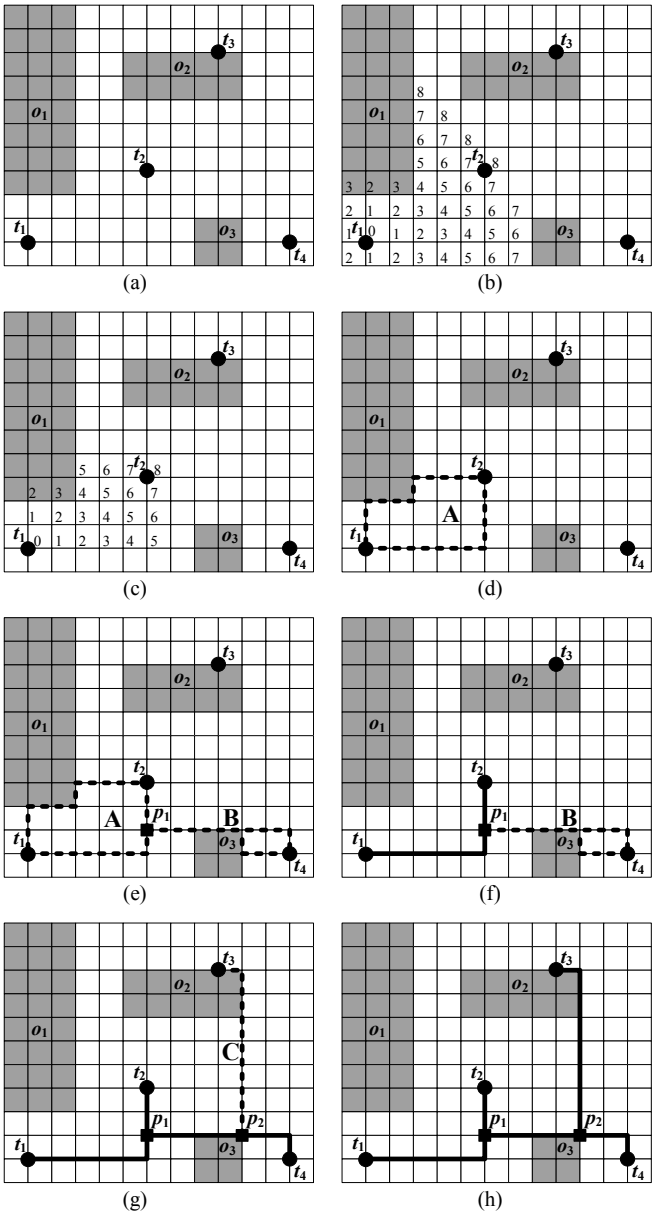

Figure 3. An example of constructing an OARSMT by using our algorithm.

3.1 Parallel-Connect

In Watanabe's PAR-1 algorithm [12], a parameter named *expansion distance* (denoted by D_{ex}) is used to control the quality of routing during front-wave propagation phases. When D_{ex}=1, the PAR-1 algorithm is equivalent to Lee's algorithm [14], and a wire whose length is the shortest between two given points can be obtained. On the other hand, when $D_{ex}=\infty$, a wire which has the minimum number of bends can be generated, although the wire length may not be the shortest.

The procedure PARALLEL-CONNECT() is used to connect a Steiner point with other points, including terminals and/or other Steiner points, within a region. The technique of front-wave propagation is also used in the procedure. However, the procedure is parallelized and parameter D_{ex} is set to infinity. Therefore, connections will be made within the region and have the minimum number of bends. As a result, final routing results generated by our algorithm can have minimal total wire lengths and minimal number of bends.

An example for illustrating detailed steps of PARALLEL-CONNECT() is shown in Fig. 4. In this example, we assume that Steiner point p_1 has been found, and we need to connect p_1 to t_1 as well as connect p_1 to t_2, as shown in Fig. 4(a). Also, connections must be made within region A. After the front-wave propagation phase, which starts from p_1, with D_{ex} set to ∞ is finished, distance numbers for visited grid points are shown in Fig. 4(b). In the backtracking phase, terminal t_1 must be connected to p_1 and terminal t_2 must also be connected to

p_1. Since t_1 and t_2 must be located on different corners of region A and p_1 must be on the boundary of region A, the two connection processes are independent and can thus be parallelized. Therefore, the connection between t_1 and p_1 can be made by one thread while the connection between t_2 and p_1 can be made by another thread. Because there are two possible routes for the connection between t_1 and p_1, one of the two possible connection results, shown in Fig. 4(c) and Fig. 4(d), will be generated.

After all the terminals have been visited during iterations of double front-wave expansion, there may still exist terminals that have not been connected. These terminals will be connected via procedure FINAL-CONNECT().

3.2 Parallel-CleanUp

After each iteration of the first and the second front-wave propagation phases, an intersection region R can be obtained, as mentioned previously. However, distance numbers for grid points which are not located in the intersection region must be reset to zero before the next iteration of double front-wave expansion starts. The process of resetting distance numbers of grid points is named the *clean-up* process and can be parallelized. Fig. 5(a) illustrates an example where region A has been generated. After the execution of the clean-up process, distance numbers for grid points outside region A will be reset, as shown in Fig. 5(b).

Another occasion that requires the invocation of the clean-up process is when wire connections within a region have been made, and the region must be removed in preparation for the next iteration of double front-wave expansion. For example, in Fig. 5 (c), region A has been generated, followed by the generation of region B. Also, Steiner point p_1 has been obtained. After terminals t_1 and t_2 have been connected to p_1, therefore, distance numbers for grid points after performing double front-wave expansion as well as distance numbers for grid points inside region A must be reset. However, distance numbers for grid points inside regions which have not been removed must be kept intact. The result after executing the clean-up process is illustrated in Fig. 5(d).

Since the two occasions for performing the clean-up process can be merged, we implemented the clean-up process in procedure PARALLEL-CLEANUP(). The procedure can be parallelized because there is no data dependency while resetting distance numbers for individual grid points.

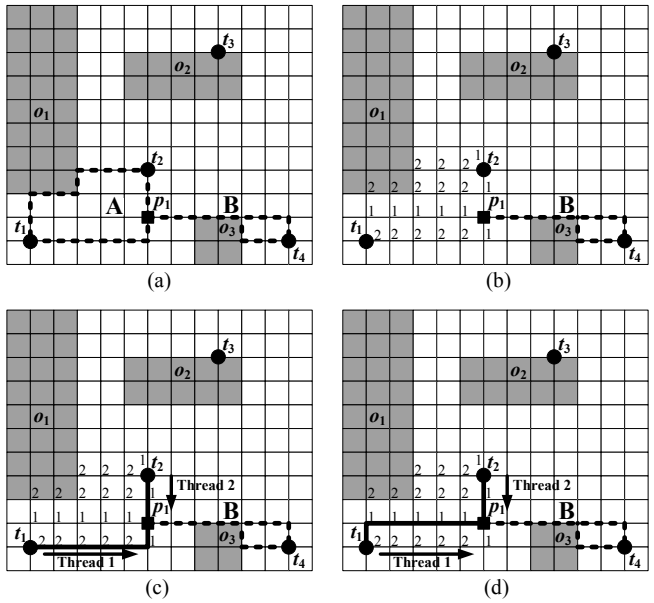

Figure 4. An example for illustrating detailed steps of PARALLEL-CONNECT().

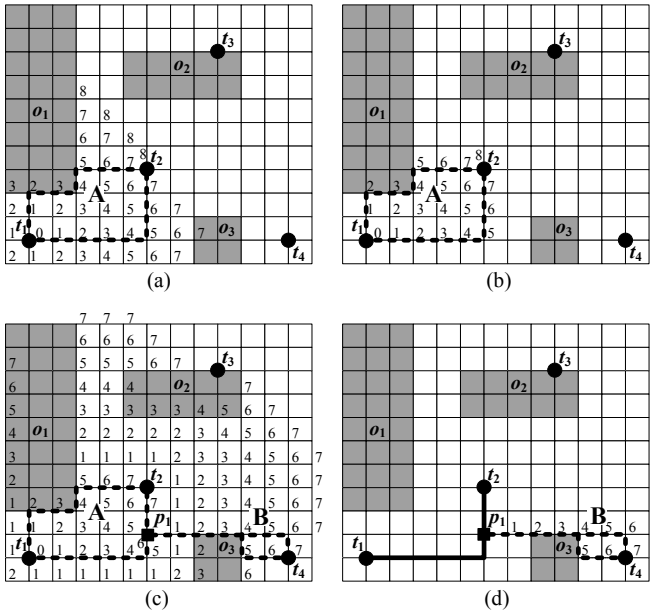

Figure 5. Examples for illustrating functionalities of procedure PARALLEL-CLEANUP().

4 Experimental Results

The algorithm presented in Fig. 2 has been implemented in C++ with the use of OpenMP [13]. Experiments were carried out on a Linux workstation containing two Quad-Core Xeon E5520 2.26GHz processors and 32GB of RAM. Table I shows statistics information for each of 21 benchmark testcases; the information includes the number of terminals (denoted by #Pin) and the number of obstacles (denoted by #Obs). Among these benchmark testcases, five were industrial testcases (ind1 to ind5) from Synopsys, eleven testcases (rc01 to rc11) were used in [7, 8], and five randomly-generated testcases (rt01 to rt05) were used in [1, 8]. Table I also shows the execution times of our program for solving these benchmark testcases. On average, 23% speed-up can be achieved while executing the parallel program using 4 threads for solving these benchmark testcases.

Table II presents comparisons of total wire lengths for routing results generated by different OARSMT algorithms; the testcases listed in the table are the same as the ones listed in Table I. Additionally, Table III shows comparisons of total wire lengths for routing results generated by different

OARSMT algorithms when all the obstacles in each of the benchmark testcases have been removed. As can be seen in both tables, our approach is very competitive in terms of minimizing total wire lengths.

5 Conclusion

We proposed a parallel algorithm which is capable of constructing obstacle-avoiding rectilinear Steiner minimal trees (OARSMTs) in the gridded *xy* plane. The algorithm is based on maze routing and double front-wave expansion. Although our approach does not use refinement techniques, experimental results have shown that it is very competitive in terms of minimizing total wire lengths. Moreover, 23% speed-up can be achieved on average while executing the parallel program using 4 threads on a multi-core computer system.

Bacon: A GPU Programming System With Just in Time Specialization

Nat Tuck

Email: ntuck@cs.uml.edu

***Abstract*—This paper describes Bacon, a data-parallel programming system targeting OpenCL-compatible graphics processors. This system is built upon the existing OpenCL standard in order to make it easier for programmers to write high performance kernels for GPU accelerated applications. The OpenCL C syntax is extended into a new language, Bacon C, intended to make development significantly more convenient and enabling pre-optimizations based on just-in-time specialization as this code is compiled via OpenCL at runtime.**

Benchmarks are provided for matrix multiplication comparing two Bacon implementations to similar OpenCL implementations. Speedups are demonstrated both for naive implementations and when comparing a Bacon implementation of generalized block decomposed matrix multiplication to a hand-vectorized OpenCL kernel. This latter result demonstrates the benefit of the total loop unrolling enabled by just-in-time specialization.

I. Introduction

The use of Graphics Processing Units (GPUs) for general purpose parallel computing has become increasingly feasible over the last few years. In response to the platform specific programming solutions from NVIDIA and Microsoft, Apple developed the OpenCL standard as an open and cross platform programming interface to this hardware. This standard has since been implemented by a number of major vendors including AMD, NVIDIA, Intel, and IBM.

The OpenCL standard[1] consists of two major pieces. First, it defines a programming language called OpenCL C for writing compute kernels to run on parallel hardware. Second, it defines runtime APIs for C and C++ that allow these kernels to be compiled, loaded, and executed from programs running on a host machine.

OpenCL C uses the syntax of C99 and provides a set of built in data types and functions that expose the numeric computation capabilities common to modern GPU devices. The specification explicitly disallows the use of various C99 functionality that is not supported by GPU hardware, including function pointers, recursion, and any sort of dynamic memory allocation or array sizing.

Rather than providing a stand-alone program to compile OpenCL C kernels, the OpenCL C and C++ APIs give developers the pieces necessary to build a compiler into their host program. This allows OpenCL programs to be portable across different hardware archetectures by delaying compilation until runtime when the target GPU device is known. Unfortunately, it also requires each developer to write quite a bit of code to load the kernel source code and perform various other bookkeeping activities.

This paper introduces Bacon, a parallel programming system built on top of OpenCL. Bacon provides two main benefits to developers over the direct use of OpenCL. First, it provides a better user experience through syntax extensions and automatic generation of interface code. Second, it uses an optimization technique called just-in-time specialization which can speed up kernel execution significantly.

Just-in-time specialization operates by delaying compilation of a Bacon kernel until after it is called with a concrete set of argument values. When a Bacon kernel is written, some integer arguments can be marked as specialization variables. When a kernel is first called with a given set of values for those arguments a specialized version of that kernel is generated with the values of those arguments held constant. Just in time specialization enables several optimizations and capabilities that could not be provided otherwise.

These improvements are evaluated using matrix multiplication as a well-known test case. Both simpler code and improved performance are demonstrated.

II. Related Work

A. Partial Evaluation

Specialization, also known as partial evaluation, has been shown to be a very effective optimization by projects such as Tempo[2], which does general partial evaluation of C code at compile time. Just in time specialization was popularized by its use in typing dynamic languages, as shown in the Self language[3]. Just in time specialization on values has been used in Prolog systems by Bolz[4].

B. OpenCL Libraries and Front-Ends

Bacon is not the first attempt to provide an improved programmer experience for OpenCL. Rick Webber has developed an improved C++ API called clUtil[5]. Bindings for other languages, like the JOCL[6] binding for Java, provide APIs at a variety of levels of abstraction.

Another very interesting approach allows the programmer to describe the computation to be executed on the GPU in the same language as the rest of the program. An OpenCL kernel is then generated automatically. This has the potential benefit of increased expressive power and programmer familiarity at the cost of increased complexity and necessarily leaky

```
kernel
Array2D<float> // (1) return values
mat_mul(Array2D<float> aa, Array2D<float> bb)
{
 SETUP: // (2) in-kernel setup section
    global Array2D<float> cc[aa.rows, bb.cols]; // (3) parameterized types

 BODY:
    @range [cc.rows, cc.cols]; // (4) parallel range declaration

    float sum = 0.0;
    assert(aa.cols == bb.rows, // (5) error checking and handling
        "Matrices must have compatible dimensions.");
    for (int kk = 0; kk < aa.cols; ++kk) {
        sum += aa[$row, kk] * bb[kk, $col]; // (6) multi-dimensional arrays
    }
    cc[$row, $col] = sum; // (7) special index variables
    return cc; // (8) return variable declared and selected in-kernel
}
```

Listing 1: Naive Matrix Multiplication in Bacon C

abstraction when the host language contains features that can't be cleanly transformed into GPU code. Examples of this approach include CLyther[7] for Python and ScalaCL[8] for the functional language Scala.

III. The Bacon C Language

Bacon C is based on OpenCL C with extensions for improved usability and to enable the automatic generation of C++ wrapper code. Sample Bacon C kernels that perform matrix multiplication and demonstrate nine of the new features of the language are shown in Listing 1 and Listing 2.

Bacon preserves the OpenCL single program multiple data (SPMD) computation model. A kernel is executed in parallel over a 1D, 2D, or 3D range. Each executing instance of the kernel can query its position in that range to determine which part of the work it is responsible for performing. For example, the kernel in Listing 1 will be executed in parallel once for each element in the output matrix.

Each kernel is separated into SETUP and BODY sections. The SETUP section ((2) in the Listing 1) is for code that will run serially on the host processor while the BODY section contains the code to be executed in parallel. In practice, the SETUP section is primarily used to declare output arrays that can be returned to the host application and to compute the sizes of these arrays.

Unlike OpenCL C kernels, Bacon C kernels can return values ((1) in Listing 1). Any variable of a simple type can be returned, as can any array passed as an argument or declared in the SETUP section. The return statement occurs in the kernel BODY ((8) in Listing 1) and can selected conditionally (e.g. by an `if` statement), but the behavior if different parallel instances of the kernel try to return different values is undefined.

Each BODY includes an `@range` declaration ((4) in Listing 1) that specifies the range it will be executed over in parallel. Within the BODY, the current position in that range is held in special Bacon-specific variables named `$col`, `$row`, and `$dep` for the first, second, and third dimension respectively ((7) in Listing 1). The range is formatted like an array declaration, so a BODY with `@range[4]` will be executed 4 times in parallel with `$col` having the values 0, 1, 2, and 3. Since this is only a 1D range, the values of `$row` and `$dep` will both be zero.

Bacon provides parameterized types ((3) in Listing 1) for 1D, 2D, and 3D arrays using C++-style angle bracket syntax. Both declarations and element access use a comma separated list of numbers in square brackets ((6) in Listing 1). The dimensions of these arrays can be accessed using struct-style dot notation. For example, a three by three by three array of integers called "cube" could be allocated with `int cube[3,3,3];` and the width of that array could be accessed with `cube.cols`.

Additional error handling is provided through the `assert` ((5) in Listing 1) and `fail` keywords which will stop kernel execution and raise exceptions in the host process if triggered. A `fail` is triggered if execution in any thread reaches that statement, while an `assert` is only triggered if its associated condition is false.

Each Bacon kernel has a set of specialization variables. These fall into two categories. First, the dimensions of any arrays passed as arguments to a kernel are always specialization variables. Second, additional specialization variables can be specified explicitly by declaring arguments using the `const` qualifier (like the `blksz` argument in Listing 2). Whenever a kernel is called with a new set of values for its specialization variables a specialized version of that kernel is generated and

Sequence	Traditional (e.g. FORTRAN Kernel)	OpenCL Kernel	Bacon Kernel
1.	Developer writes host application (C++) and kernel (e.g. FORTRAN).	Developer writes host application (C++) and kernel (OpenCL C).	Developer writes host application (C++) and kernel (Bacon C).
2.	—	Developer writes wrapper code (C++) to load and run kernel.	Bacon compiler generates wrapper code (C++) to load and run kernel.
3.	Host application and kernel are compiled.	Host application and wrapper code are compiled.	Host application and wrapper code are compiled.
4.	Host application is run.	Host application is run.	Host application is run.
5.	—	—	Input data is read.
6.	—	—	Bacon library generates specialized OpenCL kernel.
7.	—	Target GPU is identified.	Target GPU is identified.
8.	—	Kernel is compiled for target GPU.	Kernel is compiled for target GPU.
9.	Input data is read.	Input data is read.	—
10.	Kernel is executed on input data.	Kernel is executed on input data.	Kernel is executed on input data.

TABLE I: Lifecycle of Bacon and OpenCL Kernels

executed. Specialized kernels are cached for future calls with the same set of specialization values.

This specialization, in addition to providing performance benefits, allows variable sized arrays in thread-private memory as long as the array size depends only on `const` variables and array dimensions. Since OpenCL does not allow any form of in-kernel dynamic memory allocation, this makes it possible for users to write kernels that would have been difficult to write using OpenCL directly. The blocked matrix multiply kernel in Listing 2 gives an example of this feature.

IV. Kernel Lifecycle

The basic technique of separating out high performance "kernels" from an application and implementing them in a separate language has been used in software development for decades. This even occurs for purely sequential programming. For example, an application written primarily in C++ may have high performance routines written in hand optimized assembly code or FORTRAN. Traditionally, the host application and kernel code are compiled into separate modules and then linked together before execution. This basic sequence is shown in the first column of Table I.

Compiling everything before execution, or ahead-of-time (AOT) compilation, has one major downside: the target hardware is set when the application or module is compiled. Just-in-time (JIT) compilation avoids this problem by delaying compilation until the program is run on a specific machine, allowing the target hardware to be detected dynamically at runtime. OpenCL uses JIT techniques to allow the portability of kernels across the variety of compute-capable GPUs and other parallel acceleration hardware that provide support for the standard. The JIT OpenCL kernel lifecycle is shown in the second column of Table I.

Bacon takes delayed compilation one step further, waiting to compile a kernel until it is actually called and the characteristics of the arguments can be examined. This allows just-in-time specialization to be performed, as shown in the third column of the table.

V. Implementation

The Bacon system consists of two pieces: the Bacon compiler and the Bacon runtime library. The compiler runs at application compile time and parses the Bacon C source, generating a C++ wrapper and a serialized abstract syntax tree (AST). The Bacon runtime library is called from the generated wrapper as the host application is running to load the AST, generate specialized OpenCL C code when a kernel is called, and run that code on the GPU using the OpenCL runtime.

The system is built using Perl and C++. The Bacon compiler parses the source code using Parse::Yapp[9], a yacc-compatible parser generator for Perl. This constructs the abstract syntax tree as a Perl data structure. The C++ wrapper is then generated by traversing this tree.

The generated C++ wrapper provides a C++ function with the kernel's type signature that can be called from the user's application. When this functions is called, the Bacon runtime library loads the AST and traverses it to generate the specialized OpenCL code. Optimizations are performed at code generation time directly from the AST without the use of a traditional low level intermediate representation.

The two optimizations that are performed by the Bacon runtime library are constant propagation and loop unrolling. Constant propagation calculates the values of all the variables that have been marked as `const` by the programmer. If the value of any of these variables cannot be computed from the specialized arguments to the kernel, the Bacon runtime library will throw an exception. This information is used to construct a symbol table, and references to these variables are replaced with their constant integer values in the generated OpenCL code.

Loop unrolling is performed on any loops for which the iteration count and range can be determined after constant propagation. Short loops are fully unrolled. In this case, no loop is passed to the compiler at all. An example of this is shown at (10) in Listing 2. Longer loops are unrolled by some factor that evenly divides the iteration count.

This specialized and optimized OpenCL C code is then passed to the OpenCL compiler provided with the vendor SDK which will perform further optimizations on the generated

```
kernel
Array2D<float>

Listing 2: Blocked Matrix Multiplication in Bacon C

code, including more aggressive constant propagation and possibly static register-load scheduling enabled by the Bacon pre-optimizations.

The implementation of Bacon is available publicly under an open source license. The current version can be downloaded from the public git repository[1].

VI. Ease of Use

We believe that Bacon provides an improvement in ease of use compared to OpenCL by itself. A number of syntactic improvements are described in Section III. More significantly, the automatic generation of wrapper code performed by the Bacon compiler significantly reduces the number of lines of code that the developer is required to write.

As a concrete example of the reduction in lines of code required by Bacon, we consider naive matrix multiplication kernels like the one shown in Listing 1. Our OpenCL C version of this kernel is the same length: 17 lines of non-whitespace code. Unfortunately, even ignoring the application-specific code required to construct the input matrices, it takes 174 lines of non-whitespace C++ code to compile and call this 17 line OpenCL kernel. In contrast, the Bacon version only requires three lines to load, specialize, and call; all the bookkeeping is done either by the automatically generated wrapper code or by the Bacon runtime library.

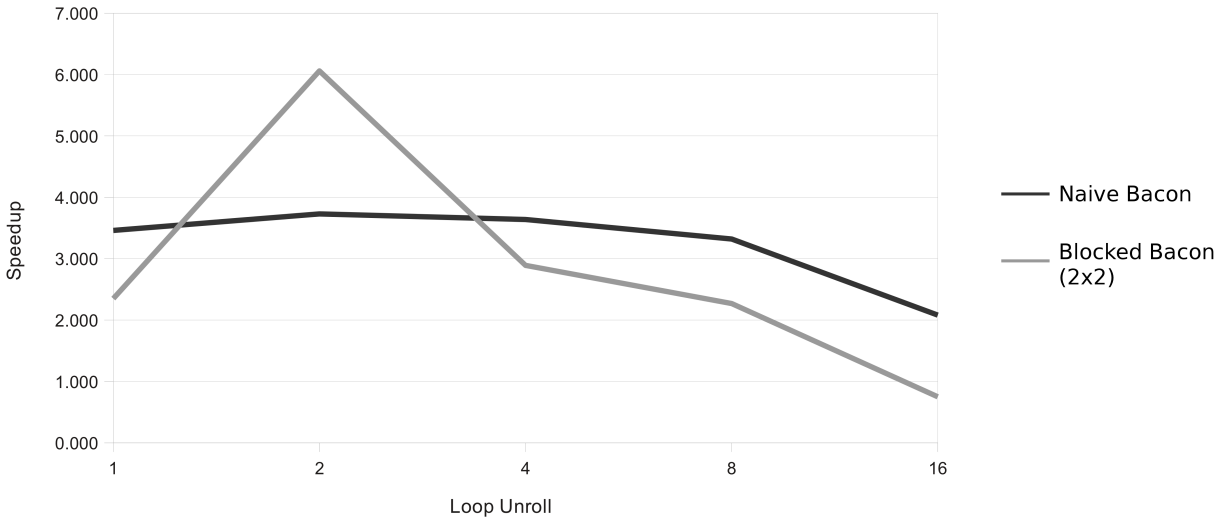

Fig. 1: Speedup on 4k matrix multiplication with unrolled loops over naive OpenCL implementation.

Test	Time (s)	Speedup
OpenCL - Naive	11.9	1.0
OpenCL - Hand Vectorized	2.54	4.7
Bacon - Naive (Best)	3.45	3.5
Bacon - Blocked (Best)	1.97	6.1

TABLE II: Summary of 4k Matrix Multiplication Performance

VII. Performance

In order to evaluate the performance of the Bacon system, we compare the run time of matrix multiplication kernels written in both Bacon C and OpenCL C. These results are summarized in Table II, which shows that Bacon is able to provide measurable performance improvements over similar programs written directly in OpenCL C.

Testing was performed on an AMD Radeon HD 5830 GPU. This is a mid-range GPU intended for high definition computer gaming. At the time of this writing, the card is a full hardware generation out of date, but it still has a theoretical parallel compute capacity of 1.7 teraflops, which is more than an order of magnitude greater than a high end CPU like the Intel Core i7 3930 at 154 gigaflops[2].

Four implementations of matrix multiplication were tested:

Bacon - Naive
: A textbook implementation of parallel matrix multiplication. Shown in Listing 1.

OpenCL - Naive
: An OpenCL implementation equivalent to the naive Bacon code.

Bacon - Blocked
: Shown in Listing 2. This generalizes a 2D unrolling of the computation into square blocks.

[2]FLOPS ratings from manufacturer specifications

OpenCL - Hand Vectorized
: Hand unrolled to compute 4x4 blocks at once. Explicitly uses OpenCL's native vector types. Based on a sample from the AMD OpenCL SDK.

The execution time of these four kernels was tested on randomly generated 4096x4096 matrices. Each test was performed five times and the average result was taken. The times were very consistent; most tests had a coefficient of variation under one percent. The speedups over the naive OpenCL implementation are shown in Figure 1.

A. Discussion

These measurements show that value specialization provides significant speedups over a non-specialized OpenCL kernel. This result can be explained by the fact that providing constant values and unrolled loops at compile time allows the OpenCL C compiler to do extensive constant propagation-based optimizations.

Unlike constant propagation, which provides a clear and consistent performance benefit, loop unrolling is more complicated. Unrolling loops too much drastically decreases performance, most likely due to the exhaustion of registers on the GPU device. Still, when properly tuned, loop unrolling provides significant speedups allowing the blocked Bacon kernel to beat the hand vectorized OpenCL kernel by nearly 30 percent.

Somewhat surprisingly, Bacon's loop unrolling is able to beat the vectorized OpenCL code without the explicit use of native vector types. From this we conclude that either vectorization is being done automatically by the AMD OpenCL compiler or the use of vector types doesn't have a significant performance benefit for this matrix multiplication algorithm.

VIII. Future Work

The Bacon system could benefit from a number of extensions to improve its performance, generality, and utility

to developers. One obvious area of improvement would be to automatically determine the best factor for loop unrolling rather than expecting it to be tuned manually. The unrolling analysis could also be extended to the implicit parallel "loops" created by the range of the computation; optimally, it should be possible to generate kernels like the blocked matrix multiplication shown from the naive matrix multiplication kernel. Another simple improvement would be to perform strip mining (Wolfe [10], section 9.8) and generate explicit vector code for loops, but this may be unnecessary if the OpenCL compilers are doing it themselves.

Just in time specialization as a method to improve performance on parallel computations seems very promising in general, but there are some limitations imposed by the use of OpenCL as a compiler target. An implementation of this technique targeting a parallel processor at a lower level would allow for more flexibility and much faster specialization times.

IX. Conclusion

We have shown that Bacon allows a high performance GPU compute kernel to be written in a naive style and executed with nearly the performance of a hand-vectorized OpenCL kernel due to the performance benefits of just in time specialization. Further, we have shown that by re-writing that kernel with a generalized block strategy and selecting appropriate loop unrolling settings, the performance of a hand-unrolled OpenCL kernel can be exceeded.

We are distributing this tool in the hope that it will be practically useful for developing kernels targeting OpenCL compatible GPU devices.

Abstract - *MapReduce is an efficient distributed computing model on large data sets. The data processing is fully distributed on huge amount of nodes, and a MapReduce cluster is of highly scalable. However, single-node performance is gradually to be a bottleneck in compute-intensive jobs, which makes it difficult to extend the MapReduce model to wider application fields such as large-scale image processing and image mining. As an attempt, this paper presents an approach of GPU-accelerated MapReduce, which is implemented by Hadoop and OpenCL. Being a distinctive feature, it aims at general and inexpensive hardware platform, and it is seamlessly integrated with Apache Hadoop, the most widely used MapReduce framework. As a heterogeneous multi-machine and many-core architecture, it targets at both data- and compute-intensive applications. An almost 2 times performance improvement has been validated, without any special optimization.*

Keywords: MapReduce; GPU acceleration; Hadoop; OpenCL

1 Introduction

MapReduce is a distributed computing model oriented at huge datasets. Proposed by Google, it has been successfully applied to Google`s large-scale data processing [1]. For its excellent price/performance characteristic on low-cost clusters, nowadays, various MapReduce implementations are being utilized by more than 150 IT companies, making the data processing much faster, easier and more efficient [2].

MapReduce model simplify the complex parallel computing problem into two simple steps. First is called *Map*. The master node divides the input into smaller sub-problems, and distributes them to mapper nodes. Next step is *Reduce*. Reducer nodes collect answers to all sub-problems and combine them in some way to form the final output. All works across nodes are in highly parallel.

Among various MapReduce applications, compute-intensive tasks is an important class of applications, which is characterized by the fact that execution of the map function is significantly longer than the data accessing time, by an order of magnitude at least. In the case that the cluster scale is limited, some nodes have to process a large number of key/value data. This situation may be more serious during the Reduce stage of some programs, which is always the bottleneck of the whole system.

In order to handle this issue, conventional solutions have been presented:

- Scale-out [3, 4]: Adding more Mapper or Reducer nodes, artificially or automatically. Sometimes it works. However, the cluster scale`s expanding will pose some challenges, such as side-effects in scheduling and node faults, especially when the cluster scale is larger than 1000 nodes.
- Parameters optimization [5]: By adjusting the proportion of Mappers and Reducers, the file block size, data compression, etc., the cluster can get more perfect performance. Performance optimization is very useful in same cases; however, the ability of optimization is limited. This process is often time-consuming, and it needs skills. Moreover, one such optimization works on only one or one kind of jobs. That means it has to be re-turned when the program is changed.

Recent efforts therefore mainly focus on improving the availability, reliability and scalability for super large cluster, and cluster performance testing, etc. Researches are relatively less in the aspect of farther increasing the parallel computing capacity of single-nodes. However, the computing capacity within a node is a critical factor for performance improvement besides communication efficiency [6].

Analyzed the program of compute-intensive tasks, we can find some characteristics. It often contains many nesting loops in these programs, which often consume major running time. Nevertheless, sometimes the data dependency is quite low between loops, which determine that it is feasible to assign one loop to one thread, and execute these threads in parallel.

Heterogeneous computing architecture, a state-of-the-art tendency of high performance computing pattern [7, 8], has been emerged in recent years. Up to the end of 2011, three of the 5 most powerful supercomputers in the world take advantage of GPU acceleration. Comparing with multicore

CPUs, concurrent threads in GPUs are far more than CPUs. Hundreds of lightweight threads can be easily launched in concurrent [9]. And this number, with the development of chip technologies, will continually increase without the limitation of Moore`s law. GPUs are much good at parallel numerical calculation and steaming processing. GPU computation is of huge potential in compute-intensive tasks although it has not been completely released yet. Therefore, utilizing computing power of GPUs to enhance the single-node performance is our basic motivation.

Original MapReduce model targets at multi-machine. Hence, some implementation frameworks port on large cluster via distributed file system, e.g., the Google-MapReduce framework upon Google File System (GFS) and Apache Hadoop framework upon Hadoop File System (HDFS). In addition, some implementations extend it to multicore CPUs and shared-memory multiprocessors architecture, such as the Phoenix framework [10] proposed by Stanford University. Although these are all excellent implementation, they didn`t take huge potential of GPUs acceleration into consideration.

Related research didn`t bog down here. Some achievements have been proposed yet, such as:

- B.He et al. [10] presented an SMS-based MapReduce framework: Mars. It is implemented by NVIDIA CUDA and Phoenix [11].
- K.H.Tsoi and W. Luk [6] presented a MapReduce framework with mixed hardware accelerator: Alex, a heterogeneous cluster with FPGAs and GPUs.

Nevertheless, one limitation is that they all need dedicated hardware or bind with software platform, which makes it difficult to port on general and inexpensive platforms.

This paper presents our early work of an approach of MapReduce with GPU acceleration on general platform, which is implemented by Hadoop framework [12] with Open Computing Language [13]. We attempt to extend the parallelism of MapReduce model, from multi-machine alone to multi-machine with many-core, so as to enlarge the application domains of Hadoop framework, e.g. large-scale image processing. Its performance has been validated by our experiments.

The rest of this paper is organized as follows. Section 2 provides an over-view of MapReduce and GPGPU computation. In section 3, we take mathematics method to evaluate the ideal acceleration performance, and then the architecture and implementation are presented with the experiment. Our experimental results are presented in section 4. Finally, we conclude this paper and outline our future work.

2 Preliminaries

2.1 MapReduce model and Apache Hadoop

The original MapReduce model is proposed by Google for the purpose of supporting its critical services such as web search, log analysis, data mining, etc. in petabyte-level datasets. Apache Hadoop-MapReduce project is an open-source implementation. Hadoop is not only the most popular and widely used MapReduce framework by masses of enterprises, but also a distributed store and compute platform. It is designed as orienting at inexpensive commodity hardware, but it is of excellent fault-tolerance mechanism so as to successfully support super large clusters and petabyte-level data processing.

Being a programming model, MapReduce allows programmers to write functional-style code that is automatically parallelized and scheduled in a distributed system. Although its implementation is quite complex, a MapReduce program is rather easy to understand in logical. As is shown in Figure 1, a big input dataset is split into small chunks, and then stored in the distributed file system (e.g. HDFS). Each Map task can process a local input split. The intermediate outputs are transferred to Reduce nodes, then reduce tasks combine them in some way to form the final output.

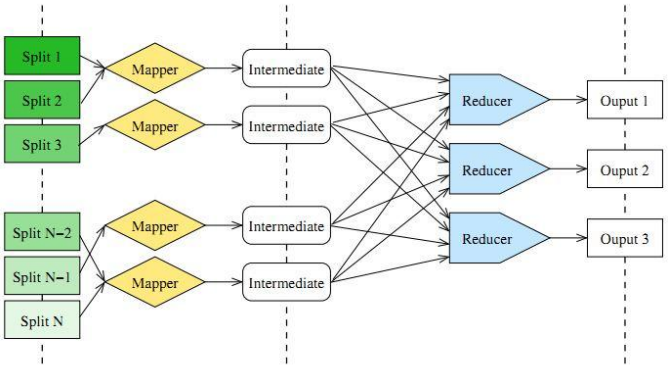

Figure 1. A Basic Process of a MapReduce task (Diagram courtesy of Apache Hadoop.)

Utilizing the distributed file system, data-locality optimization [14] maximizes the amount of data throughput, which makes the processing of data-intensive applications much faster. However, although the sub-tasks` running are in parallel, the default program running within each node is still in serial, that is inefficient comparing with multi-thread programs.

Therefore, improving the program parallelism of single-node is critical if we need farther performance improvement, especially when we are facing compute-intensive applications such as text processing, data compression, digital graphics processing, etc. In CPUs programing, multi-thread

programing is of difficulties and its performance improvement is rather limited because of CPUs` architecture.

Nevertheless, the situation is quite different in GPUs.

2.2 GPGPU and OpenCL

The Graphic Processing Unit (GPU) is a many-core processor that can concurrently execute hundreds of threads. Originally, it was a dedicated processor for graphics processing acceleration. But recently, being an extension of stream processor, the General Purpose Graphics Processing Unit (GPGPU) turns the massive floating-point computational power of a modern graphics accelerators` shader pipeline into general-purpose computing power [15].

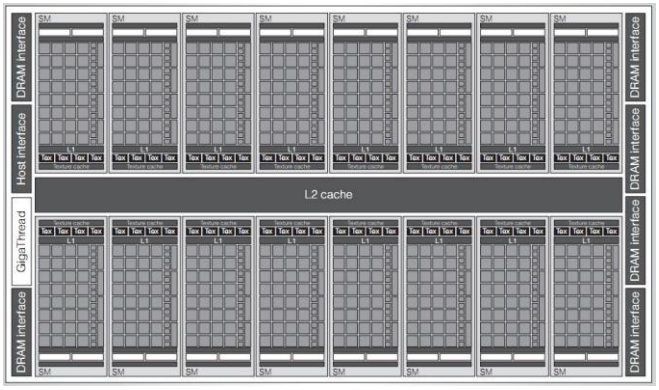

Figure 2. Fermi GPU architecture; 8 cores each streaming processors, and 16 processors each chip (Diagram courtesy of NVIDIA.)

For the ease of development, some GPGPU programing framework have been developed, such as NVIDIA CUDA, AMD CTM, and Brook+ developed by Stanford University, etc. They are all bind with appointed hardware or programing language.

Different from these, the Open Computing Language (OpenCL) aims at the general-purpose multicore computing. Initially sponsored by Apple Inc., OpenCL is the state-of-the-art open standard for cross-platform, parallel programming of modern processors found in PCs, servers and embedded devices. OpenCL gives any application access to the GPGPU for graphical or non-graphical computing.

An OpenCL program usually consists of two parts:

1) OpenCL Kernel: Kernel is the program that runs on multicore devices (e.g. GPUs). It is written by the OpenCL language, which is similar to C language.

2) Platform-control program: For the purpose of control the OpenCL runtime environment, a suit of API is necessary. It has several language bindings that can be chose by programmers, such as C, C++, Java, etc.

3 GPU acceleration and Algorithm

The substance of GPU acceleration is multi-threaded execution on multi-core hardware. There is usable scope that GPU acceleration is not applicable to all programs, although most MapReduce jobs are of natural fitness with GPU acceleration. We can use mathematics method to evaluate the acceleration performance and then validate it by experiments.

3.1 Acceleration theory

A MapReduce program is always both data- and compute-intensive. Commonly, there are many loop operations in it, especially in the *reduce* function. Owing to the large scale of input dataset and the complexity of data processing, the time consuming caused by loops is much longer than the other operations. In practice, supposed that if there is a low data dependency between each loops, codes inner the loop can be executed as an independent thread, and each thread processes different input data.

This is the Single Instruction, Multiple Data (SIMD) [16], which is the basis of GPU acceleration. The stream processors (SMs) in GPUs are far more than CPUs, so we can assign each small task on one thread, 100x decreasing the total executing time.

The Relative Speedup (Sp) [17] can well measure the acceleration performance. Relative speedup refers to how much faster a parallel improvement is.

In logical, a program can be divided into two parts. The first is all codes executed in sequential, which is denoted by S here; the second part is k m-dimensional loops that are denoted by L.

So, the running time of the whole program is $T = T_s + T_l$.

Suppose that the average executing time for each program statement is t, and there are n statements in each loop. Then the time consuming of the loop operation is:

$$T = T_s + k \times (n \times t)^m \qquad (1)$$

Using GPU acceleration, we suppose the quantity of concurrent threads is N, then the executing time is:

$$T_a = T_s + \frac{k \times (n \times t)^m}{N^m} \qquad (2)$$

When Tl is long enough, Ts is negligible. Thus, the related Sp for an m-dimension loop is:

$$Sp(m) = \frac{T}{T_a} = N^m \qquad (3)$$

We can see that the relationship between speedup and the quantity of nesting-level of loops is positive correlation.

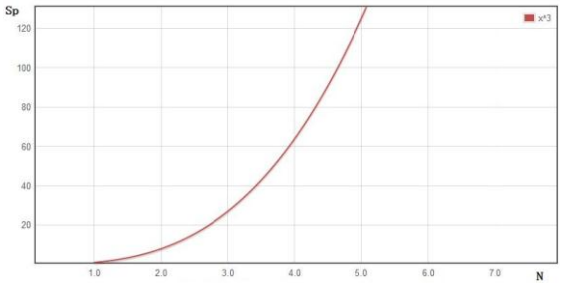

Figure 3. The relationship between Sp and N; (m = 3)

Parallel acceleration can be used to reduce the running time of programs with many parallel-able loops. Hence the GPU acceleration should be applied to heavy and repeated tasks. However, logical transaction functions of GPU are limited, i.e. GPUs can not substitute CPUs. Within our heterogeneous MapReduce node, CPU is in charge of program control, task distributing and I/O accessing, when GPU is responsible for intensive computing. CPUs and GPUs cooperate to accomplish a data- and compute-intensive application. We call it a heterogeneous computation cluster.

This method would help us evaluate the ideal performance improvement, which can be used to make initial decision about whether we would take advantage of GPU acceleration. However, the program should satisfy prerequisites of utilizing parallel acceleration.

3.2 Prerequisites of parallel acceleration

Analyzed from characteristics of SIMD and our experiments, prerequisites of utilizing GPU acceleration can be concluded as follows:

- The program contains many and/or high-dimensional loops: The amount of cycle number of loops should be far more than the number of CPU cores and close or greater than the number of concurrent threads in GPU. If the cycle number is too small, the loss outweighs the gain because the parallel environment context also needs time to initialize. But too big cycle number is not recommended either, e.g., the disparity between concurrent threads number and cycle number is larger than one order of magnitude. For this case, it should be considered about multi-GPUs or even larger cluster.
- There is no complex condition branches inner loop code: Flow-control-heavy tasks are not fit for GPUs. The performance loss caused by frequently cut-off between GPUs and CPUs can not be ignored either.
- The data dependency should be low enough: Ideal condition is that there is no synchronization or data dependency across iterations. In this case, we can gain fully data parallel. If this constrain can not be perfectly satisfied, there must be a tradeoff between the program complexity and performance improvement.
- Task type: Numerical calculation, text or graph processing are recommended.

First three are necessary conditions, when the last is an additional condition. If all can be well satisfied, then the GPU can play its most powerful effect.

3.3 The Algorithm of Performance Test

We have performed 3 kinds of experiments, including Matrix Multiply, String Match and KMeans [10], which are compute-intensive or data-intensive. Here we describe a typical test case which is both data-intensive and compute-intensive.

First, the algorithm description is given here:

LineFilter*: The input data is a very big text file (1GB, 10GB… 1TB), each line of which is consisted by 512 random digit from 0 to 9. For each group of five digits, it needs to calculate the medium value, and then substitute it to the first digit of the group. Keep doing this until the end of this file. Then statistics that how many the two adjacent numbers` difference is greater than 5. The results should be stored in an output file.*

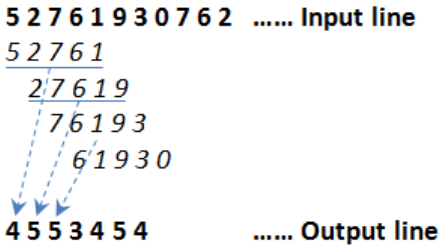

Figure 4. A Sample of DataTestMap

And here is the pseudo code:

Algorithm LineFilterMap:

```
LineFilterMap(key lineOffset, value line)
   line = data_formate(line)
    do until  the end of this line
    {
       for each line[j]…line[j+4] belong
to this line
```

```
      result = (line[j] + line[j+1] +
               line[j+2] + line[j+3] +
               line[j+4]) / 5
      line[j] = result
   }
   write(key, line)
```

Algorithm LineFilterReduce:

```
lineFilterReduce (key lineOffset, value
line)
   do untile  the end of this line
   {
      for each line[j]
      if( abs(line[j]-line(j+1))>=5)
num++
   }
   write(lineOffset, num)
```

This test is analog to the smoothing operation in digital image processing, which is a typical data- and compute-intensive task.

In the *lineFilterMap* function, there is a 1-dimensional loop, which will be executed 512 times in linear on one compute-core. However, it can be founded that the sub-dataset is not intersectional between each loop. That is data independence. This fine characteristic permits that it can be executed in parallel.

3.4 Implementation details

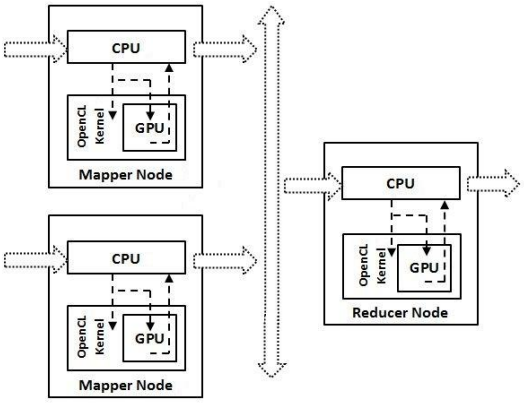

Figure 5. The Data Flow of the Architecture

When performing the GPU-accelerated program design, one of the most important questions is deciding which part of the program should be assigned to GPUs. Hence, we provide our recommended program design principal according to our experiments.

Responsibilities of CPUs are concluded as follows:

- Program control: Main frame of a MapReduce program.
- Tasks distributing: Launching the compute-intensive part to the GPU, including initializing OpenCL context, kernels establishing, data interchange between host memory and device memory, and OpenCL objects collection.
- Data accessing: I/O operations, including data accessing from local disk or distributed file system.

In our implementation, we suggest that a map or reduce task should be executed by several CPU threads, and each single CPU thread will spark lots of GPU threads. The programmable units of the multi-core CPU follow a Multiple Instruction, Multiple Data (MIMD) programming model. These few heavyweight but multifunctional CPU threads can execute much more complex tasks.

Comparatively, the functions of Kernels are much simpler. GPU focuses on intensive computing and efficiency. Considering the performance, there should be not any I/O operations in Kernels. For the same reason, the frequency of data transfer between host memory and device memory should be designed as low as possible [18].

The real process of *LineFilter* program is demonstrated as follows:

When the context of Hadoop-MapReduce runtime is initialized in the whole cluster, each data node (or *TaskTracker*) has got its task and data. In each Map program, there are two CPU sub-threads in Map function: First is to initialize the OpenCL platform context; another is to format input data into the form that can be processed by GPUs. When these two sub-threads have been done, the OpenCL kernel program begins to run on GPU. All these GPU computation results will be pushed into a high-bandwidth device buffer cache in parallel. Then, the results will be written to local disk.

Part of the Map Kernel:

```
int iGID = get_global_id(0);

if (iGID >= numElements)  {

      return;

} else {

   result[iGID] = ( a[iGID] + b[iGID] +
         c[iGID] + d[iGID] + e[iGID] )/ 5;

}
```

Next step is processing the massive intermediate outputs. Facing more than 2000000000 lines data, it is really a big job. However, with 3 Reduce nodes and 1000 threads per node running in our experiment environment, this scale is reduced to be less than 67000. The structure of Reduce function (lineFilterReduce) is similar to the Map function. It also

include OpenCL acceleration, however, if the Reduce node is coincidentally also the Map node, the time of OpenCL context initializing has been designed to be saved, since the kernel function of Reduce is integrated into the kernel file, and that is also initialized when the Map function is started.

4 Experiments

For getting an intuitionistic comparing between the native MapReduce and our improving, experiments have performed.

4.1 Experiment environment

The experiment environment is deployed on a 7 nodes cluster of DELL commodity PCs. The cluster statistics are:

- 7 nodes and 3 nodes per a rack
- 1 dual core Xeons @ 2.0Ghz per a node
- 2G RAM per a node
- 1 ATI Radeon HD 5450 GPU per a node
- 1 SATA disk per a node
- 1 Gigabit Ethernet on each node
- 8 Gigabit Ethernet uplinks from each rack to the core switch
- Ubuntu11.10 Enterprise Linux Server
- Oracle Java JDK 1.7.0_01-b08
- Hadoop 0.20.203
- OpenCL 1.1

Performance and compatibility are the main considerations. For the purpose of reaching a native performance, the Hadoop framework in this test is deployed on bare nodes without virtualization or hypervisor. The distributed file system is also the native HDFS.

Since the Java language is the best practice in Hadoop programing, for achieving a better seamless-integration, we select an Java language binding (JOCL) of OpenCL to integrate these two frameworks together. JOCL use Java Native Interface (JNI) to call the kernel program that drives the GPUs. Mixed programming guarantees their well-integrated meanwhile the performance loss will be the least.

4.2 Results

Under the different orders of magnitude, we have completed 5 groups of experiments. The MapReduce program with GPU acceleration is denoted by *MRCL*. Each group includes the performance comparison: the native MapReduce program, denoted by *MR*. Each group has been run for 5 times. The average value is recorded. Final result of experiment 1 is listed as follows:

TABLE I. RESULTS OF EXPERIMENT 1 ON DIFFERENT INPUT SCALE

Input Scale	Performance		
	MR Elapsed time	***MRCL Elapsed time***	***Sp***
1GB	3m:26s:159ms	2m:8s:373ms	1.606
10 GB	16m:51s:073ms	9m:12s:507ms	1.797
100 GB	53m:03s:112ms	28m:17s:331ms	1.875
1 TB	223m:39s:581ms	115m:59s:026ms	1.942

As is shown in this table, the speedup is all greater than 1.6 and it is gradually close to 2 with the input scale`s increasing. However, the program in this test only contains a 1-dimentional loop. If there are more high-dimensional loops, we can expect an even larger speedup.

Furthermore, in all test cases of experiment 1, the map function gets only one line of data each time. It is the simplest manner, but it is not the best practice. Because it will lead to "GPU hunger" and the overhead caused by frequent data transmission by PCI-E is considerable. A better choice is to submit more data per time, e.g. 5 lines each batch. But this number is not the more the better. Hence, we perform the second experiment to quest the optimized number of batch submission to GPU.

We override the RecordReader class of Hadoop framework. Then we perform the experiment 2 under 1 GB input scale. In figure 6, we can find that the best case appears when 3 lines (3×512 bytes) of data are submitted to GPU per one batch.

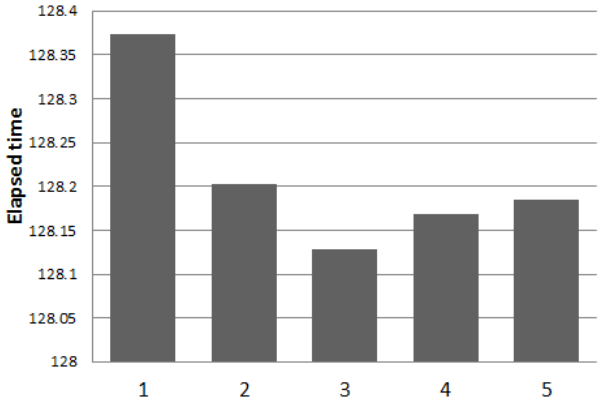

Figure 6. The comparison of elspsed time in different batch

We therefore perform the experiment 1 again (denoted by experiment 3) using the new *RecordReader* class. Figure 7 shows the peak speedup of experiment 3 is 1.959.

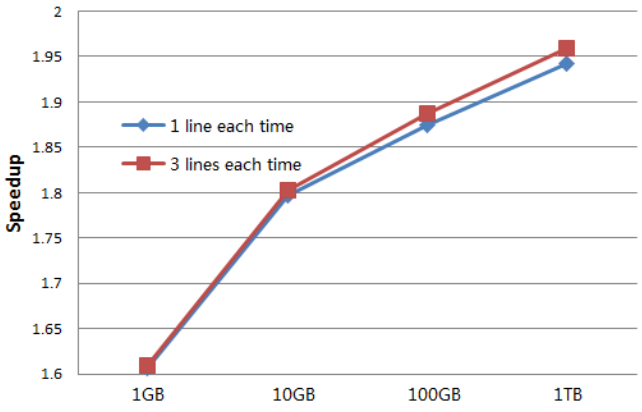

Figure 7. Performance Speedup of the Experiment 3 over the Experiment 1 counterpart.

It has to be noted that, to obtain an original contrast, there is not any special optimization in MRCL program. The structure of MRCL program is almost the same with the MR program except the part of GPU acceleration. That means there is still considerable improvement space.

5 Conclusions

Big data processing requires both high-capacity distributed storage and higher cluster computing performance. In this paper, we proposed an approach to take advantage of GPUs for reaching a higher single-node performance. An outstanding feature is that it is platform independence and can be seamless-integrated with existing framework. Utilizing Hadoop and OpenCL, a low-cost computing cluster can achieves more powerful computing capacity. With an almost 2 times performance improvement, we can expect it will be applied in both data- and compute-intensive applications.

Current work is still the technology demonstration, which has validated the feasibility of this technology roadmap. Future work will be focused on framework integration for the ease of development and farther performance improvement.

A top-down algorithm for clustering in large-scale distributed networks

A. Bui, S. Clavière and D. Sohier
PRiSM Laboratory, CNRS, Université de Versailles St-Quentin en Yvelines, Versailles, France

Abstract— *In this article, we propose a distributed top-down clustering algorithm for large-scale systems subject to topological changes. The objective of this clustering is to divide large systems into smaller subsystems on which distributed algorithms can be executed efficiently. The main parameter of distributed algorithms complexity is the size of the system, which leads us to focus on bounded-size clusters. Top-down approach allows us to build a cluster naming from which we derive an efficient inter-cluster routing scheme. Clusters are built by a token moving from node to node according to a random walk scheme. When the cluster reaches a maximal size defined by a parameter K, it is divided (when possible) and tokens are created in both of the new clusters. The new clusters are then built and divided in the same fashion. A spanning tree is built during the construction. These spanning trees, together with the edges along which clusters have been divided, constitute a spanning tree of the system, which allows routing thanks to a consistent routing scheme. In a dynamic system, the clustering may be divided into two disjoint structures. This is also the case when multiple initiators begin the clustering process. When two structures meet, one is "adopted" by the other. This adoption mechanism allows the clustering to adopt transparently to topological changes*

Keywords: Distributed algorithms, hierarchical clustering, bounded-size clusters, dynamic graphs, random walks

1. Introduction

Large-scale distributed systems raise new challenges to distributed computing. In this paper, we focus on dividing a large-scale distributed system into smaller subsystems that can be managed separately and coordinated. We are willing to compute size-oriented clusterings: given a target size K which is a parameter of the algorithm, clusters should all have size roughly K. More precisely, we would like that all clusters are connected and have a size between K and $2K$ (allowing for a process considering only one cluster to detect when it is too large and to fix it).

However, such a clustering cannot be achieved on some topologies. Consider for instance a star graph on $M > 2K$ nodes. The central node is in a cluster $\mathcal{C}$. Then, either all nodes are in $\mathcal{C}$, which breaks the requirement, or some clusters are of size 1, which is also contradictory to the specification. This is why we introduce the notion of divisible cluster: a cluster is divisible if can be divided into two connected clusters of size greater than K. The clustering we are computing is such that all clusters are of size greater than K, and none is divisible. It can be seen as a distributed approximation of a clustering with all clusters of size K.

Since the algorithm is based on the size of clusters, each cluster must be *"aware"* of its size. Thus, nodes should be recruited one by one, and to model this, we use a recruitment token. The token must follow a traversal scheme to ensure that all nodes can be recruited. Since no assumption is made on the topology of the system and the topology is unknown and possibly dynamic, we use a random walk traversal scheme [14]. Properties of random walks allow to design a traversal scheme using only local information and to ensure local load balancing; such a scheme is not designed for one particular topology and needs no adaptation to fit other ones [6], [9]. In the course of its walk, the token builds a spanning tree of the cluster which it uses to divide the cluster when required. This tree is also the basis for routing messages in the cluster, and between clusters.

Each cluster is then represented by its recruitment token, that stores all information relevant to it (in particular, this spanning tree and inter-cluster routing information).

Thus, the walk recruits unclustered nodes and maintains an adaptive spanning tree of them, until it reaches size $2K$. At this point, the token holder checks whether the tree is divisible, and if it is the case, divides the cluster. Since the spanning tree is adaptive, if the cluster is divisible, the tree is eventually divisible too. The division process is carried out by the propagation of a wave on the spanning tree. Each node changes its cluster id accordingly, and the roots of the two subtrees create new tokens, while the former one is discarded. The edge along which the division was performed is recalled by nodes of both clusters, and will be used for inter-cluster routing. We call these edges inter-cluster routing edges (ICRE in the following).

This algorithm is top-down. This choice allows us to design a naming scheme for clusters to efficiently route messages between clusters. Each cluster has a name in $(0|1)^*$. During a division, the resulting clusters take the name of the divided cluster, and add a 0 or a 1 at the end. Thus, two clusters the names of which differ only by their last bit are siblings, and know a link to each other. They may be further divided, but one of the descendants of each of them will keep track of this link, thus allowing inter-cluster routing. Other descendants will recall which sub-cluster holds this link.

Clusters are named in the course of the divisions: initially, an initiator node starts building cluster 1. When a cluster with id x is divided, it leads to two new clusters, one named $x0$, and the other $x1$. x is then used as a name for the union of clusters $x1$ and $x0$; A cluster x is called *elementary* if $x0 = \emptyset$ and $x1 = \emptyset$. A non elementary cluster is called a *virtual cluster*. All clusters belonging to the same (virtual) cluster 1 form a *structure*. In a structure, the level of a cluster is the length of its id.

This naming scheme, together with the inter-cluster routing edges computed during the divisions, provide the basis for inter-cluster routing. The set of all cluster tree edges and inter-cluster routing edges form a spanning tree of the structure.

In the event of a topological change, if this change does not affect a cluster tree or an inter-cluster routing edge, the algorithm goes on unaffected. If the change discards a cluster tree edge or a inter-cluster routing edge (for instance, if a clustered node disappears), we have no structure spanning tree any longer, and we cannot guarantee that the structure is connected. Then, the structure is divided into two: a wave is broadcast along its tree allowing a consistent renaming of clusters.

In such a situation, or when there are several initiators, several structure grow in parallel. To ensure communication between their clusters, they have to be merged. This is realized by making one of them *"adopt"* the other. To avoid mutual adoption, a total order between structures is introduced (based on the ids of the nodes in their first division edge). When a walk in the weaker structure reaches a node in the stronger one, it broadcasts an adoption wave on its structure to make it a substructure of the stronger structure. More precisely, if the walk hits a node in cluster x, cluster x is renamed $x0$, and all clusters in the adopted structure add x as a prefix to their cluster name, so that the adopted structure becomes the $x1$ substructure of the structure.

All communications that occur inside a structure during an absorption process are carried out transparently.

1.1 Routing in a binary hierarchy of named clusters

For the sake of simplicity, we do not distinguish between a cluster and its id.

We consider a binary hierarchy of clusters such that:

- all nodes have a binary cluster id (clusters $x0$ and $x1$ are called siblings; their reunion, with id x, is called their parent);
- nodes with a given cluster id prefix form a connected subgraph;
- each elementary cluster (ie cluster with no sub-cluster) has a spanning tree (local tree in the following);
- given a non-elementary cluster x, there exist a node i in $x0$ and a node j in $x1$ such that i and j are neighbors, and all nodes in $x0$ are aware of $(i(x0y), j)$ with $x0y$ a cluster to which i belongs, and all nodes in $x1$ are aware of $(j(x1z), i)$ with $x1z$ a cluster to which j belongs; we call (i, j) and inter-cluster routing edge.

The algorithm proposed in the next section, once all nodes are clustered in the same structure, provides such a binary hierarchy of clusters. For a more detailed explanation of the routing scheme below, see [7].

The set of edges of the local trees and of inter-cluster routing edges forms a spanning tree of the system, we call the global tree. It contains at most $n-1$ edges, since the local tree of a cluster of size k has $k-1$ edges, and each cluster shares one ICRE with its sibling; affecting the ICRE to the sibling that has not been affected the upper level ICRE, each elementary cluster has k edges except for one (the highest level ICRE is affected to only one of the highest level siblings). Hence there are $n-1$ edges in this subgraph.

We show in the following that routing can be achieved through the global tree, which proves that it is connected, and thus a tree.

Consider two different clusters x and y. Let z their longest common prefix (at worst, $z = 1$). Then, $x = zt$ and $y = zu$. By definition of z, u and t begin with different bits. Assume for instance that $t = 0t'$ and $u = 1u'$. Then, to route a message from x to y, we will first route it to $z1$. All this routing, except for its last step, will take place in $z0$. Once the message is in $z1$, either it is in y and the process is finished; or it is not, and then the same process will be used, but inside $z1$. This guarantees the progression of the process, and that the message is eventually delivered to the intended cluster.

To route the message to $z1$, the node looks at its ICREs. Consider $(i(z0v), j)$ the ICRE to $z1$. If $z0v = x$, then i is in x, and the local tree allows to compute a path to it. If $z0v \neq x$, then the message has to be routed to $z0v$. The longest common prefix between x and $z0v$ is longer than z, which allows to run this algorithm recursively.

No edge is used twice in this routing process; thus this routing process is a compact version of the routing tables that can be deduced from the global tree.

1.2 Related work

The algorithms of [4], [8], [12], [13] produce clusters with radius one. Each cluster has a node called a *clusterhead*, and all other nodes in that cluster are neighbors of the clusterhead. Clusters can be built using a hierarchical method: the clustering algorithm is iterated on the overlay network obtained by considering clusters as nodes, until a single cluster is obtained [11], [15], [17]. These solutions are bottom-up processes while we propose a top-down approach [16]. The algorithms in [5], [9] are based on random walks. In [9], the clusters are built around bounded-size connected dominating sets. In [5], the algorithm recursively breaks the network into two clusters as long as every cluster satisfies a lower bound.

The solution given in [3] builds k-hop clusters (clusters of radius k) and in [10], a self-stabilizing – a self-stabilizing system is a system that eventually recovers a normal behaviour after a transient fault – a $O(n)$-time algorithm is given for computing a minimal k-dominating set; this set can then be used as the set of clusterheads for a k-clustering.

1.3 Outline

Section 2 presents the algorithm. First, we present the mechanisms involved in the management of static networks with a unique initiator. Then, we present the reactions of the algorithm to topological changes. Last, we present the way to deal with multiple initiators building multiple structures, and how the algorithm merges them.

Section 3 gives a sketch of the proof of this algorithm, following the same progression.

In section 4 are provided some results on the complexity of this algorithm.

We conclude this paper by giving some conclusions and perspectives.

2. Algorithm

We consider a distributed system as an undirected connected graph $G = (V, E)$, where V is a set of nodes with $|V| = n$ and E is the set of bidirectional communication links with $|E| = m$. A communication link (i, j) exists if and only if i and j are neighbors. Every node i maintains a set of its neighbors ids denoted by N_i.

P_i is the id of the cluster the node i belongs to. Initially each node i sets $P_i = 0$ to indicate that it has not yet joined a cluster. These node are then qualified of *unclustered* node.

$Parent$ is an array describing the spanning tree of a cluster: $Parent_i[j]$ is the parent of j as known locally by node i; note that $Parent_i[i]$ is the current parent of node i, since a node changes its parent only when receiving the token, and then updates its $Parent$ array. Initially, each node i sets $Parent_i[j] = \perp$ for all j in V.

$ICRE_i$ is an array on node i containing all inter-cluster routing edges relevant to the cluster: consider $(a(x), b)$ as the k-th entry of $ICRE_i$. x is a prefix of a's cluster id. The route to the cluster with id consisting in the first $k-1$ bits of the name of the current cluster, and the k-th bit different goes through edge (a, b); to reach this edge, one must first route the message to x.

In the following, $ICRE[0]$ is used as a structure identifier to break symmetries (since it is known by all nodes in the structure). Before the first division, since this $ICRE$ is not yet defined, we set $ICRE[0]$ to the id of the initiator of the structure. The ordering is the following: a structure that not yet been divided is always smaller than one that has been; for structure that have been divided, $(i, j) < (i', j')$ iff $\min\{i, j\} < \min\{i', j'\}$.

Each time a division occurs, an ICRE is created, and the set of all ICRE creates a spanning tree of the clusters. The union of ICREs and cluster tree edges is thus a spanning tree of the whole structure, in which messages are routed.

All algorithms below are described on node i. The emitter of the message is triggering the algorithm is e.

2.1 Initialization

Nodes wake up either spontaneously, or upon reception of a message. If they wake up spontaneously, they are initiators and execute the following code.

Algorithm 1 On waking up (initiator)

1: $Parent_i[i] \leftarrow i$
2: $ICRE_i \leftarrow \{i\}$
3: $P_i \leftarrow 1$
4: Send $Token(P_i, Parent_i, ICRE_i)$ to $k \in N_i$ chosen at random
5: $Parent_i[i] \leftarrow k$

An initiator creates its cluster, with id 1, and sends a token message to one of its neighbors according to the random walk scheme. Then, it updates its local copy of the spanning tree $Parent$, taking into account that the node they sent the token to will be its parent as soon as it receives the token (see algorithm 2).

2.2 On reception of Token messages inside a structure

a) Algorithm 2: On reception of a Token message (unclustered node, or node in the same cluster): When an unclustered node receives a token, or a node receives a token from its own cluster, it joins the cluster, updates the spanning tree, checks its consistency with local topology (see 2.4), checks if the cluster should be divided with function $isDivisible$, and, in this case, initiates the division process, and sends the token to a random neighbor.

Function $isDivisible(Parent)$ returns either a node id corresponding to the root of one the subtree of tree $Parent$ which is divisible or -1 if tree $Parent$ is not divisible into two subtrees of size $\geq K$. The division process is detailed in section 2.3, in particular message $Child0$ and function $Sub0$ are defined.

Algorithm 2 On reception of *Token* $[P_t, Parent_t, ICRE_t]$ message with $P_i = 0$ or $i \in Parent_t$

1: **if** $P_i = 0$ **then**
2: {Join the cluster.}
3: $P_i \leftarrow P_t$
4: $ICRE_i \leftarrow ICRE_t$
5: **end if**
6: {Update cluster tree.}
7: $Parent_i \leftarrow Parent_t$
8: **if** $Parent_i[e] \neq \perp$ **then**
9: {$Parent_i[e] = \perp$ means that the token has been bounced by e which then does not belong to the cluster, see algorithm 3}
10: $Parent_i[e] \leftarrow i$
11: **end if**
12: $Parent_i[i] \leftarrow i$
13: {The next instruction is a call to Algorithm 7 checking if a topological change has outdated the spanning tree}
14: $LocalCheck()$
15: {Check whether the cluster is divisble, and initiates the division if necessary}
16: $d \leftarrow isDivisible(Parent_i)$
17: **if** $d \neq -1$ **then**
18: $P_i \leftarrow P_i.0$
19: **for all** $k \neq i$ such that $Parent_i[k] = i$ **do**
20: Send $Child0[Parent_i, d]$ to k
21: **end for**
22: $(Parent_i, ICRE_i) \leftarrow Sub0(Parent_i, ICRE_i, d, P_i)$
23: **end if**
24: {The walk resumes, and the node stores the next node it will visit}
25: Send $Token[P_i, Parent_i, ICRE_i]$ to k chosen at random in N_i.
26: $Parent_i[i] \leftarrow k$

b) Algorithm 3: On reception of a Token from a different cluster in the same structure: When receiving a token from another cluster in the same structure (two nodes i and j are in the same structure if $ICRE_i[0] = ICRE_j[0]$), the node ignores it and sends it back if the cluster is already of size greater than K. If the cluster is smaller than K (following a topological change), it should be deleted. The treatment of the message $Endcluster$ is given by Algorithm 8.

Algorithm 3 On reception of *Token* $[P_t, Parent_t, ICRE_t]$ message with $i \notin Parent_t$ and $ICRE_i[0] = ICRE_t[0]$

```
if |Parent_t| < K then
    Send EndCluster[e] to e
else
    Send Token[P_t, Parent_t, ICRE_t] to e
end if
```

2.3 Division

The division of a cluster along edge (k, j) is carried out through a wave on the tree: all nodes above j receive $Child0$ messages and switch to cluster $P.0$; all nodes in the subtree rooted in j receive $Child1$ messages and switch to cluster $P.1$. j receives a $Child0$ message and propagates $Child1$ messages to its descendants; then, it creates its new cluster token.

During a division, the list of ICRE has to be updated. Consider a cluster with id x, with an ICRE (a, b). Then, a is only in one of the sub-clusters, for instance $x0$. Then, $x0$ keeps the ICRE (a, b), and $x1$ updates its ICRE list by listing $(a(x0), b)$, meaning that to reach the ICRE (a, b) from $x1$, one must first send the message to $x0$.

Functions $Sub0$ and $Sub1$ compute the subtrees of the tree given as an argument obtained by removing the edge between node j (third argument) and its father. $Sub0$ computes the top subtree and $Sub1$ the bottom. The ICRE list is updated as explained above.

Top subtree

Algorithm 4 On reception of $Child0[Parent_t, j]$ message

```
if i ≠ j then
    P_i ← P_i.0
    for all k such that Parent_t[k] = i do
        Send Child0[Parent_t, j] to k
    end for
    (ICRE_i) ← Sub0(Parent_t, ICRE_i, j, P_i)
else
    P_i ← P_i.1
    for all k such that Parent_t[k] = i do
        Send Child1[Parent_t, j] to k
    end for
    (Parent_i, ICRE_i) ← Sub1(Parent_t, ICRE_i, j, P_i)
    Send Token[P_i, Parent_i, ICRE_i] to k ∈ N_i chosen at random
end if
```

Bottom subtree

Algorithm 5 On reception of $Child1[Parent_t, j]$ message

```
P_i ← P_i.1
(ICRE_i) ← Sub1(Parent_t, ICRE_i, j, P_i)
for all k such that Parent_t[k] = i do
    Send Child1[Parent_t, j] to k
end for
```

2.4 Topological changes

c) Algorithm 6: Topological change detection: The parent of a node i in the tree is $Parent_i[i]$. When a node detects that its parent is no longer a topological neighbor, it initiates the destruction of the cluster subtree rooted in it, since the cluster may not be connected anymore. The token is necessarily on the other side of the tree.

Algorithm 6 On failure of the link $(i, Parent_i[i])$

```
DestroyCluster()
```

The $LocalCheck$ procedure (*cf.* algorithm 7) checks the consistency of the tree with local topological information. If a node listed as a child of the current node in the tree is not one of its neighbors, the subtree rooted in the node that is no longer a neighbor is deleted from the tree. This may lead to the loss of some ICRE. In this case, $EndGate$ messages are propagated to make the structure consistent. If the cluster is smaller than K, either it grows and reaches size K, or it is eventually deleted (Algorithm 3).

Algorithm 7 $LocalCheck()$

```
for all (j ≠ i such that (Parent_i[j] = i) ∧ (j ∉ N_i)) do
    Parent_i ← Sub0(Parent_i, ICRE_i, j, P_i)
end for
for all (j such that (((l(P_i), j) ∈ ICRE_i)) ∧ l ∉ Parent_i) do
    {(l(P_i), j) is listed as an inter-cluster routing edge with l in the cluster, but l is not in the cluster}
    {Update local structure.}
    for all k ≠ i such that Parent_i[k] = i ∨ (i(P_i), k) ∈ ICRE_i do
        Send EndGate[(l, j), i] to k
    end for
    (P_i, ICRE_i) ← Prune((l(P_i), j), i)
end for
```

d) Algorithm 8: On receiving an *EndCluster*$[Node]$ message: $EndCluster$ messages are used to propagate the deletion of a cluster. If the message comes from its father, a nodes leaves its cluster. If the message comes through an ICRE, then the node updates its ICREs.

Algorithm 8 On reception of *EndCluster*$[Node]$ message

```
if Parent_i[i] = e then
    DestroyCluster()
else if ∃j/ICRE_i[j] = (i, Node) then
    UpdateGate(j, i)
end if
```

To propagate the destruction of its cluster (that can be initiated only by the token holder, ie the tree root), a node sends $EndCluster$ messages to its children in the tree and to nodes to which it is linked by an ICRE (so that they can update their ICRE list). Then it leaves the cluster and falls asleep. It will wake up when it receives a message, or spontaneously.

Algorithm 9 DestroyCluster()

1: **for all** k such that $Parent_i[k] = i \vee (i(P_i), k) \in ICRE_i$ **do**
2: {Propagate the changes in cluster.}
3: Send *EndCluster*$[i]$ to k
4: **end for**
5: $P_i \leftarrow 0$
6: Fall asleep

$UpdateGate$ (*cf.* algorithm 10) updates the ICRE list to take into account the loss of edge $ICRE_i[j]$. To do so, $EndGate$ messages are propagated on the structure tree, and a call to $Prune$ suppresses all unreachable edges in the ICRE list.

Algorithm 10 UpdateGate(j,n)

1: **for all** $k \neq e$ s.t. $Parent_i[k] = i \vee Parent_i[i] = k \vee (i,k) \in ICRE_i$ **do**
2: {for all neighbors in the structure tree}
3: Send *EndGate*$[ICRE_i[j], n]$ to k
4: **end for**
5: $(P_i, ICRE_i) \leftarrow Prune(ICRE_i[j], n)$

e) Algorithm 11: On receiving an *EndGate*$[ICRE, n]$ message: When receiving an $EndGate$ message, if the missing edge appears in the node ICRE list, the node updates its list to take into account the loss of this edge.

Algorithm 11 On reception of *EndGate*$[ICRE, n]$ message

1: **if** $(\exists j / ICRE_i[j] = ICRE)$ **then**
2: UpdateGate(j,n)
3: **end if**

2.5 Merge process

f) Algorithm 12: Initiation of a Merge process: When a node in a structure receives a token from a structure with a lesser id, the latter is absorbed in the node structure. A wave is propagated on the absorbed structure to add the name of the absorbing cluster as a prefix of all clusters name, and a wave is propagated on the absorbing cluster to add 0 as postfix to its name. The link along which the token was sent is added as an ICRE.

To trigger a Merge process, both structures must have been divided (P_t ,$P_i \neq 1$). Else, if the cluster t is smaller than K or his structure has not yet been divided, it should be deleted; to avoid mutual deletion, we use the id of the node that initiated the cluster to break symmetry.

Algorithm 12 On reception of $Token[P_t, Parent_t, ICRE_t]$ message with $P_i \neq 0$ and $ICRE_t[0] \neq ICRE_i[0]$

1: **if** P_i, $P_t \neq 1$ and $|Parent_t| > K$ **then**
2: **if** $(ICRE_t[0] < ICRE_i[0])$ **then**
3: {Absorption process.}
4: $ICREtmp \leftarrow ICRE_t$
5: $append((i(P_t.P_i), e), ICREtmp)$
6: $append(ICRE_i[0], ICREtmp)$
7: **for all** $k \neq e$ s.t. $Parent_i[k] = i \vee Parent_i[i] = k \vee (i(P_i), k) \in ICRE_i$ **do**
8: Send *Absorb*$[ICREtmp, P_t]$ to k
9: **end for**
10: $(P_i, ICRE_i) \leftarrow IRCEUpdate(P_t, ICREtmp)$
11: $P_t \leftarrow P_t.0$
12: $append((e(P_t.0), i), ICRE_t)$
13: Send $Changes[Parent_t, (e(P_t.0), i)]$ to e
14: **end if**
15: Send $Token[P_t, Parent_t, ICRE_t]$ to e
16: **else if** $|Parent_t| < K$ or ($P_t = 1$ and ($P_i \neq 1$ or $ICRE_i[0] < ICRE_t[0]$)) **then**
17: {Token structure is not large enough to be absorbed}
18: Send *EndCluster*$[e]$ to e
19: **else**
20: {Token structure large enough to be involved in merge processes}
21: Send $Token[P_t, Parent_t, ICRE_t]$ to e
22: **end if**

g) Algorithm 13: Propagation of a merge (absorbing cluster): $Changes$ messages are propagated in the absorbing cluster to make all nodes update their cluster name and take into account the new ICRE.

Algorithm 13 On reception of $Changes[Parent, ICRE]$ message

1: $P_i \leftarrow P_i.0$
2: $append(ICRE, ICRE_i)$
3: **for all** k such that $Parent[k] = i$ **do**
4: {Propagate the changes in cluster.}
5: Send $Changes[Parent, ICRE]$ to k
6: **end for**

h) Algorithm 14: Propagation of a merge (absorbed cluster): $Absorb$ messages are propagated in the absorbed structure so that all nodes in it prepend the identifier of the absorbing cluster to their cluster name. The procedure *Prefix*$(P, ICRE_1, ICRE_2)$ returns a prefix of P of length i such as $ICRE_2[i] = ICRE_1[|ICRE_1| - 1]$. It is used to break symmetry between two absorptions from the same structure.

Algorithm 14 On reception of *Absorb*$[ICRE, P_1]$ message

1: **if** $(\exists y : ICRE_i[y] = ICRE[|ICRE|-1]) \wedge ((ICRE[0] < ICRE_i[0]) \vee ((ICRE[0] = ICRE_i[0]) \wedge (P_1 < Prefix(P_i, ICRE, ICRE_i))))$ **then**
2: {Absorption.}
3: **if** $(y \neq 0)$ **then**
4: {Cancel previous absorption.}
5: **if** $(\exists k \in N_i$ such that$(i(P_i), k) = ICRE_i[y-1])$ **then**
6: Send *EndGate*$[(k, i), k]$ to k
7: **end if**
8: $(P_i, ICRE_i) \leftarrow Prune(ICRE_i[y-1], i)$
9: **end if**
10: **for all** $k \neq e$ such that $Parent_i[k] = i \vee Parent_i[i] = k \vee (i(P_i), k) \in ICRE_i$ **do**
11: Send *Absorb*$[ICRE, P_1]$ to k
12: **end for**
13: $(P_i, ICRE_i) \leftarrow IRCEUpdate(P_1, ICRE)$
14: **end if**

Procedure *Prune*$(Edge, j)$ deletes in $ICRE_i$ all ICREs rooted in the node k such that $ICRE_i[k] = Edge$. When an entry is deleted, the corresponding bit in identifier P_i is deleted. The new identifier P_i and the new structure $ICRE_i$ are returned. j is added in $ICRE_i$ if it is empty. j is the identifier of the node who has detected the missing edge.

For example, in cluster 110110, node 209 detects a missing link with node 40. This link is the edge for the fourth level (a, edge between 11011 and 11010). With its *Token* (or a local copy), node 209 knows a subtree rooted by edge $(209, 40)$. It can delete all unreachable levels. For instance, if

$Parent_{110110}$:

1	4	5	6	11	16	209
4	209	4	5	209	11	209

$ICRE_{110110}$:

$(1_{(110110)},12)$	**$(14_{(1101)},3)$**	$(2_{(110111)},30)$	**$(209_{(110110)},40)$**	$(6_{(110110)},7)$

after the application of $Prune$, we obtain for cluster 1110:

$Parent_{1110}$:

1	4	5	6	11	16	209
4	209	4	5	209	11	209

$ICRE_{1110}$:

$(1_{(1110)},12)$	$(2_{(1111)},30)$	$(6_{(1110)},7)$

Procedure *ICREUpdate*$(P_1, ICRE_1)$ returns the new identifier and the new structure of an absorbed cluster after an absorption.

- All edges $(n_1(x), n_2)$ in $ICRE_i$ are replaced by $(n_1(P_1.x), n_2)$;
- $P_i \leftarrow P_1.P_i$;
- For all $j < |ICRE_1| - 2$ such as $ICRE_1[j] = (n_1(P_1), n_2)$ do $ICRE_1[j] \leftarrow (n_1(P_1.0), n_2)$;
- $ICRE_i \leftarrow ICRE_1 \cup ICRE_i$;

3. Sketch of proof

We give below a sketch of the proof of this algorithm.

3.1 Static network with unique initiator

A detailed proof of this algorithm in a static network with a unique initiator can be found in [7]. Below are given the lemmas that structure this proof. The following lemmas hold if no topological change occur.

Lemma 1: There is exactly one token in each elementary cluster.

Lemma 2: Once a node is in a cluster, it remains in it (possibly in its sub-clusters).

Lemma 3: $Child$ messages circulate only between nodes that are part of the cluster being divided. A $Token$ message either comes from a node in the $Token$'s cluster or is bounced back to it.

Lemma 4: Clusters are connected.

Lemma 5: Given a $Token$ message t, $Parent_t$ contains a spanning tree of the elementary cluster t rooted in the last node that held the token.

Lemma 6: If a division process is initiated, based on a broadcast on a tree, the cluster is eventually divided into two sub-clusters.

Lemma 7: Clusters are eventually steady.

Lemma 8: Eventually, all clusters are of size greater than K (provided that there are more than K nodes), and no cluster is divisible.

3.2 Topological changes

Lemma 9: The set of all edges (i, j) such that there is a token with $Parent_t[i] = j$ or $Parent_t[j] = i$ or $(i, j) \in ICRE_t$ is a spanning tree of the visited nodes.

In the sequel, we call structure the set of nodes that have been visited by a token or its descendants.

We now consider the various topological changes that may occur at any point during the execution of the algorithm.

Lemma 10: The apparition of a link has no effect on the algorithm, nor on the specification.

Lemma 11: The disappearance of a link that is not part of the tree described in lemma 9 has no effect on the algorithm, nor on the specification.

Lemma 12: The apparition of a node leads to a configuration corresponding to a possible execution of the algorithm.

Indeed, the same execution of the algorithm is possible on the graph with the extra node.

Lemma 13: After a link in a local tree has disappeared, nodes in the tree below this link are unclustered by algorithms 6, 8 and 9. Eventually, the $Parent$ variable of the $Token$ message (or of the $Token$ messages of children clusters) are corrected to be consistent with the current topology of the system. If the cluster does not reach a size over K, it is eventually deleted.

A node disappearing has the same effect as all its adjacent links disappearing (in particular, those that are part of the tree).

Lemma 14: If a cluster is deleted, its sibling takes the name of its father.

Lemma 15: After a topological change breaking the global tree into two, clusters are renamed consistently with the new global trees.

Lemma 16: After a topological change, the configuration eventually corresponds to a configuration resulting from the algorithm executed on a static network (possibly with multiple initiators).

3.3 Multiple initiators

Lemma 17: If several structures exist, eventually, a token from a weaker structure hits a stronger one (*"weaker"* meaning that the id of the top ICRE is smaller). The weaker structure then triggers its absorption into the other.

Lemma 18: A wave on the global tree of the absorbed structure and a wave on the local tree of the absorbing structure leads to a renaming consistent with a unique structure.

Lemma 17 does not exclude that several absorption are triggered simultaneously.

Lemma 19: In the case of several absorptions triggered simultaneously, only one is carried out.

4. Complexity

All elementary clusters have a size greater than K. Thus, there are less than n/K elementary clusters. Thus, the binary tree of clusters has n/K leaves: since it is a binary tree, its height is between $\log_2(n/K)+1$ and n/K. The building of clusters of disjoint subtrees is parallel. So the time complexity of this algorithm is the height of the clusters tree times the complexity of the building of a divisible cluster starting from a newly divided cluster.

A cluster resulting from a division has at least size K. Now, assume all connected subgraphs of size M in G are divisible. Then, if the cluster reaches size M, it is divisible, and will be divided as soon as its cluster tree is divisible itself. To reach size M (if $M-K$ unclustered nodes exist in its neighborhood), it takes less than the time for a random walk to cover M nodes, the expectation of which is between $O(M \log M)$ and $O(M^3)$.

If the tree is balanced, which should be the case for instance in random graphs, then the height of the tree is less than $\log_2(n/K) = O(\log_2(n))$. In this case, the complexity of the algorithm is $O(\log_2(n))$.

The reactions to topological changes, as well as the merging of different structures, imply waves on the local and global trees. If the global tree is balanced, the extra cost is less than $O(\log_2(n))$. These processes are transparent to a message routed in a sub-structure that is not affected by a topological change.

5. Conclusion

The top-down approach used in this algorithm allows to design a lightweight routing scheme based on the naming scheme. It also lets us devise an approximation of bounded-size clusters.

However, the management of multiple initiators requires then some extra procedure, that can be carried out transparently and efficiently thanks to spanning trees built in the course of the algorithm.

The main step to self-stabilization is to guarantee the existence and the unicity of the token of each cluster, thanks to a process like the one in [6], adapted to the case of random walks in clusters.

FPGA Based Physically Unclonable Functions and Neural Networks for Preventing Counterfeiting Problems

Swetha Pappala[1], Mohammed Niamat[1], and Weiqing Sun[2]
[1]Electrical Engineering and Computer Science, University of Toledo, Toledo, Ohio, USA
[2]Engineering Technology, University of Toledo, Toledo, Ohio, USA

Abstract - *Anti-counterfeiting technology/methods have entered a new era with the implementation of critical designs and confidential information transfer protocols. Manufacturing, assembly, and testing are now moving globally outside the company's facility to be done at contract manufacturers making the security of the critical design and information a top priority. According to the Anti-Counterfeiting Bureau, USA, counterfeiting and piracy costs the economy a loss of more than $250 billion in revenue and 750,000 jobs every year. To counter such threats, methodologies have been developed that require a unique signature key for every fabricated chip. Physically Unclonable Functions (PUFs) can be used for such signature generation. This paper presents a design for cryptographic applications that can be implemented on an FPGA taking advantage of its unique architecture. The first part of the research involves techniques for the generation of uniquely distinguishable responses from Ring Oscillator PUFs (ROPUFs) and the latter part involves error correction techniques using Artificial Neural Networks. The proposed design is implemented on several identical Xilinx Spartan FPGAs and the Hamming distances for the responses are computed and analyzed. The uniqueness of the responses is found to be 49.0625%. The results of the proposed Error Correcting Code also prove to be computationally better than the conventional BCH codes.*

Keywords: FPGA, PUF, Security, Error Correcting Code, Neural Network, Bidirectional Associative Memory.

1 Introduction

The complexity in developing security mechanisms and routing protocols for embedded systems continues to increase; on the other hand, cost and size constraints have been lowered. In this scenario, trustworthy authentication of a device is of extreme importance for secure protocols. The continuous increase in density and capability of FPGAs are motivating designers to implement valuable designs using FPGAs. With FPGAs being used in more and more applications that implement valuable designs, significant security features are required. Traditional methods of storing the identity of an object using non-volatile memory are insecure [1]. Hence, a concept of generating a unique digital signature has a wide range of applications in embedded systems security and IC piracy. Physically Unclonable Functions (PUFs) can be used as novel chip identifiers. PUF is a function which produces secret output response based on the underlying properties of a physical device while adhering to various properties based on the deployment and the level of security intended from the device.

PUFs exploit manufacturing process variations in a die to generate non-volatile chip unique signatures exploiting manufacturing process variations of FPGAs. They derive confidential information from uncontrollable random components rather than storing them in the memory. Lack of control over sub-micron process variation makes a PUF unclonable. This enables chip authentication and cryptographic key generation. These process variations are mainly due to the inability to precisely control the diffusion of dopants and due to the inability to robustly fabricate geometric features [1]. These variations result in key electrical parameters of circuit devices and interconnects that increase the uncertainty in the outcome of the design process. PUFs exploit these uncertainties to generate a device specific key.

The quality factor of a PUF, which includes uniqueness, reliability and attack resiliency, is negatively affected by factors like voltage fluctuations and environmental temperature [1]. These factors degrade the stability of the PUF signatures. Hence, an error correction method is necessary to stabilize the circuit. Conventionally, BCH (Bose-Chaudhuri-Hocquenghem) have been used for the error correction process. In this work, Artificial Neural Networks (ANNs) have been used. ANNs are a relatively new signal processing technology. They have a remarkable ability to learn and derive information from complicated and imprecise data that can be used to extract patterns. This characteristic property of ANN gives an advantage over the conventional error correcting codes such as BCH codes [2, 3].

Section II discusses the basic operation of the proposed ROPUFs. Section III discusses the concepts of supervised learning in neural networks and the application of these algorithms to correct the flipped bits in the PUF responses. Section IV concludes the paper.

2 Physically Unclonable Functions

There have been various implementations of PUFs and several sources of variation in silicon PUF. Silicon PUFs can be broadly classified as Memory-based PUFs [4], Delay-based PUFs (RO PUFs) [5, 6] and Glitch Count-based PUFs [7]. The RO PUFs have certain advantages over the other PUFs when implemented on an FPGA platform. Firstly, the implementations of ring oscillators are simplified and can be optimized while routing. Secondly, it has been experimentally observed that under a wide range of temperature fluctuations, RO PUFs are more stable and reliable [2]. Considering the above advantages, RO PUFs have been chosen for the key generation process followed by an error correction technique.

Ring Oscillator PUFs (ROPUFs) are based on variations in frequencies of identical oscillators to produce a secret PUF response. Figure 1 shows the basic principle of RO PUFs. Traditionally, RO PUFs exploit the fact that uncontrollable wire delays and voltage transfer characteristics due to fabrication process variations of FPGA devices cause random but static variations in the frequency of identically laid out oscillators. The response vector, in such PUFs, is generated by a pair-wise comparison of the ring oscillator frequencies. These comparisons are represented as the challenge-response pairs, where the chosen ring oscillator pair is the challenge and the output of the comparator is the response. For an RO PUF with N K-stage identical ring oscillators, there are *N*(N-1)/2* challenge-response comparisons [8]. The oscillators are designed to have identical layouts to ensure that the frequency variations between them are strictly due to process variations.

In this research, we propose a design to implement the RO PUFs on FPGAs using LUTs and multiplexers that are the basic components of FPGA architectures. Figure 2 shows an oscillator of the proposed RO PUF design. Multiple instances are instantiated to generate a multi-bit PUF signature. Two LUTs (LUT X and LUT Y) in a Xilinx Spartan 2 XC2S100 FPGA are used in shift register mode. The shift register contents are initialized to complementary values. As indicated in the figure, the LUTs are initialized to $(0x5555)_{16}$ and $(0xAAAA)_{16}$ respectively. The outputs of the LUTs drive the select input pins of a chain of multiplexers as

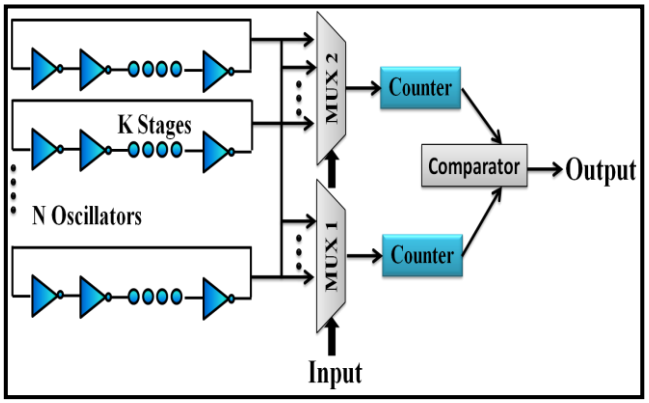

Figure 1. Basic Principle of ROPUFs.

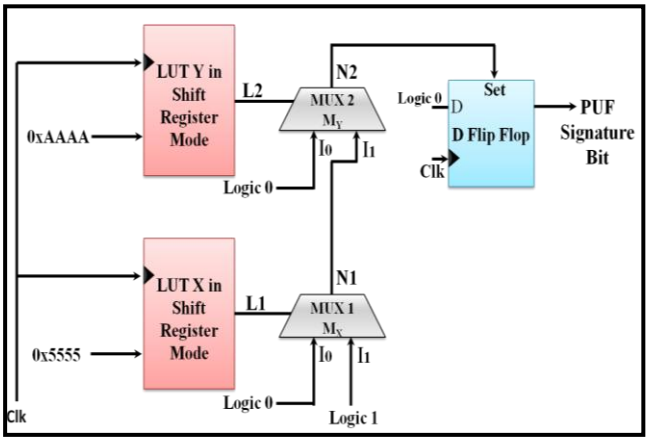

Figure 2. Oscillator Circuit based on the Proposed PUF Circuit.

shown in Figure 2. It is to be noted that both the multiplexers have their I_0 data input tied to logic '0'. The I_1 data line for the bottom multiplexer is tied to logic '1'. On the other hand, the I_1 data line of the top multiplexer is driven by the output of the multiplexer below. The output of the last multiplexer is connected to a D-flip flip which increases the width of the pulse and produces an appropriate output response. The flip flop is initialized to logic '0'.

Due to the complementary initialization values, the shift register implemented in LUT X produces a sequence complementary to LUT Y. Initially, the output of LUT X is logic '0' and the output of LUT Y is logic '1', i.e., signal L1 is logic '0' and signal L2 is logic '1'. Thus, the signals N1 and N2 are both at logic '0'. At the triggered clock edge, the output of LUT X changes from logic '0' to logic '1' and the output of LUT Y changes from logic '1' to logic '0'. Although LUT X and the multiplexer it drives (M_X) are identical to LUT Y and its corresponding multiplexer (M_Y), the two circuits experience different delays due to random process variations. There are two cases worth highlighting. They are:

Case 1: LUT X and the multiplexer it drives are faster than LUT Y and its corresponding multiplexer. In this case, when LUT X transitions from logic '1' to logic '0', the slower LUT Y changes from logic '0' to logic '1', i.e., L1 transitions from logic '1' to logic '0' before L2 transitions from logic '0' to logic '1'. When the signal L1 transitions from logic '1' to logic '0' the signal N2 is held at logic '0'. Thus, the signal N2 is held constant throughout the process.

Case 2: LUT Y and the multiplexer it drives are faster than LUT X and its corresponding multiplexer. In this case, LUT Y transitions from logic '0' to logic '1'when the slower LUT X changes from logic '1' to logic '0', i.e., L2 transitions from logic '0' to logic '1' before L1 transitions from logic '1' to logic '0'. Due to the difference in the delay periods, when L2 has transitioned to logic '1' but L1 is still at logic '1', the select lines of both the multiplexers are held at logic '1' due

TABLE I. SIGNAL TRANSITIONS OF THE PUF.

	L1	L2	N1	N2	Output
Initially	1	0	1	0	0
Case 1 (LUT X faster than LUT Y)	1→0	0	0	0	0
Case 2 (LUT Y faster than LUT X)	1	0→1	1	1(glitch)	1

to which a short positive pulse (glitch) appears in the signal N2. The presence or absence of a glitch on signal N2 and the width of the pulse are due to process variations that impact the relative delays of LUT X and LUT Y. The signal N2 is connected to the SET input line of a D-flip flop as shown in Figure 2. When the glitch appears on the signal N2, the flip flop output and the PUF signature bit becomes logic '1'. In all other cases, the PUF signature bit remains at logic '0'. Table 1 summarizes the operation of the PUF.

Responses of 128-bit length are evaluated using 5 Xilinx Spartan XC2S100 FPGAs at 50MHz. The implementations on each FPGA have eight instances. The Hamming distances for 40 implementations on 5 Spartan 2 FPGAs, i.e., (40*39)/2 = 780 data points are calculated and plotted.

The Hamming distances for intra-chip and inter-chip responses are also analysed. Figure 3 and Figure 4 show the distribution of Hamming distances for the inter-chip and intra-chip 128-bit responses signifying the uniqueness of the PUFs. The figures clearly show the clustering of the distribution around the ranges [61:65] and [56:60]. From the graphs, it has been observed that the uniqueness in the responses is higher in case of inter-chip response bits when compared to the intra-chip response bits. The percentage uniqueness of the PUF responses is calculated to be 49.0625% which is higher than the uniqueness of the responses of a conventional ring oscillator [2] (43.40%) and the chain implementation (48.51%) discussed in [9].

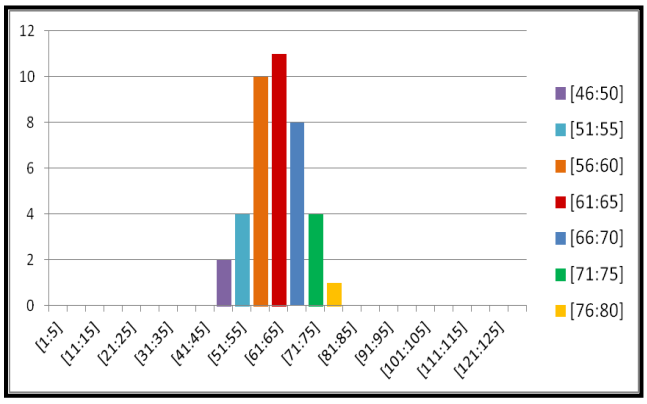

Figure 3. Distribution of Hamming Distances for Inter-Chip Response Bits.

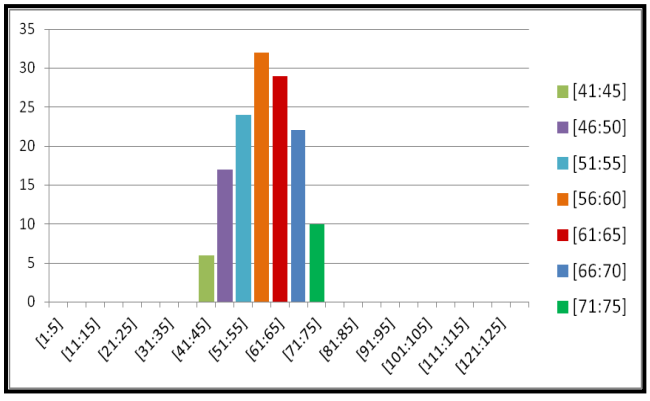

Figure 4. Distribution of Hamming Distances for Intra-Chip Response Bits.

The main advantages of this design are its smaller size and ease of implementation using synthesis, and place and route tools. For example, this design does not need any external routing and the use of hard macros which make them easier to implement.

The stability and reliability of the PUFs are degraded by the slight dependency of the response bits on environmental temperatures and voltage fluctuations. Due to this dependency, a bit generated from a pair of ring oscillators might flip when the operating temperatures change considerably. Thus, the outputs obtained for the same challenge on the same CLB slice may differ slightly. To stabilize the circuit, Artificial Neural Networks (ANNs) are used for its error correction process. The remarkable ability of ANNs to learn and derive information from complicated and imprecise data is used to extract patterns. This gives an advantage over the conventional error correcting codes such as BCH codes [10].

3 Error Correction Process

The BCH codes are a generalization of Hamming codes for multiple error correction. Binary BCH codes were first discovered by A. Hocquenghem, R.C. Bose and D.K. Ray-Chaudhuri. A major disadvantage in case of BCH codes are its complex computations. The computation needed to generate the error correcting syndromes increase drastically with the increase in the number of error bits.

We propose an error correction process using Artificial Neural Networks (ANNs). Our analysis has proved that the learning ability of ANNs has an immense effect on the results produced when compared to the conventional BCH codes. Supervised learning algorithms are effective in dealing with unexpected and changing conditions unlike previously used codes. Bidirectional Associative Memories are used to train the network.

Adaptive Bidirectional Associative Memory (BAM) is a type of recurrent neural network. BAM was proposed by Bart Kosko (1988) [11] as an extension to the Hopfield Network by incorporating an additional layer to perform recurrent auto-associations as well as hetro-associations on the memories. In BAM, bi-directionality, forward and backward

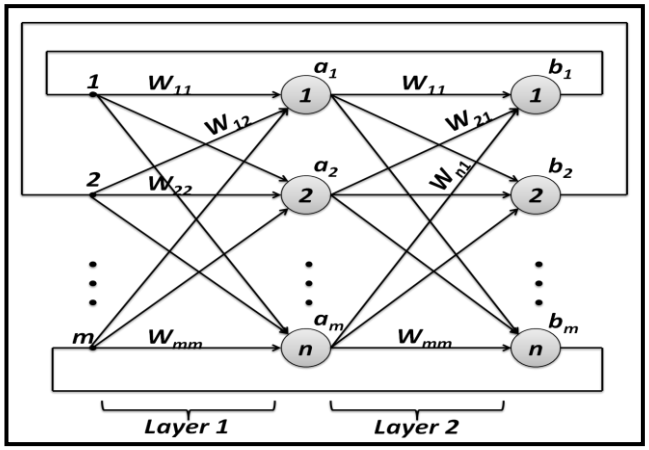

Figure 5. Generalized BAM Architecture.

information flow, is implemented in neural networks to produce two way associative searches for a set of challenge-response associations. The network evolves to a two pattern stable state when the BAM neurons are trained. Hetro-associations are encoded in a BAM by summing correlation matrices. The generalized BAM architecture is shown in Figure 5. The neurons in one layer are fully interconnected to the neurons in the second layer as shown in this figure. There are no interconnections among neurons in the same layer. Layer 1 and 2 operate alternatively. The neuron's output signals are transferred towards the right by using the weight matrix W, and then transferred towards the left by using the transpose of the weight matrix W^T.

In BAM, the correlation matrix for each pattern pair is the matrix product of the transpose of the input vector X^T and the output vector Y. PUF responses are used to train the neural networks. Every weight matrix is bi-directionally stable for bivalent and continuous neurons. The associative weight matrix has been calculated as the sum of all correlation matrices. The mathematical representation is shown in (1).

$$W = \sum_{m=1}^{M} {X_m}^T . Y_m \qquad (1)$$

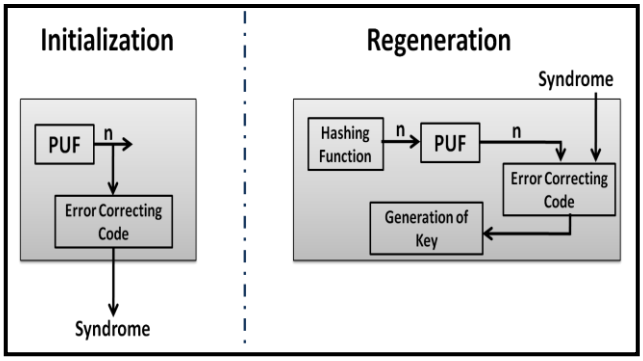

Figure 6. Different Phases of Error Correction Process.

where M is the number of pattern pairs stored in the BAM, X is the input vector and Y is the output vector.

The error correction process has two phases: Initialization Phase and Regeneration Phase. In the initialization phase, multiple outputs are generated from the PUF circuit and an error correcting syndrome is computed by training the neural network. In the regeneration phase, the noisy/corrupt signal is sent to the trained neural network for the errors to be rectified. Figure 6 shows the two phases of an error correction process.

3.1 Training Algorithm

3.1.1 Initialization Phase

To test and analyze the error correcting code, PUF responses are converted into the bipolar binary format. The values are stored in matrix form. The training phase of the neural network generates the weight matrix (error correction syndrome). This is the initialization phase of the error correction process.

3.1.2 Regeneration Phase

In the regeneration phase, a noisy/corrupt signal is sent to the trained neural network for the errors to be rectified. The testing part of this phase has two tasks. Firstly, to ensure no false negatives, the BAM is tested to retrieve any vector from the input matrix. To verify that the network is capable of correctly retrieving any vector from the input matrix, a vector from the input matrix is applied to the neural network. The vector is retrieved using (2).

$$Y_m = sign\ (W^T . X_m)\ where\ m = 1, 2, 3 \ldots . M \qquad (2)$$

The trained vectors are successfully retrieved eliminating false negatives. Secondly, the network should be able to retrieve exact values at the output layer even when a noisy/corrupt input signal is given at the input layer. A noisy test vector is given as an input to the trained network and the error correction process is initialized. The output is calculated using (2). The output values are back-propagated and the input is updated using (3) and the process is repeated iteratively till the input and the output vectors attain equilibrium. Equilibrium is attained when the input and the output vectors remain unchanged with further iterations.

$$X_m = sign\ (W . Y_m) where\ m = 1, 2, 3 \ldots . M \qquad (3)$$

Trained networks have successfully corrected faulty test vectors. In this work, 64 bit, 128 bit and 256 bit vectors are used to test the networks. In the error correcting codes, BAM architecture is used to learn continuous mapping and to rapidly extract bivalent associations from several noisy samples. From the results obtained, it has been observed that learning tends to improve with the increase in the sample size.

MATLAB is used for testing and analyzing the error correction method.

The major advantages of this method over BCH codes are its simple computations which take less time and the ability for group processing. The error correcting syndromes are calculated for a set of PUF outputs rather than one single output vector. All the vectors used to train the network can use the same error correcting syndrome to correct the noisy bits.

The proposed error correcting code using bidirectional associative memories has two other advantages. The technique generates a secure syndrome that does not pose any threats to the PUF response bits used to generate the syndrome. The second major advantage is the robust nature of the algorithm. The failure rates of the error correction code can be driven below 1ppm.

4 Summary and Conclusions

This Silicon PUFs, Delay Based PUFs in specific, are novel chip identifiers based on the slight variations due to the manufacturing processes of identically designed devices. On the other hand, supervised learning algorithms are used to train a network according to given specifications. Our research combines the concepts of ROPUFs, designed using a Xilinx FPGA, with artificial neural networks to generate a unique key for cryptographic applications.

The proposed PUF circuit is implemented on 5 Xilinx Spartan 2 XC2S100 FPGAs and an Agilent 16801A logic analyzer is used to obtain the PUF responses. The intra chip and inter chip responses are analyzed and plotted using Hamming codes. From the graphs, it is concluded that the uniqueness in the responses is higher in case of inter-chip responses than the intra-chip responses. The uniqueness of the responses is found to be 49.0625% which is higher when compared to conventional circuit which signifies higher uniqueness of the responses.

The stability of the PUFs needs to be improvised considering the characteristics of the PUFs drastically affect the performance of the security system. The latter part of the research involves the implementation of an error correction technique using Artificial Neural Networks. The networks are tested using the PUF responses. The networks have successfully corrected the error bits. The failure rates of the proposed method are below 1ppm. Future work includes characterizing the stability of PUF response bits across a wide range of environmental changes and improving the learning rate of the error correcting code to decrease the failure rate.

A GPGPU Implementation of Approximate String Matching with Regular Expression Operators and Comparison with Its FPGA Implementation

Yuichiro Utan, Masato Inagi, Shin'ichi Wakabayashi, and Shinobu Nagayama
Graduate School of Information Sciences, Hiroshima City University, Hiroshima, Japan

Abstract— *In this paper, we propose an efficient GPGPU implementation of an algorithm for approximate string matching with regular expression operators, originally implemented on an FPGA, and compare the GPGPU, FPGA and CPU implementations by experiments. Approximate string matching with regular expression operators is used in various applications, such as full text database search and DNA sequence analysis. To efficiently handle a long text in the matching, a hardware algorithm for FPGA implementation has been proposed. However, due to the limitation of FPGAs' capacity, it cannot handle long patterns. In contrast, our proposed GPGPU implementation is able to handle long patterns efficiently, utilizing the scalability of GPGPU programming. Experimental results showed that the GPU implementation is more than 18 times as fast as the CPU one when the pattern length is greater than 3200, while the FPGA one could not handle such a long pattern.*

Keywords: approximate string matching, regular expression, GPGPU, FPGA, CUDA

1. Introduction

Approximate string matching [1] is the problem to find substrings in a given string (*text*) which are similar to another given string, called a *pattern*. The degree of similarity between two strings, called *edit distance*, is obtained by deriving the *edit distance matrix*. Approximate string matching is one of the major problems in information science, and used in keyword search in databases, DNA sequence analysis in bioinformatics, and network intrusion detection, *etc*. Since the problem size is exponentially increasing, some efficient algorithms using special hardware [2] or a graphics processing unit (GPU) [3] have been proposed.

Although approximate string matching is more flexible than exact string matching, both kinds of matching deal with only simple patterns which consist of only alphabet characters. Such simple descriptions lead unacceptably long patterns in some applications in which the target substrings vary under certain rules (*e.g.*, network intrusion detection). Thus, matching that can deal with more efficiently described patterns is being required. One of the methods for efficiently describing patterns is regular expression. In this paper, we call a variant of approximate string matching in which patterns can include some regular expression operators, *approximate regular expression matching*. A systolic hardware algorithm for approximate regular expression matching has already been proposed and implemented on an FPGA in [4]. However, in this algorithm, the acceptable pattern length is limited by the amount of hardware resources (*i.e.*, the FPGA's capacity), and thus only short patterns can be handled.

Recently, parallel processing methods using GPUs are attracting attention. GPUs are originally application specific processors for graphics processing. However, since GPUs have highly parallel architectures to render pixel images in real-time, general-purpose computation on GPUs (GPGPU) [5] has been actively being studied to utilize GPUs' high performance. As a development environment for GPGPU, compute unified device architecture (CUDA) is provided by NVIDIA Corporation to facilitate the utilization of GPUs for general-purpose computing. GPGPU is based on homogeneous multithreading, and threads more than hardware resources (*e.g.*, ALUs) are automatically scheduled and allocated to the resources. Thus, GPGPU programming is scalable in terms of the number of threads.

Utilizing the high parallelism of GPUs, a GPGPU implementation of approximate string matching has been proposed in [3]. This method enhances the degree of data parallelism by handling multiple texts in parallel. Thus, it cannot fully utilize a GPU's parallelism when performing matching with a single text and a long pattern.

In this paper, we propose an efficient GPGPU implementation of approximate regular expression matching for long patterns. Our method is based on the FPGA implementation [4]. Comparing to the FPGA implementation, the main advantages of the GPGPU implementation are:

1) our method can handle much longer patterns, and
2) it requires no special hardware, like FPGAs.

The main differences of our proposed method from [3] are:

1) it can handle some regular expression operators, and
2) it is suitable to high-speed matching with a single text.

The method proposed in [3] divides the edit distance matrix into parallelogram regions. In the method, when only a single text is given, up to 32 elements in a region are calculated in parallel, and the regions are sequentially handled. Our

method divides the matrix into parallelogram regions in the same way. In our method, however, up to 32 elements in a region are calculated in parallel, and up to 16 regions are calculated in parallel, considering the data dependencies among regions. (The degrees of parallelism depend on the GPU.) This makes our method more efficient for matching with a single text than [3].

In addition, we evaluate the GPGPU implementation comparing to the FPGA implementation by experiments. The experimental results showed that the FPGA and GPU implementations were 8.3 and 2.9 times as fast as a CPU implementation when the pattern length is 320, respectively. Furthermore, the GPU implementation was more than 18 times as fast as the CPU one when the pattern length is greater than 3200, while the FPGA one could not handle such a long pattern.

The rest of this paper is organized as follows. In Section 2, the definitions of approximate string matching and approximate regular expression matching are described, and GPGPU is explained. Section 3 shortly describes the existing FPGA implementation of approximate regular expression matching [4]. Section 4 presents our GPGPU implementation of approximate regular expression matching. In Section 5, we compare the GPGPU, FPGA and CPU implementations by experiments. Finally, conclusions are given in Section 6.

2. Preliminaries

2.1 Approximate String Matching

Here, we define the approximate string matching problem and explain an algorithm for the problem. Given two strings P (pattern) and T (text), and a non-zero integer k (threshold), the approximate string matching problem is to find a substring of T whose edit distance [6] from P is less than or equal to k. Now, let us consider transforming a string S_1 to another string S_2 by iteratively applying single-character deletions, insertions and substitutions. When the costs of deletions, insertions and substitutions are given, the edit distance between S_1 and S_2 is the minimum total cost required to transform S_1 to S_2. Thus, the calculation of edit distance is essential to the approximate string matching problem.

Next, we explain how to calculate the edit distance. The edit distance between S_1 and S_2 is calculated as $D(m,n)$ defined in the following by using dynamic programming (DP), where $m = |S_1|$ and $n = |S_2|$.

$$D(i,j) = \min\{ \begin{array}{l} D(i-1,j) + \text{del}, \\ D(i,j-1) + \text{ins}, \\ D(i-1,j-1) + s(i,j) \end{array} \}, \quad (1)$$

where

$$s(i,j) = \begin{cases} \text{sub}(S_1[i], S_2[j]) & 1 \le i \le m, 1 \le j \le n \\ \infty & \text{otherwise,} \end{cases}$$

$S_1[i]$ and $S_2[j]$ are the i-th character of S_1 and the j-th character of S_2, respectively, $D(0,0) = 0$, and $D(i,j) = \infty$ if $i < 0$ or $j < 0$. ins and del in the formula are constants and denote the insertion and deletion costs, respectively. $\text{sub}(a,b)$ is the substitution cost of two characters a and b. sub is represented as an $\alpha \times \alpha$ two-dimensional array, where α is the number of alphabet characters. For discussion, let D be an $(m+1) \times (n+1)$ two-dimensional array such that $\text{D}[i,j] = D(i,j)$. D is called the edit distance matrix.

2.2 Approximate Regular Expression Matching

Here, we explain how to introduce regular expression operators and other operators into approximate string matching. Hereinafter, "a string P matches a string S" means that the edit distance between P and S is zero. The definitions of the main target operators are as follows.

1) *Single-character don't care* (*SCDC*) (?)
   The pattern "?" matches any single character.
2) *Variable-length don't care* (*VLDC*) (?*)
   The pattern "?*" matches any string, including the zero-length string "ε", where ε is the empty character.
3) *Negation* ($\bar{p}$)
   A pattern "$\bar{p}$" matches any single character other than p.
4) *Empty character matching* ($p@$)
   A pattern "$p@$" matches p and the empty character ε.
5) *Character-by-character matching* (*CC matching*) ($[p_1p_2\cdots p_l]$)
   A pattern $P =$ "$[p_1p_2\cdots p_l]$" matches only the string "$p_1p_2\cdots p_l$". If P and S have different lengths, the edit distance between P and S is ∞. Otherwise, the edit distance between P and S is the same as that between "$p_1p_2\cdots p_l$" and S.
6) *Exact matching* ($\langle[p_1p_2\cdots p_l]\rangle$)
   A pattern $P =$ "$\langle[p_1p_2\cdots p_l]\rangle$" matches only the string "$p_1p_2\cdots p_l$". If S is not "$p_1p_2\cdots p_l$", the edit distance between P and S is ∞.
7) *Kleene operator* (p^*)
   A pattern "p^*" matches any strings that do not include any character other than p.

The other target operators are shown in [4].

Due to space limitations, we here explain only the DP formulation of exact matching. Assume $P = \langle[p_1p_2\cdots p_l]\rangle$. Let $\text{ins}(i)$ be the insertion cost of a character between p_i and p_{i+1}. Also, let $\text{sub}(p,t)$ be the substitution cost from a pattern character p to a text character t. Exact matching is realized by setting the deletion, insertion and substitution costs as defined in Expressions (2), (3) and (4), respectively. Note that although insertions right after p_i ($1 \le i < l$) are not allowed, insertion right after p_l is allowed if some pattern characters follow the exact match (*e.g.*, "$\langle[abc]\rangle e$" matches "$abcde$"). Thus, the constant insertion cost $\text{ins}(= k)$ in the original DP formulation is replaced by the function $\text{ins}(i)$.

$$\text{del} = \infty \quad (2)$$

Table 1: Definitions of del, ins, and sub for each operator

operator	del	ins	sub
w/o operator			
p	del	ins	$\mathrm{sub}(p,t)$
1. SCDC			
$?$	del	ins	0
2. VLDC			
$?^*$	0	0	0
3. Negation			
$\bar{p}$	del	ins	$\mathrm{sub}(\bar{p},t)$
4. Empty character			
$p@$	0	ins	$\mathrm{sub}(p,t)$
5. CC matching			
$[p_1p_2\cdots p_l]$			
$1 \le i < l$	∞	∞	$\mathrm{sub}(p,t)$
$i = l$	∞	ins	$\mathrm{sub}(p,t)$
6. Exact matching			
$\langle[p_1p_2\cdots p_l]\rangle$			
$1 \le i < l,\ p = t$	∞	∞	0
$1 \le i < l,\ p \neq t$	∞	∞	∞
$i = l, p = t$	∞	ins	0
$i = l, p \neq t$	∞	ins	∞
7. Kleene operator			
p^*	0	$\min\{\mathrm{ins}, \mathrm{sub}(p,t)\}$	$\mathrm{sub}(p,t)$

$$\mathrm{ins}(i) = \begin{cases} \infty & 1 \le i < l \\ k & i = l \end{cases} \tag{3}$$

$$\mathrm{sub}(p,t) = \begin{cases} 0 & p = t \\ \infty & p \neq t \end{cases} \tag{4}$$

The other operators can be realized by similarly replacing the deletion cost del, insertion cost ins and substitution cost sub. The definitions of del, ins and sub for each operation are shown in Table 1.

2.3 GPU

A graphics processing unit (GPU) is an application specific processor for graphics processing and one of the main components of PCs. Utilizing GPUs for general-purpose computing is called GPGPU (general-purpose computation on GPUs) [5]. In recent years, GPUs without video outputs were developed for general-purpose computing by some semiconductor companies (*e.g.*, Tesla C2070 by NVIDIA Corporation and FireStream 9350 by Advanced Micro Devices, Inc.).

2.3.1 GPU Architecture

Fig.1 illustrates an architecture of NVIDIA's GPUs, called Fermi. It is composed of two LSIs, a GPU itself and a memory chip, called device memory. A GPU has up to 16 streaming multi-processors (SMs), each of which corresponds to a core in a multicore CPU. An SM has 32 streaming processors (SPs), each of which corresponds to an arithmetic logic unit in a CPU core. An SP has only limited functions such as arithmetic operations, and SPs execute instructions decoded by an SM in a SIMD fashion. That is, all the SPs in an SM simultaneously execute the same instruction. In addition, an SM has a memory shared by all the SPs in the SM and some memories to cache data from and to the device memory.

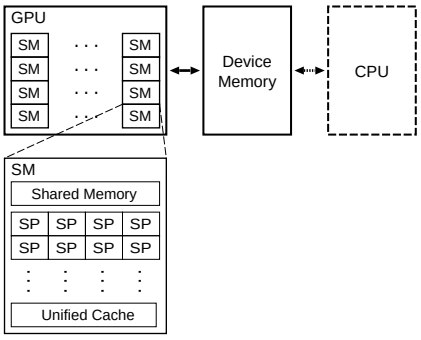

Figure 1: Architecture of NVIDIA Tesla series GPU

GPUs have a hierarchical memory architecture. The memory architecture of the Fermi GPUs is as follows:

1) Global memory
   Global memory is a high-capacity memory realized by the device memory. It is accessible from any SPs in the GPU. The size of the memory is up to several giga-bytes. On the other hand, its latency is high and it requires 400 to 600 clock cycles to access. Accesses from SPs to the memory are cached in the SM to which the SP belongs. It is the only memory readable/writable from both the GPU and CPU.
2) Shared memory
   Each SM has a 64KB on-chip memory, and 16KB or 48KB of the memory is used as its shared memory. The rest of the on-chip memory is used as the L1 cache of global memory. All the SPs in an SM are quickly accessible to the memory.
3) Register
   Each SP has its own registers. Registers are the memory most quickly accessible from SPs. Registers in an SP is not accessible from the other SPs. Each SM has 8K to 32K registers, depending on the GPU.
4) Constant and texture memories
   Constant and texture memories are read-only memories realized by the device memory. They are accessible from any SPs in the GPU. Accesses from an SP to the memories are cached in the SM to which the SP belongs. They are writable from the CPU. In addition, texture memory has some additional functions, such as address space normalization to [0,1] and data interpolation between adjacent data points. Since the proposed method does not use those memories, we omit the detailed explanation of them.

2.3.2 CUDA

CUDA is a programming environment for developing and executing general-purpose applications on NVIDA's GPUs.

It makes multi-thread applications run on GPUs efficiently. An extended C/C++ is used as the programming language in CUDA.

In CUDA, concepts to manage threads, called *grid* and *thread block*, are introduced. A group of threads is called a thread block. The maximum number of threads in a thread block is 512. A group of thread block is called a grid. Each thread block in a grid is managed by adding a two-dimensional ID. The maximum number in each dimension of a thread block ID is 65,535.

Each thread executes a code, called a *kernel*. Each thread has a unique ID, by which threads handle different data, executing the same code. Threads in the same thread block shares data in the high-speed shared memory. On the other hand, a thread cannot access to shared memories in different thread blocks. Thus, codes need to be written so that there are as few data dependencies between thread blocks as possible. In addition, although threads in different thread blocks cannot be synchronized during a kernel execution, threads in the same thread block can be synchronized using a command and keep data consistency.

3. FPGA Implementation of Approximate String Matching with Regular Expression Operators

In this section, a hardware algorithm for approximate regular expression matching proposed in [4] is explained. Our proposed method is based on the same idea and adjusted to GPUs.

3.1 Architecture

The architecture for the hardware algorithm is shown in Fig. 2. Let $m = |P|$ and $n = |T|$. Then, it is a one-dimensional array of $m+1$ units, called *cells*, each of which compares a pattern character and a text character. That is, each cell calculates the elements in a row of the edit distance matrix D, shown in Fig. 3. Note that each dimension of D is expanded by one element in order to calculate the edit distances between the pattern and substrings of the text (please refer to [4] for more detail). The $m+1$ cells calculate the elements on a diagonal line in parallel and the calculation proceeds from the top-left corner to the bottom-right corner as shown in Fig. 3. Thus, its calculation time is $O(m+n)$. The resultant edit distances are output from the right-most cell and input to a comparator. The comparator compares the user-defined threshold k and an edit distance. If the edit distance is less than or equal to k, the comparator outputs a match signal. Since each cell handles one character in a pattern, the length of patterns is limited to the number of cells.

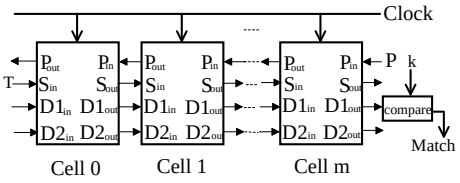

Figure 2: Architecture of Hardware Engine

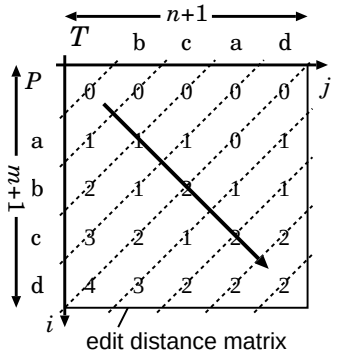

Figure 3: Order of Calculation in D

3.2 Basic Structure and Behavior of Cell

Fig. 4 shows the structure of a cell. C_p and C_t are registers and store one character in the pattern and one character in the text, respectively. DM is a memory to store the table of substitution costs. DM is a two-dimensional array of substitution cost from alphabet α_1 to α_2, called a distance matrix. That is, DM$[\alpha_1, \alpha_2]$ stores the value of sub(α_1, α_2). The distance matrix DM is set before starting matching. (In our experiment, the substitution costs of any two characters are set to 1 and DM is omitted.) $D1$ and $D2$ are registers to temporarily store elements of D. $D1$ stores the newest element the cell calculated, and $D2$ stores the second newest element.

Next, we explain the behavior of the cell. A cell i handles one character of the pattern, p_i, and calculates $D[i, *]$. When the cell i calculates $D[i, j]$ at a clock cycle T_k, $D[i, j-1]$, $D[i-1, j]$ and $D[i-1, j-1]$ are necessary. $D[i, j-1]$ was calculated at the cell i at the clock cycle T_{k-1} and currently stored in $D1$. $D[i-1, j]$ was also calculated at the cell $i-1$ at the clock cycle T_{k-1} and currently stored in $D1$ of the cell $i-1$. $D[i-1, j-1]$ was calculated at the cell $i-1$ at the clock cycle T_{k-2} and currently stored in $D2$ of the cell $i-1$. Thus, all the elements necessary to calculate $D[i, j]$ are stored in the cells i and $i-1$.

4. GPGPU Implementation of Approximate Regular Expression Matching

In this paper, we propose an efficient GPGPU implementation method of the hardware algorithm for approximate

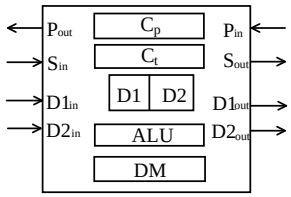

Figure 4: Structure of Cell

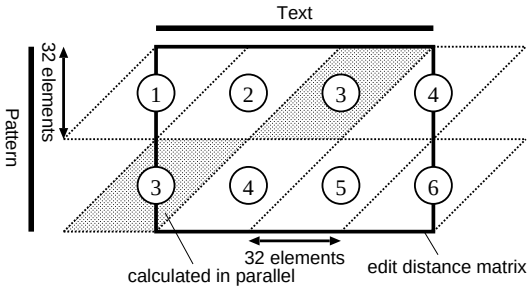

Figure 5: Parallel Calculation on GPU

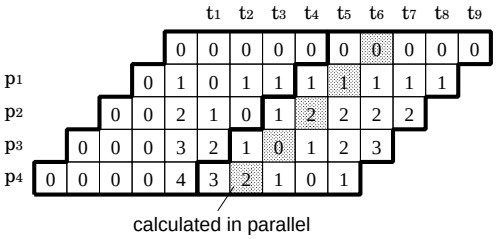

Figure 6: Calculation in Parallelogram Region

regular expression matching [4]. Although GPUs are processors specific to graphics processing, some studies have been conducted to utilize their highly parallel architecture for string matching (*e.g.*, [3]).

In [4], the hardware algorithm is implemented on an FPGA. However, since the length of patterns is limited to the number of cells and the number of cells is limited by the capacity of the FPGA, long patterns cannot be handled by the FPGA implementation. For example, the one implemented in the experiments in [4] can handle no more than 250 pattern characters. In contrast, since in a GPU an SM can handle multiple thread blocks in a time-division manner (*i.e.*, an SP handles multiple threads), a GPU can handle patterns whose length is greater than the number of SPs by allocating the function of each cell to a thread. This fact makes approximate regular expression matching applicable to the applications with long patterns (*e.g.*, analysis of DNA sequences).

In the following, we first show the overview of our method for approximate string matching (without regular expression) on GPUs. Then, we explain the effective memory access method for our matching method. Finally, we introduce regular expression operators to the method.

4.1 Division of Edit Distance Matrix D

In this paper, we propose an efficient approximate regular expression matching method that can handle long patterns utilizing a GPU. In our method, we divide the edit distance matrix D into multiple parts and effectively dispatch them to SMs.

First, we divide the edit distance matrix into the parallelogram regions so that the length of each side of the regions is 32, as shown in Fig. 5. This is because each SM handles 32 threads as one executable unit, called a *warp*. Then, we dispatch the calculations in parallelogram regions to SMs in a GPU. Since SPs in different SMs cannot be synchronized, the parallelogram regions are calculated in the order shown in Fig. 5 to maintain data dependencies. The parallelogram regions with the same number are calculated by multiple SMs in parallel. The calculations of the parallelogram regions with each number are started by calling a kernel and thus synchronized. The elements on a line parallel to the right and left sides of a parallelogram are calculated in parallel by the SPs in a SM. This division realizes an effective use of SMs and SPs in a GPU for the calculation of the edit distance matrix with a long pattern.

Fig. 6 shows the calculation in each parallelogram region. The elements in a region have the same data dependencies as that of Fig. 3. Thus, we allocate the function of a cell to a thread to calculate the elements on a line parallel to the right and left sides of the parallelogram region in parallel.

In summary, in our proposed method, the edit distance matrix is divided into parallelogram regions, and the regions are calculated in the order shown in Fig. 5 in parallel. In each region, the elements on a line parallel to the right and left sides of the parallelogram region are allocated to SPs and calculated in parallel.

4.2 Calculation of Edit Distance on Shared Memory

Here, we describe how to calculate the edit distance using shared memories. The calculation of the edit distance is easily implemented by placing whole the edit distance matrix D to the global memory. However, the cost to access to the global memory is very high and the latency is 400 to 600 clock cycles. Therefore, we utilize shared memories to calculate the matrix.

To calculate the value of elements in a parallelogram region, the calculation results of other regions are necessary. Since different regions are handled by different SMs, it is necessary for SMs to access the global memory to communicate each other. On the other hand, since SMs do not need to communicate each other when calculating inner

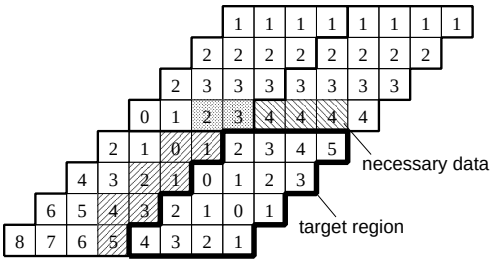

Figure 7: Data Dependencies among Parallelogram Regions

elements of regions, shared memories can be used to quickly calculate the elements. To calculate the elements on the i-th line parallel to the right and left sides of the parallelogram region, only the elements on the $(i-1)$-th and $(i-2)$-th lines need to be stored in the shared memory of the corresponding SM.

The data dependencies among parallelogram regions are shown in Fig. 7. The calculation in the parallelogram region enclosed by a heavy line requires only the shaded elements. Thus, in our method, only those elements are stored in the global memory. In other words, only the elements on the last two lines parallel to the right and left sides of a parallelogram region and those in the bottom row in the region are stored in the global memory.

Fig. 8 shows the pseudo code of the kernel. In the code, *r_D* is a register to temporarily store an element of the edit distance matrix, $D[i, j]$. *r_left*, *r_top*, and *r_diag* are registers to temporarily store the elements $D[i-1, j]$, $D[i, j-1]$, and $D[i-1, j-1]$, respectively. The register *r_left* is used to send the value of $D[i-1, j]$ for the calculation of $D[i+1, j]$ without using shared memories. The registers *r_top* and *r_diag* are used to shorten the *then* and *else* statements in the *if-then-else* statement. This is because a GPU executes both of *then* and *else* statements to execute threads in a SIMD fashion. Without *r_top* and *r_diag*, both of the *then* and *else* statements need to include similar codes (corresponding to the 18th line, which becomes more complicated when regular expression operators are introduced), and it degrades the performance. *idx* is the ID number of the thread in the grid, *tid* is the ID number of the thread block, and *b_id* is the ID number of the thread block. *text*, *top*, and *down* are arrays located in the shared memory to store text characters, the elements on the region, and the elements in the bottom row in the region, respectively.

In the 1st to 7th lines of the code, the data needed by the thread block are read from the global memory to the shared memory. Note that the data are read in parallel by using all the thread in the thread block. In the 8th to 24th lines, the elements in a row are calculated. Note that different threads in a thread block handle different rows, and the elements in the rows are calculated in parallel. In the 9th line, a text character is read to the register *t*. DM in the 10th line is a

```
01.  text[tid] = T[tid+(a-1)*SIZE];
02.  text[SIZE+tid] = T[tid+(a)*SIZE];
03.  top1[tid+1] = D[(b_id)*(SIZE+n+1)+tid+(a+1)*SIZE];
04.  s1[tid] = D[(idx+1)*(SIZE+n+1)+a*SIZE];
05.  s2[tid] = D[(idx+1)*(SIZE+n+1)+a*SIZE-1];
06.  r_E = D[(idx+1)*(SIZE+n+1)+a*SIZE];
07.  p = P[idx];
08.  for(i=0; i<SIZE; i++){
09.      t = text[tid];
10.      sub = DM[p*128+t];
11.      if(tid==0){

Figure 8: Pseudo Code of Kernel

two-dimensional array to store the substitution costs. In this line, the substitution cost of the pattern character and text character is obtained. In the 11th to 17th lines, $D[i-1, j]$ and $D[i-1, j-1]$ are read from the shared memory to registers. In the 18th line, $D[i, j]$ is calculated. In the 19th to 22nd lines, $D[i, j]$ and $D[i, j-1]$ in the shared memory are updated. Note that only the newest and second newest lines of elements are stored in the shared memory. In the 23rd line, all the threads in the thread block are synchronized (because each SP handles multiple threads). In the 25th to 27th lines, the date necessary to calculate the next regions are sent from the shared memory to the global memory.

4.3 Introduction of Regular Expression Operators

As shown in Section 2, our target regular expression operators can be realized by replacing del, ins and sub in the DP formula of the edit distance calculation. To input patterns with the regular expression operators to the kernel, we introduce an array of characters *OP* ($|OP| = |P|$) for representing operators to the corresponding pattern characters, and an array of integers *e* ($|e| = |P|$) for representing the first and last characters of the target substring of an operator, as input data to the kernel. In the kernel, *OP* and *e* are copied from the global memory to the shared memory like as pattern *P*.

5. Comparison of GPGPU and FPGA Implementations

To compare FPGA, GPGPU and CPU implementations, we conducted some experiments. For those implementations,

we used a PC equipped with an Intel Core i7 950 CPU (3.06GHz), 24GB main memory, CentOS, an NVIDIA Tesla C2070 (1.15GHz) GPU with 4GB device memory, and an FPGA board with a Xilinx Virtex-4 FPGA. The GPU and the FPGA board are connected to the PC with PCIe 2.0 x16 and conventional PCI buses, respectively. The FPGA implementation is written in Verilog HDL and mapped using Xilinx ISE 13.1.

In our GPGPU implementation, one thread block consists of 32 threads. Thus, each thread block uses 1060bytes of the shared memory. Each thread uses 42 registers. Since in the Tesla C2070 each SM has a 48KB shared memory, each SM can handle up to 45 thread blocks ($45 \times 1060 < 48$K). Therefore, our GPGPU implementation can handle long patterns whose length is less than or equal to 20,160 = $14 \times 45 \times 32$ = (the number of SMs) $\times$ (the maximum number of thread blocks per SM) $\times$ (the number of threads in one thread block). In contrast, since only 250 cells can be implemented on the target FPGA, the FPGA implementation can handle only patterns whose length does not exceed 250. The maximum clock frequency was 140MHz.

Table 2 shows the execution times of the GPGPU and CPU implementations when $|T| = 3,200,000$ and $|P| = 320$, and that of the FPGA implementation when $|T| = 3,200,000$ and $|P| = 250$. Note that the execution times include data transfer time from the main memory. As a result, the FPGA and GPGPU implementations were 8.3 and 2.9 times as fast as the CPU implementation, respectively.

Table 3 and Fig. 9 show the results in the cases of long patterns. We found that 1) the execution time of the CPU implementation is proportional to the pattern length, 2) that of the GPGPU implementation is stepwise in terms of the pattern length (there is a gap between $|P| = 3200$ and $|P| = 4800$). In addition, the GPGPU implementation when $|P| \geq 3200$ was more than 18 times as fast as the CPU implementation.

These results indicate that the FPGA implementation is the fastest and suitable to the cases of short patterns, and the GPGPU implementation is scalable and suitable to the cases of long patterns, such as analysis of DNA sequences.

Table 2: Execution Time when $|T| = 3,200,000$

Method	$\|P\|$	Time
CPU	320	23.60 [s]
GPGPU	320	8.23 [s]
FPGA	250	2.89 [s]

Table 3: Execution Time when $|T| = 320,000$ [ms]

$\|P\|$	320	640	1280	3200	4800	6400
CPU	2399	4803	9612	24020	36030	47960
GPU	1079	1102	1131	1212	1922	2031

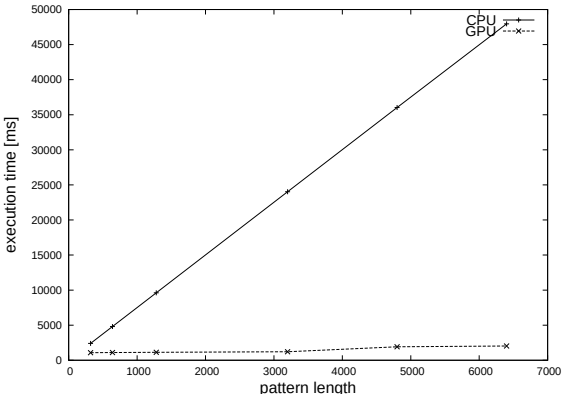

Figure 9: Execution Time of CPU and GPU Implementations

6. Conclusions

In this paper, we proposed an efficient GPU-based method for approximate regular expression matching with long patterns. Experimental results showed that 1) our proposed method and an FPGA-based method [4] are 2.9 and 8.3 times as fast as a CPU implementation, respectively, when the length of patterns is 320; 2) our method is more than 18 times as fast as the CPU implementation when the length of patterns is more than 3200. Our future work includes further improvement of memory access efficiency in our GPU-based method.

Accelerating and Characterizing Seam Carving Using a Heterogeneous CPU-GPU System

Ronald Duarte and Resit Sendag
Department of Electrical, Computer, and Biomedical Engineering,
University of Rhode Island, Kingston, RI, USA

Abstract - *Seam carving has been widely used for content-aware resizing of images and videos with little to no perceptible distortion. Unfortunately, for high-resolution videos and large images it becomes computationally unfeasible to do the resizing in real-time using small-scale CPU systems. In this paper, we exploit the highly parallel computational capabilities of CUDA-enabled Graphics Processing Units (GPUs) for accelerating the content-aware resizing of videos and images. The performance results show that our implementation of the seam carving algorithm achieves up to 100x and 14x speed-ups on the computationally-intensive part of the algorithm compared to the faster single-threaded and the faster multithreaded CPU implementations, respectively, on the systems tested. The overall resizing operation is over 6x and 2x faster than the best single-threaded and multithreaded CPU implementations, respectively, which demonstrates the potential to resize videos and large images in real-time.*

Keywords: Seam carving, GPU, CUDA, parallelization, heterogeneous system

1 Introduction

One of the most popular uses of diverse mobile devices today is for browsing images and playing videos. However, different devices have different resolution capabilities, so it is necessary to resize images and videos efficiently and effectively to fit them into diverse displays (such as cell phones, PDAs, desktop displays, etc), preferably without distortion.

Cropping [1-5] has been one of the most popular approaches to resize images. However, cropping may lose an unacceptable amount of visual information when important structures lie at all edges of an image. In addition, it can only remove information, but it cannot add information to expand the image. Scaling methods, with or without interpolation, tend to produce distorted images, especially when an image is scaled in one direction.

Avidan and Shamir [6] recently provided a new approach to image and video resizing, called *seam carving*. Seam carving functions by establishing a number of seams (paths of least importance) in a digital media and automatically removes or inserts seams to resize the media. This content-aware resizing method has been shown to effectively resize images and videos with little to no perceptible distortion. Seam carving is a computationally-intensive operation. For high-resolution images and videos, it could be difficult to perform the resizing in real-time by using the CPUs in a desktop-scale computer.

The advent of commodity massively parallel architectures, such as modern GPUs, is a compelling option for inexpensively removing the computationally-intensive operations from the CPU. In this paper, we exploit the data-parallel execution model of GPUs for the implementation of content-aware image and video resizing. This paper makes the following contributions:

1) We evaluate GPU-based seam carving algorithm on two CUDA-enabled NVIDIA GPUs.
2) We compare single- and multi-threaded CPU versions of the algorithm with the GPU versions.
3) We demonstrate that GPUs facilitate low-cost real-time resizing of images and videos.

2 Seam Carving

Seam carving [6] transforms the size of images and videos by carving-out pixels that form a path of low-energy. These low-energy connected paths, called *seams*, go from top to bottom or left to right for vertical or horizontal resizing, respectively. The seams are added to or removed from an image[1] in order to increase or reduce its size with minimal observable distortion. Figure 1 shows the steps of horizontally resizing an example image. Since the majority of execution time is spent on the energy function and seam map computations (see section 5), in this paper, we focus on accelerating these two computationally-intensive parts.

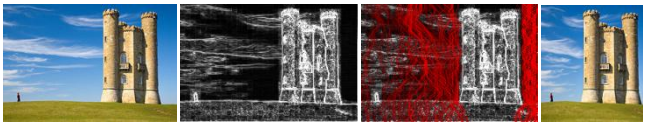

Figure 1[2]: Seam Carving Steps. (a) The original image. (b) The energy of the image using gradient magnitude. (c) The low energy seams with the energy function. (d) Resized image after the seams are removed.

2.1 Energy function

Seam Carving can utilize a variety of energy functions to generate seams [6]. The magnitude of the gradient approach uses equation (1) to compute the energy of each pixel relative

[1] For most of the paper, we only discuss images. However, a video is a set of images or frames displayed at the video rate of 30 frames per seconds. Seam carving is equally applicable to both images and videos.
[2] Image taken from Wikimedia Commons.

to its surrounding pixels by quantifying the amount of change in color from one pixel to the next.

$$e(I) = \left\|\vec{\nabla} I\right\|_1 = \left|\frac{\partial I}{\partial x}\right| + \left|\frac{\partial I}{\partial y}\right| \quad (1)$$

The energy function computation exhibits vast data parallelism. However, attention must be given to memory access patterns, which may have a huge implication on performance. The need for accessing neighboring pixels to compute the energy function strongly influences the way we access memory on the GPU.

2.2 Seam map

After finding the energy of each pixel, the result is used to locate the lowest-energy paths or *seams*. We focus on the implementation of the seams required for horizontal resizing, i.e. the vertical seams. The first row of the seam map is directly obtained from the first row of the energy function. Starting from the second row of the image, we use a dynamic programming approach (2) to compute the seam map value at every pixel.

$$S_{i,j} = \begin{cases} E_{0,j} & \text{if } i = 0 \\ E_{i,j} + \min\left(S_{i-1,j-1}, S_{i-1,j}, S_{i-1,j+1}\right) & \text{otherwise} \end{cases} \quad (2)$$

In equation (2), S is the seam map table, E is the energy function table, and i and j are the rows and columns indices of the tables. This dynamic programming approach produces the optimal seam/s [6]. The values in the final row of the seam map table correspond to the cumulative energy of the seams. The most important point to note about equation (2) is that the computation for each element is entirely dependent on the result of the three elements directly above it, as shown in Figure 2. Therefore, unlike the energy function, the data in the seam map computation is not 100% separable. This makes parallelizing the seam computation much more difficult than the energy function.

3 Hardware resources

All of the implementations presented in this paper were executed on two different heterogeneous computer systems. The First system is a Mac Pro running the Mac OS X 10.6 operating system powered by two 2.8GHz quad-core Intel Xeon E5462s CPUs. The Mac pro has an NVIDIA 8800GT GPU (G80 architecture) with 112 cores and 512MB of GDDR3 memory.

The second system is a newer machine running the Ubuntu Linux 10.04 operating system, powered by a single 3.4 GHz quad-core Intel Core i7 2600k CPU. The GPU on the Linux machine is the NVIDIA GTX580 Featuring the Fermi architecture with 16 SMs (32 cores per SM) for a total of 512 SPs. The GTX580 has 1.5GB of GDDR5 memory, 768KB L2 cache, and 64KB configurable L1 cache/shared memory per SM. The Intel Core i7 supports simultaneous multithreading (SMT) while the Intel Xeon does not support SMT [8, 9].

The parallelization tool for the CPU implementation is POSIX threads (pthread). Both of the CPU implementations were optimized and compiled with *gcc* -O2 optimization level. Finally, the heterogeneous implementations were compiled with the NVIDIA *nvcc* compiler, which uses *gcc* and the -O2 flag to compile the CPU code

4 Implementation

4.1 CPU implementation

4.1.1 Energy function

The single threaded CPU implementation of the energy function utilizes a set of nested *for-loops* to compute each of the partial derivatives (Algorithm 1, lines 1-7), and utilizes the result to compute the magnitude of the gradient (Algorithm 1, lines 8-9). The one-half is factor out of the derivatives and applied after the sum in order to save one multiplication operation per pixel. Instead of directly storing a 2D image in a 2D array, we store the 2D image in a 1D array and map the 1D to a 2D array. This minimizes the allocation time, and the data is stored in a more suitable manner to take advantage of spatial locality. Note that the derivative of each pixel is computed once, the purpose of the nester loops is to ease the computation, but each derivative has O(n) time complexity.

Given that there are no data dependencies in the computation of the energy function, we are able to divide the computation into as many threads as the operating system supports. However, the performance is dictated by the hardware and the CPUs' ability to execute threads simultaneously. We divide the input image into tiles consisting of consecutive rows. The height of each tile is computed based on the number of threads and the height of the image. Figure 3 illustrates the decomposition of the input image for an execution configuration of eight threads. The Algorithm for the multithreaded version is very similar to Algorithm1 with the exception that each thread only loops through its corresponding portion of the image.

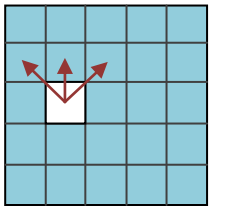

Figure 2. Seam map example.

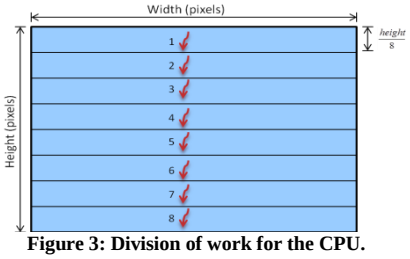

Figure 3: Division of work for the CPU.

Alg. 1 Single threaded Energy function

```
1: Set all elements of Ix and Iy to 0
2:    for i ← 0 to height – 1
3:       for j ← 1 to width – 2
4:          Ix(i, j) ← I(i, j+1) – I(i, j-1)
5:    for i ← 1 to height – 2
6:       for j ← 0 to width – 1
7:          Iy(i, j) ← I(i+1, j) – I(i-1, j)
8:    for all pixel in the image
9:       energy = 0.5 * (|Ix| + |Iy|)
```

Alg. 2 multithreaded Seam map

```
1: for i ← 1 to height – 1
2:    for j ← t_start to t_end
3:       if (j-1 < t_start)
4:          wait for S(i,j-1) to be unlock
5:       if (j+1 > t_end)
6:          wait for S(i,j+1) to be unlock
7:       S(i,j) ← Min(S(i-1,j-1),
            S(i-1,j), S(i-1,j+1))+energy(i,j)
8:       Unlock S(i,j) //initially locked
```

4.1.2 Seam map

Unlike the energy function, the seam map computation uses a dynamic programming approach that is not parallelization-friendly (see section 2.2). Therefore, we have to perform a row-by-row computation of the seam map, which serializes the execution of rows. We achieve parallelism by dividing each row into fixed-width tiles and computing these tiles in parallel. We synchronize all threads after the execution of each row. This method does not yield any significant benefit over the single-threaded version; in fact, with more than two threads, the program spends more time synchronizing than performing the computations.

In an attempt to optimize the seam map implementation, we used locks to create local barriers in place of global barriers. Instead of stalling threads until every thread finishes its part, each thread is only concerned with the execution of its neighboring threads. We therefore use an array of locks to allow each thread to manage the availability of the seam map results of its boundary element on every row. This approach is illustrated in Algorithm 2 where *t_start and t_end* are computed by dividing the width of the image by the number of threads and assigning each thread their respective areas.

4.2 Energy function on the GPU

4.2.1 Naive implementation

The first GPU method presented in this paper is the *naive-non-aligned* implementation. In this implementation, the image was partitioned into 16x16 tiles containing 256 pixels as illustrated in Figure 4a. In addition to loading the corresponding data into shared memory, the kernel also needs to load the pixels immediately adjacent to the tile. These outer pixels are known as the tile apron, shown in white in Figure 4b. Each tile utilizes one 2D block of 324 threads (18x18), thus assigning one thread per pixel load.

All CUDA threads in the Naive kernel execute Algorithm 3. First, each thread calculates the necessary pixel indices to copy a pixel from the global to the shared memory (lines 1-4). Line 6 caches the pixels in shared memory and line 8 ensure that all data transfer completes before performing the computation. Finally, we use 256 out of 324 threads to compute the gradient and store result (lines 10-12).

At first, we used a three-byte data structure to store the RGB components of each pixel. A three-byte data structure causes unaligned memory accesses, which reduces performance. We solved this problem by aligning pixels to word length (4 bytes). This implementation waste 25% of the total memory. However, if the memory size is sufficient, this is an excellent tradeoff. In addition, there are times when we are interested in preserving the alpha component of all pixels; this implementation guarantees that all pixels retain the original alpha value. Another optimization technique is to allocate memory on the device using the *cudaMallocPitch* function [7]. Using the two-dimensional allocation and copy functions (*cudaMemcpy2D*), we guarantee that each row of the image starts on a 64- or 128-bytes boundary in global memory depending on the device architecture.

Alg. 3 Naive implementation of the energy function in CUDA

```
1:   col ← block_x * tile_width + x – 1     // x : thread_x
2:   row ← block_y * tile_height + y –1     // y : thread_y
3:   k ← row * image_width + col
4:   i ← y * bw + x                         // bw : block_width
5:   Ix ← 0,  Iy ← 0
6:   if (k is an index within the image)  SMEM(i) ← image(k)
7:   else  SMEM(i) ← 0
8:   Synchronize_threads
9:   if (x > 0 and x ≤ tile_width and y > 0 and y ≤ tile_height)
10:      Ix ← SMEM(i+1) – SMEM(i–1)
11:      Iy ← SMEM(i+bw) – SMEM(i–bw)
12:      ENERGY(k) ← 0.5 * (|Ix| + |Iy|)
```

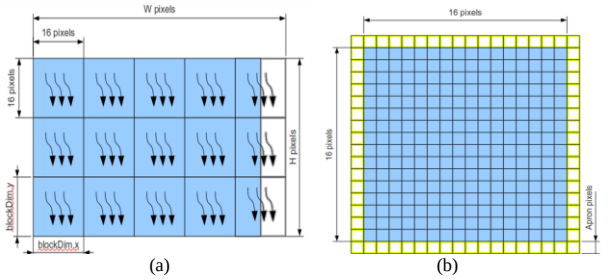

Figure 4: (a) Division of work between threads in the naive GPU implementations; the white area represents idle threads. (b) Partition of block; the tile apron is shown in white and the writable pixels in blue.

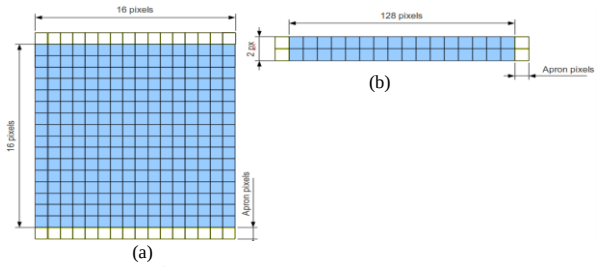

Figure 5: Partition of the image. (a) Vertical tiles. (b) Horizontal tiles. White represents the apron pixels and blue/dark the workable pixels

4.2.2 Split-aligned implementation

To achieve nearly full coalesced memory access, we decided to separate the energy function calculation into two separate kernels, a horizontal and a vertical gradient kernel, and combine the results of the two. This allows us to reorganize the thread grid to suit the kind of memory accesses expected for each direction of the derivatives. Both the apron pixels and workable pixels in the vertical direction are always aligned to 16 pixels as shown in Figure 5a, allowing coalesced accesses of 64 bytes.

For the horizontal calculation, it is not possible with this approach to avoid uncoalesced memory accesses because the apron pixels lie outside the alignment boundary. However, by increasing the tile width to 128 pixels (Figure 5b), some of the wasted bandwidth due to uncoalesced memory accesses is hidden. This improves the memory efficiency allowing only two uncoalesced loads per every eight coalesced loads, and thus increasing bandwidth usage. Algorithm 4 and 5 show the implementation of the *split-aligned* method to compute the energy function.

Alg. 4 Vertical implementation of the gradient in CUDA

```
1:  col ← block_x * bw + x   // x/y : thread_x/y,  bw : block_width
2:  row ← block_y * tile_height + y –1
3:  k ← row * image_pitch + col
4:  i ← y * bw + x,  Ix ← 0,  Iy ← 0
5:  if (k is an index within the image )  SMEM(i) ← image(k)
6:  else  SMEM(i) ← 0
7:  Synchronize_threads
8:  if ( y < tile_height )
9:      row ← row + 1,  i ← i + bw
10:     k ← row * energy_pitch + col
11:     if (row < image_height)
12:         Iy ← SMEM(i + bw) – SMEM(i – bw)
13:         ENERGY(k) ← |Iy|
```

Alg. 5 Split-aligned implementation of energy in CUDA

```
1:  col ← block_x * block_width + thread_x
2:  row ← block_y * block_height + thread_y
3:  k ← row * image_pitch + col
4:  x ← thread_x + 1,  y ← thread_y,  Ix ← 0
5:  i ← y * HORIZ_WIDTH + x
6:  if (k is an index within the image)  SMEM(i) ← image(k)
7:  if (thread_x == 0 and row < image_ height)
8:      pbase ← col * image_pitch
9:      SMEM(y * HORIZ_WIDTH) ← image(pbase + block_width * block_x – 1 )
10:     SMEM(y * 2 * HORIZ_WIDTH – 1) ← image(pbase + (block_width+1) * block_x)
11: Synchronize_threads
12: if (col < image_width)
13:     k ← row * energy_pitch + col
14:     Ix ← SMEM(y * HORIZ_WIDTH + x + 1) – SMEM(y * HORIZ_WIDTH + x – 1)
15:     ENERGY(k)← 0.5 * (|Ix| + ENERGY(k))
```

4.2.3 Locality-aware implementation

The *split-aligned* method has the potential to reduce the number of uncoalesced memory accesses by a significant amount, but it does not make the best use of locality. Therefore, when porting the implementation to the newer heterogeneous system, we decided to revise the *split-aligned* method in order to take advantage of locality and the new capabilities provided by the Fermi architecture. The GTX580 offers approximately 4.5X more SPs than the 8800GT. It also supports memory accesses of up to 128-bytes on a single coalesce load.

Apart from the two outermost pixels that surround the entire image, all pixels are utilized four times in the energy function computation; twice for each of derivatives. Even when these pixels are cached in shared memory, which saves one global load per derivative, the *split-aligned* method requires that each pixel be loaded twice. Therefore, we decided to go back to implementing the energy computation using a single kernel to compute both partial derivatives.

The *locality-aware* method breaks the image into 2D blocks of 512 threads. Each tile contains 64 columns and 8 rows. With a 64x8-block configuration, two warps are assigned per row. All 32 threads in a warp are able to cache their corresponding pixel on a single coalesce load of 128-bytes for 16 fully coalesce loads. Loading the top and bottom aprons also results in fully coalesce loads. The uncoalesce loads are introduced by the left and right aprons of the tile. Increasing the number of rows in a tile improves locality, but increases the number of uncoalesce loads. Increasing the block width minimizes the number of uncoalesce loads, but reduces locality. After careful analysis and performance tests, we found that 8 rows and 64 columns generate the best performance. Algorithm 6 gives an in-depth description of the *locality-aware* implementation of the energy function.

Alg. 6 Locality-aware implementation of the energy in CUDA

```
1:  col ← block_x * block_width + thread_x      // We ensure col
2:  row ← block_y * block_height + thread_y     // and row are within
3:  k ← row * image_pitch + col                 // the image width
4:  j ← thread_x + 1,  i ← thread_y + 1         // and height
5:  SMEM(i, j) ← image(k)
6:  if (thread_x == 0 and col ≠ 0)  SMEM(i, 0) ← image(k – 1)
7:  if (thread_x == block_width–1 and col ≠ image_width–1)
8:      SMEM(i, block_width + 1) ← image(k +1)
9:  if thread_y == 0 and row ≠ 0
10:     SMEM(0, j) ← image(k – image_pitch)
11: if thread_y == block_height–1 and row ≠ image_height–1
12:     SMEM(block_height + 1, j) ← image(k + image_pitch)
13: Synchronize_threads
14: Ix ← 0,  Iy ← 0,  k ← row * energy_pitch + col
15: if pixel are not on the edge of the image
16:     Ix ← SMEM(i, j + 1) – SMEM(i, j –1)
17:     Iy ← SMEM(i + 1, j) – SMEM(i – 1, j)
18: else if pixel is in the first or last rows
19:     Ix ← SMEM(i, j + 1) – SMEM(i, j – 1)
20: else if pixel is on the first or last columns
21:     Iy ← SMEM(i + 1, j) – SMEM(i – 1, j)
22: ENERGY(k)← 0.5 * (|Ix| + |Iy|)
```

4.3 Seam map on the GPU

The GPU implementation of the seam map computation is very similar to the multithreaded CPU implementation, which is described in Section 4.1.2. Each row of the image is broken into horizontal tiles, whose width is carefully selected in order to maximize the occupancy of the GPU. Given that, blocks are not scheduled deterministically and that there is no synchronization among threads on different blocks, we must resort to calling the kernel once per row and synchronize in between calls. For this implementation, wider images should perform much better than narrow images. Similar to the multithreaded CPU implementation, a significant amount of the data is not separable. This limits the amount of parallel execution per kernel launch.

4.4 Page-Locked Memory

The CUDA runtime environment has functionalities to allocate and use *page-locked* memory in place of regular *pageable* host memory [7]. We included this feature in our heterogeneous implementation to optimize the memory transfer. In the performance evaluation, we demonstrate that *page-locked* memory does not affect the performance or results of individual kernels, but it improves the execution time of the memory transfer between the host and device.

5 Performance evaluation

The overall time that it takes to remove a single seam of an image depends highly on the size of the image. The energy function takes the largest fraction of the total execution time, followed by the seam computation. Hence, in this paper, we focus on improving the energy function and the seam map computations. However, we also compare and discuss the total execution times.

5.1 CPU evaluation and results

5.1.1 Energy function

Figure 6 illustrates the performance gained by multithreading the energy function computation and executing the implementation on the Intel Core i7 (4-cores each with SMT) and Xeon CPUs (8-cores, no SMT). The execution of the energy function single-threaded implementation takes 31.5 ms to complete on the Intel Xeon CPU. This is the base system in Figure 6. Results show that the newer Intel Core i7 CPU outperforms the Intel Xeon processor for all of the thread configurations. The best CPU performance for the energy function computation of a 1200x900 image is with the Intel Core i7 and 16 threads. Overall, the energy function computation scales well on multi-core CPUs. With eight cores, the Intel Xeon achieves 7x performance improvement. With four cores and eight hardware threads, the Intel Core i7 achieves 7x speedup over its single-threaded execution. In addition, the Intel Core i7 achieves a 10x performance improvement over the Intel Xeon single-threaded execution. Finally, as the number of threads launched increase beyond the number of hardware threads in the system, the performance gain becomes smaller due to the thread switching overheads. The only exception is the 16-thread execution of the Intel Core i7, which needs further research and it is left as future work.

5.1.2 Seam map

In section 4.1.2, we discussed the implementation of the seam map on the CPU and the dependability among rows of pixels. We emphasized how dependability due to the dynamic programming approach serialized the execution of rows. However, the results exposed another problem that significantly affects the parallelization of the seam map computation. Figure 7 illustrates the performance results of the seam map. The Figure shows that barriers impose a substantial overhead, resulting in a zero gain in performance. In the multithreaded implementation, the performance is worse than that of the single-threaded implementation.

As mentioned in section 4.1.2, a more efficient approach is to synchronize locally instead of at the global level. This implementation performs better because locks inflict less overhead. However, we are only able to achieve 26% and 60% improvement with 2 threads on the Intel Xeon and Intel Core i7, respectively. This speedup is minor in comparison to the speedups achieved for the energy function. Beyond two threads, we see a large drop in performance even though both systems have eight hardware threads.

5.2 GPU performance evaluation

5.2.1 Naive-non-aligned energy function

On the 8800GT, the *naive-non-aligned* method achieves 5.7x and 8x performance improvement over the single-threaded CPU implementation executing on the Intel Xeon and Core i7, respectively, as shown in Figure 8. This performance improvement is similar to that of the multithreaded CPU implementations. However, this implementation does not take advantage of the GPU's wide memory bus. Its memory access patterns are not coalesced due to the data not being aligned. Since the *naive-non-aligned* method only utilizes three bytes per pixel, a warp will only load 96 bytes and a half of a warp will load 48 bytes. Such memory access pattern is not aligned. The *naive-non-aligned* method was initially designed with the G80 architecture in mind. However, with minimum modifications, this implementation yields 89.7x and 62x performance improvement on the Fermi GTX580, over the single-threaded implementation running on Intel Xeon and Intel Core i7, respectively (see Figure 9).

5.2.2 Naive-aligned energy function

The changes to transform the naive method from a non-aligned to an aligned implementation (see Section 4.2.1) improve the performance relative to the single-threaded version from 8x to 18x and 5.7x to 12.4x on their respective systems as shown in Figure 8. Utilizing the CUDA profiler, we were able to determine the remaining source of our performance problems, uncoalesced accesses. The first naive version incurred over 500,000 uncoalesced loads and 300,000 uncoalesced stores for a 1200x900 image (≈ 1 megapixel); the improved aligned version incurred only 100,000 uncoalesced loads and 50,000 uncoalesced stores. This is still significantly more than one would expect, as an image with

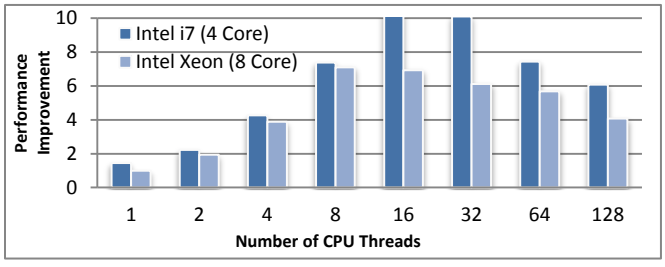

Figure 6: Improvement of the energy function over the single-threaded executing of the Intel Xeon for a 1200x900 image.

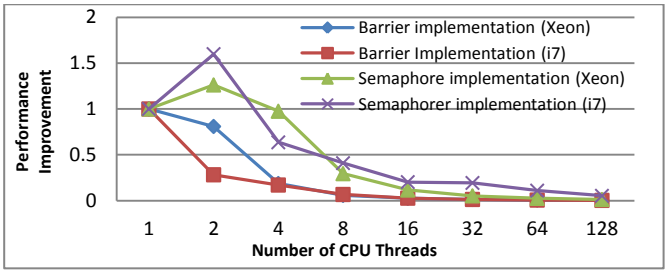

Figure 7: Performance of multi-threaded implementations of Seam map

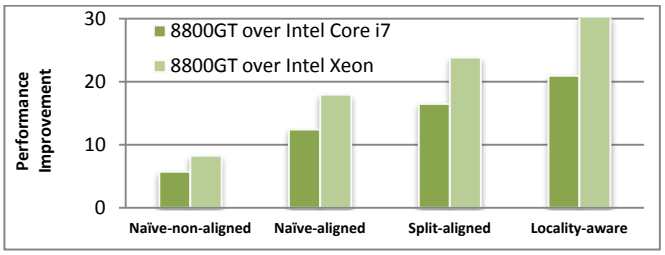

Figure 8: speedup of the energy function over the single threaded CPU

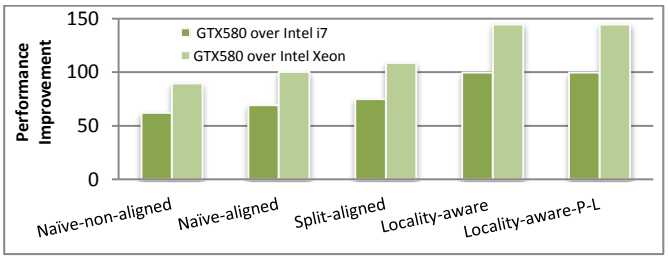

Figure 9: Improvement of the energy function on the GTX580 (Fermi) over the single threaded CPU implementations

this amount of pixels should only need 16,875 loads assuming the GPU can bring in 64 bytes per coalesced loads. The *naive-aligned* method was also designed for the 8800GT. When executed on the GTX580, this implementation shows a performance improvement of 100x and 69x over the respective Intel Xeon and Core i7 single-thread CPU implementations (see Figure 9).

5.2.3 Split-aligned energy function

The *split-aligned* method described in Section 4.2.2 achieves an average of 850 megapixels per second throughput, a 24x and a 16.5x improvement over the single-threaded CPU version on the Intel Xeon and Core i7, respectively, as shown in Figure 8. As expected, the CUDA profiler reveals that for a 1200x900 image, approximately, only 31,000 loads and 15,000 stores were needed (each pixel must be loaded from global memory twice; once for each directional kernel), reducing the total memory access latency by an order of magnitude. On the GTX580, the *split-aligned* achieves 108.6x improvement over the Intel Xeon CPU and 75x over the Intel Core i7 as shown in Figure 9.

5.2.4 Merging the split-aligned method

The l*ocality-aware* method described in section 4.2.3 achieves the highest performance improvement on both GPUs for the energy function computation. By merging the computation of the two derivatives in a way that the number of coalesce loads remains close, and by further taking advantage of locality of accesses, we manage to improve the performance of the energy function by 144.5x and 100x over the single-threaded CPU version on the Intel Xeon and Core i7, respectively, as shown in Figure 9. In addition, when executed on the 8800GT, this method shows a performance improvement of 30x and 21x over the Xeon and Core i7 single-threaded version (Figure 8).

5.2.5 Seam map

The seam map GPU implementation exhibits approximately 4x performance improvement over the single-threaded CPU implementation on the Intel Xeon and no improvement over the Intel Core i7 single-threaded implementation (figure not shown). This performance gain is relatively small in comparison to the energy function speedup. The performance is heavily impacted by the profound dependability among rows in the image. This limits the amount of parallel computation by serializing the execution of rows. Another significant performance impact is the lacking of optimal methods for synchronizing threads among different blocks. Launching the kernel 899 times for a 1200x900 image imposes a significant overhead. Approximately 57% of the seam map execution time is due to kernel launch overhead. Minimizing the launch overhead could potentially improve the performance by a factor of two.

5.3 Evaluation of total execution time of the resizing operation on the GTX580

As previously stated, the energy function and seam map computations account for the largest fraction of the execution time of seam carving. Therefore, by improving these two parts, one would normally achieve a high overall performance improvement. However, there is a penalty when performing computation on the GPU device. The data must be copy from the host memory to the device memory. Once the computation is performed, we must copy the results back to the host memory; if we care to use the results on the CPU side. Both of these operations introduce additional overhead. For extensive GPU computation, the overhead is easily hidden. However, this is not the case for seam carving given that the computations are in the order of micro and milliseconds.

In order to use this GPU implementation of the seam carving in a real word application, we need to utilize the operation described above. Therefore, we need to incorporate the total time that it takes to copy the image from the host to the device, compute both the energy function and the seam map, and copy the result back to the host memory. Figure 10 illustrates the total time that the entire operation takes on the Intel Core i7 and on the GTX580, respectively. This heterogeneous system is selected because it performs the best for both the CPU and the GPU. Figure 11 shows the performance improvement for the entire operation.

Figures 10 and 11 illustrate that the GPU methods perform better than the CPU methods, especially when the size of the image increases. Overall, Figure 11 shows that the total execution time of the best resizing implementation on the GTX580 is about 6x faster than the best single-threaded CPU implementation and over 2x faster than the best multithreaded CPU implementation. The best execution time on entire operation is achieved with the *locality-aware* method using *page-locked* memory. The reason is that the CUDA run-time environment can optimize the host to device and device to host memory copy if the CPU memory is allocated as *non-pageable* memory (see [7]). We therefore modified our fastest implementation, *locality-aware*, to take advantage of *page-locked* memory, which yields the best overall performance as shown in Figures 10 and 11.

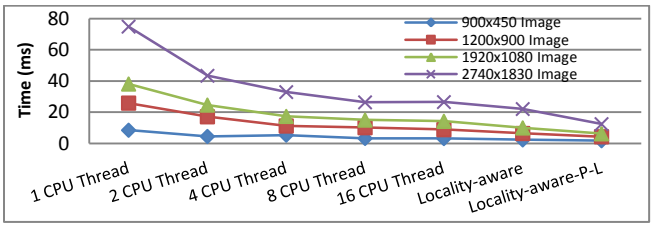

Figure 10: Total time to copy to and from the device, compute the energy function and seam map on the GTX580 and Core i7

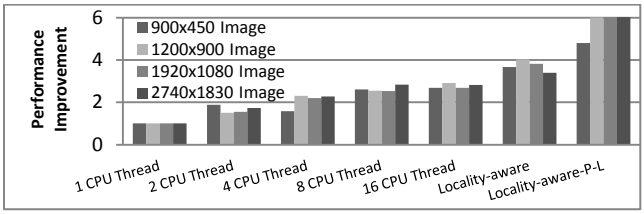

Figure 11: Total time to copy to and from the device, compute the energy function and seam map on the GTX580 and Core i7

6 Related work

Resizing images and videos have been studied extensively in the literature. One of the most popular approaches is to perform cropping [1-5], which involves finding the best rectangular sub-window in the image. However, cropping may lose an unacceptable amount of visual information when important structures lie at all edges of an image. Scaling methods, with or without interpolation, tend to produce distorted images, especially when an image is scaled in one direction.

Avidan and Shamir [6] recently provided a new approach to image and video resizing, called *seam carving*. Seam carving is an algorithm for content-aware resizing of images and videos with little to no perceptible distortion. Seam carving is a computationally-intensive method, which makes it difficult to perform on large images or videos in real-time.

To the best of our knowledge, this paper is the first to implement a real-time content-aware resizing method on GPUs. Our implementation works very well on computing the energy function (over 100x and 144x is possible), but the other computationally-intensive part, *seam map*, is implemented using dynamic programming which limits the amount of data parallelism that can be exploited (only 4x speedup over the Intel Xeon and no improvement over the i7). A recent work [10] implemented a faster way to compute the seam map by finding the optimal matches within a weighted bipartite graph composed of the pixels in adjacent rows or columns. In future work, we will adapt this method, which we believe will improve our results greatly for the seam map computation.

7 Conclusion and future work

Seam carving is a powerful method for resizing images and videos. This content-aware resizing method has been shown to effectively resize images and videos with little to no perceptible distortion. However, the seam carving algorithm is computationally-intensive and for high-resolution images and videos, it may become impossible to perform the resizing in real-time by using the CPUs in a desktop-scale computer.

In this paper, we exploit the highly parallel computational capabilities of CUDA-capable GPUs in a heterogeneous computer system for accelerating the resizing of videos and images through seam carving. Out of the four different GPU methods that we implemented, our results show that the best is the *locality-aware* method using *page-locked* memory, which achieved a performance improvement of 100x over the best single-threaded execution time and 14x over the best CPU multithreaded version of the energy function executing on the Intel Core i7. Overall, our results show that the GPU-based implementation has a significant impact on the performance of seam carving and has the potential to resize videos and large images in real-time.

In the future, we are planning to vectorize the CPU implementation to take advantage of the SIMD instructions on the Intel CPUs. Another important part of our future work is to find a better approach to parallelize the seam map computation.

A Novel Quantum-dot Cellular Automata Switch for Field Programmable Gate Arrays

Hemant Balijepalli[1] **and Mohammed Niamat**[1]
[1]Dept. of Electrical Engineering and Computer Science, University Of Toledo, Toledo, Ohio, USA

Abstract - *In this paper, we propose a novel Quantum-dot Cellular Automata (QCA) based Programmable Switch Matrix which can be used as a routing element for future nano Field Programmable Gate Arrays (FPGAs). QCA technology is an emerging technology based on encoding binary information in charge configuration within quantum dot cells. In FPGAs, the Programmable Switch Matrix (PSM) is the interconnection circuit which switches the signals at the intersection of the horizontal and vertical routing channels. The main goal behind the design of QCA based PSM is to design a routing element for transistor-less nano FPGAs. The proposed QCA based Programmable Switch Matrix (QPSM) has an advantage over the area and the number of cells compared to earlier designs. The proposed QPSM is implemented and simulated using the QCA Designer tool.*

Keywords: Quantum-dot Cellular Automata, Field Programmable Gate Arrays, Programmable Switch Matrix.

1 Introduction

Moore's law states that the number of transistors on a unit area doubles every 24 months [1]. Over the decades, the exponential scaling of the feature size and increase in the processing speed has been provided by CMOS technology for implementing the VLSI systems [2]. The CMOS technology due to the reduction of the feature size is facing consequences like power dissipation, diminishing returns in switching performance, diffusion barriers, gate depletion, stray capacitances and electro-migration [3, 4]. Various technologies have been investigated in the past to find a potential replacement for the CMOS technology in the future. Some of these technologies are Single Electron Transistors (SETs), Resonant Tunneling Diodes (RTDs), Carbon Nano Tubes (CNTs), and Quantum-dot Cellular Automata (QCA) [5, 6]. Proposed by Lent and others in 1993, QCA technology uses arrays of coupled quantum dots to implement the boolean logic functions. Each QCA cell comprises of four electron wells and two free electrons. The electrons can tunnel between the dots through electron tunneling [7]. Due to Coulombic repulsion, the electrons repel each other and align themselves in the opposite corners of the cell. The electron configuration on the diagonals lead to two different state polarizations which are labeled as logic '0' and logic '1', as shown in Figure 1. The cell with polarization -1 represents the binary state 0 and the cell with polarization +1 represents binary state 1. The major advantages of QCA are the small circuit size, higher clock frequency, and lower power consumption.

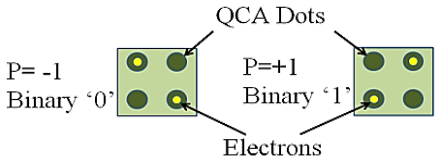

Figure 1. Logic States of QCA

By arranging the QCA cells in different ways, QCA devices such as QCA wires, QCA inverters and Majority voters can be designed (Figure 2). The QCA Majority voter (MV) has logic function MV (A, B, C) = AB + BC + AC. The QCA based AND gate and the OR gate can be designed by setting one of the inputs of MV to 0 (P=-1) and 1 (P=+1), respectively.

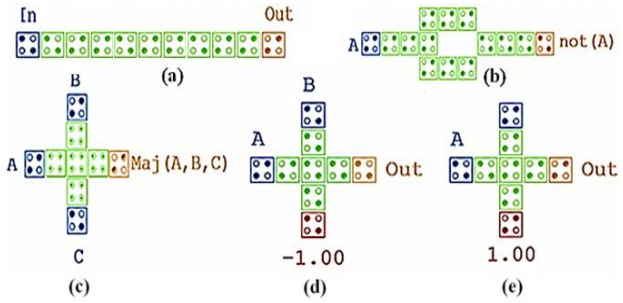

Figure 2. Basic QCA Devices a) Binary QCA Wire b) QCA Inverter c) Majority Voter Gate d) AND Gate e) OR Gate

In QCA, individual wires and gates are clocked. The clocking amplifies the signal and provides the direction of flow to the signal. The clock wires are run underneath the layer consisting of the QCA cells. The clock in QCA is divided into four phases with each phase incurring a 90^{o} phase delay. The four clocking zones are named Switch, Hold, Release and Relax [8] as shown in Figure 3.

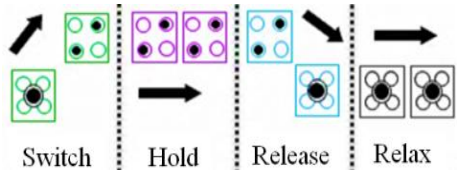

Figure 3. QCA Clock Phases

The clocking scheme allows the arrays of cells to perform the computations based on the position of inter dot

potential barriers and the result is given as the input to the successor array. If the potential barrier is held high, the cell gets polarized and if the potential barrier is lowered, the cell becomes unpolarized. The cell switches to polarized state in the switch phase, remains polarized in hold phase, becomes unpolarized in release phase and finally stays unpolarized in the relax phase until it gets polarized in the next switch state. In this manner, the information is transferred through QCA cells by maintaining the ground state polarizations.

The QCA based routing elements of an FPGA have been proposed in the past. Niemer and others have proposed the design for FPGA logic block and interconnects in QCA [9]. The work in [9] explains that there is no possibility to create equivalent pass transistors using the QCA devices. Thereby they have defined unclocked zones where the cells can remain unpolarized. This is possible by unclocking the cells by fixing their barrier potential to a certain value or by keeping the cells in release phase of the clock. Niemer designed routing elements of various sizes using the unclocking concept. Based on a similar idea, Andrej and others have proposed a basic universal crossing element in QCA [10] which can be used as a switch matrix in FPGAs. In this paper, we propose a novel QCA based Programmable Switch Matrix of an FPGA by keeping the cells in a particular region in the release phase of the clock. Initially, a (1x1) QCA Programmable Switch Matrix (QPSM) is designed based on which switch matrices of any size can be designed. Size of the switch matrix is defined by the number of inputs and outputs of the switch matrix. The concept of coplanar crossover of QCA wiresis also used. The designs are simulated using the QCA Designer tool [11].

The rest of the paper is organized as follows: Section II details the design of the different QCA Programmable Switch Matrices. The simulation results are illustrated in Section III. Section IV includes the conclusion.

2 Design of a QCA Programmable Switch Matrix (QPSM)

The Field Programmable Gate Arrays consists of arrays of logic blocks (cells) placed in an infrastructure of interconnections. The FPGAs can be programmed at the logic cells, at interconnections between the cells, and at inputs and outputs [12]. The major elements of an FPGA are the Configurable Logic Blocks (CLBs), Programmable Switch Matrices (PSMs) and Input and Output blocks (IOBs). The CLB is a basic programmable block implementing digital logic in an FPGA. The CLBs can be configured to perform basic logic functions using the Look up Tables (LUTs). The CLBs are interconnected through Programmable Switch Matrices to form the units which can perform complex functions. The I/O blocks provide programmable I/O connections between the FPGA and the peripherals of the system. It is anticipated that future nano FPGAs will find applications in fields such as telecommunication, medicine, aerospace and industrial control.

In FPGA, the Programmable Switch Matrix is used to switch signals at the intersection of horizontal and vertical routing channels. The switch matrix establishes a communication between different elements of an FPGA. The PSM is used to make the required connections between various logic blocks and input output blocks. Today, many commercially available FPGAs use island-style architecture in which logic blocks are organized in an array separated by horizontal and vertical routing channels (Figure 4). The CLBs are connected to the horizontal and vertical lines using a connection block (C block) and the signals are switched at the intersection of channels by a switch matrix (PSM block) [13] as shown in Figure 4.

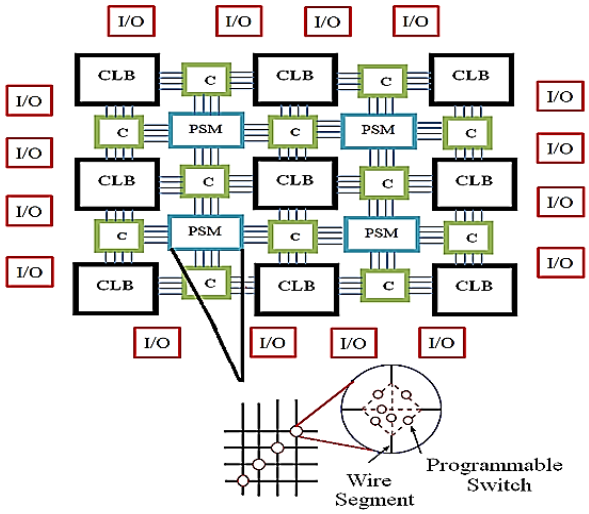

Figure 4. Island style architecture of an FPGA

In the PSM, the crossway consists of six pass transistors that lets the signal flow in either of the four possible directions. In earlier research described in [9,10], QCA based interconnects and routing elements were designed by proposing unclocking select cells or setting the cells in the release phase of the clock. However, the circuits were not simulated. Based on the concept of keeping cells of a certain region in the release phase, we propose a novel design of a QCA Programmable Switch Matrix (QPSM). Using QPSM, the signals can be transferred from one wire to another wire of an FPGA in all the possible directions. As the QCA Designer tool does not support unclocking, we have designed the switch matrices by selectively setting the group of cells in the release phase of the clock.

The (1x1) QCA Programmable Switch Matrix (1-QPSM) is used to switch signals between single horizontal and vertical channels. The PSMs designed in this work have the vertical channel as QCA inverted wire and the horizontal channel as normal QCA wire. When a normal QCA wire crosses an inverted QCA wire, there is no interaction between them. This is possible as the energy between the standard cell and the rotated QCA cell cancels out making the kink energy zero. This crossover of wires is called the coplanar crossover [14]. The two wires are connected by

tapping a normal cell at half way of the rotated cells of QCA inverted wire and connecting it to the normal QCA wire. This is designated as a QCA Connector in this paper. For the signals to flow on the respective individual wires, the connector cells are kept in the release phase of the clock so that they do not affect the cells of either of the wires. For the signals to flow from one wire to the other, correct clocking must be provided to the QCA Connector. In Figure 5, the QCA Connector cells are kept in the release phase so that the inputs In1 and In2 appear at the outputs Out1 and Out2, respectively. Based on the (1x1) QPSM, (n x n) QPSMs can be designed where 'n' is the size of the switch matrix.

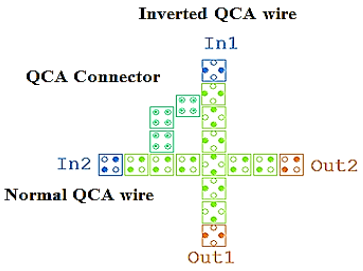

Figure 5. A (1x1) QCA Programmable Switch Matrix (1- QPSM)

In Figure 6, the design of a (4x4) QCA Programmable Switch Matrix (4- QPSM) is shown. The input signals In1-In4 can be routed in vertically up, down and horizontal directions. By providing the respective clock to the QCA Connectors (dotted purple box), the signals travel from the horizontal channels to vertical channels. The signals are then transferred in up and down direction by clocking the appropriate cells in the vertical channel. The other QCA Connectors are kept in the release phase of the clock so that they do not affect the signals flowing on the horizontal channel. Therefore, the signals are transferred from one wire to the other by providing the clock in the direction the signal has to flow and keeping the rest of the cells in the release phase of the clock.

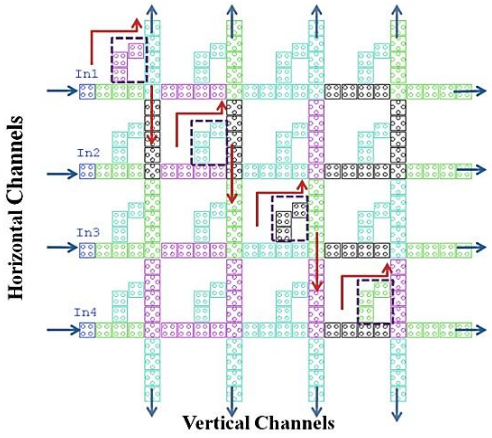

Figure 6. A (4x4) QCA Programmable Switch Matrix (4- QPSM)

In FPGA, the Connection Block connects the horizontal and vertical channels to the CLBs. We have designed the QCA Connection Blocks (QCB) to provide these connections. A four input QCB (4-QCB) is shown in Figure 7. The inputs In1-In4 on the horizontal channels can be routed in three directions (straight, up and down). Select QCA Connectors are clocked to allow the signals to flow in the desired direction, the rest of the Connectors are kept in the release phase. For example, if the signals are supposed to connect to the CLB at the top and not to the CLB at the bottom, the QCA connectors above the horizontal channels are clocked and the QCA connectors below the horizontal channels are kept in the release phase. Similarly, the QCB which connects the vertical channels to the CLB can be designed.

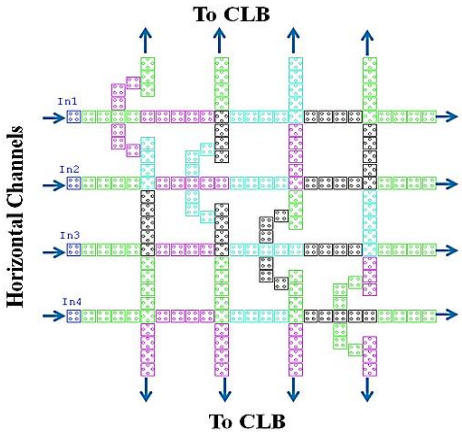

Figure 7. A (4x4) QCA Connection Block (4- QCB)

A layout of an island style FPGA with the proposed QPSMs is shown in Figure 8. In the figure, PSM1-PSM4 represents the 4-QPSMs and C1-C5 represents the 4-QCBs. The inputs are shown by blue arrows and the outputs are shown by orange arrows.

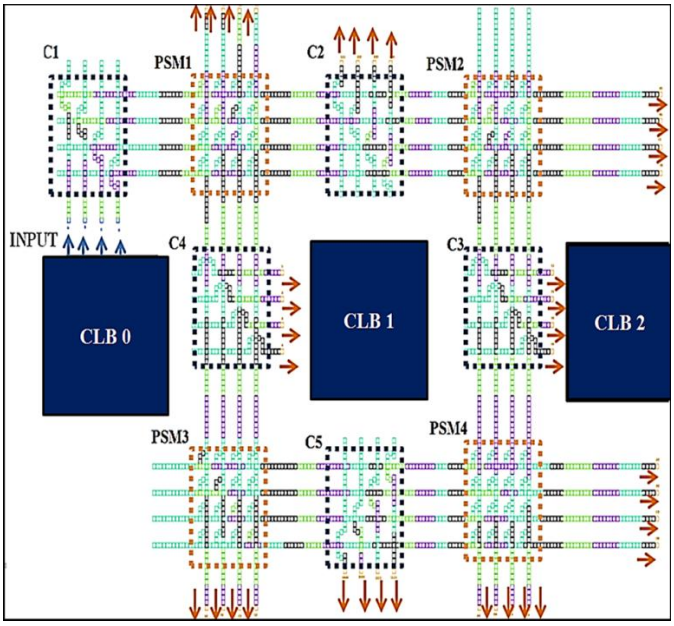

Figure 8. QCA layout showing the QCA Programmable Switch Matrices (QPSM) and QCA Connection Blocks (QCB)

To verify the functionality of the proposed QPSM, signals are transferred in multiple directions in the layout. Table I shows the flow of the signal through each Connection block.

TABLE I. FLOW OF THE SIGNALS IN THE QCA LAYOUT

Block	Flow of the signal	Block	Flow of the signal
C1		PSM1	
C2		PSM2	
C3		PSM3	
C4		PSM4	
C5		-	-

3 Results

The proposed QPSMs are simulated using the QCA Designer tool for functional verification. In Table II, the number of QCA cells and the area occupied by different sizes of QPSMs are listed. It is found that, for a QPSM of size 'n', the number of QCA cells required are given by 4n (3n+1) cells and the area occupied is given by [n (n+1) -1] / 100 (μm^2). The simulation result of a 4- QPSM is shown in Figure 9. For the inputs In1-In4, the QPSM gives the correct outputs Out1-Out4 (indicated by the arrows). Similarly, the input signals can be switched in other directions and the expected outputs obtained.

TABLE II. NUMBER OF CELLS AND AREA OF EACH SWITCH MATRIX

Size of the QPSM (n)	Number of QCA cells = 4 n(3n+1) cells	Area = $\frac{n\,(n+1)-1}{100}$ (μm^2)
1	16	0.01
2	56	0.06
3	120	0.11
4	208	0.19
5	320	0.29
6	456	0.41

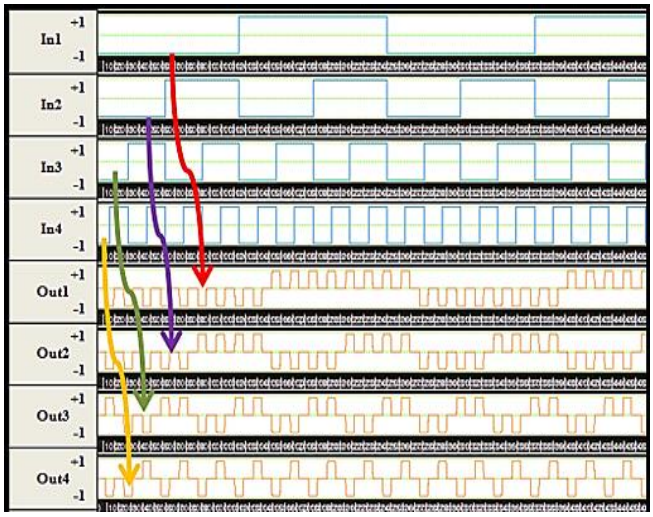

Figure 9. Simulation result of 4-QPSM

4 Conclusion

In this paper, design of a QCA based Programmable Switch Matrix is proposed for nano Field programmable Gate Arrays. The proposed PSMs can be used as potential routing elements in the 'beyond CMOS era'.

Abstract— *Clusters using multiple GPUs have been already widespread to build a high performance computer economically. However, since the number of plugged GPUs into a CPU is limited, such clusters are consisting of multiple host PCs each of which has a few GPUs. This conventional multi-GPU cluster requires programmers to learn parallel programming skills for controlling communication between nodes as well as GPU programming.*

In order to show the illusion that a large number of GPUs to a single host, a multi-GPU system with ExpEther is proposed. The multi-GPU system allows interconnecting a single host PC and multiple GPUs by ExpEther which extends PCIe interface to Ethernet.

Execution of the application program with two to six GPUs achieved 1.99, 2.96, 3.92, 4.83 and 5.14 times speedup at most, as those with a single GPU. Also, the influence of the bandwidth of the network used in the multi-GPU system is evaluated quantatively.

Keywords: Graphics processing unit, cluster, Parallel Computing, Scalability

1. Introduction

The GPGPU (General Purpose Computing on Graphic Processing Units) has become a major way for high performance computing. Recent GPUs have multiple SIMD (Single Instruction Multiple Datastreams) units each of which provides more than hundreds processors, and support thousands of concurrent threads. GPUs are much superior to general purpose multi-core CPUs from the viewpoint of both performance per cost and performance per power. Also, their growth of performance per year is also much higher than that of CPUs.

Although the programming of GPUs was difficult for common programmers, it has been rapidly improved. For instance, NVIDIA and AMD support c-like GPU programming languages, Compute Unified Device Architecture (CUDA) [1] and ATI Stream SDK [2], respectively. Open Computing Language (OpenCL) [3] has been widely spread as a programming environment for various accelerators including GPUs. Such programming environment lowers the barrier for introducing of GPU in the many fields.

In order to obtain the performance beyond a single GPU, clusters with GPUs are popularly used in the field of high performance computing. Japanese Tsubame 2.0 [4] system, a supercomputer using GPUs is in the Top500 of would supercomputers ranking. Generally, these multi-GPU systems are consisting of a large number of network connected PCs each of which provides a few GPUs plugged into each slot. This structure comes from that the the GPU needs support of CPU to control data transfer and kernel execution.

This conventional multi-GPU system cause two problems. The first is an increase of the latency of the communication between nodes. The communication between GPUs must be done via its connected CPU, and it often stretches the latency and limits the bandwidth. When the latency of the communication is large compared with the computation time of GPUs, the time for communication can bottleneck the system, especially when the number of nodes becomes large. The second is the programming complexity of parallel processing. In order to use such a cluster efficiently, programmers are required to describe hierarchical parallel programming: that is, the coarse grained parallel programming which controls the communication between GPUs in MPIs or other message passing library and the fine grained parallel programming for intra-GPUs in GPU specialized programming language such as CUDA and OpenCL. Although some tools have been developed to reduce the multi-GPU systems programming difficulty[5][6], they require some performance overhead.

We address these problems by using ExpEther, the Ethernet-based virtualization technology. ExpEther extends PCI Express(PCIe), the standard interface used for connecting hosts and GPU devices to Ethernet. It provides a transport function for PCIe packets by encapsulating them within an Ethernet frame and tunneling between the con-

nected modules.

The proposed multi-GPU system with ExpEther, which is called GPU-BOX, has only a single host PC connected with a large number of GPUs by the Ethernet consisting of conventional switches and cables. GPU-BOX provides PCIe ports and power supply for GPUs together with the function of ExpEther. This system releases programmers from the requirement to learn communication programming between nodes, and enables users to select the number of GPUs independent of a host PC's capacity. Moreover, the latency for communication between GPUs is not so stretched, since the data is communicated between GPUs without using CPUs.

The rest of this papers is organized as follows. We introduce some related work about multi-GPU systems in Section 2. The key technology, ExpEther is explained in Section 3, and then a multi-GPU system by using GPU-BOX is proposed in Section 4. In Section 5, our experimental results are shown. Finally, we conclude this study with future work in Section 6.

2. Related Works

There are some equipments to increase the number of GPUs which a single host PC provide. PCI Express Switches provided by some vendors such as IDT[7] increase PCIe slots of the host PCs. They enable host PCs to connect GPUs over the number of slots provided with host PCs. Also, PCI-SIG announced the availability of the PCI Express External cabling 1.0 specification[8]. It focuses on the implementation of cabled PCIe. Based on the specification, there are external expansion units of PCIe, for instance CONTEC provides some of bus expansion units for PCI Express[9]. However, compared with the system connected by network, extending with these equipments has less flexibility and extensibility.

Some tools for reduction of the complexity of parallel programming are also developed. Vegeta[5] and Hybrid OpenCL[6] virtualize the communication between nodes. By using them, programmers can use multi GPUs without describing communication program in message passing library, but they require some performance overhead. FLAT[10] also has the same policy, though the target program is described in CUDA instead of OpenCL which is the target of Vegeta and Hybrid.

Our proposed multi-GPU system has only a single host and is connected by Ethernet. It doesn't require to describe communication program between nodes since a single host is used. The flexibility and extensibility are not degraded compared with conventional systems.

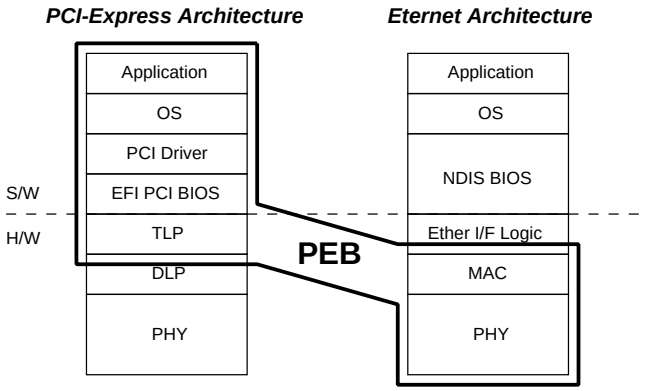

Fig. 1: Overview of PEB

3. ExpEther

ExpEther[11], a key technology of multi-GPU system, is the Ethernet based Virtualization technology developed by NEC[12]. It extends PCIe which is high performance I/O network but limited to small area around the cabinet to much wider area by using Ethernet. Various types of I/O devices on distant location can be connected as if they were inside the cabinet.

In this section, we describe the function of ExpEther, PCI Express-to-Ethernet bridge (PEB) and and Ether-Forwarding-Engine (EFE).

3.1 PEB

As Fig. 1 shows, PEB is the function of ExpEther to bridge the TLP layer in PCIe and the MAC layer in Ethernet. PEB encapsulates a PCIe packet, Transaction Layer Packet (TLP) into Ethernet frame, and decapsulates it for extending PCIe to Ethernet. Moreover, the target Ethernet is virtualized so that the connected devices can be treated as if they were plugged into host PCs without Ethernet. PEB is implemented with a conventional operating system, device driver, PCIe interface, Ethernet Switch and others. That is, the ExpEther technology can be easily introduced into the systems only with PCIe interfaces.

3.2 EFE

EFE is the delay-based protocol which supports repeat and congestion control instead of TPC, the loss-based protocol. The congestion control system in EFE consists of the following steps.

1) It sends a certain number of probe packets, when communication starts.
2) It decides the initial transmission bandwidth based on the acknowledging packets for the probe packets.

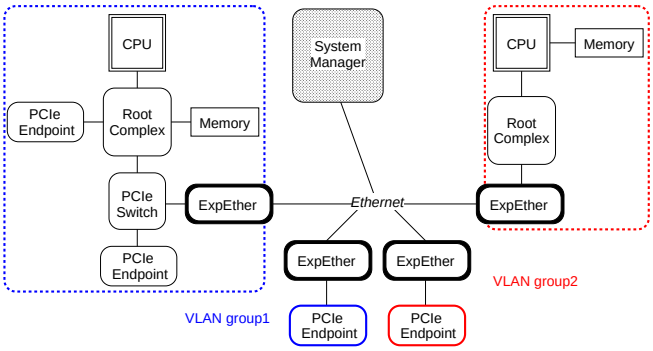

Fig. 2: Example of the System with ExpEther

3) After this, it adjusts the transmission bandwidth for RTT.

EFE employs Go-back-N as a flow-control method. Compared with Selective-Repeat, Go-back-N has the advantage of hardware cost which does not need the reorder buffer. Also, although a number of retransmitted packets are required in the environments of low round-trip propagation delay which ExpEther targets, packet retransmission would not frequently happen.

3.3 System Example using ExpEther

Fig. 2 shows an example of the basic system with ExpEther. On the system of ExpEther, servers and PCIe endpoints are managed and grouped by VLAN ID, which each server or endpoint has in the register of ExpEther bridges. The VLAN ID group consists of a single server and multiple PCIe endpoints. The system manager allocates servers and endpoints the VLAN ID, and can flexibly constitute the groups. On the data transfer, the Ethernet frame has the VLAN ID tag which is referenced to distinguish the group to which the frame belongs.

Though ExpEther doesn't support direct CPUs connection, it can be done by using Remote Direct Memory Access (RDMA). By using the RDMA, CPUs can communicate each other by accessing memory of another CPU directly. It provides low latency and high throughput communications, and suppresses the CPU workload.

4. Design and Implementation

In this section, we propose a multi-GPU system with ExpEther, and show an implementation using GPU-BOX.

4.1 System Design

Fig. 3 shows an overview of the multi-GPU system with ExpEther. It allows to interconnect a single host PC and multiple GPU devices with a common Ethernet through the

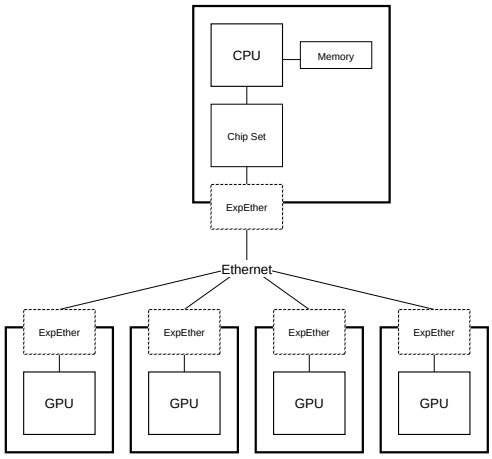

Fig. 3: Multi-GPU System with GPU-BOX

PEB. The network consists of the common Ethernet equipments such as switches and cables. Programmers can treat the multi-GPU system as if all of GPU devices were directly ported into a single host PC, since the PEB encapsulates communication for the control via the network. On the multi-GPU system with only a single host, programmers can make the use of computing power of multiple GPUs without learning programming skill of communication between nodes such as MPI.

The following is a list of the benefits and advantages that the multi-GPU system with ExpEther provides.

- Performance: Stretching the latency of communication between GPUs is suppressed by using ExpEther.
- Programmability: Even programmers who can't describe communication between GPUs can use the system with multiple GPUs.
- Portability: The existing GPU program can run with only a small change about the number of devices in GPU programming language for instance CUDA.
- Flexibility: When the number of GPUs is changed, the application on multiple GPUs can run with only program modification of device size and extending network with Ethernet switches.
- Compatibility: GPUs are accessible to a conventional operating system, device driver, PCIe interface, and Ethernet switch. Thus, they can be used without special modification.
- Future Prospect: The proposed multi-GPU system can receive the benefit of Ethernet technology improvement which will constantly continue in future.

5	10x1024x1024	4000

4.2 GPU-BOX

Here, multi-GPUs with ExpEther is implemented in GPU-BOX which provides PCIe ports and power supply together with the function of ExpEther for extending PCIe interface of GPUs to Ethernet network.

The target GPU-BOX in this paper has slots for eight GPUs. That is, it provides the environment of eight GPUs in term of PCIe slots, Ethernet interface, power supply and space. The power supply of the GPU-BOX is up to 3000W. The Ethernet interfaces are two SFP+ interfaces per a GPU, thus 20 Gbps bandwidth is available in total. Each PCIe in GPU-BOX is extended to Ethernet by ExpEther NIC implemented on FPGAs.

5. Evaluation

In this section, we evaluate the performance of the multi-GPU system with GPU-BOX by executing programs in CUDA.

5.1 Experimental Environment

Table 1 shows the multi-GPU environment used in the evaluation. The evaluated environment uses six GPUs, each of which is NVIDIA Tesla C2050, while the number of slots in the target GPU-BOX is eight.

5.2 Application

For performance evaluation, we implemented two application programs, the simulation of particles motion and the calculation of Advection term.

One has no communication between devices, while the other needs a considerable amount of communication.

These application programs are mainly consisting of following three parts;

- computing in GPUs,
- data transfer between host and GPU, and
- data exchange between GPUs.

The calculation of particle has only two parts, computing and data transfer between host and GPU, while the calculation of Advection term includes all of them.

5.2.1 Simulation of Particle Motion by the Runge-Kutta Method

This application simulates particle motion when initial particle distribution and velocity field are given and there is no interference between particles. It divides time into several steps, and on each step, each particle position is updated with the velocity field by the Runge-Kutta method. For the motion of each particle is independent from another, it is possible to perform every particle motion computation in parallel, and there is no communication between GPUs in multi-GPU environment.

Here, five combinations of parameters are executed for evaluation. Table 2 shows the combinations of problem size and steps.

5.2.2 Calculation of Advection term by Cubic Lagrange Interpolation

Calculation for Advection term of Cartesian grid method is a kind of fluid dynamics computation. It simulates the movement of ink when initial concentration, distribution, and velocity field are given. On this calculation, it separates the entire surface into grid and updates each value of the grid using values of the surrounding grids in a certain time step. On each step, updating of the grid value is independent from other computations. However, in case of computing with

Table 3: Problem Size of Advection Term

Number	X	Y	Steps
1	256	256	1024
2	1024	1024	10280
3	4096	2048	10280

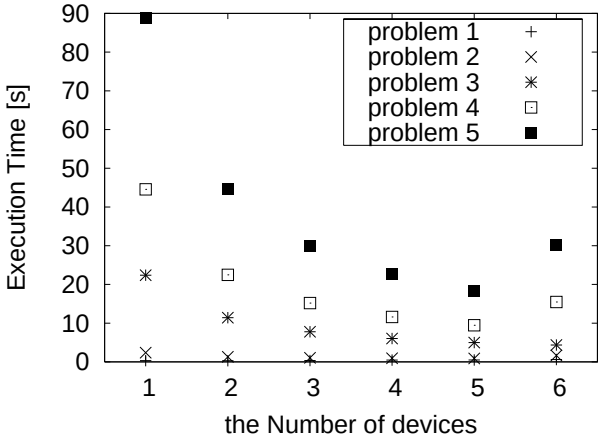

Fig. 5: Execution Time of Calculation of Particle Motion

multiple GPUs, we have to exchange data around memory-boundary between GPUs. Problem size of Cartesian grid method on this evaluation is shown in Table 3.

5.3 Performance versus the number of GPUs

5.3.1 Simulation of Particle Motion

Fig. 5 shows relationship between execution time and the number of GPUs when the particle motion simulation is executed. It is found that the execution time decreases as increasing the number of GPUs. However the execution of the case with six GPUs in the GPU-BOX spent larger time than one with five GPUs. That is caused by the EFE protocol tuning which is not adequate for the system with more than five GPUs.

Fig. 5 shows the performance speedup of the different number of GPUs over a single device. Respectively, the multi-GPU system provided speedup of 1.99, 2.96, 3.92, 4.83 and 5.14 times at most for execution on two to six devices. While performance speedup is directly proportional to the number of devices roughly in case of large problem size, there are cases to get no performance improvement by increasing the number of GPUs. It is mainly caused by the overhead of data transfer between the host processor.

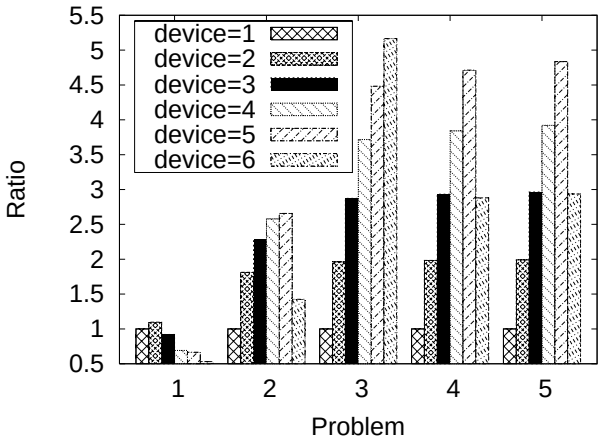

Fig. 6: Performance rate of Calculation of Particle Motion

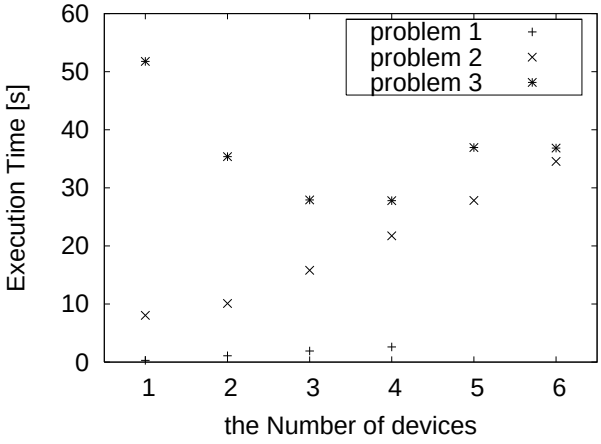

Fig. 7: Execution Time of Calculation of Advection term

5.3.2 Calculation of Advection term

Fig. 7 shows relationship between execution time and the number of GPUs when the Advection term is calculated. In the problem 1, the cases with five and six devices can't be evaluated, since the problem size is so small that there is no data allocated to fifth and sixth device in this application program.

Fig. 8 shows the performance enhancement of the different number of GPUs over a single one. Respectively, the multi-GPU system achieved speedup of 1.45, 1.85, 1.86, 1.40 and 1.41 times in problem 3 for execution with two to six devices. On the other hand, we can see performance degradation on calculating small size problems; problem 1 and 2. The performance degradation is caused by the frequently executed data exchange part for the calculation of

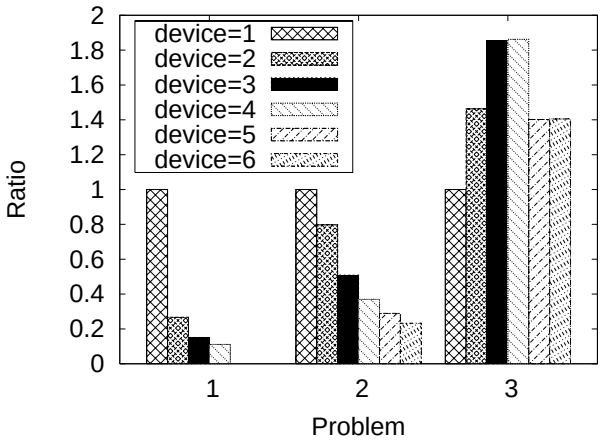

Fig. 8: Performance Rate of Calculation of Advection term

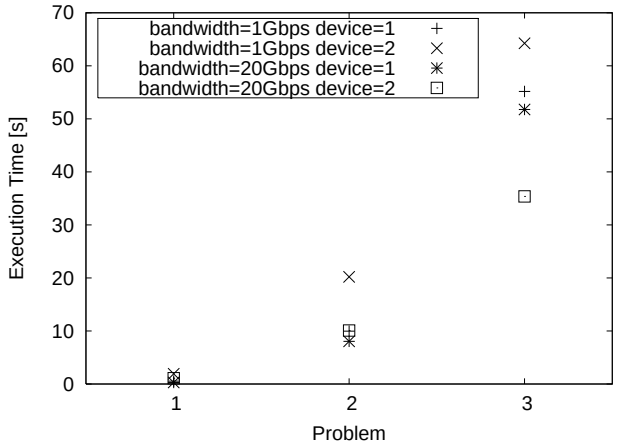

Fig. 9: Relationship between Network and Execution Time

Table 4: Data Transfer Bandwidth in CUDA

Ethernet	1 Gbps	20 Gbps
Host to Device	0.320 Gbps	7.66 Gbps
Device to Host	0.445 Gbps	9.86 Gbps
Device to Device	0.355 Gbps	7.92 Gbps

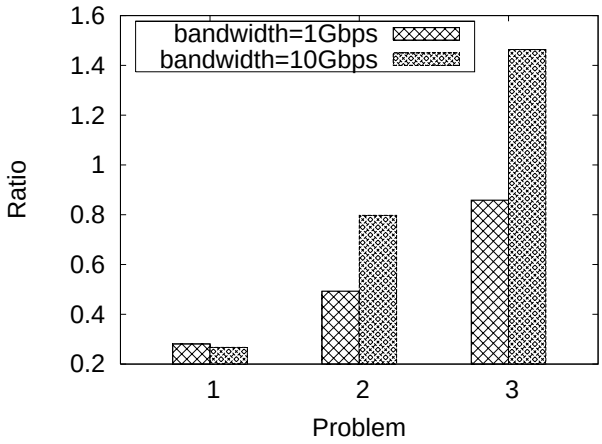

Fig. 10: Relationship between Network and Performance Improvement

Advection term. The data exchange speed mainly depends on the bandwidth of the network, while the exchanged data amount in this application is proportional to the number of GPUs. Although it is difficult to enhance performance in such small problems, their execution time is not so large and the effect of applying multi-GPU system is originally limited. Improving the performance of Ethernet will stretch the target which can be accelerated to smaller size problems.

5.4 Influence of the Network Performance

In this subsection, we evaluate the influence of the network equipment in the GPU-BOX. Table 4 shows the bandwidth of data transfer from the host to the GPU, from the GPU to the host, and between GPUs in CUDA by using Ethernet 1 Gbps and 20 Gbps.

5.4.1 Influence to Application performance

Fig. 9 shows performance of Advection term calculation the case when 20 Gbps and 1 Gbps Ethernet are used with a single and two GPUs. When a single GPU is used for calculation, the difference of the execution time with 1 Gbps and 20 Gbps Ethernet is small. However, 1 Gbps Ethernet increases the execution time on calculating with two GPUs, while 20 Gbps Ethernet can decrease it.

Fig. 10 shows the speedup with two GPUs normalized to that with a single GPU. As the problem size becomes larger, the difference of achieved speedup becomes large between two Ethernets, although the multi-GPU system provides more performance in both. As a result, the speedup of the multi-GPU system is 0.86 with 1 Gbps network, and 1.45 with 20 Gbps network. These results indicate that the multi-GPU system with GPU-BOX obtains benefits of developing Ethernet technology, and GPU-BOX enables user to select network construction according to the application.

6. Conclusion

In this study, we proposed and evaluated multi-GPU system with ExpEther. It allows to interconnect a single host PC and multiple GPU devices with ExpEther which extends PCIe interface to Ethernet.

For evaluating the multi-GPU system, two application programs are used. First, we evaluated performance on the different number of devices. For the program without inter-GPU communication, a system with six GPUs achieved 5.14 times performance as that with a GPU.

On executing the application including data exchange between GPUs, the largest performance improvement was 1.86 times with four GPUs. Then, we evaluated performance using the different networks. From the results, it appears that the bandwidth of network used in GPU-BOX greatly affects the performance of the multi-GPU system.

The following is a list of future work:

- The performance of multi-GPU system with ExpEther must be compared with conventional multi-GPU clusters,
- The performance must be evaluated with the other applications and more number of GPU.
- A larger system which uses multiple switches must be evaluated.

Abstract - *In this paper, we present an efficient implementation of parallel algorithms to remove noise in digital images using different Graphics Processing Units (GPUs). The algorithm, based on the concept of peer group, uses a fuzzy metric for finding wrong pixels and the Arithmetic Mean Filter (AMF) to correct it. There are many factors to study in order to get an optimal implementation of an algorithm on a GPU. Our algorithm has been implemented with two different approaches to access the data: Shared and Texture memory. Also, the number of threads and its arrangement have been studied. The test has been conducted on two different cards: Tesla-Fermi and GeForce.*

Keywords: Parallel Algorithm, GPU, Tesla, Noise removal in images.

1 Introduction

Many filters have been introduced in other papers in order to reduce the noise in images. Some works are based on the concept of peer group, the fuzzy metric, Arithmetic Mean Filter (AMF) and Vector Median Filter for the detection and elimination of noise [1], [2]. These types of filters have recently shown good quality results but the execution takes too much time. In this paper, we use the advantages of parallelism offered on the GPU to speed up the process of removing noise in a digital image using CUDA [3].

There are not many jobs reporting accelerated algorithms on GPU to remove noise in an image, therefore some works of image processing using the GPU are presented in [4], [5], [6], [7], [8], [9]. Some irregular data structures such as graphs that involve dynamical memory management are accelerated using Graphical Processing Units (GPUs) and CUDA [10].

The applications running on the GPU should take advantage of the parallel hardware to achieve good performance. The hardware optimizations are considered depending on the application. The application is executed in on different hardware to compare its performance, therefore is necessary to perform the appropriate optimizations in order to take advantage of the available hardware and performance improvement.

The GPU has several types of memory, the way to access them and the computational cost is different for each case. In this paper, we perform an analysis to access the data in GPU memory using two optimizations (Shared memory and Texture memory) in order to find the best type of memory with the best performance.

The Shared memory is expected to be a low-latency memory near each processor core, for this reason we take the advantage to performance optimization applying the implementation of this type of memory.

We present the performance obtained by running the algorithm in the architecture Tesla M2050 (compute capability 2.0), and we compared the results with the performance in the architectures GeForce GT 120 and GeForce 9800 GX2, both with compute capability 1.1. In order to observe the behavior in each architecture for different amount of processed data, we have used an image taken from the Kodak database [11], which we have re-sized and added impulsive noise [3].

We need to analyze the algorithm to know which parts are more appropriate to be parallelized to achieve high efficiency.

The main contributions of this paper are: to identify the parallelism in the algorithm to eliminate noise in an image and the use of the best optimization depending on the GPU architecture and the amount of data to be processed.

This paper is organized as follows: In Section 2, we review the method of peer group and fuzzy metric to eliminate impulsive noise. The relevant features of the CUDA GPU architecture are described in Section 3. In section 4 we expand on details our serial and parallel implementations of the method. We present performance results in Section 5 and, we offer some conclusions and further work in Section 6.

a) b) c)

Figure 1. a) Original Image, b) Noisy Image and c) Filtered image

2 Method Peer Group and Fuzzy Metric (PGFM)

The method to remove noise in digital image uses the concept of peer group and fuzzy metric. It consists of two steps. In the first step (detection), erroneous pixels are detected and corrected in the second step (filtering). In the detection step, the pixels are labeled as corrupted and uncorrupted. Each pixel is analyzed in windows (W) of size nxn (n =3, 5, 7 …), until complete all the pixels of the image. The corrupted pixels are corrected through Arithmetic Mean Filter (AMF) in the second step (filtering step).

The concept of Peer group [2] and the fuzzy metric [3] are used for classification of the pixels. The peer group of the central pixel (x_i) is defined as the set of its neighbour pixels (x_j) which present similar features according to an appropriate distance or similarity measure. Fuzzy metric is an example of metric between two pixels.

The pattern of the fuzzy metric used in this work is:

$$M(x_i, x_j) = \prod_{l=1}^{3} \frac{\min\{x_i(l), x_j(l)\} + k}{\max\{x_i(l), x_j(l)\} + k}, \quad (1)$$

where the value of k is greater than zero and ($x_i(1)$, $x_i(2)$, $x_i(3)$) is the color vector for the pixel x_i in space color RGB.

The pattern of the peer group with this fuzzy metric is:

$$P(x_i, d) = \{x_j \in W \ : M(x_i, x_j) \geq d\}, \quad (2)$$

where $0 \leq d \leq 1$ is the threshold distance.

Implementing a similar process to work [12], we have obtained the optimum values of k, m y d. The values are: m = 3, k = 1024, d = 0.94.

Arithmetic Mean Filter is defined as:

$$AMF_{x_i} = \frac{\sum_{x_j \in W, i \neq j} x_j}{(nxn - 1)} \quad (3)$$

where x_j corresponds to a pixel within the window (W). The AMF is obtained for each RGB color.

Figure 1 shows the original image (512x768) as well as, noisy image and filtered image after running the method PGFM.

3 NVIDIA GPU Architecture and Features

In recent years, the GPUs have become very popular as compute accelerators for non-graphics applications, especially in the field of high-performance computing.

NVIDIA introduced CUDA, a technology which enables these units to be used to develop programs for other calculation purposes, which introduces a few extensions to C++ language.

GPU architecture details are described in [1], but here is a brief summary of the memories and other characteristics of GPU used. This summary will help to explain the parallel implementation to remove noise in an image.

Physically, the GPU, called a device in CUDA terminology, contains a set of multiprocessors. These execute programs following the SIMD (Single Instruction, Multiple Data) model, where by each of the multiprocessor's processor clock cycles executes the same instruction applied to different data, taking into account each application if this instruction is performed by a different thread.

A device has a physical memory that can be used in different ways. The main use is as global shared memory among the GPU multiprocessors. However, this memory also permits its several areas to be used in other modes, as local memory, as Texture and as a constant reading area, shared between all the threads.

Internally, each multiprocessor has four kinds of memories: a set of registers, a read/write cache memory, a constant read-only cache memory, and a read-only cache memory called Texture cache. These memories explain in detail in [9].

The large variety of memories and their different features complicate the task of achieving optimum performance in programs using CUDA.

The design problems of a CUDA program are:

- Deciding the number of threads and their organization in blocks.
- Deciding at each moment the best location (among the different available memories) for the input and output data, and how to access to them, performing the necessary copies at the appropriate time.

The main features of the GPU hardware that we have used in this work are shown in table 1. The compute capability of GeForce GT 120 and GeForce 9800 GX2 is 1.1 and of Tesla M2050 is 2.0 (Fermi architecture).

Bandwidth is one of the most important gating factors for performance. We have maximized the use of the available memory bandwidth for each category of memory. Figure 2 shows the bandwidth and the size of the memory device for each one of the architectures.

The number of threads used per block is therefore restricted by the limited memory resources of a processor core. In NVIDIA Tesla architecture, a thread block contains 1024 threads.

Table 1: Hardware features of GPUs

Model	*Mp*	Global Memory	Shared Memory	CUDA cores
GeForce GT 120	4	512 MB	16 KB	32
GeForce 9800 GX2	16	512 MB	16 KB	128
Tesla M2050	14	3 GB	48 KB	448

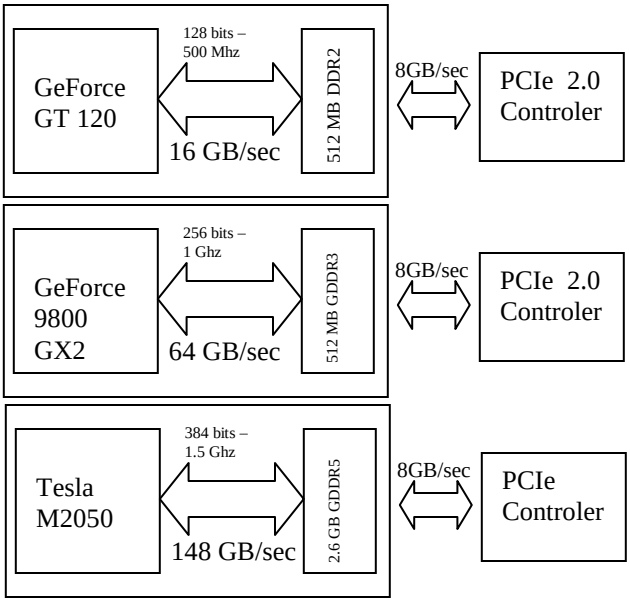

Figure 2. Bandwidth and memory size of the device for three GPU architectures.

The blocks are organized into a one-dimensional or two-dimensional grid of thread blocks. In our case, we handle 2D blocks. The total number of threads is equal to the number of threads per block multiplied by the number of blocks. Each block within the grid can be identified as a one or two-dimensional.

The number of thread blocks in a grid is typically dictated by the size of the data being processed rather than by the number of processors in the system. This number can greatly exceed the number of block threads.

The performed work by a processor in each GPU depends on the blocks launched by the kernel, considering the size of the image. We have handled 2D structures, so the total number of threads per block should be as close as possible to the maximum number of threads per block in each one of used the architectures. The GeForce maximum amount of threads per block is 512, so that the threads building blocks of 16x16 for a total of 256 threads, thus there will be two blocks running simultaneously on each processor. In the Tesla, the maximum number of threads per block is 1024, so we can make blocks of 32x32 for a total of 1024 or 16x16 for a total of 512 threads in each block.

4 Algorithm to remove noise in digital images

In this section, we describe the sequential CPU implementation and parallel GPU implementation of the proposed method in section 2.

4.1 The Sequential CPU Implementation

Algorithm 1 shows the sequential implementation on the CPU to remove noise in an image. This Algorithm is a modification of [2]. It is divided into two phases: detection and filtering.

Algorithm 1: Detection and Filtering using the Peer Group Filter (PGF). Sequential Implementation.

Input: pixels of the image, *m*, *k*, *d*, *n=3*.
Output: Filtered Image.
//Detection
for each pixel x_i of the image **do**
  Building *W* of size *n* x *n* centered in x_i
  if ($M(x_i,x_j) \geq d$) **then**
    $x_j \in P(x_i,d)$;
  end if
  if ($\#^* P(x_i,d) \geq (m+1)$) **then**
    x_i *is declared as uncorrupted pixel;*
  else
    x_i *is declared as corrupted pixel*;
  end if
end for
//Filtering
for each *corrupted pixel* x_i **do**
  Building *W* centered in x_i;
  Calculate the AMF of uncorrupted pixels of the *W ;*
  Replace x_i with the output of the AMF;
end for

* (#) = cardinality

4.2 Implementation on GPU

In order to speed up the processing of the algorithm 1 described in the previous subsection, we have made a parallel implementation on the GPU. The algorithm has been modified to work in parallel. We have done the detection step on the GPU through a kernel (detection kernel). Another kernel (filtering kernel) was defined to run filtering step.

In order to obtain a good performance in applications, one of the factors to be considered is the number of threads and blocks in each launched kernel. This factor depends on the maximum number of threads supported by the graphics card and the size of data to consider.

In this work, we calculate the number of blocks that are released into the kernel depending on the size of the data. After memory space is allocated for the GPU to store the

image, data are transferred from RAM-Host to RAM-GPU. Once the data are in graphics card then the detection kernel and filtering kernel are launched. After launching the detection and filtering kernel, the threads are synchronized. Once the filtering kernel has finished, the data is transferred from RAM-GPU to RAM-Host. These steps are described in pseudo-code in Algorithm 2.

We used 2D linear memory allocation in the memory device to store data. To speed up image transfer between host and device memory we use page-locked. Device memory can be allocated as either linear memory or as CUDA arrays. We have used for this application linear memory.

The amount of threads to launch is the same number of pixels as the image has. Each thread corresponds to one pixel of the image and it builds its window of size *n*x*n*. The thread classifies as corrupt or not corrupt the central pixel of the window, ie marks the pixel that is analyzed while the neighbours are analyzed simultaneously by other threads. We reserve one byte for each pixel which we will call it padding (*p*) in order to assign the state of the pixel (corrupt or not corrupt), one pixel is composed of 4 bytes (RGB*p*). All the pixels after detection kernel are labeled as corrupt or not corrupt. For the filtering kernel, we launched the same amount of threads as in the first step. Some threads will not work because they do not correspond to pixels labeled as corrupted. Considering that the computational cost of the memory transfers between RAM-Host and RAM-GPU is high, we prefer to launch the same amount of threads that are released in the detection kernel.

Algorithm 2: Pseudocode for the parallel GPU implementation.

```
Allocate device memory for the pixels;
Data transfer from Host memory to Device memory;
do in parallel on the device using T threads:
    call Detection_kernel
    Synchronization of threads;
do in parallel on the device using T threads:
    call Filtering_kernel
    Synchronization of threads;
Data transfer from Device memory to Host memory;
Free device memory;
```

The detection kernel is described in Algorithm 3. In this algorithm the called *fuzzy_metric_function* (a_pix, b_pix), is the function to calculate the fuzzy metric between central and neighbour pixels of the window. *a_pix* is the central pixel and *b_pix* is a neighbour pixel.

The filtering kernel is described in Algorithm 4. In this algorithm the called *mean_function* (b_pixOK), is the function to calculate the AMF, described in equation 3. *b_pixOK* is an array of the uncorrupted pixels.

When using Shared memory, the processes that are performed in each kernel, are described in algorithms 3 and 4 with the following changes :

Sentence 4 of algorithm 3 and sentence 5 of algorithm 4, is replaced by:

a_pix← load from device memory to Shared memory RGB value of x_i from row and col;
Synchronizes with all the other threads of the block;

Sentence 7 of Algorithms 3 and 4, is replaced by :
b_pix← load from device memory to Shared memory RGB value of neighbour in (i,j) from row and col;
Synchronizes with all the other threads of the block;

Algorithm 3: The Detection_kernel

Input: pixels of the image, *m*, *k*, *d*, *n=3*.
Output: pixels labeled as corrupted or uncorrupted.
For each thread that is associated with a pixel x_i:

```
1: col ← global thread ID in col;
2: row ← global thread ID in row;
3: byte padding (p) is initialized to zeros;
4: a_pix ←load RGB value of x_i from row and col;
5: for i←-1 to 1 do
6:    for j ←-1 to 1 do
7:       b_pix ← load RGB value of neighbour in (i,j)
                 from row and col.
8:       dist ←load the distance obtained after of
                 call fuzzy_metric_function (a_pix, b_pix)
9:       if dist ≥ d then
10:          //pixel (b_pix) ϵ P(a_pix,d)
11:          cardinality ← cardinality+1;
12:      end if
13:   end for
14: end for
15: if cardinality < (m+1) then
16:    //pixel is declared as corrupted;
17:    c_pix ← load in four byte (p) a value of 1;
end if
```

Fuzzy metric and peer group are calculated reading the data of Shared memory.

A texture can be any region of linear memory or a CUDA array, the GPU is especially well-suited to address problems that can be expressed as data-parallel computations. When we use Texture memory, we declare a texture to access the data. The texture is used in both detection and filtering kernel.

Sentence 4 of algorithm 3 and sentence 5 of algorithm 4, is replaced by:

a_pix← load from Texture memory RGB value of x_i from row and col ;

Sentence 7 of Algorithms 3 and 4, is replaced by:
b_pix← load from Texture memory RGB value of x_i from row and col.

Algorithm 4: The Filtering_kernel

Input: pixels of the image labeled as corrupted, n=3.
Output: Filtered Image.
For each thread that is associated with a corrupted pixel x_i:
1: col ← global thread ID in col;
2: row ← global thread ID in row;
3: a_pix ← load RGB value of x_i from row and col;
4: **if** (a_pix in byte p) ==1 **then**
5: **for** i ←-1 to 1 **do**
6: **for** j ←-1 to 1 **do**
7: b_pix ← load RGB value of neighbour in (i,j) from row and col.
8: **if** (b_pix in byte p) == 0 **then**
9: b_pixOK ← load b_pix
10: **end if**
11: **end for**
12: **end for**
13: mean ← load the media obtained after of
14: **call** mean_function (b_pixOK)
15: a_pix ← load the mean value;
16: **end if**

5 Performance Evaluation

5.1 Experimental Study

In the experiments, we used one image obtained from [10] which we have re-sized and added 10% of impulsive noise with *imnoise* instruction of MATLAB. Table 2 summarizes the sizes of the images that we used.

Table 3 shows the blocks configuration, threads and occupation of the cores in each one of the GPUs used. The number of blocks per core is obtained by dividing the total number of blocks by the CUDA cores available (table 1). For the Tesla architecture the number of blocks created for the first image size and 32x32 threads per block is 96 blocks and CUDA cores are 448, ie, 352 cores are inactive. For the second image size, 64 cores are inactive. From the 3rd. image size, all cores have to work. The algorithm 2 was implemented for each size image in order to eliminate the noise in the image. We use three architectures (GeForce GT 120, GeForce 9800 GX2 and Tesla M2050) with different characteristics.

Table 2. Size image used in the experiments.

Case	*Image Size*
1	256x384
2	512x768
3	1536x1024
4	3072x2048
5	6144x4096

Table 3. Configuring blocks and grids.

	Image size	Max. Threads per block	Threads per block	Number of blocks	Number of blocks per core
GeForce GT 120	1	512	16x16	16x24=384	12
	2			32x48=768	24
	3			64x96=1536	48
	4			128x192=3092	96
	5			256x384=6144	192
GeForce 9800 GX2	1	512		16x24=384	3
	2			32x48=768	6
	3			64x96=1536	12
	4			128x192=3092	24
	5			256x384=6144	48

	2			32x48=768	1
	3			64x96=1536	3
	4			128x192=3092	6
	5			256x384=6144	13
	1	1024	32x32	8x12=96	1
	2			16x24=384	1
	3			32x48=1536	3
	4			64x96=6144	13
	5			128x192=24576	54

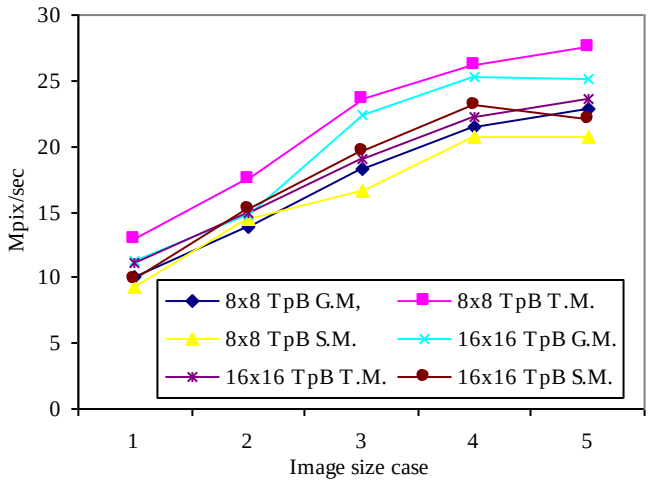

Figure 3. Performance Mpix/sec when using block size 8x8, 16x16 and 32x32 with diffrent image size on GeForce GT 120.

5.2 Results and Analysis

In this section we evaluate the GPU performance when running the noise elimination algorithm.

The first experiment was to study the performance on the GPU with two possible combinations of block size (8x8 and 16x16) in GeForce GT 120 and (8x8, 16x16 and 32x32) in M2050.

The results of the GeForce GT 120 architecture are shown in figure 3. We can see that the best block size is 8x8 with Texture memory and 16x16 for the other two accesses. Shared memory with 16x16 blocks is best than texture memory with 16x16 blocks and global memory with 8x8 blocks. The reason is that the processor is inactive, waiting for

more data, in other words, the relationship between the processor clock speed and the bandwidth are not appropriate. The results are the same in GeForce 9800.

The results of Tesla architecture using the two forms of access (directly to Global memory or through Texture memory) are shown in figure 4. We can see that when using the Global memory the best block size setting is 16x16 and the worse is 8x8. It obtains more Mpix/sec when accessing data through the texture memory. For the largest size that we have tested (larger than 512x768) and 32x32 threads per block, we can see that the results of using Global memory or Texture memory have very good behavior.

In the rest of the paper, the results are shown with 16x16 block size except for texture memory in the GeForce GT 120 and GeForce 9800 GX2, in this case is used 8x8 block size.

Figure 5 compares the performance of Mpix/sec obtained in the three architectures of GPU used and the three types of access to data in global memory.

The performance of the GeForce GT 120 is better when Texture memory is used compared to the other two forms. We also note that in the image with size 6144x4096 the performance with Shared memory decreases, due to the overhead associated with the transfers. All the threads gets data from Global memory to Shared memory.

The performance obtained using the parallelized algorithm on GeForce9800 GX2 with the Texture memory is the best option to access the data followed by Shared memory. In image sizes 6144x4096 with Global memory and Texture memory the performance decreases, due to the overhead generated by the transfers. In this case the processor clock speed with the bandwidth is tightly coupled; this is reflected in the difference between global memory and Texture.

Texture memory is also the access that provides better performance when using M2050 architecture. The use of Shared memory access and the Global memory access provides very similar results. We can see that in Tesla M2050, regardless of the type of access, the performance of the image size 512x768 is lower than other image sizes. This is because there are insufficient data to allow cores to work.

We also see that the Tesla-Fermi architecture outperforms compared with the other two GPU architectures at all image sizes. If there is more bandwidth, the accesses are faster. For the three architectures the performance is better with Texture memory for any image size.

With these results, we can say that using the Texture memory is the best option for all ways of access to data. Shared memory architectures should be used in architectures with similar features to the GeForce 9800 GX2.

Figure 6 shows that the processing time on GPU depends on the percentage of noise in the image. As we can see, when the image has more noise, processing time is greater. The increase is in the filtering step; in the detection step the processing time is independent of the percentage of noise. A quality study of this parallel algorithm has been analyzed in work [9]. In that paper, we showed that the quality achieved by implementing the algorithm is competitive compared with other algorithms.

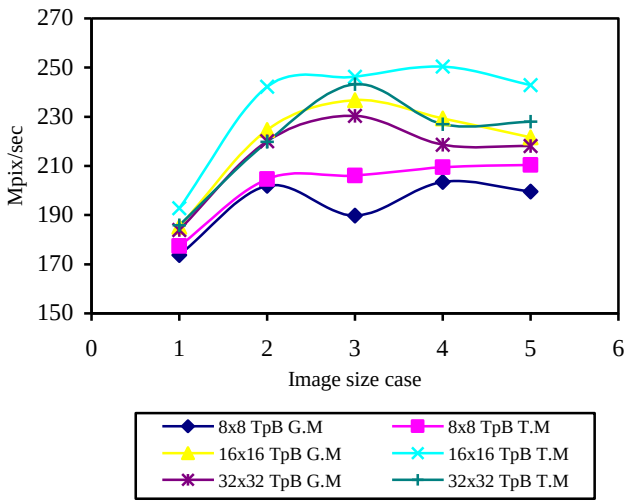

Figure 4. Performance of Mpix/sec. when using block size 8x8, 16x16 and 32x32 with different image size on Tesla.

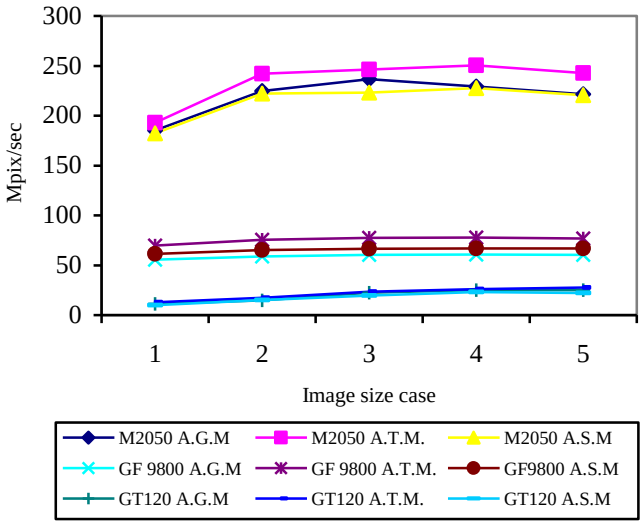

Figure 5. Performance in the three models of GPU and the three ways to access the data.

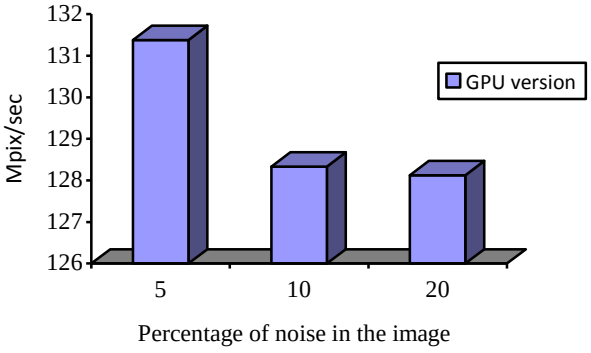

Figure 6. Mpix/sec processed for different percentage of noise.

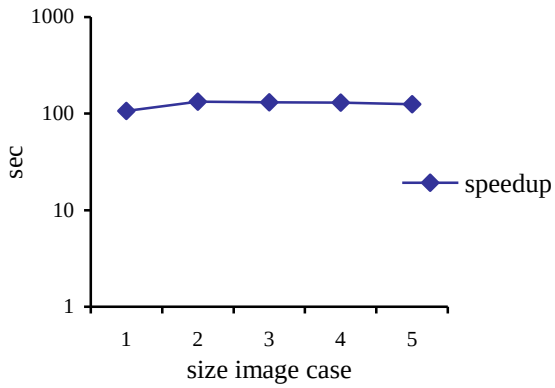

Figure 7. GPU vs CPU speedup for different image sizes.

Finally, we report in Figure 7, the speedup of the sequential version of the algorithm running on the CPU and GPU-parallel version using Texture memory and Tesla architecture. As noted, in the worst case the GPU version (parallel) is 106 times faster than sequential, which is an excellent result, showing that using the GPU is the best for noise correction.

6 Conclusions

In this paper, we present efficient implementations of parallel algorithm to remove noise in digital images using different Graphics Processing Units. The algorithm uses the concept of peer group, the fuzzy and Arithmetic Mean Filter (AMF) to detect and remove noise. When accessing to the pixels of the global memory, we have considered two ways to optimize the access to them; one is through Shared memory and the other through Texture memory. We have presented an analysis of the performance of these two models of graphics cards (GeForce vs Tesla-Fermi) with different forms of access and different image sizes. We have performed an analysis of optimal block size for these two architectures. Tesla architecture supports a bigger number of threads per block, being 256 threads per block the best size. The results show that using the Texture memory is the best. Global memory is not an option for reading the data from the GPU memory for this application and with GPU architectures used. In the Fermi-Tesla architecture we process 165-215 Mpix/sec higher than the GeForce, running the algorithm to eliminate noise in an image with the largest tested size. In a future work we will see, if this behavior is similar to other kinds of architecture with similar hardware characteristics to this application.

Acknowledgment

This work was funded by the Spanish Ministry of Science and Innovation (Project TIN2011-26254) and Ma. Gpe.would also like to acknowledge DGEST ITCG for the scholarshipawarded through the PROMEP program (Mexico).

GPU Computing and CUDA technology used to accelerate a mesh generator application

Adriana Gaudiani[1], **Santiago Montiel**[1], **and Javier Pimás**[1]
[1]Instituto de Ciencias, Universidad Nacional de General Sarmiento
San Miguel, Buenos Aires, Argentina

Abstract— *The potential of GPU computing used in general purpose parallel programming has been amply shown. These massively parallel many-core multiprocessors are available to any users in every PCs, notebook, game console or workstation. In this work, we present the parallel version of a mesh-generating algorithm and its execution time reduction by using off-the-shelf GPU technology. We use commodities GPUs as a useful CPU co-processor to improve this kind of applications, characterized by a high level of data parallelism. Compared to the sequential algorithm, our techniques achieve 6X overall performance for GPU-CPU implementation; furthermore we achieve 50X speedup when implementing core operations of the algorithm. Results show that GPU provides a helpful platform for high performance computing to improve the execution time of these applications.*

Keywords: Parallel algorithms, Multicore processors, Graphics processing units.

1. Introduction

In the past few years, Graphics Processing Units Computing (*GPUs*) has demonstrated to provide an increased performance computing architecture for applications which can be written to take advantage of many core GPUs. The idea to use the GPU for general purpose computations starts about 2003. However, it was reserved only for specialist developers in graphic rendering. It was possible since 2007, when NVIDIA released the software technology called Compute Unified Device Architecture (CUDA) simultaneously with its TESLA Architecture [1] [2]. Since then, GPUs have increased in capability and programmability and have gained wide popularity among research community [3]. Owens et al. widely explain why GPUs increased faster than CPUs. Furthermore, this technology is available, inexpensive and can be found in off-the-shelf graphics cards for PCs. CUDA is designed for extended standard C/C++ code with GPUs parallel features and it provides a unified computing platform to take advantage of the GPUs power and to leverage general purpose parallel applications [4].

In this paper, we present as we used cutting-edge computing resources, such as GPUs multicores and CUDA, to accelerate the execution time of a finite element mesh generator algorithm, achieving a significant parallel speedup.

Mesh generation is a key step in many scientific computations and computer graphics. It had its origin in the 50's with structural analysis problems. Finite element is a numerical method used to solve partial differential equations approximately; whose first step is mesh generation.

We use GPUs as a floating point parallel CPU coprocessor to improve the mesh generation algorithm *Distmesh*, created by P. Persson and G. Strang. Distmesh authors wrote an efficient Matlab algorithm to provide a simple code to produce high quality meshes. We wrote a parallel version for this algorithm to introduce an interesting general purpose application for GPU computing.

Organization: The paper is structured as follows. In section 2 we present a general view of Persson-Strang mesh generator algorithm and an overview of architectural features of GPUs. In section 3 we present our sequential version of Distmesh algorithm and highlight its features. Section 4 describes the design and implementation of our GPU version of mesh generator algorithm. Section 5 gives experimental results. In section 6 we briefly introduce related works and section 7 gives conclusions.

2. Background

In this section we present important background concepts, relevant to this paper. First, we present a briefly description of Persson-Strang Algorithm. Then, we outline some important issues for using GPU.

2.1 Persson-Strang Algorithm

Per-Olof Persson and Gilbert Strang developed a simple and public mesh generator code for Matlab, called Distmesh [5]. They offer an iterative technique based on a physical analogy between a simple mesh and a trust structure, combining a signed distance function and forces movement at each node. The results obtained are high quality meshes.

Many problems are defined on irregularly shaped domains, so unstructured meshes, far better than structured meshes, can be flexibly tailored to the physics of these problems. The problem that arises is the complex, and nearly inaccessible, meshing software code. We have chosen Persson and Strang algorithm because of its simplicity and accuracy. We present below a brief description of the algorithm.

Initial nodes position may be chosen by equally spaced distribution, and this works well for simple geometries. The user can define a function *h* to set mesh resolution. This function *h(x,y)*, in 2D, is used to refine complex geometry mesh and thus achieve geometrical adaptivity; it needs to be resolved by small elements. The meshpoints define the truss structure and a Delaunay triangulation algorithm determines the topology. Delaunay method set triangles in 2D, or tetrahedra in 3D, to fill the convex hull of the input domain mesh points [6]. In response to the mechanical analogy, triangle edges correspond to bars (or springs) and mesh points correspond to truss joints. The numerical method assumes that a displacement force is exerted on the bars. In every iteration, the new location of the points is obtained by calculating a force of static equilibrium. Delaunay triangulation is needed whenever the points are separated far; thus adjust the topology. For a very detailed explanation on the Persson method, the interested reader should consult [7].

2.2 GPU and CUDA overview

GPU is a massively multi-threaded multiprocessor architecture and its data level concurrency stand out. The threads are organized in two-level hierarchy. The lower level is a *block*, which contains a large number of threads. The higher level is a *grid*, which consists of a group of blocks. The maximum dimension of blocks and grids is determined by the GPU architecture. Parallel threads share memory and synchronize using barriers [8], [9].

The key to effectively using GPU is to understand its memory hierarchy, which consists of three levels of memory. Programmers can explicitly manage data stored in them. *Device memory* is the global GPU memory which is accessible from all the threads. *Shared memory* is an on-chip memory. It's a low latency memory shared by all the threads within a block. *Texture and constant memory* are used to store explicitly declared read only data.[10].

NVIDIA's CUDA enables to divide the parallel program execution in tasks that can run across thousands of concurrent threads, over hundreds of processor cores. This programming model is known as a Single-Program Multiple-Data (SPMD) and it allows to program GPUs for general purpose. Tesla GPU, the NVIDIA device used for our experiences, manage efficiently a huge sum of threads employing a *Single-Instruction Multiple-Thread* (SIMT) parallel programming architecture. The task performed by every thread is managed writing special functions, called *kernels*. The kernel task is mapped over a set of threads, representing the work to be done at a simple point in the domain. We wrote the kernels using C and CUDA, an extended version of C; in this way, we mapped the kernels on the GPU manycore processors. For a more detailed description of CUDA, GPU architecture and Tesla architecture, you can refer to [10][11][12].

3. General features of sequential version

We first implemented a C++ sequential code of Distmesh algorithm. We took into account some important items in the original version of the mesh generator algorithm, as we describe below.

- A distance function d determines the domain geometry by means of a signed distance, which is negative inside the region. It was an essential decision, as authors remark. This function is calculated at a meshpoint set and also for calculating nodes distance to the closest boundary point.
- This implementation uses a linear function for repulsive forces, but it does not allow attractive forces.

$$f(l, l_0) = \begin{cases} k(l - l_0) & \text{if } l < l_0 \\ 0 & \text{if } l \geq l_0 \end{cases}$$

- The resultant force *FTot* is the sum of all force vectors meeting at a mesh node. Each bar exerts a force $f(l, l_0)$ depending on its actual length l and its relax length l_0.
- The relax length l_0 is constant for uniform meshes and it's required $f = 0$ for $l = l_0$. Distmesh authors choose l_0 slightly larger than the length desired -20% is a good rate- This calculation depends on the total sum of bars length.
- The time step for Euler method is Δt parameter. The parameter *geps* is used to calculate the tolerance in geometry evaluations, and it's used to decide whether a point is outside.
- All points going outside the domain during the update, p_n to p_{n+1}, are projected back to the boundary. The numerical gradient of d gives the direction of the point movement.

The following are the key steps of our sequential code. In general terms, these steps correspond to those of Distmesh. Although, we modify the original data structures for better performance of the sequential algorithm. We will refer to this later.

Data Input: As a first step, we create a uniform distribution of mesh points within the input desired geometry. These points are the mesh-nodes. The resulting mesh points are regularly placed at a distance h_0 from their closest neighbors.

Triangulation: An important step in this algorithm is Delaunay triangulation. At every iteration, we compare the actual points positions with that of the previous triangulation. When the maximum displacement is greater than a predefined tolerance, a Delaunay retriangulation determines the new meshpoints set replacing the old ones, in order to guarantee Delaunay properties.

Update: The bars lengths are used to calculate the bar forces components. The resultant node force is the sum of the force vectors, from all bars meeting at a node. This result contributes to update node positions.

Projection: The update process may place some points outside the geometry. Once these points are found, they are

projected back to the boundary, in response to a normal force. We use the numerical gradient of the distance function to calculate their move direction to the closest boundary point.

Our first CPU sequential code was a translation of Matlab Distmesh algorithm. Distmesh is an efficient algorithm for Matlab, it's completely vectorized to avoid loops. The authors use a sparse matrix to compute mesh-nodes movement. The sparse matrix dimension is determined by total points (n) and bars (m) of the mesh. Distmesh code uses a Delaunay Matlab function in order to determine truss topology. We selected the Delaunay C-code written by Geoff Leach for triangulation step, an open-source program. The author improved the divide and conquer Guibas-Stolfi algorithm and he got a factor of 4-5 speedup. This is a $O(nlog(n))$ algorithm [13].

The update step move the points to the new position, using the scalar force calculated for each bar. This is the main action taken by the algorithm and this is carried out using a large matrix of movements. Every matrix element ($M_{i,j}$) stores the movement of the i^{th} point which is one end of the k^{th} bar. The total move for n_i node is $P_i = \sum_{j=0}^{j=n-1}(M_{i,j})$. However, only a few bars converge at each mesh point.

This serial version is an easily implemented way to guarantee a correct execution and to facilitate the writing of a correct parallel version.

4. Our GPU-based Algorithm

As argued, Distmesh algorithm is highly suitable for GPUs architectures. Most of the operations, performed by the sequential mesh algorithm, were easily mapped on GPUs multiprocessors. The parallelism in Distmesh code is exploited by dividing the vector operations among the threads. Distmesh loop iterations are distributed to kernel blocks, so each data is fetched by a thread and every thread executes the same kernel.

Figure 1 presents a high-level overview of our parallel GPU-version of Distmesh algorithm. It outlines where the GPU acts as a parallel CPU co-processor in a collaborative way. The initial phase is executed on the CPU. CPU generates the first triangulation and copies points and bars from host (RAM) to device (GPU global memory). CPU launches the GPU kernels function to start the GPU mesh generation process. When GPU concludes, only final positions of points are copied from device to host. Data transference between host and device is performed at initial and final steps of the algorithm. During core operations, data remain at device memory. During kernels execution, bars length and data movements array remain resident in GPU device memory. We implemented our parallel mesh generator in this way, to exploit GPU threads concurrency. In next section, we describe the different steps we designed to run our parallel algorithm of Distmesh on a GPU.

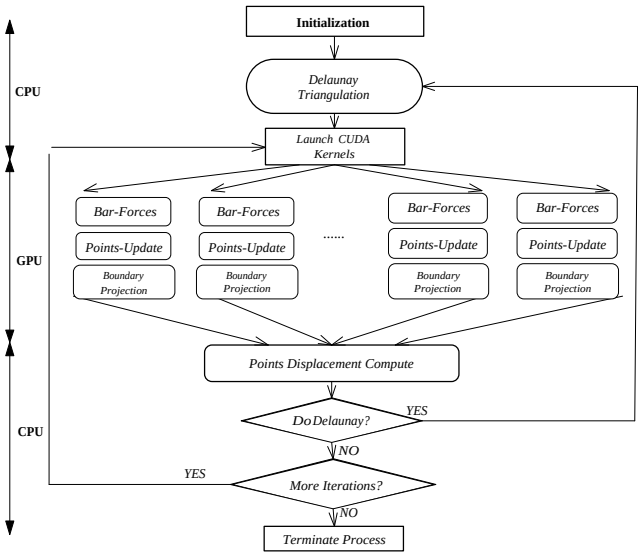

Fig. 1: Mesh Generator Algorithm in CPU-GPU.

4.1 GPU kernels

As a first step in writing the parallel CUDA program, we had to identify those code blocks we could separate from sequential program as a CUDA kernel. Here we explain each kernel written to exploit both data parallelism of the algorithm itself and the GPU architecture. Once written, data on the GPU is persistent unless it is deallocated or overwritten, remaining available for subsequent kernels.

Every node location remains fixed during its total force computing, that's why this task may be parallelized. Figure 2 shows data structures, kernels and the relationship between them. Data structures were selected to avoid the branch instructions in kernels code. This was possible by increasing the compute over the array elements, in order to minimize the use of *if-then-else* control instruction. The general description of each kernel is expressed bellow.

Bar length: We mapped a thread per bar, making every thread compute its corresponding bar length. Threads read every data stored in *Bars* array and store their results in *Length Bar* array. This was a suitable condition for thread computing. Subsequently, we had to do a sum over all elements of the lengths array, and so calculate relax length l_0. This was not a suitable condition for thread computing, we will refer to this later.

Scalar Forces: This kernel launch a thread per length bar. Data are supplied by length array, at global device memory. Every thread applies the same operation to every data, to calculate the resultant scalar force applied to each bar. Then stores the results in a new data structure, *Move*. Move array dimension is in correspondence with the number of bars.

Points Movements: This kernel reads data movement -

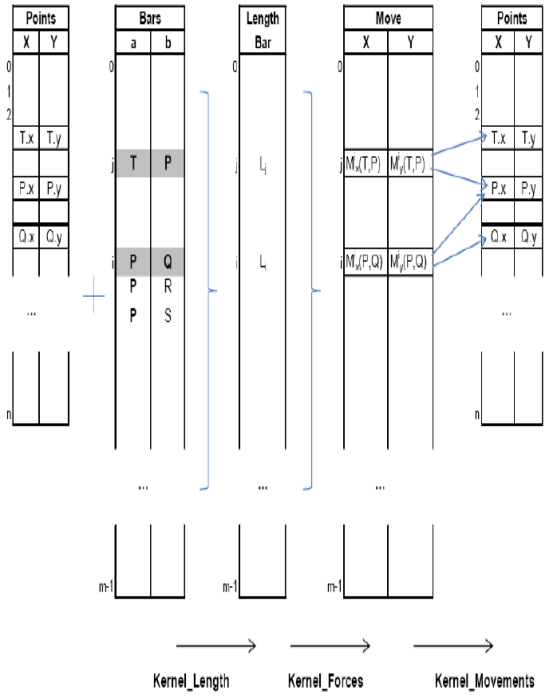

Fig. 2: Data Structures created by the kernels in GPU.

which was calculated with Scalar Forces kernel- in every bar. Each bar contributes to the total movement of all the meshpoints, affecting their extreme points. The final position of each point is obtained by summing all these movements, as shown in Figure 2.

Boundary Projection: Some points go outside the geometry after updating process. This kernel is in charge of projecting the points moved out from the domain, by relocating them to the nearest point in the border. This relocation is performed by calculating the numerical gradient.

The next step in writing a CUDA program, was to manage data transfer between RAM memory and the GPU global memory.

4.2 GPU kernels optimization

As we explained before, the data transfer from host to device is made only twice, before launching the kernels and when GPU process ends. We don't have the bottleneck memory transfer problem during GPU computation [14]. As shown in Figure 3, the data transfer time is 5.7% of GPU time, for the entire process. This graphic was obtained with CUDA Profiler tool. The kernels outlined above are limited by the rate at which the GPU can issue instructions; they are compute bound. To improve the performance, we optimized memory access using shared memory. CUDA uses share

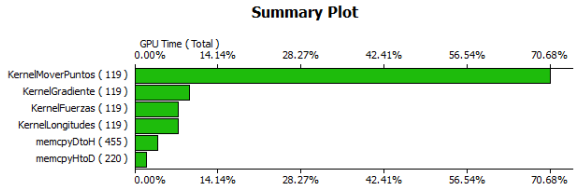

Fig. 3: Kernels and data transference.

memory to help reducing overfetch [15]. To avoid multiple simultaneous accesses to memory, we could efficiently load data arrays from global to share device memory, thus ensuring coalesced readings [16]. CUDA *Atomic Add* functions are the core arithmetic operations to sum array elements and to calculate forces and points movement. These functions ensures that the readings will be done without any interference from other threads. Synchronization is guaranteed by CUDA if multiple threads, in different blocks, access to the same variable to perform *read-modify-write* operations [10][11].

Bars length kernel optimization: In a first version, relax length l_0 was performed by one thread. The other threads remain idle in the meantime. The run time was improved copying lengths bar structure to a new array in share memory and using atomic functions to sum lengths bar. Figure 3 shows its little kernel runtime compared to the total kernels execution time. This kernel uses a CUDA Atomic-Add function on share memory to sum bar lengths.

Points movements kernel optimization: We modified this kernel to avoid using a huge data array. It was possible performing atomic operations. This kernel reads movements stored in move array, as shown in Figure 2, launching a thread per row. Each row represents the scalar force at a bar and it contains x and y component of points movement, then each thread modify the position of two points. This action was optimized by using the CUDA *ATOMIC_FLOAT_ADD* function, obtaining a significant improvement in performance.

We present the experimental results in next section.

5. Experimental Results

In this section we evaluate the computational performance of our GPU parallel version of Distmesh on a platform consisting of a Intel Xeon dual-core processor with 4GB of main memory running at 3.2 GHz, connected to a NVIDIA Tesla C2070 with CUDA driver and runtime version 4.0. This GPU is comprised of 14 streaming multiprocessors (SMs) of 32 streaming processors (SPs) for a total of 448 SPs CUDA cores and its CUDA capability is 2.0.

Table 1 shows CPU and GPU execution time. These measurements of time consider the complete execution of

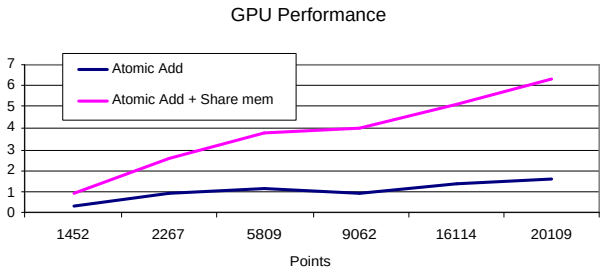

Fig. 4: Comparison of execution time.

Table 1: GPU Version: Execution Time (sg.)

Node Points	*CPU Time*	*GPU Version1*	*GPU Version2*	*Speedup Complete*
1452	0.035	0.130	0.037	0.95
2267	0.290	0.320	0.112	2.59
5809	0.687	0.580	0.183	3.75
9062	1.689	1.820	0.425	3.97
16114	3.388	2.510	0.666	5.09
20109	7.786	4.860	1.239	6.28

the algorithm, including both the executed phase by the CPU and the GPU, including memory transfer overhead. The maximum speedup achieved is: 6.28. GPU execution time was measured performing atomic add operations in *Version 1*, and performing atomic add operations at shared memory in *Version2*. We obtain a significant improvement in the second case. The execution time evolution, for a complete run, is presented in Figure 4.

To ensure consistent results when computing our sequential(CPU) and parallel(CPU+GPU) algorithms, we compared the number of iterations done and how many of those invoked to Delaunay. In Table 2, we present the relationship between Delaunay and Persson iteration, with the aim of showing consistency between CPU and GPU implementation. Rate values are close enough in both cases, allowing ensure satisfactory results, in accordance with original Distmesh results in Matlab. Moreover, we achieve a substantial improvement by measuring only core operations in the GPU version of mesh generator. The speedup reached 53X. We call core operations to GPU kernels outlined in section 4.

6. Related works

In this section we give a brief overview on mesh generator algorithms on GPU. Démian Nave et al. present their approach to parallelizing the Delaunay mesh generation, which can be parallelized in a natural way. This is a similar

Table 2: GPU-CPU execution: Delaunay and Persson iterations.

situation to our work. They emphasize the importance of mesh generation algorithm and of Delaunay method in particular [17]. In 2008, Rong et al. present their approach to GPU computing. They enhance Delaunay triangulation using GPUs as a parallel co-processor in charge of the triangulation on a given set points in 2D. The best results are obtained for a large number of points, when they achieve a 53% improvement compared to *Triangle* Delaunay algorithm [18]. An interesting GPU mesh generator algorithm is presented in [19]. The authors propose a two-phase iterative GPU based method, that transforms any 2D planar triangulations and 3D triangular surface meshes into their respective Delaunay form. They used this algorithm to simulate sten deformation, where the geometry of triangulation changes dynamically and requires restore Delaunay conditions to interactive real time levels. This situation is similar to points retriangulation needed in our work, where we use Delaunay triangulation too. We are working on Delaunay parallelization to improve our work, and we are interested in the previous papers.

7. Conclusions

We wish to highlight the GPUs technology suitability to improve performance of mesh generators algorithms. We showed how the efficient Matlab Distmesh algorithm can be parallelized by processing its mesh nodes concurrently and taking advantage of its data structures. Our results gives us an idea of the computing power offered by GPUs and the virtual machine defined by CUDA, which exhibit scalability to programmers. We initially ran our application in a NVIDIA G80 series card; despite being old devices, we obtained good results. Then, we could run the CUDA program in a TESLA card making minimal changes to the kernels code. This architecture enabled us to use Atomic functions in floating point.

We presented in this paper a developmental stage of our work and it shows our initial experiences, which resulted in a significant decrease of algorithm execution time. The Persson method generates high-quality meshes, which were perfectly reproduced for domains in 2D with our parallel

algorithm. This approach requires improving the management of large amount of data when dealing with complex geometries and non-uniform meshes. Anyway, we intended to provide a contribution to this topic development, in the search of high performance in GPUs computing.

Abstract - *JPEG2000 has become one of the most rewarding image coding standards. It provides a practical set of features which weren't necessarily available in the previous standards. The features were realized as a result of two new techniques, namely the Discrete Wavelet Transform (DWT), and Embedded Block Coding with Optimized Truncation (EBCOT). The complexity of EBCOT Tier-1 makes its implementations very difficult and time consuming.*

In this paper, we focus on accelerating JPEG2000 encoder by using general-purpose processing on Graphical Processing Unit (GPU). We use CUDA platform to implement DWT and EBCOT Tier-1 as the most important sections of JPEG2000. Resulting implementation of proposed architecture performs very well compared to other available implementations.

Keywords: *JPEG2000, GPU Computing, CUDA*

1 Introduction

JPEG2000 has become one of the most rewarding image coding standards. It provides a practical set of features which weren't necessarily available in the previous standards. JPEG2000 [1][2] offers numerous advantages over JPEG. These advantages include: ROI (Region Of Interest) coding, quality vs. resolution compression, lossless and lossy compression, progressive image compression/transmission by resolution/quality, random code-stream access and error resilience. Such characteristics add to the functionality of a system that is employing JPEG2000 as an image compression technique. The features and performance of JPEG2000 make this standard superior to JPEG. The features were realized as a result of two new techniques, namely the Embedded Block Coding with Optimized Truncation (EBCOT) [3]-[6] and Discrete Wavelet Transform (DWT) [7]. The complexity of EBCOT Tier-1 makes its implementations very difficult and time consuming.

During the process of encoding, an image is partitioned into data matrices called Tile-components. Each Tile-1 component is then coded separately. The process of coding is made up of different sections. These sections are depicted in Figure 1 and each is described below.

1.1 Component Transform

This section is optional in JPEG2000 and is used to improve compression efficiency [3]. The transform converts the RGB data into another color representation, with a luminance (or intensity) channel and two color difference channels.

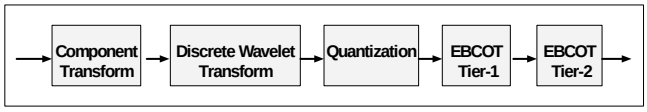

Figure 1. JPEG2000 encoder block diagram

1.2 Discrete Wavelet Transform (DWT)

DWT [7] is a domain transform that transforms an image Tile-component from special domain to frequency domain and provides a special decorrelation. This transform can be executed for as many levels as necessary. The spatial decorrelation provided by the DWT improves as the number of transform levels increases. The output of each level of DWT is categorized into four sub-bands. DWT can be performed either by the traditional convolution based filter or by the lifting scheme based filter which has lower computational complexity compared to the former filter.

1.3 Quantization

Quantization [4] is the process by which the sub-band samples generated by the DWT are mapped onto quantization indices for coding.

1.4 EBCOT Tier-1

This section receives the quantized wavelet coefficients and encodes them into bit-streams. These coefficients are sliced into code-blocks before they are fed into the EBCOT Tier-1 [4]. EBCOT Tier-1 is composed of two parts: Bit-Modeler and MQ-Coder [5][6]. Bit-Modeler is a bit-plane (a matrix that contains all the bits of the same order of all the coefficients of a code block) coder. A Bit-Modeler exploits the symmetries and redundancies within and across the bit-planes and generates corresponding contexts for each bit. After the context is generated, the MQ-Coder will code the bits (decisions) based on their associated contexts.

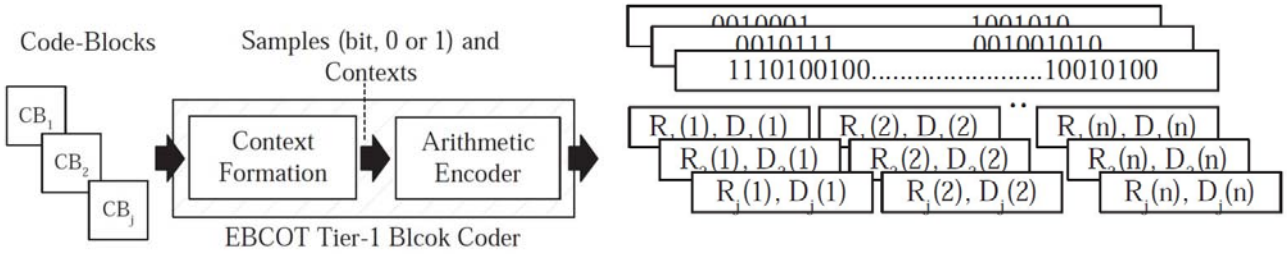

Figure 2. Entire coding process of EBCOT Tier 1 block coder

Table 1 Run time percentage for different modules in JPEG2000 encoder

Operation	Lossy	Lossless
Component Transform	10.1	3.64
DWT	25.14	10.41
Quantization	6.4	N.A.
EBCOT Tier-1	44.86	67.35
EBCOT Tier-2	13.5	18.6

1.5 EBCOT Tier-2

EBCOT Tier-2 [2] is for rate allocation. The rate allocation is responsible for acquiring the highest quality for the output while maintaining a predetermined resolution, or acquiring the highest resolution while maintaining a predetermined image quality.

The execution time of different modules in the JPEG2000 algorithm is presented in Table I. It is noted from this table that DWT and EBCOT Tier-1 algorithms, as the main modules in JPEG2000 standard, occupies %70 of the execution time of the whole procedure. In this paper, we focus on accelerating JPEG2000 encoder by using general-purpose processing on Graphical Processing Unit (GPU) [9]. We used CUDA [10] platform to implement DWT and EBCOT Tier-1 as the most important sections of JPEG2000. Resulting implementation of proposed architecture performs very well compared to other available implementations.

This paper is organized as follows: in the next section a deep analysis of the EBCOT Tier-1 will be presented. In section III DWT transform will be described. In the next section GPU computing using CUDA will be explained. Our proposed implementation is introduced in sections V-VI. Experimental results are presented in section VII followed by the conclusion.

2 EBCOT Algorithm

EBCOT [3] is a two-tiered coder, where the first tier is a block coder and the second tier is for rate-distortion optimization and bitstream formation. Although Tier 2 is part of EBCOT algorithm, the practical implementation detail is not defined in the standard and not restricted in the design of an encoder.

Tier 1 of EBCOT is actually a context-based adaptive arithmetic encoder. Code-blocks are independently coded by this block coder into sub-bitstreams. According to the functionality, the block coder can be further partitioned into two steps, Context Formation (CF) and Arithmetic Encoder (AE), as shown in Figure 2. The transformed coefficients of a code-block are coded bit-plane by bit-plane from most significant bit-plane (MSB) to less significant bit-plane (LSB) instead of coefficient by coefficient. CF scans all bits within a bit-plane of a code-block in a specific order, and generates corresponding contexts for each bit by checking the status of the neighborhood bits. AE then encodes each bit according to the adaptively estimated probabilities from its contexts. The outputs of the arithmetic encoder are the sub-bitstreams of each compressed code-block data. Also, the rate and distortion information are calculated for each pass for subsequent tier 2 processing.

Before CF, the quantized (in lossy mode) or non-quantized (in lossless mode) wavelet coefficients are converted from two's complement representation to sign-magnitude format. The scanning order in a code-block is from the most significant bit-plane of the magnitude part to the least significant bit-plane. A sample is called "significant" after the first "1" bit is met while encoding the magnitude part from the MSB to the LSB, and it is called "insignificant" before the first "1" bit appears. The sign bit, is coded immediately after the first "significant" bit is coded. Within a bit-plane, every four rows form a "stripe," and the scanning order is stripe by stripe from top to bottom. In every stripe, data are scanned bit by bit from top to bottom, and column by column from left to right. To improve embedding, fractional bit-plane coding method is used. Embedded coding, which is useful for scalability and for efficient rate control, is actually one of the main features of JPEG 2000. Under this fractional coding method, one bitplane is further decomposed into three passes according to coefficients' significant situations. While scanning from the top bitplane, all-zero bit-planes are skipped. When the first nonzero bit-plane is found, only pass 3 coding is used to encode all bits in this bit-plane since no bits will be coded in pass 1 and pass 2 according to the coding rule. The subsequent bit-planes are scanned three times each following the scanning order described above. The first scanning is for pass 1, and is followed by pass 2 and pass 3 scanning. Each bit in a bit-plane is encoded in one of the three

passes. Pass 1 is named "Significant Propagation Pass." During pass 1 scanning, those samples that are currently insignificant, but have at least one immediate significant neighbor are coded first. Clearly, these samples are most likely to become significant. Pass 2 is called "Magnitude-Refinement Pass." Samples that have become significant in previous bit-planes are coded in this pass. The last pass, pass 3, is "Clean-Up Pass." Samples not coded in the first two passes are coded in this pass. The two bits that are coded in pass 2 in this bit-plane have become significant in the previous bit-plane. Those bits coded in pass 1 are near those two pass 2 positions due to the significance propagation characteristic.

Once a bit is checked and decided to be coded in one pass, its context is generated according to the status of its neighbors using four coding primitives, Zero Coding (ZC), Run-Length Coding (RLC), Sign Coding (SC), and Magnitude Refinement (MR) primitives. There are total 19 contexts defined in JPEG 2000 [3]. The context of a bit should be generated and sent to arithmetic encoder along with the bit to be coded. Among the four coding primitives, ZC and SC primitives are used in the first and the third pass, MR primitive is used in the second pass only, and RLC primitive is used in the third pass. ZC and MR primitives check the eight immediate neighbors' significant states to decide the context, and the RLC primitive is applied when the four bits in a column do not have any significant neighbors. The SC primitive has to check the four immediate neighbors' sign and significant states.

After the context is generated, the arithmetic encoder will code the bits (decisions) based on their associated contexts, called MQ-Coder. Generally, a BAC encodes a code-stream consisting of a sequence of symbols. Each symbol (logic '0' or logic '1') is classified into one of these categories: the More Probable Symbols (MPS), and the Less Probable Symbols (LPS), based on the probability of their occurrence. In BAC an interval is considered as a probability model. This interval is divided into two subintervals, each one, corresponding to the probability of each symbol. When a symbol occurs, the subinterval associated with that symbol becomes the new interval. The recursive splitting of the current interval continues until all symbols are received. When the last symbol is received the characteristics of the last subdivided interval represents the encoded data.

As indicated above, BAC algorithm requires many multiplication operations in order to encode each symbol, and multiplication is time consuming. In addition, since a compressed data will only be generated when the last symbol of an input stream has been received by the encoder, serious loss of data occurs when the last symbol of a stream is not received. Finally after each subdivision of the probability model, the precision required for presenting the new interval increases. This leads to an increase of the required storage space for the interval values.

The MQ-Coder is an adaptive BAC implementation used in the JPEG2000 standard. MQ-Coder has eliminated multiplications by choosing special extremes for the intervals that are used in the probability model. In addition, the MQ-Coder periodically sends out the last byte of the stream which represents the encoded data, therefore addressing the problems associated with the increasing precision and compressed data being generated only after receiving the last symbol.

3 Discrete Wavelet Transform (DWT)

Discrete Wavelet Transform (DWT) [7] is a broadly used digital signal processing technique with application in diverse areas. DWT allows us to study a digital signal in different resolutions as sets of coarse and fine values. Wavelet transforms are used in domains of digital speech recognition, multi-resolution video processing or data compression. In the context of JPEG2000 standard, DWT is the key prerequisite of the compression process. Most of advanced features of JPEG2000 rely on DWT as well as the superior low-bitrate performance does.

JPEG2000 standard species use of LeGall (CDF) 5/3 DWT filter-banks [8] for lossless compression process and Daubechies-Feauveau (CDF) 9/7 DWT filter-banks [8] for lossy processing. Wavelet transforms can be implemented by convolution or by lifting scheme.

The advantage of lifting scheme over convolution is in reduced memory and computational complexity. Lifting scheme allows for in-place data manipulation and reduces memory dependencies.

Lifting scheme analysis [7] proceeds as follows. An input signal is split into even and odd subsequences denoted as and respectively. These values are further modified using alternating prediction (denoted as p) and update (denoted as u) steps. In the prediction step, the algorithm takes an odd sample in a turn and substracts a linear combination of its (even) neighbors from it; a prediction error is formed:

$$d_i^1 = d_i^0 - p(s_i^0 + s_{i+1}^0) \tag{1}$$

In the update step, a linear combination of already modified adjacent odd samples is added to each even sample and updated even sequence is formed:

$$s_i^1 = s_i^0 + u(d_{i-1}^1 + d_i^1) \tag{2}$$

The output of the last update stage, , is actually a low-pass output of DWT filter and similarly output of the last prediction stage, is a high-pass output of the filter. So the result of the wavelet transformation is a signal divided into low-pass and high-pass subbands.

2D signals (e.g., images) are usually transformed in both dimensions. 1D DWT transform is first applied to all rows then to all columns resulting in four subbands LL, HL, LH, and HH. The LL subband is an approximation of the original signal and can be further transformed recursively.

4 GPU computing based on CUDA platform

CUDA [10] is software and hardware platform designed for general purpose computing on GPUs. GPUs have a parallel architecture capable of running thousands of threads in parallel. In CUDA computing model, such threads are grouped into so called thread blocks. Threads within a block can cooperate among themselves by sharing data through a shared memory. As opposite to a large global memory, shared memory is relatively small and very fast. The advantage of global memory is that it is accessible to all threads, whereas shared memory is visible only to threads of the block. Common work flow is to copy data from RAM to global memory of GPU. Once data is ready in global memory, a GPU program can be executed. Each thread block initially fetches a small portion of data from the global memory into the shared memory. Data is then processed by threads in the block and the result is moved back to the global memory.

The global memory access pattern is perhaps the most important performance consideration in programming for the CUDA architecture. In a nutshell, when 16 adjacent threads access adjacent locations in global memory then memory loads and stores are coalesced in one transaction.

5 GPU-Accelerated implementation of DWT

The key part of our GPU-accelerated DWT is the design how to split the work between thread blocks in order to provide maximum utilization of the GPU. Since we need to compute the transform in both dimensions, it is natural to choose a 2D partitioning of source image data. Also size and shape of thread blocks needs to be determined. Because the lifting scheme algorithm alternately works with even and odd samples, an efficient approach is to have one even and one odd data sample per each thread in a block, i.e., to have twice as much data samples as threads in each block. Resulting partition of image data. Each thread block has its dimensions Bx×By where Bx = Dx, By = Dy/2 , and Bx,By and Dx,Dy denote number of threads and samples in horizontal and vertical direction respectively. Thus that thread blocks are of rectangular shape while data blocks are of squared shape.

Each thread has its exact position within the block, which is determined by indices Tx, Ty where $0 \le Tx \le Bx-1$ and $0 \le Ty \le By-1$. We can see that threads overlap only the upper half of the block, i.e., MAX(Ty) = Dy/2-1, which means that threads are directly mapped only to samples in the upper half of block data and we will have to change this mapping to be able to process both halves.

The first step of computation is to fetch image data from global memory into fast shared memory. It is crucial here to comply with coalesced global memory access. Considering the proposed data partitioning, each thread loads corresponding data sample into the upper half first, and then into the lower half of data block. The horizontal block size should be multiple of 16, so that coalesced access is not broken by thread block misalignment.

DWT coefficients are then computed according to lifting scheme relations 1 and 2. To calculate first dimension of the transform, DWT filters are applied to every row separately. Afterwards, each row contains a sequence of interleaved coefficients of low-pass and high-pass subbands. Each particular prediction and actualization step is calculated respectively as follows:

$$s[T_x][2T_y+1] = s[T_x][2T_y+1] + p.(s[T_x][2T_y] + s[T_x][2T_y+2]) \quad (3)$$

$$s[T_x][2T_y] = s[T_x][2T_y] + u.(s[T_x][2T_y-1] + s[2T_y+1]) \quad (4)$$

Where Tx and Ty determine the thread position in horizontal and vertical direction respectively and s[x][y] is the shared memory 2D array. Note that we propose transposed thread mapping for efficient data processing as follows. Threads are directly mapped into the upper half of block only, so that we have to change the thread mapping to be able to process whole block. In (3) and (4), we have swapped 3 thread indices Tx, Ty so that the threads cover the left half of the data block instead of the upper half which was covered originally. (3) then predicts all odd samples and (4) updates all even samples in the block. To calculate the second dimension of the transform, we just apply same filters to the columns.

The result of the application of lifting filters to rows and columns is composed of coefficients of four DWT subbands. Coefficients of LL and HL subbands are alternately located on even rows and LH and HH coefficients on odd rows of the shared memory s.

The final step of the CUDA-based transform is to move result from shared memory back to global. Particular subbands, however, needs to be stored separately in global memory. Because there are twice as much data samples as threads in the block, we store even lines first. Even lines contain all LL and HL samples and because those are interleaved, we use first half of threads to store all LL samples and second half to store HL samples. The access to the global memory is hereby coalesced.

Note that proposed implementation of DWT is optimized for maximum performance and its limitation is that it does not take into account sample values exchange between blocks borders. The proposed algorithm does not introduce any visual artifacts provided both forward and reverse transformations work with the same data blocks dimensions.

6 GPU-Accelerated implementation of EBCOT Tier-1

Architecturally, the parallel algorithm for the bit plane coder is optimized to match the existing graphics hardware. A number of code blocks are processed independently and each code block samples should be processed in parallel using the

state prediction method. Hence, each work group is in charge of handling one code block, and multiple processing elements (PE) of the work group can process the samples in parallel. In particular, the usage of memory resources has to be carefully optimized, control flow operations must be minimized as they result in costly processor stalls, and the workload must be distributed so as to maximize hardware resources occupancy and hide memory latency when stalls are unavoidable.

In GPGPUs any flow control instruction (i.e. if, switch...) can significantly affect the instruction throughput by causing threads of the same parallel thread block to diverge; that is, to follow different execution paths. GPGPUs provide great arithmetic capability at low hardware cost, but to achieve this goal, the cores in each multiprocessor often share only one instruction decoder and one small branch control unit. Therefore a single instruction is executed over N threads in parallel, where N is specific to the hardware chip and often has value of 32 or 64. As a result, control instructions and branch divergences on GPGPUs tend to be very expensive.

Unfortunately, the context formation process in JPEG2000 requires many control operations. For example, when the BPC scans a 3×3 window of neighboring samples (8 neighbors of a given sample), the algorithm may take 256 different execution paths. Additionally, the BPC needs to select one out of 19 contexts based on that information. If the bitplane coder (BPC) is implemented with a standard switch/case construct its performance would be bound to be very low. Fortunately, the context decision rules are predefined so look-up-tables (LUT) for context formation can be constructed to avoid the branching control flow. A LUT should have 256 entries, where the indices for the entries are formed from the 8 neighbor state bits and the value is selected based on the context rule. However it is inefficient to concatenate the state bits to form a LUT index every time. Therefore the state bits are stored in a 16-bit state flag instead, as shown in Figure 3. Each sample has one corresponding state flag that stores the state information itself and the state bits of its neighbors. This organization allows the BPC to easily retrieve an LUT index by applying a bit mask.

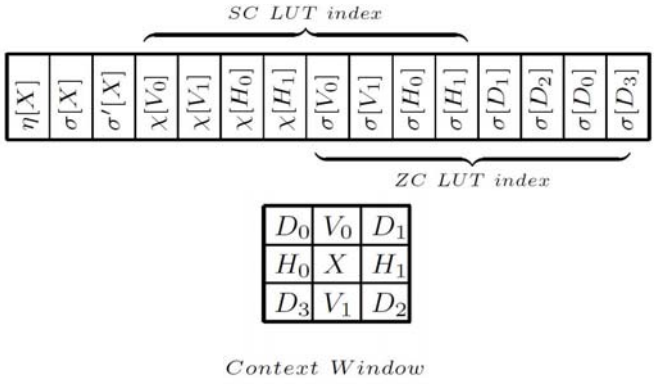

Figure 3. 16-bit state flag of a sample. The index of ZC or SC LUT can be extracted from the flag by applying a binary mask

It is very critical to optimize memory usage for the BPC where the context formation process executes massive numbers of memory and arithmetic operations. Particularly on GPGPUs, an efficient memory utilization can not only significantly reduce the latency but it also can increase the resource occupancy of computational resource to speedup the computing time.

The first optimization considered is to efficiently allocate different sets of data into the most suitable of memory blocks based on the application's demand to reduce latency and conflict. When the BPC processes one sample, it not only refers to the sample but also to its 8 neighbors. Consequently, there is a high degree of memory conflicts in the BPC, particularly in parallel BPC where multiple threads concurrently access different samples. However, both the memory conflict rate and memory latency can be dramatically reduced with very fast, multi-way shared memory that resides locally on chip. The shared memory on modern graphics cards has from 16 to 32 banks which can be accessed independently with a latency of only one clock cycle. It is also very important to optimize allocation of the context output buffer since it is the intermediate buffer for context formation and arithmetic coder. Storing this buffer in the global memory would be very inefficient since the BPC would write to global memory and then the arithmetic coder would have to read back from global memory immediately after BPC write. Therefore this output buffer should be also stored in on-chip shared memory. Additionally, since the BPC refers to the LUTs and the state flags very frequently, these data structures should also be placed in the shared memory as well. The LUTs are read-only and small enough to reside in fast the constant cache memory. The code blocks are initially stored in the off-chip global memory then each multiprocessor will copy its respective code block into its shared memory. The LUTs are stored in constant memory and fetched to multiprocessors' constant cache at runtime.

After the data sets are efficiently allocated into selected memory regions, the utilization of memory, especially shared memory, should be minimized to increase the multiprocessor occupancy of the GPGPUs.

The multiprocessor occupancy is defined as the ratio of the number of resident warps to the maximum number of warps supported on a multiprocessor of a GPU. Typically the higher occupancy the better multiprocessor can hide the warps latency and increase ALU utilization which will yields better speedup. Each multiprocessor on a GPU has a set of registers and a small amount of on-chip shared memory. These resources are shared among the active thread warps. Therefore the lower shared resources are utilized by a particular warp, the higher number of warps can reside in a multiprocessor. The compiler can attempt to minimize register usage but the utilization of shared memory must be optimized by the programmer. Additionally, the number of threads per work group should be large enough, at least 4× of the warp size, to achieve the best performance.

However, it is not simple to reduce shared memory utilization in the parallel EBCOT Tier-1 coder since it

depends on the code block size which is one of the key parameters that determine JPEG2000 compression efficiency. The code block size is often varied from 8×8 to 64×64 samples, but using the largest allowed configuration is preferred because the larger code block size the better compression efficiency. On the other hand, a code block size requires a large shared memory buffer which may reduce the multiprocessor occupancy and hence reduce the performance speedup. In a naive implementation, at least 24 Kbytes of shared memory are needed to store a 64 × 64 code block and the two respective state flag, while a 8 × 8 code block requires only a small 256-byte buffer. The results show that by changing code block size from 64 × 64 to 8 × 8, the compression efficiency drops about 25% on image Bike. But by decreasing code block size the multiprocessor occupancy can be significantly improved from 17% to 50%. There is an unusual result with the 8×8 code block where the occupancy no longer increases.

It clearly shows that the large code block significantly decreases the multiprocessor occupancy which results in significant speedup drop. To overcome this problem, previous studies had to compromise compression efficiency to use a GPU-affordable code block size such as 8 × 8 but this is an impractical size. This study therefore manages to design a special strategy that can handle large code blocks with low utilization of shared memory.

7 Experimental results

This section presents the result of our proposed implementation. The parallel JPEG2000 coder is implemented using CUDA on the Nvidia SDK 3.2 running on an Nvidia GTX480 graphic card. The reference CPU platform uses an Intel Core i7, with 12GB RAM running at 2.8GHz.

There are several popular versions of JPEG2000 compression software running on CPUs, including JasPer [11], and OpenJPEG [12]. JasPer is chosen to compare against the GPU implementation since it is an open source program, with fully accessible source code, and very good performance. The image test set includes the most popular JPEG2000 test images (bike, woman, cafe, and lena).

Table II compares runtime for JasPer and the GPU implementation JPEG2000 coder. The GPU-based JPEG2000 encoder implementations are more than 17× faster than the JasPer implementation.

Table 2. Runtime comparison of our method with JasPer

Image	Time (ms)		Speedup
	Our GPU	JasPer	
lena	15.23	238.74	15.7
cafe	267.36	5214	19.5
bike	284	4398.28	15.49

8 Conclusion

In this paper, the design and development of a novel PEG2000 encoder are presented. The parallel algorithm can process data at the sample-level. In particular, this paper is the first to presents a fully parallel solution for the arithmetic coder and DWT in JPEG2000. The implementation of the JPEG2000 coder leverages widely available and massively parallel GPGPU hardware and provides a 17× performance speedup compared to the JasPer software implementation. It is believed that even greater speedup is possible with full 64-bit hardware support. Additionally, the proposed parallel algorithms are potentially applicable to a wide range of image Processing and data compression applications.

For future work, the emphasis will be on further improved implementations of the arithmetic coder. In addition, the Tier-2 routines can be parallelized in order to have a complete JPEG2000 encoding flow running on a GPU platform. Another research direction is that of implementing the proposed parallel solutions on different parallel hardware platforms to compare the different architectures on the performance and optimization strategies.

***Abstract*—Sudoku is a popular puzzle utilizing 81 squares in a 9x9 grid consisting of nine 3x3 boxes. The digits 1-9 can each appear only once in a given row, column, or box. This paper describes the implementation of Particle Swarm Optimization (PSO) to solve sudoku puzzles using GPU processing. This PSO uses our open-source PSO framework that takes advantage of CUDA-enabled GPUs. Although each row contains nine digits, permutations of nine digits can be represented as eight "picks". To find a solution each of the nine rows was treated as a permutation. This reduced the problem dimensionality from 81 to 72. With suitable parameters the algorithm was able to solve multiple sudoku puzzles. This paper describes the implementation of the algorithm , the fitness function used, and the effects of variation on PSO parameters. The original PSO framework and the Sudoku code described in this paper are available online.**

I. Introduction

An open source framework for implementing Multi-swarm Particle Swarm Optimization on GPUs using CUDA was developed and discussed in [1] . The framework was previously demonstrated on a problem to optimize the parameters of a PID controller. This was a relatively well behaved problem in a three dimensional space. It was shown that by utilizing GPU processing, the problem could be solved many times faster than was possible using the CPU.

In the previous paper it was claimed that the framework could easily be extended to other problems and higher dimensional spaces. In this paper we utilize the framework to find solutions to Sudoku puzzles. These represent a class of problems in a very high dimensional space . Furthermore, the space has large number of local minima that occur at large distances from the global minimum.

We believe that the solution of Sudoku puzzles represents a very significant optimization problem. In this paper we show that 1) the open source Multi-Swarm Particle Swarm Optimization Framework that we have previously developed is in deed general enough to extend to this problem, 2) that the dimensionality of the problem can be reduced using permutations, 3) that the use of GPUs is crucial for reducing run times from multiple days to hours, 4) that PSO can indeed solve Sudoku puzzles, and 5) that the choice of PSO parameters has a huge impact on the time to find a solution.

II. Sudoku

Sudoku is a logic puzzle that has been extremely popular in the US since about 2005 and is based around using rules and logic to determine where numbers belong. This section describes basics of the sudoku puzzle as well as its origination.

A. Origin

Sudoku is often thought to be of Japanese origin, but this is not actually true. [2] Modern Sudoku first appeared in American papers in the 1980s, but did not become popular in the US until 2005. Although the puzzle we know today only dates back around 30 years, similar puzzles originated in the late 19th century in France, where puzzles with very similar solutions to sudoku originated. [3]

B. Rules

The rules to a sudoku are to fill a nine by nine grid with nine three by three sub-boxes such that only one instance of each of the digits one through nine is contained in each column, row or box. This means in any given column or row there should no repeated numbers and no numbers other than one through nine.

C. Related Work

This was not the first time that Sudoku had collided with biologically inspired algorithms. Sudoku puzzles have been solved by both GA and GPSO in the past. This, however, is the first time using a more generic PSO and adjusting the fitness function accordingly.

Sudoku puzzles were solved by Mantere and Koljonen 2007 [2]. In the same year, Sudoku puzzles were also solved by Moraglio et al. [4], where they introduced combinatorial-based PSO algorithms (GPSO), these spaces were similar to the pick space used in this paper. Sudoku puzzles were confirmed to be solvable using GPSO by Jilg and Carter 2009 [5].

III. Particle Swarm Optimization

PSO was originally developed by Eberhart and Kennedy [6] in 1995. It is heavily biologically inspired and it mimics behaviors that can be seen often in various types of flocking or swarming animals. It is not a complex algorithm and performs very well in continuous spaces that do not have analytical solutions. PSO is an iterative algorithm in that it moves each particle, calculates fitness of its location and then repeats the process.

A. Inspiration

Particle Swarm Optimization was inspired by animals in nature. Many different types of animals travel in groups, and often they benefit from the knowledge of each other. In a school of fish, each individual can benefit from the others knowledge regarding food and predators. Flocks of birds can cover larger areas by spreading out, and informing the flock of any food found. PSO mimics this in that each particle has knowledge about the fitness (or happiness) of itself and of other particles in the swarm, and tends to move toward regions of better fitness.

B. Algorithm

As mentioned previously, particle swarm optimization is based on having many particles, or candidate solutions, moving around an error/solution space. This implementation considers the best particle the one with the lowest fitness value; however it would work just as well looking for particles with larger fitness values.

Each of the particles tries to move to a solution that is better than its current one. To do this, a particle moves in the direction of the best location of the swarm and the best location it has found so far. The particle does a random weighting of each so it will be heading towards both to some degree. The following is the equation that describes the movement towards the particle's best location as well as the swarm's best particle's location.

$$mov = rand()p_{weight}(p_{best}p) + rand()s_{weight}(s_{best}p) \quad (1)$$

Where mov is a vector in parameter space representing a movement, p_{weight} and s_{weight} are scalars chosen by the programmer, p_{best} is a position in parameter space representing the location where a particle has been the happiest, s_{best} is a position in parameter space representing the location of the happiest particle in the swarm, and p is the current particle location. $rand()$ is a randomly selected floating point number between 0 and 1.

Since mov is a vector in parameter space it generalizes to any number of dimensions depending on the parameter space. In the case of no momentum this vector is calculated and then added to the location each iteration.

The algorithm often performs better when each particle's velocity has some momentum associated with it. [7] In the framework used, the velocity was implemented with momentum, such that the new movement was composed of 90% of its old movement plus the new movement calculated above. This helps prevent particles from getting stuck in any single location, such as local minima. A velocity of the particle is calculated and saved each iteration using the following equation.

$$vel_{new} = .9vel_{previous} + mov \quad (2)$$

Where vel_{new} is a vector representing the velocity or the amount that the particle will move this iteration, $vel_{previous}$ is the velocity from the previous iteration, and mov is a vector calculated above in equation 1. Once the velocity is calculated it is added to the particles location every iteration.

C. Related Work

Our PSO framework was not the first one to reach the GPU scene; however it was the first with the goal of making the PSO framework more accessible. Zhou and Tan 2010 [8] implemented a PSO algorithm using GPUs. Rather than using multiple swarms it used a triggered mutation system on top of a standard particle swarm optimization. They were able to achieve a speedup of 25x with this system.

An asynchronous implementation of PSO was created by Mussi et al. 2011 [9]. This allowed each particle to run iterations at its own rate (which was very fast). However this was limited by the fact that only one particle was allowed per block, and the maximum number of blocks that can run in parallel limits the swarm size.

Vanneschi et al. 2010 [10] tested a multi-swarm system where the best particles from one swarm were passed to the next swarm to replace the worst particles, this was done in a ring setup of several swarms. They exchanged this information every 10 steps. This was implemented again by Solomon et al. 2011 [11].

IV. Parallel Particle Swarm Optimization Framework

The Parallel Particle Swarm Optimization Framework was an implementation of the Particle Swarm Optimization algorithm that would use CUDA and be flexible to a number of different problems. The framework was designed so that a programmer with knowledge of C, but minimal knowledge of CUDA could modify the program to solve a large range of problems. In this case the framework was modified to solve Sudoku puzzles.

A. Multi-Swarm

Since each swarm is at some point in time entirely held in CUDA shared memory, the size of each swarm is limited. The following equation defines how many particles can be in a single swarm based on the dimensionality of the problem. [1]

$$Max\#ofPart = \frac{16,384}{8 + 12 * DIM} \quad (3)$$

Since in our problem each particle will be moving within a 72 dimensional space, 72 can be substituted, giving the actual maximum number of particles.

$$Max\#ofPart = 18 \tag{4}$$

Because of this limitation the framework allows for multiple swarms to be run in parallel. To allow the swarms to cooperate in some way, particles are swapped every 1000 steps. Each time a swap occurs there is a 1% chance that any 2 particles will be swapped.

B. Modifications to Code

The only programming required by the framework are generally modifying PSO parameters, such as weights, as well as rewriting the fitness function. The first problem tested was tuning of PID Controller parameters. While this problem was good for its computational intensity, it had a very small memory footprint. When using this framework to implement a sudoku solver a bit more memory was required.

The added dimensionality of this problem will still be held within the particles individual location; however the information specifying constraints to the puzzle is common to all particles. To make this quickly accessible to all threads it was stored in constant memory on the GPU. This memory is cached for all threads to make it easily accessible. Both the "pick" space and the solution space constraints were stored in this constant memory, which will be described in section IV-G.

C. Sudoku Fitness Development

For the PSO framework being used a fitness function had to be developed. This fitness function needed to be a function that could determine if one solution was better than another and by how much. It could specify how good a solution is by filling in a floating point value inside the particle structure when the fitness calculation function was called. A better solution is interpreted to be one that has a lower fitness value than another.

D. Pick Space

It was mentioned previously that a 72-dimensional space was being used to solve the Sudokus. This Sudoku solver is using a row based solution system, where each row is viewed as a permutation. Each row can contain the digits one through nine in any order, but each digit can only occur once.

This can also be interpreted as a sequence of selections from an ordered set of the numbers one through nine. It would start with an ordered set and a empty row as shown in figure IV-D.

Available: [1 2 3 4 5 6 7 8 9]
Row: [ ]

Fig. 1. No Pick Complete

Next there are a set of "picks" that select the order in which the numbers will appear in the row. If the first "pick" is assumed to be 5, the 5 would be moved from the available set to the row, this is shown in figure IV-D.

Available: [1 2 3 4 6 7 8 9]
Row: [5]

Fig. 2. One Pick Complete

If the next pick is also 5 then the 6 is now moved from the available set to the row set, finally shown in figure IV-D.

Available: [1 2 3 4 7 8 9]
Row: [5 6]

Fig. 3. Two Picks Complete

This process continues until the row set is filled and the available set is empty. This will only take 8 picks as once the last pick is reached, there is only one number available.

It can be observed that in this "pick" space the size of each dimension decreases with each pick, starting with 9 and decreasing down to the known pick with a size of 1. In this implementation if a pick was outside the space then the nearest number would be chosen, one if it is too low and the max of the dimension if it is too high. When these picks are extended to be 8 dimensions for each of the 9 rows the problem has a 72-dimensional search space.

This "pick" space turned out to be a good intuitive space for searching Sudokus because a movement in any dimension by one unit will create a swap of two numbers. The goal of the fitness function is to make it so puzzles similar to the solution will be only a series of swaps away from the actual solution.

E. Fitness Function Basis

The first implementation was the most intuitive implementation of the fitness function that could be found. The first system was very generic in that location in the puzzle did not affect fitness at all. It would first generate the candidate solution based on the location of the particle, then it would overwrite any constraint in the puzzle. Once this was done it would have an array representing an attempted solution to the puzzle as shown below in figure IV-E. The red numbers show constraints that have taken the place of whatever value was chosen based on particle location.

To calculate the fitness each of the duplicates were counted Since any number should occur only once in each row, column or box, any duplicate can be perceived as a problem in the puzzle and therefore the more duplicates the less fit a solution is. So every column, row, and box is scanned for duplicates and the fitness is set to the sum

9				6	3	4	7	
				4				1
1				8		2		6
		3					8	9
	1		9	5	6		4	
4	9					1		
3		5		2		9		8
6				7				
	4	1	8	9				3

Fig. 4. Attempted Solution

of every duplicate. The missing numbers could have been analyzed as well; however these are actually equal to the number of duplicates, as for every duplicate that exists there is one number that was overwritten and is missing.

This fitness function performed relatively well overall, it minimized to puzzles that had very few duplicates. The problem that arose was that sometimes a puzzle with few duplicates could be far from the solution. The solution space seemed to be littered with local minima for most problems.

F. Modified Fitness Function

To increase the effectiveness of the fitness function, several aspects of the sudoku construction were observed. The first thing that lead to modifying the fitness function was that there were a large number of candidate solutions that had the same fitness value. There needed to be some way to determine if one of the solutions was better than another when they had drastically different structures.

The first modification was to make boxes to the left count more than boxes to the right. The reasoning for weighting more importance on left sided boxes is that the "pick" space chooses from the left to the right. Weighting the left side of the puzzle more heavily encourages the algorithm to fix the first dimensions of the picks in each row before moving onto the smaller dimensions on the right.

The second modification was to add a component to the fitness for having an incorrect constraint. Although the constraint boxes are overwritten to find the solution, having a wrong constraint can make it more difficult to get the correct permutation of the row. This fitness addition carried the same left-weightedness as stated in the first modification.

The final modification was to attempt to keep particles within the search space. Although being outside the search space does not cause any problems with the algorithm, it is known the actual solution will reside at a location within the range of the pick space. Because of this the fitness was increased for each dimension that was outside the bounds for that given pick.

G. Pick Space Constraints

Although the constraints push the problem in the correct direction through the fitness, there is some knowledge about the pick space locations of the true solution that can be known immediately. Figure IV-G shows only the constraints of a given puzzle that was solved, where the highlighted values are ones that have known pick constraints.

5	3	8	6	9	4	4	3	2
3	9	2	7	3	7	6	4	5
8	2	7	9	2	3	9	8	6
6	8	9	5	3	2	1	1	2
9	3	2	6	8	4	7	9	4
6	7	3	9	6	1	6	8	3
9	8	3	1	7	6	5	4	7
3	7	5	1	9	7	4	2	9
2	5	1	4	4	3	8	9	7

Fig. 5. Known Pick Space Values

This figure shows a number of boxes as highlighted, but most of them can be covered by a few simple rules. When a constraint of the puzzle is in the first column, the pick space equivalent can be determined. When a constraint of the puzzle is a 1 or a 9, then the pick is either 1 or the max of the dimension accordingly. When both of the last two columns are constraints of the puzzle, then the pick equivalent is 2 if the first is bigger than the right and 1 if not.

V. Results

At first the PSO based Sudoku solver did not work at all. Most PSO parameters showed it unable to even come up with good attempts at solving the puzzle. However through trial and error a set of parameters giving good performance were found. Since the space was so complicated a low swarm best weight was used (0.05), a high local best weight was used (1.0), with a fairly normal momentum of .9.

These were the first parameters that were able to solve the Sudoku successfully. The region around these parameters was analyzed and as described later in this section these were very close to the most optimum parameters for finding solutions

Once a solution had been found, most of the tests were run with a max number of iterations set to 1.65 Million. These tests took a half hour each on the CUDA-based PSO framework used. These same tests when run using the computers CPU, rather than GPU took slightly over 24 hours, making the speedup approximately 48. It is noteworthy that the runs described in this paper utilized the GPU processors of a GTX 260 for approximately a week of total run time. These same runs would have taken approximately a year to run on a conventional computer.

A. Solved puzzles

The first puzzle solved was the puzzle shown in IV-G. It also solved the following puzzle in figure V-A.

5	3	8	6		4			
	9	2		3	7	6	4	5
			9	2			8	
						1		2
9								4
6		3						
	8			7	6			
3	7	5	1	9		4	2	
			4		3	8	9	7

Fig. 6. Another Sudoku Puzzle

B. Effect of parameters

It was difficult at first to find any PSO parameters that would solve the Sudoku puzzles given. Because of this the effect of the PSO parameters was studied. A series of tests, each with a maximum of 1.65 Million iterations, were run on various changes in the PSO parameters. Four random seed values were chosen, for each seed a specific set of starting particles exists. Each of the four seeds were used on every set of parameters tested.

The results showed that having the momentum at 0.9 was very much a perfect spot for solving sudoku. Changing the momentum in either direction seriously interfered with the ability to find a solution. Figure V-B shows the average ending fitness compared to the momentum.

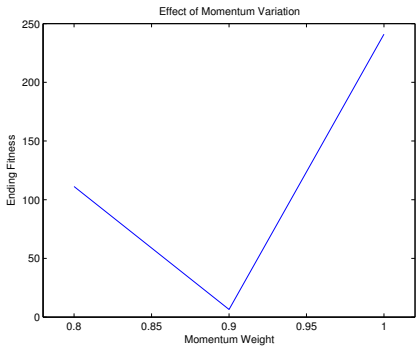

Fig. 7. Effects of Momentum Coefficient

The local best weight and the swarm best weight were varied from 0.85 to 1.15 and from 0.05 to 0.15 respectively. Through a series of previous runs it was determined that these were the areas that the algorithm could be successful. These parameters proved to be much less sensitive than the momentum. The low fitness range of the results suggest that given enough time it is possible that any of these sets of parameters could solve the puzzle. Figure V-B below shows the final fitness vs the local best weight and the swarm best weight.

Fig. 8. Effects of PSO Weights

There is an upward trend as both of the weights increase. This could suggest that the algorithm is simply taking more time and it will eventually find a solution, or it could suggest that if the weights increase too much it will be unsuccessful in finding a solution. In other isolated tests larger weights did not perform well and often would not converge or would converge in very high local minima not near the solution.

C. Random Addition

Even a small amount of testing showed that this was very clearly a very bumpy search space, full of local minima. This was shown in the last section by the heavy weighting upon particles local best and light weighting on swarm best locations. Despite this weighting some tests revealed it was possible for the algorithm to come very close to finding a solution without actually finding it.

The solution to this problem was a random addition. This had no biological basis, and the random numbers had such a small coefficient that it had virtually no affect on the running of the algorithm. However despite its small nature it did help in scenarios where the entire swarms were stuck at a single local minima. The random addition to all particles location would give them some momentum, allowing more searching of the space.

VI. Conclusions

This implementation successfully solved multiple Sudoku puzzles and has yet to be attempted on a puzzle that it did not eventually solve. The speedup of the CUDA-based PSO framework that was used was instrumental in the success of this project, as even to run 1.6 Million iterations on the GPU still took on the order of 30 Minutes to complete.

Due to the bumpy nature of the parameter space a much smaller swarm best location weight than usual must be used to solve the Sudoku puzzles using PSO. This problem also proved to be extremely sensitive in variation in the momentum coefficient.

***Abstract*—In this research, a Genetic Algorithms framework for Running On Parallel environments, which is named GAROP, is proposed. The GAROP provides the library for a parallel processing, so that users should only describe codes for genetic algorithms (GA) programs, utilizing the library implemented for the part requiring a parallel processing. In the GAROP framework, GA research provides only program codes which are concerned with GA algorithm and GAROP library supports other codes which are concerned with parallel processing. The advantage of using GAROP is to increase the user's productivity by making it possible to develop the program, which can execute a parallel processing. In this paper, the broad description of the GAROP is provided, and the development of the GAROP, corresponding multi-core CPU and GPU environments, is described. The libraries are implemented with GA which finds quasi-optimum solutions using meta heuristics, and its productivity and its parallelism are evaluated. As a result, only adding four descriptions to the program, the acceleration of the processing speed is confirmed in both of the environments; 5.26 times speed-up on multi-core CPU, and 3.0 times speed-up on GPU.**

I. Introduction

Several types of genetic algorithms (GA) are applied to solve optimization problems and some of them are large-scale optimization problems. One of the problems confronted, when using the GA, is that the excessive amount of computing time is required. It may be difficult for some problems to be solved within a realistic time. To solve this problem, the amount of computation itself should be reduced, or the processing should be accelerated. GA attains to a global search, using multipoint searches by many candidate solutions. It requires much iteration to find a solution, and results in high calculation cost. As GA searches solutions maintaining many candidate solutions, it implicitly has parallelism. As the architectures of calculators, on the other hand, hardware having various architectures has been prevailed, such as PC clusters, multi-core processor, and GPU. Therefore, to obtain environments of parallel calculations is not as hard as ever. Although an environment is easily obtainable, the programming skills are required to bring out its performance efficiently, such as the programming for heterogeneous processors, the architectural optimization for hierarchical memories, and the programming which overlaps connection and calculation to achieve the scalability. In addition, these parallel architectures have the different configurations. Thus, even using the same algorithms, it is necessary to prepare different implementation codes suitable for different parallel architectures. This complicated and disturbing programming lacks productivity. In this research, the Genetic Algorithms framework for Running On Parallel environments, which is named GAROP, is proposed. The purpose of the GAROP is to increase the user's productivity by reducing the processing time without the specific knowledge regarding parallel architecture and parallel processing. Implementing the master-slave model, the GAROP enables to execute any logical models. In this paper, the libraries for the GAROP are implemented using C language. Target parallel processing architectures are multi-core CPU and GPU. As one of the GA technique, Simple GA is implemented using the libraries, and it is evaluated in terms of an amount of codes and execution time.

II. Background

A. Genetic Algorithms

GA is a multipoint search algorithm with many candidate solutions and generate-and-test algorithm. GA is powerful algorithm in all kinds of research field, because GA makes it possible to search globally, and it does not require continuity and differentiability of target problems [1]–[5]. Under GA, a combination of variables, which is to be a candidate solution, is termed an individual. GA searches suboptimal solutions with a group of individuals. Figure 1 shows a general flow of GA. The first group of individuals is generated randomly. Generated individuals are evaluated on their objective function. Then, iteration searches are started. Parent individuals are selected from the group of individuals. Individuals are generated from selected parents as candidate children by genetic calculations, such as crossover and mutation. Generated individuals as candidate children are evaluated on their objective function. Selecting from these individuals, a group of individuals for next generation is created. Presently, various types of GA algorithms have been proposed, and these algorithms are applied to real-world problems. However, an excessive amount of computation is required to find suboptimal solutions in large-scale problems. Thus, it may be difficult for some problems to be solved within a realistic time, so that the amount of computation should be reduced, or the processing should be accelerated.

B. Parallel Genetic Algorithms

Since GA processes a search by iterative execution of an excessive amount of samplings on multiple candidate solu-

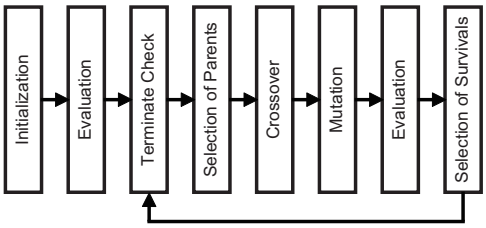

Fig. 1. A flowchart of GA.

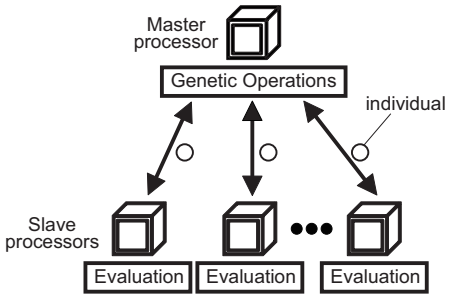

Fig. 2. A master-slave model.

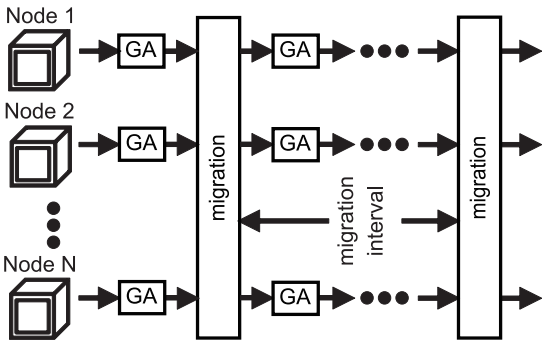

Fig. 3. An island model.

tions, it can be accommodated to parallelism. Thus, many methods of parallelization have been proposed for GA [6]–[12]. In this section, basic parallelizing methods of GA are described. There are two principal types of parallel GA. One is parallel processing in a population. This method has the same characteristic as serial GA. The other is to split a population into multiple subpopulations. Today, the latter method is frequently used, because it has the higher parallelism than the former method. There are GA methods performing very efficient parallelism, which combine the both methods. On changing the method of parallel GA, it is important to consider that it may happen to change the amount of calculations and the accuracy of solutions. That brings to the point that Parallel GA has the following two meanings.

- Parallel algorithm for increasing search performance
- Parallel implementation for reducing execution time

For example, Pospichal [13] has proposed the distributed population GA based on GPU, and achieved a high efficiency. Although this method has achieved high efficiency, GA other than the distributed population GA cannot be implemented, since GA and parallel implementation are inseparable Also, it is difficult to implement this method into architecture other than GPU. The most basic parallel models are introduced as the following.

1) The Master-Slave Model: Under GA, there is a tendency that the time consumed on evaluation calculations assumes a large share of total execution time, and the tendency strengthens as the complexity of the problem is increased. Then, the master-slave model accommodates this tendency based on the general idea of parallelization. Under the master-slave model, all the operations except evaluations are executed by a master processor. A master processor sends individuals, which are to be evaluated, to slave processors. Slave processors execute evaluating calculations on these individuals, and return the results to the master processor. Figure 2 shows the flow of the master-slave model. It is considered that this model is inferior to coarse-grained model, because this model requires relatively much communication, and a CPU is requisite as a master processor. The purpose of this model is to reduce the execution time, so it cannot increase the searching performance compared to a serial algorithm.

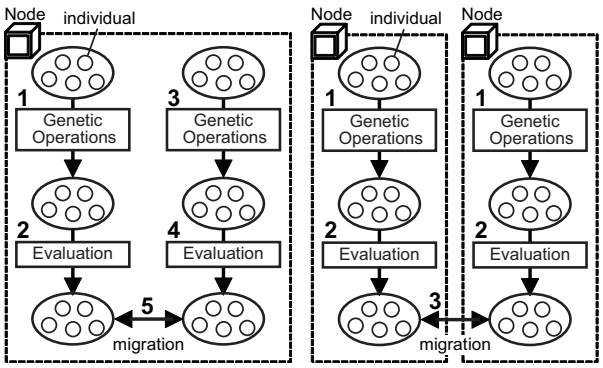
2) The Island Model: This model splits up a population into multiple sub populations and executes searching within each sub population. Then, it transports some individuals in a sub population to the other sub population. This operation is called the migration. Figure 3 shows the flow of the island model. Since this model makes communications between nodes only at the migrations, this model utilizes computational resources effectively. This model reduces its execution time and changes the performance of the search compare to a serial algorithm.

C. Problems

As previously mentioned, parallel GA has two objectives; those are to improve searching performance and to reduce execution time. Some of parallel GA models are depend on specialize particular parallel environment and these cannot be performed on other parallel environments. These types of GA models can use the calculation resources fully and high effectiveness. However, most of parallel calculation resources have difference architecture. Thus, when GA is tried to apply to other parallel architecture, GA researchers have to implement their algorithms for new architecture. To know configurations of various architectures and to implement suitable GA are the heavy burden on GA researchers. With these defects, even research have good parallel environments, it may take time to implement their algorithm.

III. Systematization of Parallel Model

As previously mentioned in chapter II, the expression of "parallel GA" has two models; one is a parallel algorithm to increase searching performance, and the other is a parallel implementation to reduce the execution time. These two models have to be distinguished clearly. In this research, these two models are defined as the followings:



(a) A serial implementation. (b) A parallel implementation.

Fig. 4. Two island models as the logical model

- The logical model: parallel algorithm to increase searching performance
- The implementation model: a parallel implementation to reduce the execution time

Figure 4(a) shows GA adopted an island model as a logical model and a serial model as an implementation model. Figure 4(b) shows GA adopted and island model as a logical model and also as an implementation model. In Figure 4, the number means the orders of processing. The logical model is a model to execute parallel searching, but it is capable to execute serial processing. Additionally, the logical model may be confined by a limitation imposed by the implementation model. For example, if the island model is adopted as the implementation model, the Simple GA cannot be adopted as the logical model. Once the implementation model is provided, only users have to do is to consider and implement the logical model. Thus, users are able to develop any algorithms without the limitation of architectures.

IV. GAROP

The GA framework for Running On Parallel environments (GAROP) is a framework in which any GA can be executed in various parallel environments. The purpose of the GAROP is that users can execute parallel processing, with the master-slave model as the implementation model, without having special techniques for parallel programming. The users of the GAROP are presumed as the developers of GA. Once the implementation for parallel processing is provided, users could receive the benefit of parallel processing, keeping the same level of productivities as sequential programs. Under the GAROP, users construct any logical models and implement some parts other than the evaluation part. Users designate the template suited to each parallel environment, and combine the template and the codes for evaluation of the problem, so that the evaluation part is implemented. The use of this template leads to hide the special communications and the implementation of scheduling for evaluation tasks. Thus, users can execute GA under parallel environments without having knowledge of communication and schedulers appropriate for parallel environments.

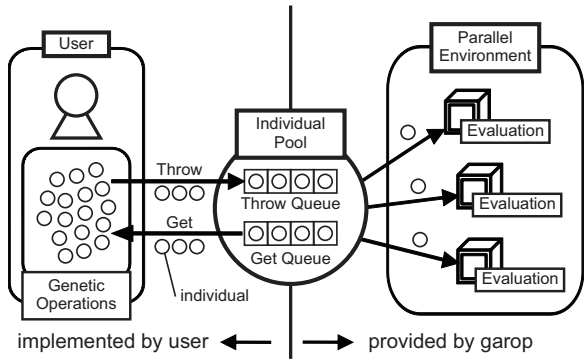


Fig. 5. Overview of the GAROP.

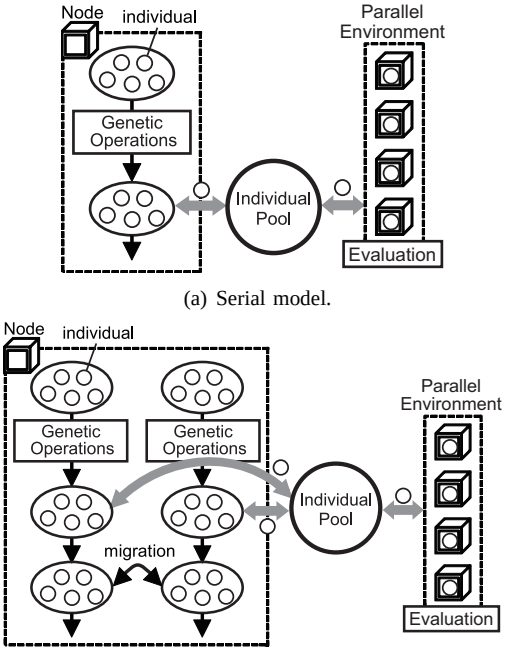

(a) Serial model.

(b) Island model.

Fig. 6. GA Examples with GAROP.

A. Requirements

To achieve the purpose as precious described, the GAROP is expected to meet the following requirements:

- Productivity of users
  In order to achieve the same level of productivity as the sequential programs, the framework should be provided as the form of libraries which call up a function group.
- Versatility of parallel environments
  Users should be able to use various parallel environments by using common descriptions.
- Independent implementation model
  In order to correspond to any GA, the implementation model which is implemented independently of algorithms is required.

TABLE I
FUNCTIONS PROVIDED BY GAROP.

Name	Action
Initialize	prepare parallel environments and the Individual Pool.
Throw	throw an individual to the Individual Pool.
Get	get an individual from the Individual Pool.
Finalize	free memories used by the Individual Pool and disconnect parallel environments.

B. Design of the GAROP

Figure 5 shows the overview of the GAROP. GAROP introduces the concept of the Individual Pool as an interface to link users to parallel environments. The Individual Pool is an archive and stores individuals which should be evaluated in parallel automatically. Under this design, any GA models can be executed in parallel without change searching performance. In Figure 6, the concepts of serial model and island model are demonstrated. In the same way, other parallel models can be performed using the GAROP.

1) The Individual Pool: The Individual Pool consists of two queues as shown in Figure 5. One of these queues is the "throw queue", which stores thrown individuals, and the other queue is the "get queue", which stores evaluated individuals. As soon as individuals are stored in the throw queue, they are sent to calculation resources and evaluated. Evaluated individuals are stored in the get queue. Users throw individual which should be evaluated to the Individual Pool one by one. Users can get the evaluated individual from the get queue, whenever they need. The Individual Pool is a useful concept which makes it possible to execute evaluating calculations and other processing simultaneously.

2) Programming Interface: The GAROP provides 4 functions as shown in Table I. This won't be changed even though the environment of the parallel computation is changed. However, the types of four functions and arguments vary depending on the environment.

3) The Template of evaluation: It is impossible to provide implementations of every single evaluation, because the evaluation depends on the problem to be solved. In the GAROP, users implement the evaluation part. This means that the implementation of the evaluating calculation exists on the memory of the master machine. However, the evaluation is executed by slave processors. Therefore, the evaluation part must be handed over from the master machine to the slave processor. It is realistic to hand over using a form of a function, which is easy to describe. In order to figure out how much memory region is needed, the types and the number of arguments and the type of return value should be known, when the function is handed over. The GAROP provides the template of an evaluate function as the following. Users can solve any problems by limiting the arguments and the return value of the function.

```
void evaluate(unsigned char* indata,
              unsigned char* retdata);
```
- indata: individual data
- retdata: evaluated individual data

This way of description is suitable for the C language. The important thing is to allocate an individual to the argument and to allocate another individual to the return value. In order for a description of an individual to be free, it employs unsigned char as a pointer. The template of the evaluating function varies depending on each of the parallel environment and the language used.

C. How to run algorithms with the GAROP

The libraries to substantiate the GAROP are provided in the form of source codes. Multiple libraries are prepared for each of the execution environments, such as compilers and languages. The user's flow is shown as the following.

- Obtaining the library (source codes) corresponding to the executing environment
- Implementing evaluate function using the templates
- Implementing GA with API of the library
- Compiling source codes
- Placing executable file into calculation resources
- Executing

List 4 is an example of evaluate function using a template. List 1 is an implementation of the serial model with the GAROP. List 2 is an implementation of the island model with the GAROP. Like this way, not only the master-slave model but also the island model can be implemented. Using the GAROP, other models such as cellular model can be implemented in the same way. Under the GAROP, the parallel environment is set up by users. For example, if users use PC cluster with MPI, users prepare cluster by themselves and give a description of machine file etc.

V. IMPLEMENTATIONS OF LIBRARIES FOR THE GAROP

The libraries are implemented to get individuals from Individual Pool and to evaluate in parallel. The environments implemented in this paper are the multi-core CPU by pthread of the C language and the GPU by CUDA. The multi-core CPU is a shared memory environment, and the GPU is a distributed memory environment. Policies of these environments are as the following.

A. Multi-core CPU

The characteristics of multi-core CPU are having not many cores and having a shared memory environment. Considering these two characteristics, the library is implemented with a constitution shown as Figure 7. A thread is regarded as a calculation resource and assigned as a slave processor. Each thread monitors the throw queues. When the throw queue has one or more data, each thread gets an individual and executes evaluating calculations. Arguments of an initialize function are number of threads, size of an individual, and pointer of an evaluate function.

List 1. Serial model with the GAROP.

```
1  population = InitPopulation();
2  Initialize(); // initialization of framework
3  FOR j = 0 to generation limit DO
4    FOR i = 0 to population num DO
5      // throw individuals to GA Pool
6      Throw( population[i] );
7    ENDFOR
8    FOR
9      // get individuals from GA Pool
10     Get( population[i] );
11   ENDFOR
12   selection( population );
13   crossover( population );
14   mutation( population );
15 ENDFOR
16 Finalize(); // finalization of framework
```

List 2. Island model with the GAROP.

```
1  population1 = InitPopulation();
2  population2 = InitPopulation();
3  Initialize(); // initialization of framework
4  FOR j = 0 to generation limit DO
5    FOR i = 0 to population num DO
6      // throw individuals to GA Pool
7      Throw( population1[i] );
8      Throw( population2[i] );
9    ENDFOR
10   FOR
11     // get individuals from GA Pool
12     Get( population1[i] );
13     Get( population2[i] );
14   ENDFOR
15   selection( population1 );
16   selection( population2 );
17   crossover( population1 );
18   crossover( population2 );
19   mutation( population1 );
20   mutation( population2 );
21   IF j % 10 == 0 THEN
22     migration()
23   ENDIF
24 ENDFOR
25 Finalize(); // finalization of framework
```

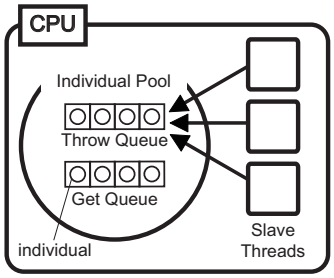

Fig. 7. An implementation of the GAROP for multi-core CPU.

B. GPU

The GPU has many cores and has a distributed memory environment. As the GPU has a distributed memory environment, the library is implemented with a constitution shown as Figure 8. In CPU, there are main thread which run GA and sub thread which communicate data to GPU. Arguments of initialize function are number of blocks and thread, size of an individual, and number of individuals that are processed at a kernel function call. Individuals sent to GPU are stored in the constant memory. Each CUDA thread acquires individual information from constant memory, and writes evaluated individual data to global memory.

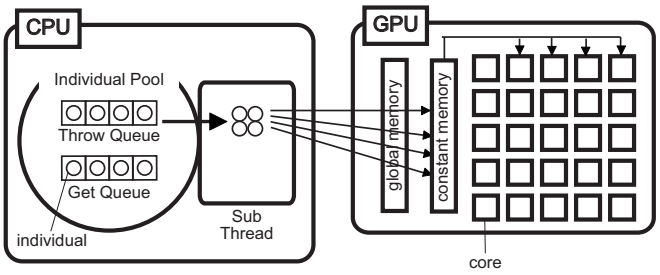

Fig. 8. An implementation of the GAROP for GPU.

TABLE II
PARAMETERS OF THE SIMPLE GA

population size	64
choromosome length	64
size of an individual	68 bytes
max generations	100
optimization problem	onemax

VI. EVALUATION

The following is the evaluation of a Simple GA [14] implemented using the GAROP, in terms of productivity and parallelism. Table II shows a parameter of the Simple GA. List 3 shows a description of an individual in this evaluation. In this experiment, onemax problem is iterated 100,000 times to mimic a large-scale problem. List 4 shows a function on the evaluation. In this GA, the evaluating calculation takes up more than 99 % of total execution time. The maximum number of parallelism is 64, since the population size is 64. Thus, number of individuals to be calculated at a kernel function call is 64 in the GPU library.

A. Environments

The architectures to be evaluated in this experiment are multi-core CPU and GPU. Table III shows the specifications of

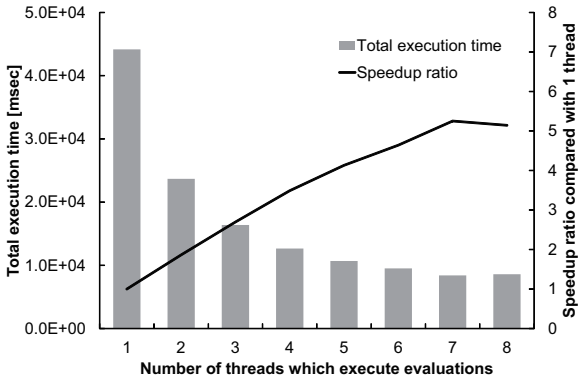
the machine used in this evaluation. This machine is mounted Tesla C2050 as shown in Table IV.

B. Results

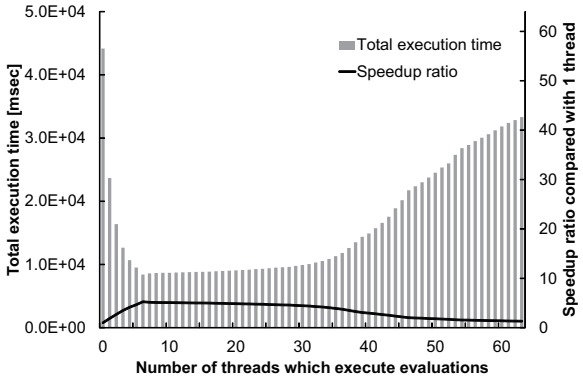
Figure 9 shows results of multi-core CPU, and Figure 10 shows results of GPU, respectively. List 5 shows the source codes which described by users on multi-core CPU. List 6 shows the source codes which described by users on GPU. List 5 and List 6 show that these descriptions are common among different architectures. It is verified that descriptions for parallel processing can be completely hidden, even though these descriptions are essentially required on parallel processing. Figure 9(a) shows that the execution time reduces when the number of threads is 1 to 7. Figure 9(b) shows that the number of threads that had the least processing time is 7, and it is improved 5.26 times compared to the situation when a thread is processed. When the number of thread is 8 or more, execution time takes longer. Figure 10 shows that the number of threads that had the least processing time is 64, and it is improved 50.01 times compared to the situation when a thread is processed. When the numbers of thread are 2, 3, 4, 6, 8, 16, 32 and 64, the execution time is extremely reduced.

VII. DISCUSSION

The C language and CUDA are the similar languages, but methods of implementation in parallel are substantially different. C is used for multi-core architecture and CUDA is used for GPU architecture. Usually, users need the parallel programming knowledge of C and CUDA for these architectures. However, using the GAROP framework and its library, users need not to prepare the codes for parallel processing. Both of the codes which GA users prepare can be used as the common descriptions. Therefore, the productivity of coding is increased using the GAROP. Reviewing the result of multi-core CPUs, when the number of threads is 8, the execution time is the shortest. Among the 8 threads, 7 of them are the threads for the slave processors and the rest is the main thread for GA operations. The calculation server for this experiment



(a) The number of threads (1 to 8).



(b) The number of threads (1 to 64).

Fig. 9. Speedup and execution time on multi-core CPU depending on number of threads.

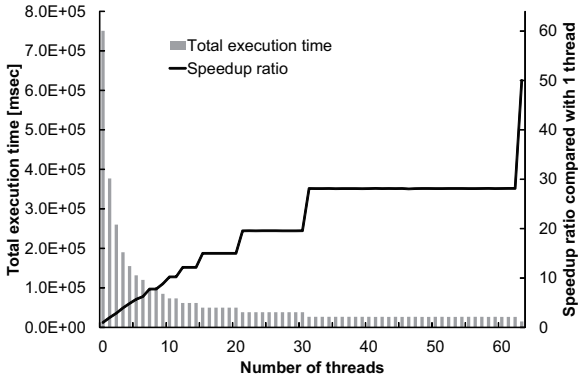


Fig. 10. Speedup and execution time on GPU depending on number of threads.

has 8 logical cores. Therefore, when 7 threads are used for the slave processors, all of the logical cores are occupied. When 8 or more threads are used, the number of threads is more than the number of logical cores, so that it prevents the speed up. When the number of threads is more than the number of cores, it may happen that CPU has to switch executing threads one after another, and this operation of switching threads produces the waiting time. In the experiment in GPU, the execution time is the shortest with 64 threads. Tesla C2050, which is the GPU

List 5. Simple GA with a library for pthread in C.

```
Individual population[POPULATION_SIZE];
// create population
InitPopulation( population );
// initialization of framework
Initialize( sizeof(Individual), THREAD_NUM, evaluate );
for( i = 1; i <= MAX_GENERATION; i++ ) {
    // throw individuals to GA Pool
    for( j = 0; j < POPULATION_SIZE; j++ )
        Throw( (unsigned char*)&population[j],
               sizeof(Individual) );
    // get individuals from GA Pool
    for( j = 0; j < POPULATION_SIZE; j++ )
        Get( (Individual*)&population[j],
             sizeof(Individual) );
    population = selection( population );
    crossover( population );
    mutation( population );     }
// finalization of framework
Finalize();
```

List 6. Simple GA with a library for GPU in CUDA.

```
Individual population[POPULATION_SIZE];
// create population
InitPopulation( population );
// initialization of framework
Initialize( sizeof(Individual), BLOCK_NUM,
            THREAD_NUM, POPULATION_SIZE );
for( i = 1; i <= MAX_GENERATION; i++ ) {
    // throw individuals to GA Pool
    for( j = 0; j < POPULATION_SIZE; j++ )
        Throw( (unsigned char*)&population[j],
               sizeof(Individual) );
    // get individuals from GA Pool
    for( j = 0; j < POPULATION_SIZE; j++ )
        Get( (Individual*)&population[j],
             sizeof(Individual) );
    population = selection( population );
    crossover( population );
    mutation( population );     }
// finalization of framework
Finalize();
```

used in this experiment, has 448 cores. Thus, it can use 64 cores for 64 threads. From the Figure 10, it is observed that the stagnation of speed up is existed from 17 to 31 threads and from 33 to 63 threads. The reason of this stagnation is that the population size 64 is not the multiple of these numbers. Because of this reason, the fraction of the individuals is existed and the fraction itself should be calculated, too. This takes time and leads to the stagnation.

VIII. Conclusions

In this paper, the GAROP which is a parallel environment framework for evolutionary computation is proposed. The GAROP is the framework where the logical model and the implementation model are distinguished, and the users prepare their algorithms as the logical model and the implementation model is prepared by systems. Thus, users can implement any type of logical model on parallel environment using the GAROP. In the GAROP, user's evolutionary algorithms are performed in parallel as master-slave model. Users implement their GA operations in the master and the evaluation part is implemented in the slave using the provided template. With the provided libraries and the implemented codes, the application, which is worked on several types of parallel environment, is compiled. In this paper, the concept and the flow of the GAROP are described and the libraries for two types of parallel environments are implemented; those are multi-core CPUs and GPUs. Using the GAROP and the libraries, Simple GA is implemented and the productivity of users and parallelism are evaluated. From the results, GA applications which can be worked on parallel environments are implemented using four types of functions which are provided by the GAROP. At the same time, execution time is also reduced.

In the future work, further discussion should be held for not only Simple GA but also for other evolutionary computation algorithms. In this paper, the libraries for multi-core CPUs and GPUs are implemented. Other types of libraries for other parallel environments will be prepared. At the same time, the productivity discussions of the GAROP should be performed with researches who are working on evolutionary computation fields.

Rapid Feature Selection Based on Random Forests for High-Dimensional Data

Hideko KAWAKUBO, Hiroaki YOSHIDA
Graduate School of Humanities and Sciences, Ochanomizu University, Tokyo, Japan

Abstract— *One of the important issues of machine learning is obtaining essential information from high-dimensional data for discrimination. Dimensionality reduction is a means to reduce the burden of dimensionality due to large-scale data. Feature selection determines significant variables and contributes to dimensionality reduction. In recent years, the random forests method has been the focus of research because it can perform appropriate variable selection even with high-dimensional data holding high correlations between dimensionality. There exist many feature selection methods based on random forests. These methods can appropriately extract the minimum subset of important variables. However, these methods need more computation time than the original random forests method. An advantage of the random forests method is its speed. Therefore, this paper aims to propose a rapid feature selection method for high-dimensional data. Rather than searching the minimum subset of important variables, our method aims to select meaningful variables quickly under the assumption that the number of variables to be selected is determined beforehand. Two main points are introduced to enable faster calculations. One is reduction in the calculation time of weak learners. The other is adopting two types of feature selection: "filter" and "wrapper." In addition, although most present methods use only "mean decrease accuracy," we calculate the magnitude of features by combining "mean decrease accuracy" and "Gini importance." As a result, our method can reduce computation time in cases where generated trees have many nodes. More specifically, our method can reduce the number of important variables to* 0.8% *on an average without losing the information for classification. In conclusion, our proposed method based on random forests is found to be effective for achieving rapid feature selection.*

Keywords: feature selection; variable selection; random forests; Gini importance;

1. Introduction

In recent years, feature selection for dimensionality reduction is becoming increasingly important in machine learning. Feature or variable selection enables improving accuracy by excluding redundant variables and facilitates the interpretation of complex data structures as well as reduces calculation time for predictors. Therefore, variable selection for high-dimensional data plays an important role in many areas including text processing of internet documents, gene expression array analysis and combinatorial chemistry. In this paper, we propose a rapid feature selection method for high-dimensional data.

There are three types of variable selection: "filter," "wrapper," and "embedded" [1], [2]. "Filter" selects subsets of variables in a preprocessing step, independent of the chosen predictor. "Wrapper" utilizes the learning machine of interest as a black box to score subsets of variables according to their predictive power. "Embedded" performs variable selection during the training process and is usually specific to given learning machines. The random forests (RF) method [3] based on the wrapper method has been widely recognized as a practical method of variable selection. In recent years, the RF method has also been applied to feature selection for hyperspectral imagery and gene selection of microarray data [4], [5]. Furthermore, the demand for variable selection has been increasing.

The RF method has two types of variable importance measures. One involves the evaluation of "out-of-bag (OOB) errors" introduced to estimate prediction errors. Several feature selection methods using this measure have been proposed [6], [7], [8].

The other measure is derived from the Gini index and is called "Gini importance." This measure is biased toward predictor variables with many categories [9]. However, it is particularly effective with data that have a high dimensionality and small sample size [10]. There also exists a feature selection method using "Gini importance" [11].

These feature selection methods, which are extended RF methods, can appropriately extract the minimum subset of important variables. Because the RF method itself is stochastic, the subsets obtained by these methods are only a candidate of the optimal solution; moreover, if sufficient computation time is provided, these methods are attractive.

In this paper, we assume that the number of important variables to be selected is decided beforehand and propose a fast method to select meaningful variables with a high accuracy. As a result of investigating the ranking of important variables derived from various datasets by using the original RF method, we obtain the following empirical rule: the rankings drawn from two types of variable importance measures slightly differ, whereas the members of the top ranked variables are almost the same. Based on this empirical rule, we improve the original RF method and successfully reduce

computation time, especially in cases where generated trees have many nodes. In addition, in our method, the number of important variables is reduced to 0.8% on an average without losing the information for discrimination. In conclusion, our proposed method based on RF is effective to achieve rapid variable selection. The reason why our method is successful is not solved mathematically; the results obtained by our method are very interesting.

In the following section, we review RF and "Gini importance"; we explain our proposed method in section 2.

1.1 Random forests algorithm

The RF method creates multiple trees using classification and regression trees (CART) [12]. When constructing a tree, the RF method searches for only a random subset of input variables at each splitting node and the tree grows fully without pruning. The RF method is recognized as a specific instance of bagging.

Random selection of variables at each node decreases the correlation among trees in a forest, thus forest error rate decreases. The random subspace selection method has been demonstrated to perform better than bagging when there are many redundant variables contributing to discrimination among classes [13], [14], [15].

The computational load of the RF method is comparatively light. The computation time is on the order of $ntree\sqrt{mtry}\ n\log n$, where $ntree$ is the number of trees, $mtry$ is the number of variables used in each split, and n is the number of training samples [3], [4].

In addition, when a separate test set is not available, an OOB method can be used. For each newly generated training set, one-third of the samples are randomly excluded; these are called OOB samples. The remaining (in-the-bag) samples are used for building the tree. For accuracy estimation, votes for each sample are counted every time a sample is included among OOB samples. A majority vote determines the final label. The OOB error estimates are unbiased in many tests [3]. The number of $mtry$ is defined by a user, and it is insensitive to the algorithm.

The RF algorithm (for both classification and regression) is as follows:

1) Draw $ntree$ bootstrap samples from the original data.
2) For each bootstrap sample, randomly sample $mtry$ predictors (variables) at each node, grow an unpruned classification or regression tree, and choose the best split among these variables (rather than choosing the best split among all variables).
3) Predict new data by aggregating the predictions of $ntree$ trees (i.e., majority vote is used for classification, average is used for regression).

Based on training data, an error rate estimate can be obtained as follows:

1) At each bootstrap iteration, predict test data not in the bootstrap sample (what Breiman calls "out-of-bag" or OOB data) using a tree grown with the bootstrap sample.
2) Aggregate the OOB predictions. Calculate their error rate, and call it OOB error rate estimate.

The RF method performs efficiently for large datasets and can handle thousands of input variables. The RF algorithm has been demonstrated to have excellent performance in comparison to other machine learning algorithms [3], [16], [17].

1.2 Gini importance

The RF method has extremely useful byproducts, for instance, variable importance measures [3], [18]. There are two different algorithms for calculating variable importance.

The first algorithm is based on the Gini criterion used to create a classification tree, CART [12]. In this paper, we call the measure "Gini importance." At each node, decreases in Gini impurity are recorded for all variables used to form the split. Gini impurity $\Delta GI(t)$ is defined as follows:

$$\Delta GI(t) = P_t GI(t) - P_L GI(t_L) - P_R GI(t_R).$$

Here, $GI(t)$ is called the Gini index and is defined as follows:

$$GI(t) = 1 - \sum_k p(k \mid t)^2,$$

where $p(k \mid t)$ is the rate at which class k is discriminated correctly at node t, $GI(t_L)$ is a Gini index on the left side of the node, $GI(t_R)$ is a Gini index on the right side of the node, P_t is the number of samples before the split, P_L is the number of samples on the left side after the split, and P_R is the number of samples on the right side after the split. The Gini criterion is used to select the split with the highest impurity at each node. The average of all decreases in Gini impurity yields the "Gini importance" measure.

The second algorithm is based on OOB observations. In this paper, we call the measure "mean decrease accuracy." Although the structure of a decision tree provides information concerning important variables, such an interpretation is difficult for hundreds of trees in an ensemble. One additional feature of RF is the ability to evaluate the importance of each input variable by the OOB estimates. To evaluate the importance of each variable, the values of each variable in the OOB samples are allowed to permute. The perturbed OOB samples will run down each tree again. Then, the difference between the accuracies of the original and perturbed OOB samples over all trees in RF are averaged.

Variable importance of "mean decrease accuracy" is defined as follows: Let $X_j (j = 1, \cdots, M)$ be the permuted variables, where M is the number of all variables. X_j and the remaining nonpermuted predictor variables together form a perturbed OOB sample. When X_j is used to predict the response for the OOB sample, the prediction accuracy (i.e., the number of samples classified correctly) decreases

substantially, if the original variable X_j is associated with the response. For each tree f of the forest, consider the associated OOB_f sample (data not included in the bootstrap samples used to construct f). The error of a single tree f in this OOB_f sample is denoted by $errOOB_f$. Now, randomly permute the values of X_j in OOB_f to get a permuted sample denoted by OOB_{fj} and compute $errOOB_{fj}$, the error of predictor f in the perturbed sample. Variable importance of X_j is then equal to

$$VI(X_j) = \frac{1}{ntree} \sum_{f} (errOOB_f - errOOB_{f_j}),$$

where the summation is over all trees f of RF and $ntree$ denotes the number of trees of RF.

2. Rapid Feature Selection Based on Random Forests

We investigate the ranking of important variables derived from various datasets by using the original RF method and obtain an empirical rule: the rankings of important variables obtained from "Gini importance" and "mean decrease accuracy" differ slightly, whereas the members of the top ranked variables are almost the same. Thus, if we can determine these members of the top ranked variables obtained from "Gini importance," we can rank variable importance by "mean decrease accuracy."

To realize this idea, we combine "Gini importance" and "mean decrease accuracy" as "filter" and "wrapper." We propose an improved method of RF and call it "rapid feature selection" method (RFS). After reducing meaningless variables by "filter," rapid feature selection evaluates variable importance by "wrapper."

"Gini importance" can be acquired from the generation process of weak learners, thus it is convenient to use the "Gini importance" measure as a "filter." However, sometimes we cannot obtain high accuracy by only using such a "filter." On the other hand, "mean decrease accuracy" is high; "mean decrease accuracy" is computationally heavy because it has to call on the learning algorithm to evaluate each subset.

The rapid feature selection algorithm is as follows:

1) Exclude OOB data and draw $ntree$ bootstrap samples from training data.
2) For each bootstrap sample, randomly sample $mtry$ variables, grow a tree up to the first node, and record all Gini impurities generated in the calculation process.
3) Choose the top v variables that are candidates for the best split, give a score that reflects the top ranked v variables for $ntree$ trees, and aggregate all scores.
4) To select the top s important variables, choose the top s_e variables at this point (s_e is larger than s).
5) Rank s_e variables by "mean decrease accuracy" of the original RF method and select the top v variables.

Table 1: Information about each dataset

Dataset	Samples	Variables	Class	Accuracy
Internet Advertisements	3,279	1,558	2	0.963
Gisette	6,000	5,000	2	0.964

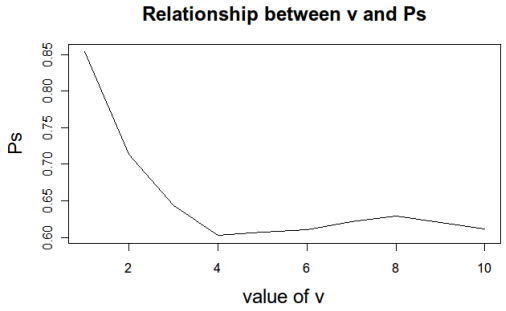

Fig. 1: Simulation: Relationship between v and P_s. Number of variables: $1,558$.

In the case that some variables are correlated, CART can choose the best split. However, CART needs the calculation of Gini impurity up to $2^{n-1} - 1$ times in the worst case, where n is the number of samples in each bootstrap sample. Thus, reducing the calculation time of CART is a significant issue in this method.

To reduce the calculation time of CART, some RF applications have an option to stop calculation at the first node. This option is effective in reducing computation time; however, the appropriate evaluation of important variables cannot be obtained. Necessary information will be insufficient when $v = 1$ owing to the nature of the data; therefore, we set a parameter v.

Under the assumption that CART can accurately rank variables and all variables are independent, we simulated the behavior of these parameters. In the simulation, we used the number of variables from Table 1.

Let P_s be a probability that the top s variables are included in the top s_e variables. The relationship among P_s and the other parameters are shown in Figures 1,2,3,4 and 5. The parameters that are not a target of the investigation are set as follows: $s_e = 35$, $s = 20$, $v = 5$ and $ntree = 100$ for the case of $1,558$ variables (Figures 1,3,4 and 5), and $s_e = 70$, $s = 55$ and $ntree = 100$ for the case of $5,000$ variables (Figure 2).

From Figures 1 and 2, we can find that the optimal v changes owing to the number of variables. Because CART cannot necessarily rank variables correctly and all variables are not independent in real data, in practice, the optimal v differs from the result of the simulation. Without changing the parameter setting, we conducted a experiment using real data to investigate about v. Internet advertisement dataset in Table 1 was chosen as a real data with $1,558$ variables. This

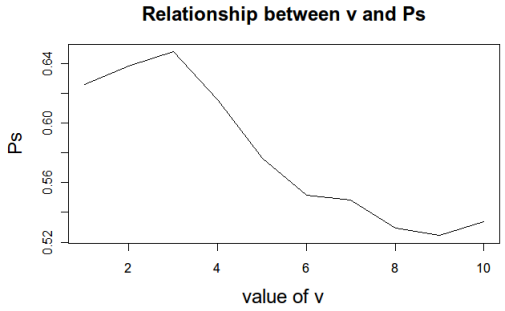

Fig. 2: Simulation: Relationship between v and P_s. Number of variables: $5,000$.

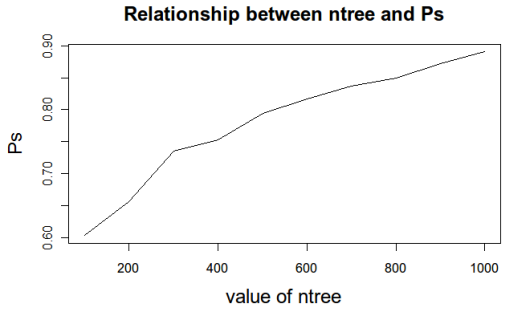

Fig. 4: Simulation: Relationship between $ntree$ and P_s. Number of variables: $1,558$.

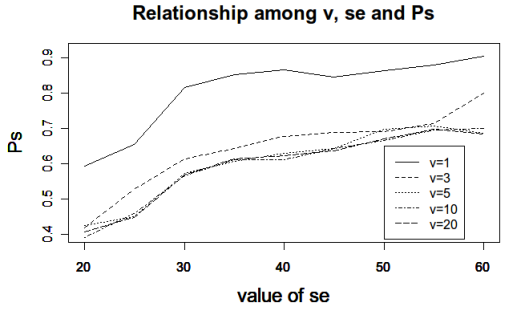

Fig. 3: Simulation: Relationship among v, s_e and P_s. Number of variables: $1,558$.

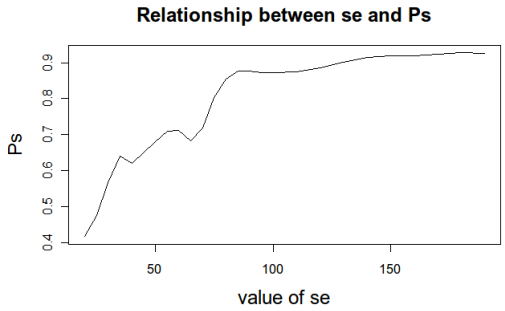

Fig. 5: Simulation: Relationship between s_e and P_s. Number of variables: $1,558$.

experiment was conducted using rapid feature selection.

Figure 6 shows that the accuracy of this real data is insensitive to the value of v. It is difficult to predict the optimal v. However, under the condition that v is 5 or more, we found that the behavior of P_s is stabilized if s_e changes. Figure 3 supports this empirical rule. Thus, we conducted experiments by provisionally setting $v = 5$, as described in the following chapter. Prediction of v is one of the future work.

Figure 4 expresses the relationship between $ntree$ and P_s, and Figure 5 the relationship between s_e and P_s. These Figures show a following relationship: The more the value of $ntree$ or s_e becomes large, the more the value of P_s approaches 1. Under the assumption that s is determined beforehand, we consider that all parameters should be set to satisfy the following condition:

$$mtry \times \frac{s}{M} \times P_s(s, s_e) \times ntree \geq s.$$

It is expected that the maximization of P_s and minimization of s_e and $ntree$ are realized simultaneously. When $1.5s = s_e, mtry \times ntree/M = 2.5$, P_s is about 0.5 is considered as one index.

3. Experiment

First, we conducted experiments to verify the performance of rapid feature selection compared with another well-known method. For comparison, we chose principal component analysis (PCA). PCA provides factor loading amount and accumulated contribution rate for variable selection. By using these values, we selected meaningful variables.

Next, to determine whether "mean decrease accuracy" used as "wrapper" in our method works effectively, we compared the performance of rapid feature selection and a method that employs only "filter" in rapid feature selection. In this paper, we refer to this method as "first split" (FS). First split does not use the evaluation from mean decrease accuracy. The first split algorithm is simple and its steps $1)$ to $3)$ are the same as those of the rapid feature selection algorithm, except that there is no need to exclude OOB data.

Because "mean decrease accuracy" consumes computation time, an alternative method is desired. To this end, we introduce weighted sampling. Gender et al. suggested selecting random $mtry$ inputs according to a distribution derived from the preliminary ranking given by a pilot estimator [19]. Based on their concept, we propose another method for rapid variable selection. In this paper, we call this method "first

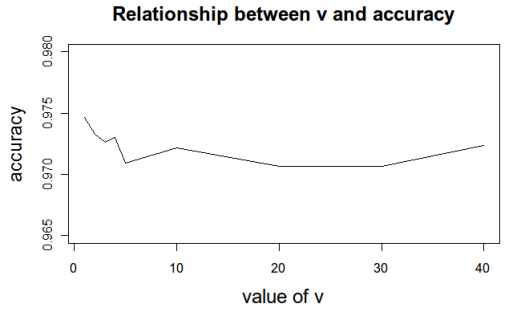

Fig. 6: Experiment: Relationship between v and $accuracy$. Dataset: Internet Advertisements.

split Gibbs" (FSG). After performing the first split algorithm, first split Gibbs normalizes the score derived from step 3) of the first split algorithm. Then, let the normalized values be $G_i (i = 1, \cdots, M)$ and calculate the Gibbs distribution by substituting G_i as a potential. The probability function of the Gibbs distribution is defined as follows:

$$P_i = \frac{\exp(-\beta G_i)}{\sum_{i=1}^{M} \exp(-\beta G_i)} \qquad (\beta > 0).$$

To sample $mtry$ variables according to the Gibbs distribution, first split Gibbs repeats the first split algorithm once again. Weighted samplings are performed by adjusting the parameter β. The original RF method samples $mtry$ variables according to the uniform distribution. Substituting $\beta = 0$ for the probability function of the Gibbs distribution, the resulting distribution equals the uniform distribution. When we substitute large values for β, the probability that the variables with large G_i are chosen increases.

Using high-dimensional data from UCI Machine Learning Repository, we investigate computation time and quality of variable selection, that is, whether important variables are properly selected. After performing PCA and the three methods, the accuracy of each is compared using only the variables selected. The score at step 3) of the rapid feature selection algorithm is obtained by giving the $1/r$ points to the rth variable ($r = 1, \cdots, v$).

As datasets for the experiment, we use an internet advertisements dataset and the Gisette dataset. Readers can refer to the details of these datasets at (http://archive.ics.uci.edu/ml/data-sets/Internet+Advertisements, http://archive.ics.uci.edu/ml/datasets/Gisette).

The experiment using internet advertisements results in trees with several nodes. On the other hand, the experiment using the Gisette dataset results in trees with many nodes. For each dataset, Table 1 shows the number of samples and variables and the accuracy calculated using all variables.

The computation environment is as follows: CPU Phenom X4 9950, OS Windows7 Professional 64bit, RAM 8GB.

Table 2: Comparison of computation time. (sec.)

Dataset	FS	FSG	RFS	RF	PCA
Internet Advertisements	8.39	16.21	9.22	272.46	38.50
Gisette	63.00	58.49	76.38	801.61	833.60

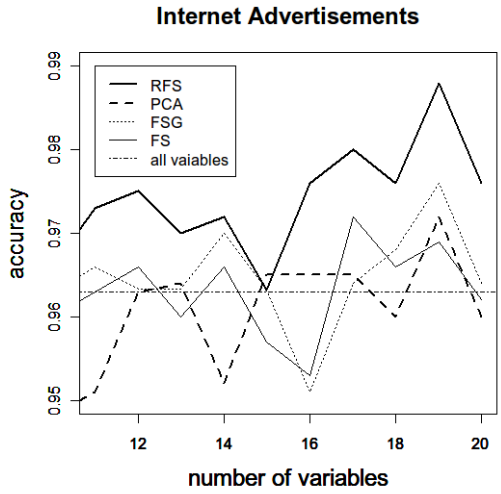

Fig. 7: Comparison of accuracy calculated using selected variables only. Method: RFS, PCA, FS and FSG. Dataset: Internet Advertisements.

4. Results and discussion

Table 2 shows the computation time of each method. The parameters used in this experiment are set as follows: $mtry = \lfloor \sqrt{M} + 0.5 \rfloor$, $ntree = 200$, $v = 5$, $s_e = 20$, $s = 15$. First split Gibbs and rapid feature selection need two-stage estimations. At each stage, $ntree = 100$ is set.

Computation time depends on the property of a dataset, thus the ranking of first split, first split Gibbs, and rapid feature selection varied slightly. However, the computation time of the rapid feature selection method was always lower than the original RF. From this result, rapid feature selection was found to be a much faster method than the original RF method.

The results of the accuracy calculated using selected variables only are plotted in Figures 7, 8 and 9. We can compare rapid feature selection, PCA, first split and first split Gibbs from these figures. In this experiment, the accuracy in Table 1 is used as the evaluation criterion regarding whether the information for classification is maintained. The result showed that rapid feature selection can maintain accuracy even if the number of dimensions becomes high.

The parameters used in this experiment are set as follows: $mtry = \lfloor \sqrt{M} + 0.5 \rfloor$, $ntree = 200$, $v = 5$, $\beta = 100$,$s = 10 - 20$, $s_e = 25 - 35$ for the internet advertisements dataset and $mtry = \lfloor \sqrt{M} + 0.5 \rfloor$, $ntree = 200$, $v = 5$, $\beta = 100$,$s = 45 - 55$, $s_e = 60 - 70$ for the Gisette dataset.

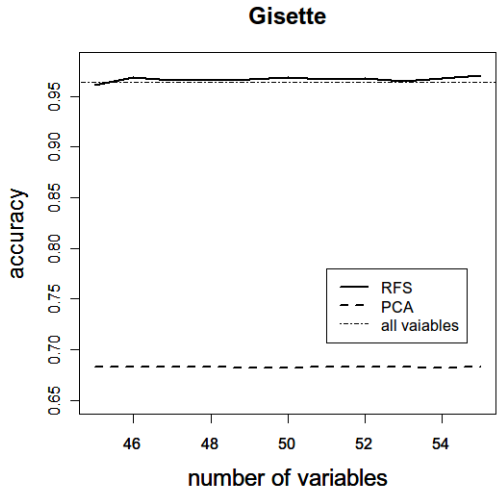

Fig. 8: Comparison of accuracy calculated using selected variables only. Method: RFS and PCA. Dataset: Gisette.

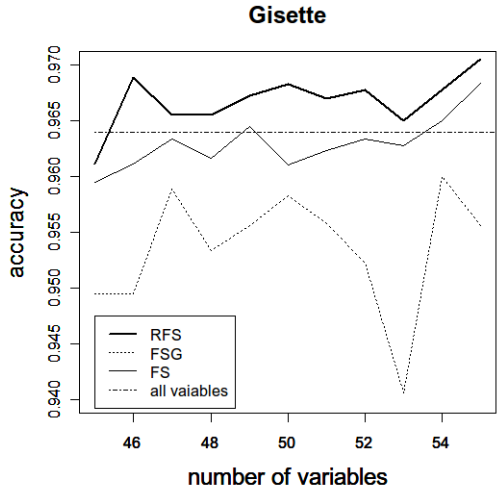

Fig. 9: Comparison of accuracy calculated using selected variables only. Method: RFS, FS and FSG. Dataset: Gisette.

Rapid feature selection needs two-stage estimations. At each stage, $ntree = 100$ is set.

From the results, we found that rapid feature selection can select important variables more accurately than first split and first split Gibbs. In addition, we found that trees with many nodes do not affect the results. Even if we reduced the number of variables to 0.6% for the internet advertisements dataset and 0.92% for the Gisette dataset, the accuracy did not fall below the evaluation criterion. These results indicate that rapid feature selection maintains the information for discrimination after variable selection.

The ranking of variables selected by each method are illustrated in Table 3. The results of the internet advertisements dataset are used for this experiment. The parameters used in this experiment are set as follows: $mtry = \lfloor \sqrt{M} + 0.5 \rfloor$, $ntree = 200$, $v = 5$, $\beta = 100$, $s_e = 34$, $s = 19$.

In the table, the values under the three methods represent the ID number of the variables. In this case, the ID number is up to $1,558$. Both rapid feature selection and first split select almost the same variables because rapid feature selection is based on first split. Here, about 11% of the variables are replaced, and the accuracy increased as a result of this change. Because "mean decrease accuracy" is introduced in step $5)$ of the rapid feature selection algorithm, the accuracy of rapid feature selection is higher than that of first split. Therefore, the effectiveness of the "wrapper" method was verified through this experiment.

First split Gibbs is also based on first split and about 37% of variables are replaced by weighted samplings. In this case, the estimation by sampling $mtry$ variables according to the Gibbs distribution was successful and accuracy was improved.

However, owing to the nature of the data, first split itself can correctly select important variables. In contrast, first split Gibbs reduces accuracy rate in such a situation. This phenomenon can be observed in Figure 9. Adjusting the value of β is difficult, thus first split Gibbs has a problem of time to adjust the value of β. However, first split Gibbs is a promising method as an alternative method of "mean decrease accuracy," if adjustment of β can be performed well.

Our study showed that rapid feature selection performs faster than the original RF method and can correctly select important variables even if trees with many nodes are generated. Rapid feature selection cannot search the minimum subset of significant variables for discrimination. However, under the conditions that the number of variables to be selected is predefined, rapid feature selection is useful to rapidly search essential variables.

5. Conclusion

In this paper, we proposed the rapid feature selection method based on an empirical rule: the rankings of important variables obtained from "Gini importance" and "mean decrease accuracy" differ slightly, whereas the members of the top ranked variables in RF are almost the same. If this empirical rule is solved mathematically, the reason our method is successful becomes clear.

The rapid feature selection method involves a two-step estimation. As the first step, candidates for important variables are chosen by a type of "filter." At this stage, variable importance is evaluated on the basis of "Gini importance." In the second stage, we select important variables by "wrapper." "Mean decrease accuracy" is adopted as the measure of variable importance. We calculate "mean decrease accuracy" using only variables chosen in the first stage. This is the reason rapid feature selection can maintain speed and accuracy.

Table 3: Illustration of variables selected by each method

Ranking	FS	FSG	RFS	PCA
1	3	3	352	2
2	1,425	1,154	1,400	1
3	1	2	1,484	3
4	2	352	3	1,244
5	969	1	1,425	1,484
6	1,154	1,400	1	1,456
7	1,423	1,484	2	1,436
8	1,199	969	1,154	352
9	1,556	1,119	1,423	1,400
10	1,255	347	1,199	1,279
11	1,119	458	1,556	549
12	1,345	896	1,255	918
13	1,400	994	1,119	360
14	1,484	1,048	1,345	541
15	1,214	1,109	1,555	557
16	1,555	1,199	1,048	337
17	352	1,225	1,109	915
18	1,048	1,230	1,144	173
19	1,109	1,424	820	1,363
Accuracy	0.973	0.982	0.979	0.973

The experimental results for computation time demonstrated that rapid feature selection is significantly faster than the original RF method. Although computation time depends on the nature of the data and the number of variables expected to be selected, it is certain that rapid feature selection selects important variables much faster than the original RF method when dealing with high-dimensional data.

Rapid feature selection was also found to be able to select important variables and maintain the information for classification. In the experiment, although the number of variables was reduced to about 0.8% and only 200 weak learners were used, rapid feature selection preserved a high degree of accuracy. These results show that our proposed method performance is sufficient for rapid variable selection.

By using rapid feature selection for various types of high-dimensional data, a means to improve the score generated at step $3)$ of the rapid feature selection algorithm may be found. Computation time may be further reduced by the combination of improved first split Gibbs and rapid feature selection. Moreover, it is necessary to not only collect empirical rules but also mathematical proof for the development of rapid feature selection.

Abstract— *In this paper, we compare with the inverse iteration algorithms on PowerXCell^{TM} 8i processor, which has been known as a heterogeneous environment. When some of all the eigenvalues are close together or there are clusters of eigenvalues, reorthogonalization must be adopted to all the eigenvectors associated with such eigenvalues. Reorthogonalization algorithms need a lot of computational cost. The Classical Gram-Schmidt (CGS) algorithm, the modified Gram-Schmidt (MGS) algorithm, and the Householder orthogonalization algorithm in terms of the compact WY representation have been known as reorthogonalization algorithms. These algorithms can be computed using BLAS level-1 and level-2. Since synergistic processor elements in PowerXCell^{TM} 8i processor archive the high performance of BLAS level-2 and level-3, the orthogonalization algorithms except the MGS algorithm can be computed high-speed on parallel computers.*

Keywords: inverse iteration, eigenvalue decomposition, Classical Gram-Schmidt, Householder transformation, modified Gram-Schmidt, PowerXCell^{TM} 8i processor

1. Introduction

The eigenvalue decomposition of a symmetric matrix is one of the most important operations in linear algebra. It is used in molecular orbital of chemical, vibrational analysis, image processing, data searches, etc..

Owing to recent improvements in the performance of computers equipped with multicore processors, we have had more opportunities to perform calculations on parallel computers. As a result, there has been an increase in the demand for an eigenvalue decomposition algorithm that can be effectively parallelized.

Any $n \times n$ symmetric matrix is transformed into a symmetric tridiagonal matrix by using a sequence of Householder transformations [4], [9]. This preconditioning process helps to shorten computational time drastically. Hence, eigenvalue decomposition algorithms of symmetric tridiagonal matrices are important. Several eigenvalue decomposition algorithms of a symmetric tridiagonal matrix have been proposed [3], [7], [10], [12], [13], [17]. They are classified into two types. The first type of algorithm computes simultaneously all the eigenvalues and the eigenvectors. Algorithms of this type include the QR algorithm [10] and the divide-and-conquer algorithm [3], [13]. The second type of algorithm computes all or some eigenvalues and all or some eigenvectors. Algorithms for computing eigenvalues include the root-free QR algorithm [12] and the bisection algorithm [10]. Algorithms for computing eigenvectors include the MR^3 algorithm [7] and the inverse iteration algorithm with the modified Gram-Schmidt (MGS) algorithm [10], [17]. LAPACK (Linear Algebra PACKage) [16], which is a software library for numerical linear algebra, has codes that integrate all the above-mentioned algorithms. These algorithms can be parallelized, except the root-free QR algorithm.

The inverse iteration algorithm is an algorithm for computing eigenvectors independently associated with mutually distinct eigenvalues. However, when some eigenvalues are very close to each other, the eigenvectors, which are computed using the inverse iteration algorithm, must be reorthogonalized. As reorthogonalization algorithms, the Classical Gram-Schmidt (CGS) algorithm [10], the MGS algorithm, the Householder orthogonalization algorithm [15] are known. Reorthogonalization algorithms need a lot of computational cost. The CGS algorithm is suitable algorithm for parallel computing. The orthogonality of eigenvectors computed by the CGS algorithm depends on the square of the condition number of the eigenvectors, which are generated using the inverse iteration, in the same cluster of the eigenvalues [20]. The MGS algorithm is sequential and inefficient for parallel computing. The orthogonality of eigenvectors computed by the MGS algorithm depends on the condition number. The Householder orthogonalization algorithm can orthogonalize eigenvectors by using the Householder transformation [19]. The orthogonality in the Householder orthogonalization algorithm does not depend on the condition number. The Householder algorithm is sequential and inefficient for parallel computing. Ishigami et. al. have developed parallel algorithms for the Householder orthogonalization algorithm in terms of the compact WY representation [15], which is named as the cWY algorithm in this paper.

In ExaFLOP computing, since it is critical issue to minimize electricity, heterogeneous environments are suitable. Consequently, it is important to validate the inverse iteration algorithms with the CGS algorithm, the MGS algorithm, and the cWY in heterogeneous environments. As a heteroge-

neous environment, cell processor has PowerPC Processor Element (PPE) and eight cores of Synergistic Processor Elements (SPEs). PPE and SPEs can share the same memory. Since SPEs are consisted as multicore, SPEs archive the high performance of BLAS level-2 and level-3 [1]. Basic Linear Algebra Subprograms (BLAS) is an application programming interface standard for publishing libraries to perform basic linear algebra operations such as vector and matrix multiplications. BLAS level-1 can compute vector operations such as inner products, dot products and vector norms. BLAS level-2 and level-3 contain matrix-vector and matrix-matrix operations, respectively. The CGS algorithm and the MGS algorithm can be computed using BLAS level-2 and level-1, respectively. The cWY needs BLAS level-1 and level-2. Note that, the Householder orthogonalization algorithm is almost computed using BLAS level-2. Therefore, these orthogonalization algorithms should be performed in SPEs. By using PPE, an implementation of an inverse iteration is easy. In this paper, we compare with the CGS algorithm, the MGS algorithm, and the cWY on PowerXCell^{TM} 8i processor.

In Section 2, we give a brief review on eigenvalue decomposition. In Section 3, we explain an inverse iteration algorithm and describe its orthogonalization algorithms. In Section 4, we confirm each performance in the inverse iteration algorithms with orthogonalization algorithms on PowerXCell^{TM} 8i processor.

2. Eigenvalue decomposition

Let A be $n \times n$ matrix such that

$$A\boldsymbol{v}_j = \lambda_j \boldsymbol{v}_j \quad (j = 1, 2, ..., n) \tag{1}$$

where λ_j ($\lambda_j : \lambda_j \in \mathbb{C}$) and $\boldsymbol{v}_j$ ($\boldsymbol{v}_j : \boldsymbol{v}_j (\neq 0) \in \mathbb{C}^n$) are an eigenvalue and an eigenvector of A, respectively. If eigenvectors $\boldsymbol{v}_j$ of A are linear independent, then

$$AV = VD, \tag{2}$$

$$D = diag\left[\lambda_1 \quad \lambda_2 \quad \cdots \quad \lambda_n\right], \tag{3}$$

$$V = \left[\boldsymbol{v}_1 \quad \boldsymbol{v}_2 \quad \cdots \quad \boldsymbol{v}_n\right]. \tag{4}$$

Since V is nonsingular, the inverse matrix V^{-1} exists and $V^{-1}V$ is equal to an identity matrix I. Hence, A is decomposed as

$$A = VDV^{-1} \tag{5}$$

Eq.(5) is called eigenvalue decomposition of A.

Let A be real symmetric, then $\lambda_j \in \mathbb{R}$ and $\boldsymbol{v}_j \in \mathbb{R}$. Moreover, eigenvectors $\boldsymbol{v}_j$ are orthogonal to each other, if $\lambda_1 \neq \lambda_2 \neq \cdots \neq \lambda_n$. Note here that V becomes orthogonal matrix by the normalization $\boldsymbol{v}_j \rightarrow \boldsymbol{v}_j / \|\boldsymbol{v}_j\|$. Then A is decomposed as

$$A = VDV^{\top} \tag{6}$$

where $V^{\top}$ denotes the transposed matrix of V.

In a famous algorithm, a real symmetric matrix A is similarly transformed into a symmetric tridiagonal matrix T by using the Householder transformations. Namely,

$$Q_A^{\top} A Q_A = T, \tag{7}$$

with suitable orthogonal matrix Q_A. After the tridiagonalization, T is decomposed as

$$T = Q_T D Q_T^{\top} \tag{8}$$

by some orthogonal matrix Q_T. Consequently, by combining Eq.(7) with Eq.(8), the eigenvalue decomposition of A is given as

$$A = (Q_A Q_T) D (Q_A Q_T)^{\top}. \tag{9}$$

3. Inverse iteration algorithm

In this section, we introduce the inverse iteration algorithm. When some of all the eigenvalues are close together or there are clusters of eigenvalues, reorthogonalization must be needed to all the eigenvectors associated with such eigenvalues, since the eigenvectors needs to be orthogonal to each other. Therefore, reorthogonalization algorithms should be adopted.

In Section 3.1, we explain a concept of the inverse iteration algorithm. In Section 3.2, 3.3, and 3.4, the CGS algorithm, the MGS algorithm and the cWY are described, respectively. In Section 3.5, these orthogonalization algorithm are compared. In Section 3.6, we descrive a relationship between BLAS and the orthogonalization algorithms.

3.1 Concept

When $\tilde{\lambda_j}$ is an approximate value of λ_j and a starting vector $\boldsymbol{v}_j^{(0)}$ are given, the inverse iteration algorithm can compute an eigenvector of T. To this end, the following equation is solved iteratively:

$$\left(T - \tilde{\lambda_j} I\right) \boldsymbol{v}_j^{(k)} = \boldsymbol{v}_j^{(k-1)} \tag{10}$$

If the eigenvalues of T are mutually well-separated, the solution of $\boldsymbol{v}_j^{(k)}$ in Eq.(10) generically converges to the eigenvector associated with λ_j as k goes to ∞ The above iteration algorithm is the inverse iteration algorithm. When m eigenvectors are computed, the computational cost of this algorithm is of order mn. The computational cost is less than that of other algorithms.In the implementation, the vector $\boldsymbol{v}_j^{(k)}$ must be normalized to avoid overflow.

3.2 Classical Gram-Schmidt algorithm

The CGS algorithm has been proposed as the first reorthogonalization algorithm. In the CGS algorithm, a basis

16: Normalize $\boldsymbol{v}_j^{(k)}$ to $\boldsymbol{x}_j$.
17: **end for**

Fig. 2: Inverse iteration algorithm with the CGS algorithm. j_1 means the index j of the first eigenvalue of a cluster.

vector $\boldsymbol{x}_j$, which is an orthogonal vector in $\boldsymbol{v}_j$, is computed as follows:

$$\boldsymbol{x}'_j = \boldsymbol{v}_j - \sum_{i=1}^{j-1} \langle \boldsymbol{v}_j, \boldsymbol{x}_i \rangle \boldsymbol{x}_i, \tag{11}$$

$$\boldsymbol{x}_j = \frac{\boldsymbol{x}'_j}{\|\boldsymbol{x}'_j\|} \tag{12}$$

In Eq.(11), $\langle \boldsymbol{v}_j, \boldsymbol{x}_i \rangle \boldsymbol{x}_i$ means an orthographic projection on the direction to $\boldsymbol{x}_i$ of $\boldsymbol{v}_j$. Through $\boldsymbol{v}_j$ is subtracted the orthographic projection, $\boldsymbol{v}_j$ can be picked out of elements $\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_{j-1}$. Thus, $\boldsymbol{x}_j$ is orthogonalized.

Figure 1 shows the orthogonalization algorithm using the CGS algorithm. Since Eq.(11) and Eq.(12) are computed using an inner product, BLAS level-1 has to be adopted. Therefore, to adopt BLAS level-2, Eq.(11) and Eq.(12) should be transformed into the following vector product.

$$\boldsymbol{x}'_j = \boldsymbol{v}_j - [\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_{j-1}] \begin{bmatrix} \boldsymbol{x}_1^\top \\ \boldsymbol{x}_2^\top \\ \vdots \\ \boldsymbol{x}_{j-1}^\top \end{bmatrix} \boldsymbol{v}_j. \tag{13}$$

Figure 2 is a code, which is based on DSTEIN in LAPACK and modified the orthogonalization process from the MGS algorithm to the CGS algorithm. Specifically, line 10 in Figure 2 is changed to Eq.(13).

17: **end for**

Fig. 3: Inverse iteration algorithm with the MGS algorithm.

3.3 Modified Gram-Schmidt algorithm

If the MGS algorithm is adopted to reorthogonalize eigenvectors, the computational cost is of order $m^2 n$. Therefore, the computational cost, for which eigenvectors of a matrix T are computed, increases significantly. In general, to implement the inverse iteration algorithm on computers, the MGS algorithm with the Peters-Wilkinson method [17] is adopted as the standard orthogonalization process. The MGS algorithm with the Peters-Wilkinson method is also available on DSTEIN, which is implemented in the LAPACK code [16] of the inverse iteration algorithm for computing eigenvectors of a real symmetric tridiagonal matrix. In the Peters-Wilkinson method, when the distance between the close eigenvalues is less than $10^{-3}\|T\|$, these close eigenvalues are regarded as members of the same cluster of eigenvalues, and all of the eigenvectors associated with these eigenvalues are orthogonalized.

Figure 3 shows the inverse iteration algorithm based on the MGS algorithm with the Peters-Wilkinson method. This loop includes the iteration based on Eq.(10) and the orthogonalization of the eigenvectors. This orthogonalization process becomes a bottleneck of the inverse iteration with respect to the computational time. The MGS algorithm is mainly based on BLAS level-1 such as the inner product operation and the AXPY operation [1].

3.4 Householder orthogonalization algorithm

The Householder orthogonalization algorithm is one of the alternative orthogonalization algorithms. When some vectors $\boldsymbol{v}_j$, $\boldsymbol{w}_j \in \mathbb{R}^n$ satisfy $\|\boldsymbol{v}_j\|_2 = \|\boldsymbol{w}_j\|_2$, there exists the symmetric matrix H_j satisfying $H_j H_j^\top = H_j^\top H_j = I$, $H_j \boldsymbol{v}_j = \boldsymbol{w}_j$ defined by

$$H_j = I - s_j \boldsymbol{y}_j \boldsymbol{y}_j^\top, \tag{14}$$

where $\boldsymbol{y}_j = \boldsymbol{v}_j - \boldsymbol{w}_j$ and $s_j = 2/\|\boldsymbol{y}_j\|_2^2$. The transformation by H_j is called the Householder transformation. Figure 4 shows the Householder orthogonalization algorithm. The

1: **for** $j = 1$ to m **do**
2: Generate $\boldsymbol{v}_j$ in an algorithm.
3: $\boldsymbol{v}'_j = \left(I - s_{j-1}\boldsymbol{y}_{j-1}\boldsymbol{y}_{j-1}^\top\right)\cdots\left(I - s_2\boldsymbol{y}_2\boldsymbol{y}_2^\top\right)\left(I - s_1\boldsymbol{y}_1\boldsymbol{y}_1^\top\right)\boldsymbol{v}_j$.
4: Compute $\boldsymbol{y}_j$ and s_j by using $\boldsymbol{v}'_j$.
5: $\boldsymbol{x}_j = \left(I - s_1\boldsymbol{y}_1\boldsymbol{y}_1^\top\right)\left(I - s_2\boldsymbol{y}_2\boldsymbol{y}_2^\top\right)\cdots\left(I - s_j\boldsymbol{y}_j\boldsymbol{y}_j^\top\right)\boldsymbol{e}_j$.
6: **end for**

Fig. 4: Householder orthogonalization algorithm.

vector $\boldsymbol{y}_j$ is the vector, in which the elements from 1 to $j-1$ are the same as the elements of $\boldsymbol{v}'_j$ and the elements from $j+1$ to n are zero. $\boldsymbol{v}'_j$ and $\boldsymbol{w}_j$ are defined as follows:

$$\begin{aligned}\boldsymbol{v}'_j &= \begin{bmatrix} v'_{j\{1\}} & \cdots & v'_{j\{j-1\}} & v'_{j\{j\}} & \cdots & v'_{j\{n\}}\end{bmatrix}^\top \\ &= H_{j-1}H_{j-2}\cdots H_2H_1\boldsymbol{v}_j, \qquad (15)\\ \boldsymbol{w}_j &= \begin{bmatrix} v'_{j\{1\}} & \cdots & v'_{j\{j-1\}} & c_j & \boldsymbol{0}\end{bmatrix}^\top, \qquad (16)\end{aligned}$$

where,

$$c_j = -sgn\left(v'_{j\{j\}}\right)\sqrt{\sum_{i=j}^{n} {v'_{j\{i\}}}^2}. \qquad (17)$$

H_j, y_j and s_j are computed using $\boldsymbol{v}_j$ as follows:

$$\begin{aligned}H_j &= I - s_j\boldsymbol{y}_j\boldsymbol{y}_j^\top \qquad (18)\\ \boldsymbol{y}_j &= \boldsymbol{v}'_j - \boldsymbol{w}_j \qquad (19)\\ \|\boldsymbol{y}_j\|_2^2 &= (v'_{j\{j\}} - c_j)^2 + \sum_{i=j+1}^{n} {v'_{j\{i\}}}^2 \qquad (20)\\ &= \sum_{i=j}^{n} {v'_{j\{i\}}}^2 - 2v'_{j\{j\}}c_j + c_j^2 \qquad (21)\\ &= 2\left(c_j^2 - v'_{j\{j\}}c_j\right). \qquad (22)\\ s_j &= \frac{2}{\|\boldsymbol{y}_j\|_2^2} = \frac{1}{c_j^2 - v'_{j\{j\}}c_j}. \qquad (23)\end{aligned}$$

The vector $\boldsymbol{e}_j$ in Figure 4 is the j-th vector of an n-dimensional identity matrix.

The orthogonality of the vectors $\boldsymbol{x}_j$ generated by the Householder orthogonalization algorithm does not depend on the condition number of a matrix T. Therefore, the Householder orthogonalization algorithm is more stable than the MGS algorithm. On the other hand, being similar to the MGS algorithm, it is sequential algorithm that is mainly based on BLAS level-1. Its computational cost is higher than that of the MGS algorithm. Thus the Householder orthogonalization algorithm is an ineffective algorithm in parallel computing.

By combination with the compact WY representation [18], the Householder orthogonalization algorithm becomes capable of computation with BLAS level-2 [20]. Hence, in this paper, the cWY is adopted to an inverse iteration. Let $Y_1 = \boldsymbol{y}_1 \in \mathbb{R}^{n\times j}$ and $S_1 = s_1 \in \mathbb{R}^{1\times 1}$. Matrices Y_j

1: **for** $j = 1$ to m **do**
2: Generate $\boldsymbol{v}_j$ in an algorithm
3: $\boldsymbol{v}'_j = \left(I - Y_{j-1}S_{j-1}^\top Y_{j-1}^\top\right)\boldsymbol{v}_j$.
4: Compute $\boldsymbol{y}_j$ and s_j by using $\boldsymbol{v}'_j$.
5: Eq.(24) and Eq.(25) : Update Y_j and S_j by using s_j, $\boldsymbol{y}_j$, S_{j-1} and Y_{j-1}.
6: $\boldsymbol{q}_j = \left(I - Y_jS_jY_j^\top\right)\boldsymbol{e}_j$.

10: **if** $j_c = 1$ and $k = 1$, **then**
11: Compute $Y_1 = \boldsymbol{y}_1$ and $S_1 = s_1$ by using $\boldsymbol{v}_{j_1}$.
12: **end if**
13: $\boldsymbol{v}'_{j_c+1} = \left(I - Y_{j_c}S_{j_c}^\top Y_{j_c}^\top\right)\boldsymbol{v}_j^{(k)}$.
14: Compute $\boldsymbol{y}_{j_c+1}$ and s_{j_c+1} by using $\boldsymbol{v}'_{j_c+1}$.
15: Eq.(24) and Eq.(25) : Update Y_{j_c+1} and S_{j_c+1} by using s_{j_c+1}, $\boldsymbol{y}_{j_c+1}$, S_{j_c} and Y_{j_c}.
16: $\boldsymbol{v}_j^{(k)} \leftarrow \left(I - Y_{j_c+1}S_{j_c+1}Y_{\mathrm{j_c}+1}^\top\right)\boldsymbol{e}_{\mathrm{j_c}+1}$.
17: **else**
18: $j_1 \leftarrow j$.
19: **end if**
20: **until** some condition is met.
21: Normalize $\boldsymbol{v}_j^{(k)}$ to $\boldsymbol{v}_j$.
22: **end for**

Fig. 6: Inverse iteration algorithm with the cWY algorithm.

and upper triangular matrices S_j is defined recursively as follows:

$$\begin{aligned}Y_j &= \begin{bmatrix} Y_{j-1} & \boldsymbol{y}_j\end{bmatrix}, \qquad (24)\\ S_j &= \begin{bmatrix} S_{j-1} & -s_jS_{j-1}Y_{j-1}^\top\boldsymbol{y}_j \\ \boldsymbol{0} & s_j\end{bmatrix}. \qquad (25)\end{aligned}$$

In this case, the following equation holds

$$H_1H_2\cdots H_j = I - Y_jS_jY_j^\top. \qquad (26)$$

As shown by Eq.(26), the product of the Householder matrices $H_1H_2\cdots H_j$ can be rewriten in a simple block matrix form. Here $I - Y_jS_jY_j^\top$ is called the compact WY representation of the product of the Householder matrices. Figure 5 shows the orthogonalization algorithm.

Figure 6 is a code, which is based on DSTEIN in LAPACK and changed the orthogonalization process from the MGS algorithm to the cWY algorithm. In other words, the MGS algorithm (from line 4 to 15 in Figure 3) is rewriten the cWY algorithm.In Figure 6, the index j_c denotes the j_c-th eigenvalue of the cluster in computing the j_c-th eigenvector. This index j_c needs to compute and update S_j and Y_j.

Table 1: Comparison of the orthogonalization algorithms [5] [20].

algorithms	*Computation*	*Synchronization*	*Orthogonality*
CGS	almost $2m^2n$	$O(m)$	$O(\epsilon\kappa(A)^2)$
MGS	almost $2m^2n$	$O(m^2)$	$O(\epsilon\kappa(A))$
House	almost $4m^2n$	$O(m^2)$	$O(\epsilon)$
cWY	almost $4m^2n$	$O(m)$	$O(\epsilon)$

Therefore, a variable j_c should be confirmed on line 9 in Figure 6.

The cWY algorithm has a stable orthogonality arising from the Householder transformations, and its mathematical calculation is mainly performed by BLAS level-2 such as the product of a matrix and a vector and a rank-1 update operation.

3.5 Comparison of the orthogonalization algorithms

The cWY algorithm has a stable orthogonality arising from the Householder transformations, and its mathematical calculation is mainly performed by BLAS level-2 such as the product of a matrix and a vector and a rank-1 update operation. As a result, this orthogonalization has more stable and sophisticated orthogonality, and it is more effective for parallel computing than the MGS algorithm. Table 1 displays the differences in performance of the four orthogonalization methods, considered in the above sections. In this table, "House" denotes the Householder orthogonalization algorithm. *Computation* denotes the order of the computational cost. *Synchronization* denotes the order of the number of synchronizations. *Orthogonality* denotes the norm $\|V^\top V - I\|$, where $V = [\boldsymbol{v}_1, \cdots, \boldsymbol{v}_n]$. ϵ denotes the machine epsilon and κ denotes the condition number of a matrix. These are the results obtained from [5] and [20].

On the other hand, the computational cost in the CGS algorithm is twice less than that in the cWY algorithm. Therefore, when high orthogonality is not needed, the CGS algorithm is also the suitable selection for the orthogonalization.

3.6 Adoption of BLAS

The line from 1 to 7 on each algorithm is the code in the inverse iteration algorithm without an orthogonalization algorithm. This computational cost mn is relatively smaller than that in the inverse iteration algorithm with an orthogonalization algorithm shown in Table 1. Therefore, we adopt SPEs to orthogonalization algorithms.

In the CGS algorithm, the line 10 on Figure 2 can be computed using BLAS level-2. In the MGS algorithm, BLAS level-1 is adopted in the line 10 on Figure 3. In the cWY algorithm, the line 13 and 16 on Figure 6 can be performed with BLAS level-2, and the line 11 and 14 can be performed with BLAS level-1.

4. Experiments

In this section, we describe some numerical experiments performed using the CGS algorithm, the MGS algorithm, and the cWY algorithm on PowerXCell^{TM} 8i processor.

In the experiments, we use GigaAccel 180, which is a PCI Express board with PowerXCell^{TM} 8i processor. PowerXCell^{TM} 8i processor is one of Cell Broadband Engine^{TM}. The theoretical performances of a single and double precision floating-point arithmetic operation on an SPE in PowerXCell^{TM} 8i processor are 180GFLOPS and 90GFLOPS in 2.8GHz, respectively. We implement those algorithms by using Cell SDK 3.1 [2], which is developed by the IBM corporate [14]. Cell SDK 3.1 includes the parallelized BLAS for Cell Broadband Engine^{TM}. The MGS algorithm is implemented in Cell SDK 3.1.

As experimental matrices, we use three types. Type 1 is a random matrix, of which elements are set to the random number on the interval from 0 to 1. Type 2 is shown as follows:

$$\begin{bmatrix} 1 & 1 & & & \\ 1 & 1 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & 1 & 1 \\ & & & 1 & 1 \end{bmatrix}. \tag{27}$$

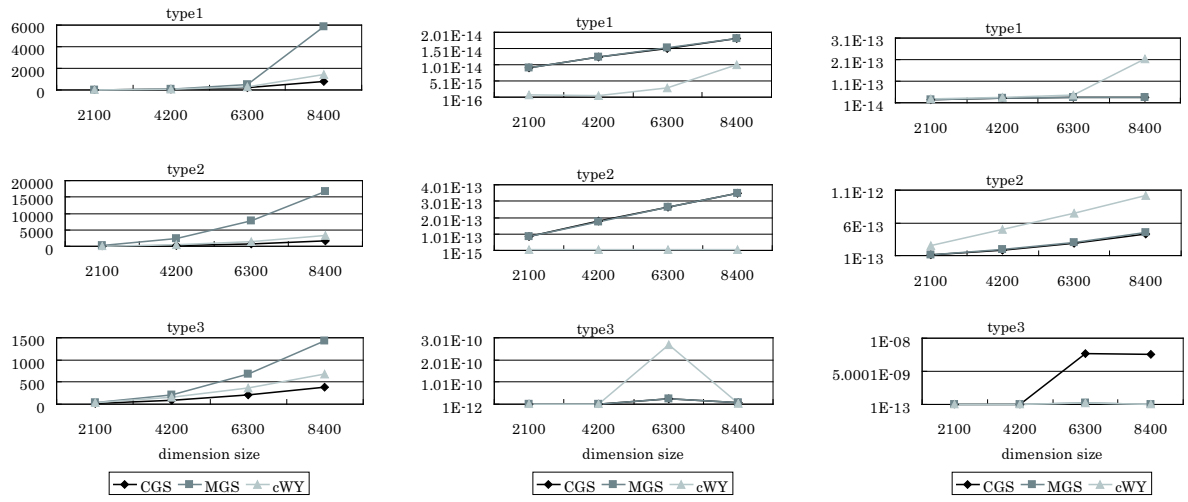
Type 3 is the glued-Wilkinson matrix $W_g^\dagger$, which is real symmetric and has dimensions on the order of thousands. The glued-Wilkinson matrix has been used to evaluate the performance of the inverse iteration algorithms as the benchmark problems of eigenvalue decomposition [6], [8]. $W_g^\dagger$ consists of the block matrix $W_{21}^\dagger \in \mathbb{R}^{21\times 21}$ and the scalar parameter $\delta \in \mathbb{R}^{1\times 1}$ and is defined as follow:

$$W_g^\dagger = \left[\begin{array}{c|c|cc|c} W_{21}^\dagger & \delta & & & \\ \hline \delta & W_{21}^\dagger & \delta & & \\ \hline & \delta & \ddots & \ddots & \\ & & \ddots & \ddots & \delta \\ \hline & & & \delta & W_{21}^\dagger \end{array}\right], \tag{28}$$

where $W_{21}^\dagger$ is defined by

$$W_{21}^\dagger = \begin{bmatrix} 10 & 1 & & & & \\ 1 & 9 & 1 & & & \\ & 1 & \ddots & \ddots & & \\ & & \ddots & 0 & \ddots & \\ & & & \ddots & \ddots & 1 \\ & & & & 1 & 10 \end{bmatrix}, \tag{29}$$

and δ satisfies $0 < \delta < 1$ and is also the semi-diagonal element of $W_g^\dagger$. Since $W_g^\dagger$ is real symmetric tridiagonal and its semi-diagonal elements are nonzero, all the eigenvalues of



(a) Computational time [sec.] (b) $\|AV - VD\|_F$ (c) $\|V^\top V - I\|_F$

Fig. 7: Relationship between dimension size and performance in the orthogonalization algorithms.

$W_g^\dagger$ are distinct and real, and they are divided into 21 clusters of close eigenvalues. When δ is small, the distance between the minimum and maximum eigenvalues in any cluster is small. In our experiments, we set $\delta = 10^{-4}$.

Figure 7 and Table 2 show the experimental results of the orthogonalization algorithms. Time in Table 2 is the computational time. $\|AV - VD\|_F$ and $\|V^\top V - I\|_F$ mean the frobenius norm of synchronization and orthogonalization, respectively.

In type 1, each eigenvalue is usually separated. On the other hand, eigenvalues in type 2 and 3 become cluster. Therefore, $\|AV - VD\|_F$ and $\|V^\top V - I\|_F$ are smaller than that in type 2 and 3.

In 2100 dimension size of type 1 in Table 2, the computational time in the MGS algorithm, which is implemented by the IBM corporate, is smaller than that in the other orthogonalization algorithms. However, the increasing rate of the computational time in the MGS algorithm is higher as shown in Figure 7(a). The MGS algorithm is computed using BLAS level-1. On the other hand, the CGS algorithm and the cWY algorithm are almost computed using BLAS level-2. Therefore, in the computational time, the CGS algorithm and the cWY algorithm are better.

In Figure 7(b) and Table 2, $\|AV - VD\|_F$ in the CGS algorithm is nearly equal to that in the MGS algorithm. $\|AV - VD\|_F$ of the cWY algorithm is the smallest, except the case of 6300 dimension size in type 3. The exception is likely to be caused by the order of $\boldsymbol{v}_j$. In the experiments, $\boldsymbol{v}_j$ is listed in descending order of eigenvalues, which are related to eigenvectors. Therefore, by using the cWY algorithm with suitable order of $\boldsymbol{v}_j$, accuracy of eigenvector computation can become more properly.

In type 1 and 2 of Figure 7(c), $\|V^\top V - I\|_F$ in the CGS algorithm is nearly equal to that in the MGS algorithm. The CGS algorithm and the MGS algorithm are focused on the orthogonality of eigenvectors. On the other hand, in the cWY algorithm, accuracy of eigenvalue decomposition is given importance. Therefore, the orthogonality of eigenvectors is something lower than that in the CGS algorithm and the MGS algorithm.

In type 3 of Figure 7(c), $\|V^\top V - I\|_F$ in the CGS algorithm is worse than that in the other orthogonalization algorithm. In $\delta = 10^{-4}$, eigenvalues in type 3 are extremely close together. Therefore, the CGS algorithm is aborted that $\boldsymbol{v}_j$ is picked out.

In summarization, the computational time in the cWY algorithm is adequate speedy. Furthermore, $\|AV - VD\|_F$ and $\|V^\top V - I\|_F$ in the cWY algorithm is sufficient accuracy. Hence, the cWY algorithm is suitable, except case that the high-orthogonality of eigenvectors is given importance.

5. Conclusions

In this paper, we validated the parallel performance of the inverse iteration algorithms with the CGS algorithm, the MGS algorithm, and the cWY algorithm on PowerXCell^{TM} 8i processor. PowerXCell^{TM} 8i processor is one of heterogeneous environments. In ExaFLOP computing, since it is critical issue to minimize electricity, heterogeneous environments are suitable. SPEs in PowerXCell^{TM} 8i processor archive the high performance of BLAS level-2 and level-3. The inverse iteration algorithms are algorithms for computing eigenvectors and need a lot of computational cost. Therefore, the algorithms should be computed with SPEs. The experimental results show that the computational time

of the CGS algorithm and the cWY algorithm are shorter and $\|AV - VD\|_F$ and $\|V^\top V - I\|_F$ of the cWY algorithm are sufficiently small.

In a future work, the inverse iteration algorithms should be compared on General-purpose computing on graphics processing units (GPGPU).

Abstract— *Unified Modeling Language (UML) has already been used in the analysis, design, and implementation of many systems. Open Source Software (OSS) is often used in software development. However, it is often the case that OSS does not contain adequate documents, so the generation of software documents is important. Documents with diagrams are especially important to understand software, so it is important to generate documents with diagrams. In order to process large-scale diagrams, or many source codes automatically, formal and declarative representation is needed. In this paper, we propose automatic generation of documentation based on an attribute graph grammar.*

Keywords: UML, graph grammar, open source software, software document

1. Introduction

In the software development environment, it is desirable to have features that support programming. Many effective tools have been developed to provide a framework for developing reliable programs. In software development, software documents are very important to develop or modify systems. Graphical representations such as flowchart or Unified Modeling Language (UML) are often used in software design and development because of their expressiveness.

UML for modeling in software development has been proposed recently. In 2005, ISO/TEC 19501 became the standard. UML has already been used in the analysis, design, and implementation of many systems. It makes use of various types of diagrams, such as class and sequence diagrams, for designing processes in system development, from upstream to downstream processes. In order to automate the processing of these graphical representations using computers, a syntax for program diagrams must first be defined. Then, in order to analyze the syntax of two-dimensional objects such as program diagrams, the relationships between each of the elements must also be described. Graph grammars are one possible effective means for implementing these methods. Graph grammars provide a formal method that enables rigorous definition of mechanisms for generating and analyzing graphs. The authors of the current paper have proposed a graph grammar for package diagrams of UML [1].

Open Source Software (OSS) is often used in software development. However, it is often the case that OSS does not contain adequate documents. Software documents are needed in order to use or modify OSS, however, there are so many examples of source code with no documents, therefore, we need to generate documents from source code. Moreover, documents with diagrams are especially important to understand software, so it is important to generate documents with diagrams. This is why we started our research so that we can obtain documents with diagrams automatically.

Thus far, much research has targeted UML or software documents. Research has also been done on UML [2] and graph grammars and graph transformations with respect to UML [3], [4], [5]. However, no research focuses on syntax formalization for visual representation. As for software document generation, some research has been done [6], [7], [8]. This research targets documentation generation through program source code or diagrams. The formal method is not treated in this framework.

In order to process large-scale diagrams, or large amounts of source code automatically, formal and declarative representation is needed. In this paper, we propose automatic generation of documentation based on an attribute graph grammar.

2. Preliminary

2.1 Graph Grammars

Definition 1. ([9],[10]) Let Σ be an alphabet of node labels and Γ be an alphabet of edge labels. A *graph* over Σ and Γ is a tuple $H = (V, E, \lambda)$, where V is the finite set of nodes, $E \subseteq \{(v, \gamma, w) \mid v, w \in V, v \neq w, \gamma \in \Gamma\}$ is the set of edges, and $\lambda : V \to \Sigma$ is the node labeling function. $E(v, w) \stackrel{\text{def}}{=} \{\gamma \in \Gamma \mid (v, \gamma, w) \in E\}$. The *label tuple* of two nodes $v, w \in V$ is $lab(v, w) \stackrel{\text{def}}{=} (\lambda(v), E(v, w), E(w, v), \lambda(w))$. □

Definition 2. ([9]) A *graph with* (neighborhood controlled) *embedding* over Σ and Γ is a pair (H, C) with $H \in GR_{\Sigma,\Gamma}$ and $C \subseteq \Sigma \times \Gamma \times \Gamma \times V_H \times$ {in, out}. C is the *connection relation* of (H, C), and each element $(\sigma, \beta, \gamma, x, d)$ of C (with $\sigma \in \Sigma, \beta, \gamma \in \Gamma, x \in V_H$, and $d \in$ {in, out}) is a *connection instruction* of (H, C). A connection instruction

$(\sigma, \beta, \gamma, x, d)$ will always be written as $(\sigma, \beta/\gamma, x, d)$. Two graphs with embedding (H, C_H) and (K, C_K) are isomorphic if there is an isomorphism f from H to K such that $C_K = \{(\sigma, \beta/\gamma, f(x), d) \mid (\sigma, \beta/\gamma, x, d) \in C_H\}$. The set of all graphs with embedding over Σ and Γ is denoted as $GRE_{\Sigma,\Gamma}$. □

Figure 1 shows an example of a graph. In Figure 1 $H = (V_H, E_H, \lambda_H)$ is a graph with $V_H = \{n_1, n_2\}$, $E_H = \{(n_1, \alpha, n_2)\}$, $\lambda_H(n_1) = a$ and $\lambda_H(n_2) = X$. Here, n_1 and n_2 indicate node ID. Furthermore a, and X indicate node labels, nodes with a lowercase node label and with a uppercase node label are terminal node and nonterminal node, respectively,

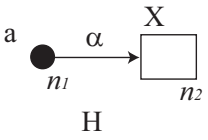

Fig. 1: An example of a graph

Definition 3. ([9]) An *edNCE graph grammar* is a six-tuple $GG = (\Sigma, \Delta, \Gamma, \Omega, P, S)$, where Σ is the alphabet of node labels, $\Delta \subseteq \Sigma$ is the alphabet of terminal node labels, Γ is the alphabet of edge labels, $\Omega \subseteq \Gamma$ is the alphabet of final edge labels, P is the finite set of *productions*, and $S \in \Sigma - \Delta$ is the *initial nonterminal*. A production is of the form $X \to (D, C)$ where X is a nonterminal node label, D is a graph over Σ and Γ, and $C \subseteq \Sigma \times \Gamma \times \Gamma \times V_D \times \{in, out\}$ is the connection relation, which is a set of connection instructions. A pair (D, C) is a graph with embedding over Σ and Γ. □

Definition 4. (cf. [9], [10]) Let $G = (\Sigma, \Delta, \Gamma, \Omega, P, S)$ be an edNCE graph grammar. Let $H_{i-1} = (V_{H_{i-1}}, E_{H_{i-1}}, \lambda_{H_{i-1}})$ and $H_i = (V_{H_i}, E_{H_i}, \lambda_{H_i})$ be graphs in $GRE_{\Sigma,\Gamma}$. In addition, let $v_i \in V_{H_{i-1}}$, and $p'_i : X \to (D'_i, C'_i) \in P$ be a production copy of G such that D'_i and H_{i-1} are disjoint. $s_i = (p'_i, v_i, D'_i, b'_i)$ is a *derivation specification* of G if $p'_i \in copy(P)$, $\lambda_{H_{i-1}(v_i)} = X$, $D'_i \cong D$, $b'_i : V_{D'_i} \to V_{D_i}$.

We write $H_{i-1} \to_{v_i, p'_i} H_i$, or just $H_{i-1} \underset{s_i}{\to} H_i$, if $\lambda_{H_{i-1}}(v_i) = X$ and $H_i = H_{i-1}[v_i/(D'_i, C'_i)]$. $H_{i-1} \underset{s_i}{\to} H_i$ is called a *derivation step*, and a sequence of such derivation steps is called a *derivation*. □

An example of a production is shown in Figure 2. In the figure, a box is a nonterminal node and a filled circle is a terminal node. X, Y, and b are node labels and v_0, v_1, and v_2 are node IDs. Nodes with the same node label can appear in a graph, while nodes with same node ID will never appear in a graph. The production of Figure 2 indicates that after the removal of a nonterminal node with label X, embed the graph consisting of terminal node with label b and the nonterminal node with label Y. Each production has connection instructions. The connection instruction of this production is $(a, \alpha/\beta, v_1, in)$, but this connection instruction is not described in the notation of Figure 2.

In Figure 3, the production of Figure 2 and its connection instruction are drawn simultaneously. The large box in Figure 3 indicates the left-hand side, and two nodes with label b and Y are on the right side of the production of Figure 2. Node labels and edge labels that are described outside of the large box indicate connection instruction such that $(a, \alpha/\beta, v_1, in)$.

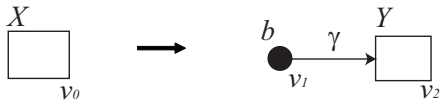

Fig. 2: An example of a production

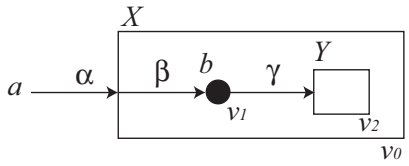

Fig. 3: An example of a production with the connection relation

An example of application of the production is shown in Figure 4. In Figure 4, $H = (V_H, E_H, \lambda_H)$ is a graph with $V_H = \{n_1, n_2\}$, $E_H = \{(n_1, \alpha, n_2)\}$, $\lambda_H(n_1) = a$, and $\lambda_H(n_2) = X$. The production copy p' of p is as follows: $p' : X \to (D', C')$ where $X = \lambda_H(n_2)$, $D' = (V_{D'}, E_{D'}, \lambda_{D'})$ such that $V_{D'} = \{n_3, n_4\}$, $E_{D'} = \{(n_3, \gamma, n_4)\}$, $\lambda_{D'}(n_3) = b$, $\lambda_{D'}(n_4) = Y$, and $C' = \{(a, \alpha/\beta, n_3, in)\}$.

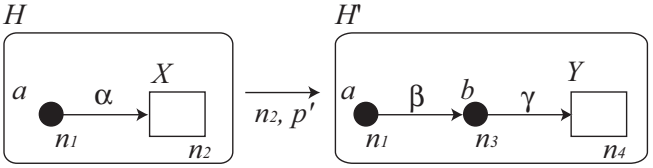

Fig. 4: An example of applying a production rule

We say that H is the *host graph* and H' is the *resulting graph*, X is the *mother node* in Figure 4, the graph consisting of terminal node with label b and the nonterminal node with label Y in Figure 2 is the *daughter graph*. At first, we remove the node X and edges that connect with node X from host graph H. Next, we embed the daughter graph, including node b and node Y. Then we establish edges between the nodes of daughter graph and the nodes that were connected to the node X using the connection instructions on the production p'. Therefore, the edge label α is rewritten to β by the production p'.

Definition 5. ([11], [12]) An *Attribute edNCE Graph Grammar* is a three-tuple $AGG = \langle GG, Att, F \rangle$, where

1. $GG = (\Sigma, \Delta, \Gamma, \Omega, P, S)$ is called an *underlying graph grammar* of AGG. Each production p in P is denoted by $X \rightarrow (D, C)$.

2. Each node symbol $Y \in \Sigma$ of GG has two disjoint finite sets $Inh(Y)$ and $Syn(Y)$ of *inherited* and *synthesized attributes*, respectively. The set of all attributes of symbol X is defined as $Att(X) = Inh(X) \cup Syn(X)$. $Att = \bigcup_{X \in \Sigma} Att(X)$ is called the *set of attributes* of AGG. We assume that $Inh(S) = \emptyset$. An attribute a of X is denoted by $a(X)$, and the set of possible values of a is denoted by $V(a)$.

3. Associated with each production $p = X_0 \rightarrow (D, C) \in P$ is a set F_p of *semantic rules*, which define all the attributes in $Syn(X_0) \bigcup_{X \in Lab(D)} Inh(X)$. A semantic rule defining an attribute $a_0(X_{i_0})$ has the form $a_0(X_{i_0}) := f(a_1(X_{i_1}), \cdots, a_m(X_{i_m}))$. Here f is a mapping from $V(a_1(X_{i_1})) \times \cdots \times V(a_m(X_{i_m}))$ into $V(a_0(X_{i_0}))$. In this situation, we say that $a_0(X_{i_0})$ depends on $a_j(X_{i_j})$ for j, $0 \leq j \leq m$ in p. The set $F = \bigcup_{p \in P} F_p$ is called the *set of semantic rules* of G. □

Attribute values are calculated by evaluating attributes according to semantic rules on the derivation tree.

2.2 UML

Unified Modeling Language (UML) is a notation for modeling object-oriented system development using diagrams. UML can be divided into structural diagrams and behavioral diagrams. Structural diagrams are used to describe the structure of what is being modeled and include class, object, and package diagrams. Behavioral diagrams are used to describe the behavior of what is being modeled and include use-case, activity, and state-machine diagrams.

Structural diagrams include class diagrams, which describe the static relationships between classes, and package diagrams, which group classes and describe relationships between packages and package nesting relationships.

Figure 5 shows an example of a package diagram. The box with a rectangle at the upper left indicates a package. The box with three compartments is a class. Each of the three parts indicates its class name, its attribute, and its methods from top to the bottom. A plus with a circle is used to represent which components the package contains. Package 1 contains Package 2 and Package 4, and Package 4 contains Class 1 and Class 2.

3. Graph Grammar for UML Package Diagrams

In this section, we describe our Graph Grammar for Package Diagrams (GGPD), for UML package diagrams.

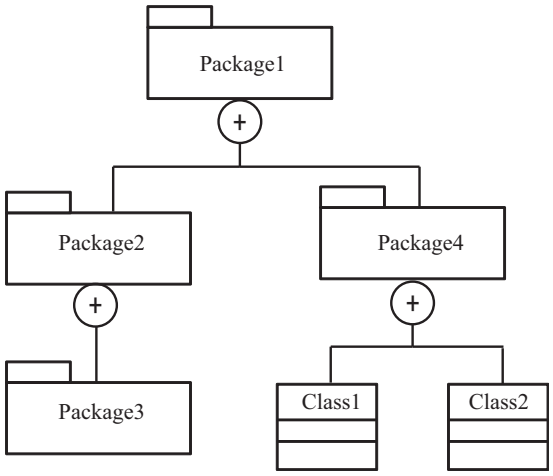

Fig. 5: An example of a package diagram

3.1 Grammar Overview

Definition 6. The Graph Grammar for Package Diagrams (GGPD), for UML package diagrams, is a six-tuple $GGPD$ = (Σ_{PD}, Δ_{PD}, Γ_{PD}, Ω_{PD}, P_{PD}, S_{PD}). Here, Σ_{PD} = { S, A, T, L, R, M, rop, sp, lep, rip, mip, lec, mic, ric } is a finite set of node labels, Δ_{PD} = { rop, sp, lep, rip, mip, lec, mic, ric } is a finite set of terminal node labels, Γ_{PD} = { $*$ }, Ω_{PD} = { $*$ }, P_{PD} = { $P_1, ..., P_{17}$ } is a finite set of production rules, and S_{PD} = { S } is the initial non-terminal. □

The GGPD generates package hierarchy diagrams. Terminal nodes generated by GGPD have the following node labels: rop (root of package), sp (single package), lep (left side package), rip (right side package), mip (package located between lep and rip), lec (left side class), ric (right side class), and mic (class located between lec and ric).

GGPD is a context-free grammar and there are 17 production rules. An example of GGPD production rule is shown in Figure 6.

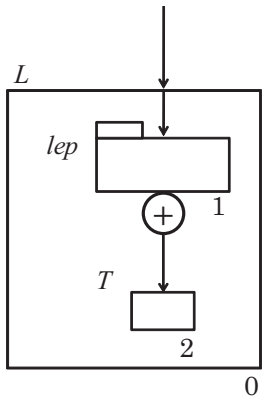

Fig. 6: An Example of a production rule of GGPD

In the figure, the production rule can be applied to a node labeled L, which is a non-terminal node, to generate a terminal node with the label lep, representing a package, and a non-terminal node labeled T.

A node with a capitalized label indicates a nonterminal node, and a node with an uncapitalized label indicates a terminal node. Our grammar generates directed graphs. However, we drew the graphs without arrows as we assumed the direction of each edge was from the top down.

We omit descriptions of all of the production rules because of space limitations.

3.2 Example of Derivation

Figure 7 shows an example of a GGPD derivation. In this example, G_0 is a graph with the node labeled S. The node ID is 1 (lower right of the node).

Then the production rule P_1 is applied to a non-terminal node labeled S with node ID 1, which is the initial non-terminal node. That is, remove a mother node with label S and node ID 1, then embed a daughter graph in the P_1. In this case, the daughter graph is the node with label A. This produces the non-terminal node labeled A with node ID 2, to which the P_3 production rule is applied. That is, graph G_1, which consists of node with node ID 2, is obtained.

After application of the production P_3, the terminal node labeled rop and a non-terminal node labeled T are generated. We apply productions to obtain a graph that corresponds to UML package diagrams. In this case, we can obtain graph G_9.

We can obtain a derivation tree from a derivation sequence of production. Figure 8 shows the derivation tree corresponding to Figure 7. In Figure 8, the labels show the names of the production rules.

4. Document Generation

In this section, we explain some attributes and semantic rules for document generation. In this paper, we target a documentation that has diagrams and explanations that correspond to diagrams. We generate documents by attribute evaluation that can be executed automatically on derivation trees.

We can obtain derivation trees after generating diagrams based on our grammar. Figure 8 shows an example of a derivation tree. In the Figure, for example, Production 3 (P3) is applied to a node that was generated by Production 1 (P1). Derivation trees describe a process of applying productions.

Every node generated by productions of GGPD has some attributes. An attribute has two types of values called inherited attributes and synthesized attributes. Attribute values are obtained by calculating semantic rules on derivation trees. Values of inherited attributes are calculated by top-down on derivation trees, and bottom-up calculation generates values of synthesized attributes.

Figure 9 shows an example of production rules and their corresponding semantic rules. The upper part of Figure 9 indicates a production rule and the lower part shows semantic rules. This production rule rewrites a nonterminal node with node label R to a graph consisting of terminal node rip and nonterminal node T.

In the semantic rules part, we then find three semantic rules that process the values of local and global attributes. The global attribute preserves the entire explanation of the diagrams. The local attribute retains local information such as parent and child relations. These attributes are categorized as synthesized attributes.

In Figure 9, local(1) stores node name of the node with ID 1 (in this case, package diagram's name); the value of local(1) is assigned to local(0).

Figure 10 shows an example of a derivation tree with document generation semantic rules corresponding to Figure 7.

In order to obtain documentation, attribute evaluation is processed following a bottom up order $P_4 \rightarrow P_9 \rightarrow P_{10} \rightarrow P_{14} \rightarrow P_6 \rightarrow P_{13} \rightarrow P_6 \rightarrow P_3 \rightarrow P_1$.

First, P_4 located at the lower left on the derivation tree is processed. In this case, we assume that the package name is "package 9," which is substituted for the local attribute of the node with ID 9. Local(9) is substituted for local(8). Null is substituted for global(9)

Next, P_9 is processed. Here, package name is substituted for local(7), and local(5) has the value of local(7). The global(5) stores a partial explanation of diagrams. In this case, global(5) holds information that node with ID 7 in Figure 7 has packages. The global(5) has the following sentence: "package 7 has package 9".

Global value is similarly obtained from the above procedure. The global(1) explains the entire diagram; in this example, global(1) is explained in Figure 11.

Since semantic rules are declarative defined, we can obtain an explanation corresponding to diagrams if once we define the semantic rules.

5. Conclusion

In this paper, we have defined attributes and semantic rules for a graph grammar for UML package diagrams. We can generate documents corresponding to diagrams automatically according to a declarative definition.

A future issue for study is the synchronization between diagram and documentation and the implementation of systems that can generate documents with animation. We would also like to construct a graph grammar for other diagrams in UML.

Koganei, Tokyo, Japan

Abstract - *In the production of electronic circuit boards in industry, electronic components are placed onto the circuit board by component placement machines. The actions of multifunction placement machines are roughly divided into pick-up phase and placing phase. In the past, these two phases were typically optimized independently of each other to be combined, which do not necessarily lead to the overall optimization. Therefore, in this paper, the action of multifunction component placement machines is modeled in a different way than that in the conventional approach, and a method for comprehensive optimization of pick-up phase and placing phase is proposed. The proposed method, which takes into account nozzle allocation, can also be applied to the load balancing of component placement machine production lines.*

Keywords: component placement machine, line-balancing

1 Introduction

Electronic circuit boards are produced through several processes (printing, placing, heat treatment, etc.), among which the process of placing the components onto the circuit boards is the most significant and often becomes the bottleneck. In this process, components are automatically placed onto the circuit boards by machines called component placement machines. Since the circuit board production efficiency is dependent on the performance of the component placement machines, a variety of research has been published on motion optimization and operation of each of the several types of component placement machines already developed. However, a relatively new type of component placement machines called *multifunction component placement machines* have a large degree of freedom of motion, and only a few researches are reported on optimization algorithms for this type of machines. In the present paper we consider multifunction component placement machines and call hereafter "component placement machines" in abbreviation.

1.1 Component placement machines

At circuit board production sites in industry, production is usually carried out through production lines composed of multiple component placement machines connected in series. More specifically, it is determined in advance which components will be assigned to each component placement machine (machine allocation). When the placing of components allocated to one component placement machine is complete, the circuit board is carried to the next component placement machine by a conveyor. To place all of the components on a circuit board, it is necessary for the circuit board to pass through all component placement machines in the line.

A simplified schematic of a component placement machine is shown in Figure 1. The component placement machine has a *head* which has multiple *nozzles* for picking up and placing components.

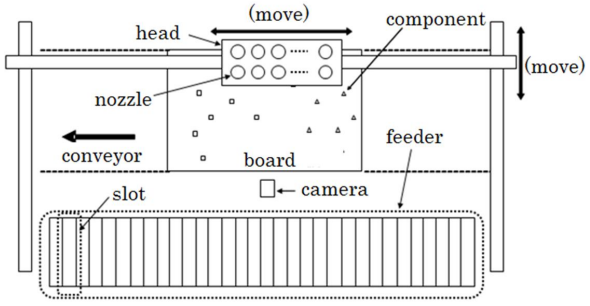

Figure1 Component placement machine

The component placement machine places components on a circuit board by repeating the following actions:

(1) The head moves to a position above the component feeder and the nozzles pick up the required components from the appropriate feed slots;
(2) The head moves to the camera which checks whether the components have been picked up correctly;
(3) When it has been confirmed that the components have been picked up correctly, the head moves above the circuit board and travels around the board, placing the components in their respective places;
(4) When all of the picked-up components have been placed, the head returns to the initial position above the component feeder.

The abovementioned sequence of actions is called a *turn*. Generally, multiple turns are carried out before all components allocated to one component placement machine have been placed.

The time required for placing components in a turn is approximately proportional to the travel distance of the head. The head travel distance is shorter if picking-up and placing positions are closer together. In order to optimize the picking up and placing actions, it is important to assign components to turns so that the total sum of travel distance of the head is the minimum.

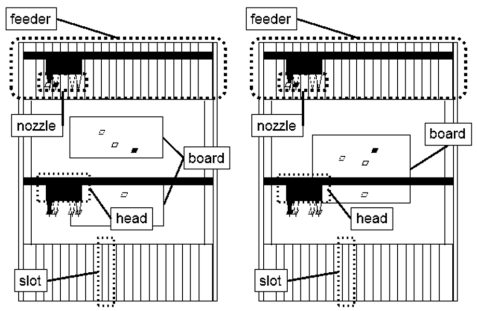
1.2 Mounting method of component placement machines

There are two typical methods of mounting for component placement machines; *alternating mounting* and *separate mounting*.

In the alternating mounting method, two heads positioned opposite each other alternately place components onto a central circuit board, and while one head is performing a component placing action, the other head performs a component picking-up action. Since placing usually requires more time than picking up, the motion time of the component placement machine is determined only by the component placing action.

In the separate mounting method, on the contrary, only one head places the components onto one circuit board; there are two conveyors, which carry two boards independently on each other. Unlike the alternating mounting method, the component placement machine's motion time in the separate mounting method is determined by both the component placing action and the pick-up action.

Most component placement machines are equipped with two conveyors, and it is possible to carry out separate mounting using two conveyors as well as alternating mounting using only one conveyor; recently, however, the most common placing method used at circuit board production sites has been shifting from alternating mounting to separate mounting. Figure 2 shows a simplified schematic of each mounting method.



(a) (b)

Figure 2 Separate mounting (a) and alternate mounting (b)

The component placement machine shown in Figure 1 is just one side of the component placement machine shown in Figure 2 (i.e., lower half of Figure 2). In the following, "one machine" refers to one side of a machine that uses the separate mounting method (upper or lower half).

1.3 Problems concerning motion optimization of component placement machines

In both the pick-up action and the placing action, the travel distance of the head may vary greatly depending on which components are allocated to which nozzle (*nozzle allocation*), because the size of the head is not negligible compared to the size of the circuit board and the component feeder. Figure 3 shows how the travel distance of the head when placing components varies by nozzle allocation.

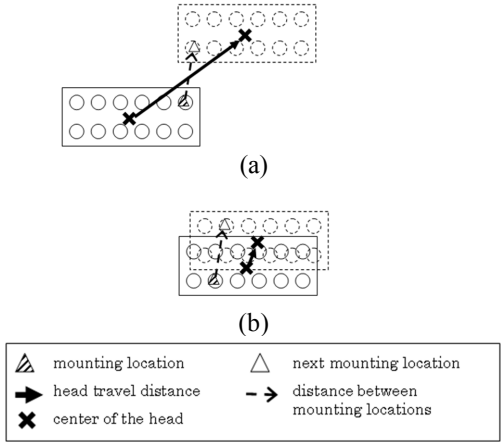


Figure3 Difference of travel distance by nozzle allocation

Also, to increase the speed of the pick-up action, recent component placement machines are capable of picking up multiple components at the same time (*gang pick*), if the interval of nozzle positions and that of slot positions of the concerning components are the same. For example, with the arrangement of the component feeder shown in Figure 4, it is possible for the two components supplied from slots 5 and 7 to be picked up simultaneously by nozzles B and D, respectively. Gang pick reduces the number of component picking-ups and accelerates the picking-up action.

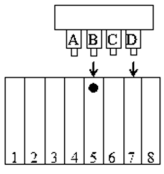

Figure4 Gang pick

Thus, considering the problem of nozzle allocation is very important.

In the former research, however, nozzle allocation was not often given sufficient consideration. Yamamoto et al. [3] proposed a method for optimizing the placing action taking the nozzle allocation into account and achieved a reduction in head travel distance of approximately 20% compared to conventional methods. This research, however,

considered the placing action only and neglected the pick-up action. When the placing time is longer than the pick-up time in the alternating mounting method, this approach is adequate. On the contrary, in the separate mounting method, both placing time and pick-up time are reflected in the circuit board production time, and so the assumption of the above approach does not hold. At actual circuit board production sites in industry, when motion optimization of component placement machines under the separate mounting method is performed, nozzle allocation is determined from the point of view of optimization of the picking-up action first and optimization of the placing action is carried out next. The method proposed by Yamamoto et al. can cope with the alternating mounting method, but it cannot sufficiently optimize component placement machines under the separate mounting method.

In this paper, we propose first a model for simultaneous optimization of picking-up action and placing action by considering nozzle allocation in one component placement machine under the separate mounting method.

At actual sites where component placement machines are in operation, multiple machines are connected to form a production line. Machine allocation, turn allocation, nozzle allocation, component pick-up action, and component placing action should really be optimized in a comprehensive way that also takes into account line balancing. As for line balancing, a method for allocating components by finding placing paths in component placement machines has been proposed, but this method does not consider nozzle allocation or component pick-up action [2].

The model proposed in this paper is basically intended for motion optimization of one machine, but line balancing can be carried out at the same time by using a simple extension.

2 Formulation of the problem

In this paper, we consider the following two problems.

2.1 Problem of motion optimization of one machine

This is the problem of finding turn allocation, nozzle allocation, pick-up order, and placing order for given components, with the aim of carrying out motion optimization of one component placement machine on a production line, where components are already allocated to machines. In this paper, the arrangement of the slots in the component feeder is given, and it is assumed that one type of component is supplied from exactly one feed slot and the same type of component is not placed in multiple slots. Also, in real component placement machines, the type of component that can be picked up and placed may be limited according to the type of nozzle, but, here, it is assumed that all types of components can be picked up and placed by any nozzle.

The motion time spent on each circuit board by the component placement machine is approximately proportional to the travel distance of the head, and so the head travel distance is used to evaluate the solution. However, to take into account the number of component pick-ups, the time spent for picking up is converted to head travel distance and added to the evaluation value. Furthermore, because the head is driven by motors operating independently in the x- and y-directions, the head travel distance is defined as the Chebyshev distance.

2.2 Problem of motion optimization of multiple machines and line balancing

This is the problem of load balancing between machines on a production line composed of multiple machines. This is an extension of the problem of motion optimization of a single machine. In this problem, it is necessary to find the machine allocation of components as well as turn allocation, nozzle allocation, pick-up order, and placing order for each machine.

The amount of time spent per circuit board in the production line is the motion time of the machine that causes bottlenecking, so the solution is evaluated by using the head travel distance of the bottleneck machine. In the same way as the problem of motion optimization of one machine, the time spent picking up is converted to distance and added to the evaluation value.

3 The algorithm

In our proposed algorithm, component turn allocation is sought in combination with nozzle allocation using a local search technique. Also, these allocations are evaluated by finding the pick-up and placing paths for each allocation and calculating the respective head travel distance and the number of pick-ups.

A flowchart of the proposed algorithm is shown in Figure 5.

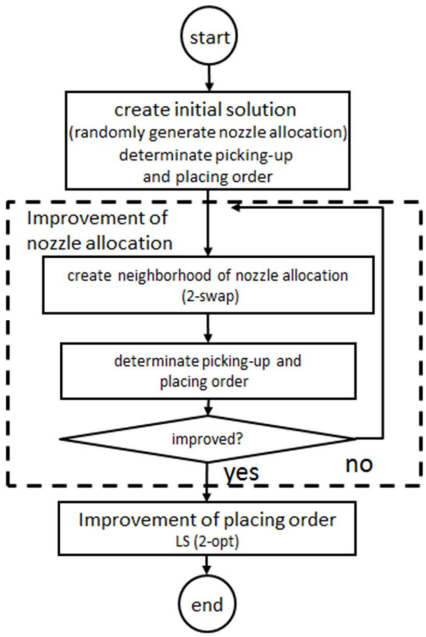

Figure5 Flowchart of the proposed algorithm

3.1 Method of expression of nozzle allocation

3.1.1 Expression of nozzle allocation for a single machine

Individual numbers are assigned to the components, and nozzle allocation is expressed together with component turn allocation by arranging the assigned component numbers, as shown in Figure 6. Component turn allocation is obtained by dividing up the arranged components based on the number of nozzles in the head, starting from the leftmost component. Also, the sequence of component numbers within a turn indicates the nozzle picking them up. Figure 6 shows an example of nozzle allocation in a component placement machine with four nozzles. The character "e" is inserted instead of a component number when the nozzle does not pick up a component.

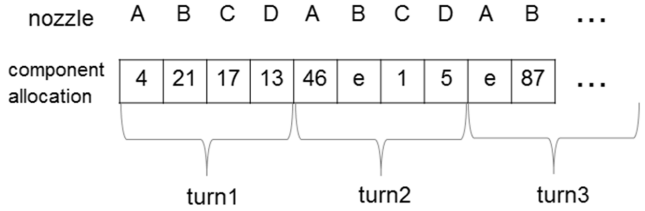

Figure6 Nozzle allocation in a placement machine

3.1.2 Expression of nozzle allocation for multiple machines and line balancing

As in the expression of turn allocation and nozzle allocation in the problem of motion optimization of a single machine, individual numbers are assigned to the components, where nozzle allocation is expressed together with component machine allocation, and turn allocation is performed by arranging the assigned component numbers. Machine allocation consists of several turns. Also, the sequence of component numbers within a turn indicate the nozzle picking them up. Figure 7 shows an example of nozzle allocation in component placement machines with four nozzles.

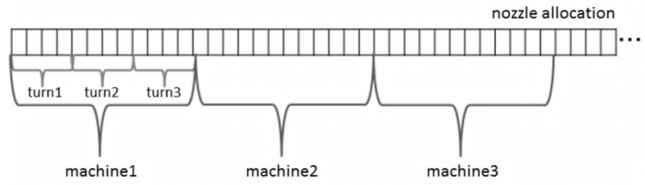

Figure7 Nozzle allocation in component placement machines

3.2 Determination of component picking-up and placing order

To evaluate a solution corresponding to a certain nozzle allocation, the component pick-up order and the component placing order are determined as described below, and the respective head travel distances and number of pick-ups are calculated.

3.2.1 Determination of the order of component picking-up order

When the nozzle allocation is given, the position of the head above the component feeder is settled. It is possible to pick up components in the shortest head travel distance by picking them up in order from the left or right of the head position. Also, the head position during pick-up may overlap for several components and, in this case, the components can be picked up at the same time with one up-down motion (gang pick mentioned before).

3.2.2 Determination of component placing order

When the nozzle allocation is given, the center of the head above the circuit board when placing each component, as shown in Figure 8, is settled. Here, the shortest path when traveling around the head centers can be regarded as a type of traveling salesman problem (TSP). Therefore, the placing order is determined using the nearest neighbor (NN) method, which is often used as the initial solution to the TSP. The NN method is a typical greedy method, and it generates a solution by repeating the operation of moving from the current point to the nearest point until all points have been visited.

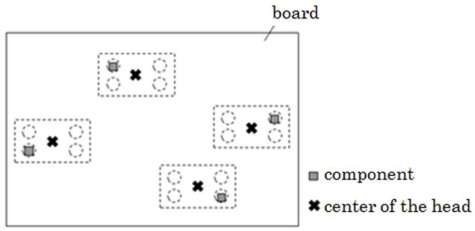

Figure8 Location of the center of the head

3.3 Improvement of component placing order

After component nozzle allocation has been improved, improvement of the placing path of each turn is carried out. A local search technique based on the first admissible move strategy using a 2-opt neighborhood is used to improve the placing path. A 2-opt neighborhood is a set of solutions generated by swapping two branches on a path, and it is often used to solve problems such as the TSP.

4 Computational experiment

A computational experiment was carried out to evaluate the effectiveness of the proposed method. The experiment environment consisted of an Intel Pentium CPU B940 2.00 GHz with 4.00 GB of memory, and the language used was C.

The number of slots in the component feeder was set at 30 and the distance between slots at 10 mm. The positional relationship of the circuit board and the component feeder and camera is set as shown in Figure 9. Also, the number of

nozzles was 16, and these nozzles were arranged on the head as shown in Figure 10. These settings were determined with reference to real component placement machines.

The experiment was done for 27 types of circuit boards randomly generated.

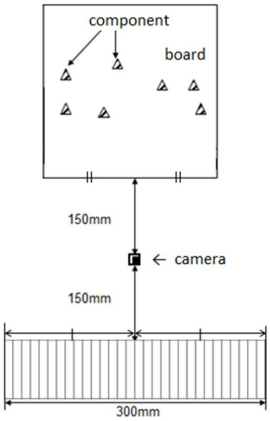

Figure9 Location of the circuit board and the component feeder and camera

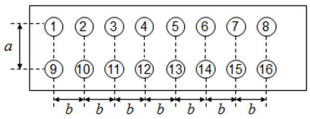

$a = b = 10$mm

Figure10 Location of the nozzles on the head

4.1 Comparison with the conventional methods in the case of a single machine

An experiment comparing the proposed algorithm and conventional methods was carried out with regard to optimization of the pick-up and placing actions of one machine.

As for conventional methods, we tried two types of methods; pick-up first and placing first. In the former (pick-up first) method, picking-up action, turn allocation and nozzle allocation are determined before placing, which is determined by NN and 2-opt methods. This method reflects the actual process of optimization in the production of electronic circuit boards in industry. In the latter (placing first) method, the order of placing, turn allocaton and nozzle allocation are fully optimized before picking-up. Although this latter method is rather imaginary and not used in real industry, we conceived it in order to explore the superiority of picking-up first and placing first.

Figure 11 shows the relationship between the computation time and the evaluation value for the proposed algorithm and the conventional method (both 2 types) with regard to Data 14. It can be seen that the proposed algorithm converges to a better solution than those by the conventional methods.

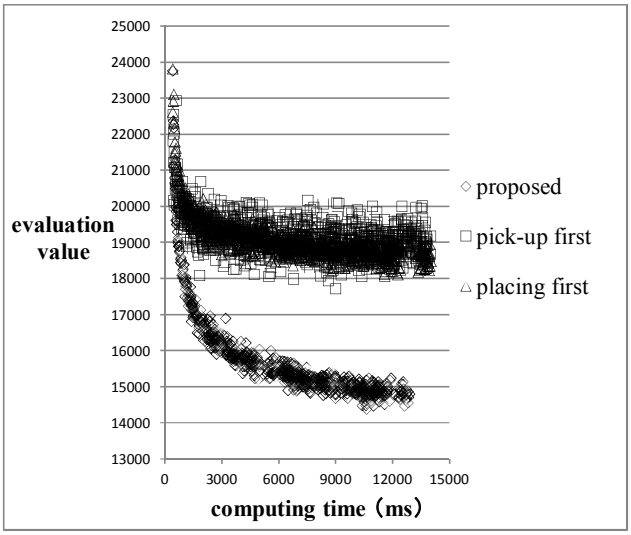

Figure11 Relationship between the computation time and the evaluation value (Data 14)

Table 1 gives the evaluation values obtained after a sufficient length of time using the algorithm of the conventional methods and the evaluation values obtained after an equivalent length of time using the proposed algorithm. The algorithm of the proposed method gives better solutions for all data than those by the algorithms of the conventional method.

As for the conventional method with pick-up first, Table 1 shows that the gap increases as the circuit board size increases. This is presumed to be because the cost of the placing action increases in proportion to the circuit board size, and so the proposed method, in which searching progresses while taking account of placing, becomes more advantageous. Table 1 shows also that the gap decreases as the number of component types increases. This is presumed to be because the greater the number of component types, the greater the cost of the pick-up action, and so improvement progresses easily, even in the conventional method.

As for the conventional method with placing first, Table 1 shows that the gap decreases as the circuit board size increases. This is presumed to be because the cost of the picking up action becomes more significant than the placing action as the circuit board size increases.

Table 2 gives the evaluation values obtained by the proposed method and the modified version of the proposed method where SA (simulated annealing) is used instead of local search with sufficient length of time. Parameters of SA have been adequately by preparatory test. Table 2 shows that local search gives relatively good solution in short time of computation, although the evaluated value itself is rather inferior to SA. In addition, the gap between SA and local search grows as the number of components increases; 3.71% for 64 components, 5.96% for 256 components, 13.98% for 512 components, and so on. This is presumed to be because when the number of components increases, the search space grows wide and LS tends to fall into a local optimal solution.

4.2 Line balancing

An example of line balancing using the proposed algorithm is given. Figure 12 shows the relationship between the head travel distance and the computation time when placing is done by 1, 2, 4, and 8 component placement machines using Data 14. Under the computation time within 2 seconds, multiple searches were performed while gradually increasing the computation time. By using the algorithm of the proposed method, it can be seen that the evaluation value improves in all of the cases using different numbers of machines. Also, the rate of improvement from the respective initial solution is 27.8% for 1 machine, 27.7% for 2 machines, 25.0% for 4 machines, and 26.5% for 8 machines.

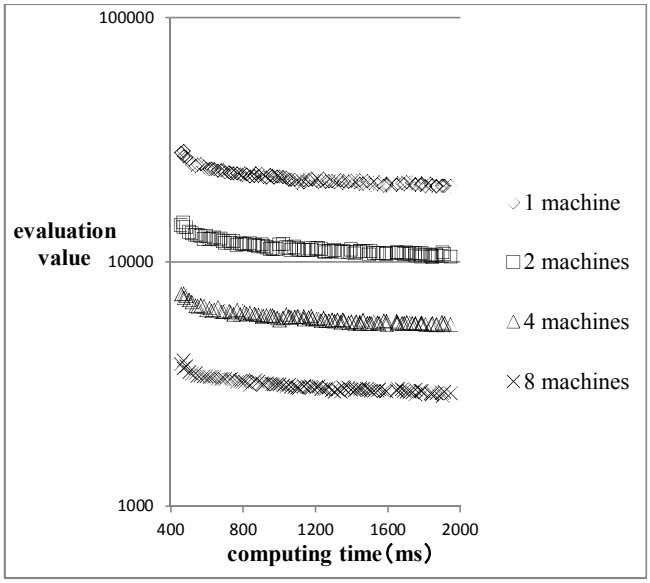

Figure12 Line-balancing of 1, 2, 4, and 8 component placement machines (Data 14)

5 Conclusions

We have discussed in this paper the motion optimization of multifunction component placement machines and proposed a model for comprehensive optimization of machine allocation, turn allocation, nozzle allocation, placing order, and pick-up order. Also, it has been confirmed by computer experiment that performing motion optimization using this model gives a sufficiently good solution compared to that of a conventional method.

Future work includes new algorithm of obtaining good solution as SA in a short time of computation even if the number of components increases. Also, it is desired to formulate the problem as an integer programming problem and obtain an exact optimal solution by IP solver and compare with the proposed method. Finally, it is hoped to create a model that can also handle cases in which some constraints for nozzle allocation is imposed, cases that also take the arrangement of components in the component feeder into account, and cases in which several types of circuit boards are produced.

Smart Home Delay Tolerant Network for an Earthquake Disaster

Raito Matsuzaki[1] **and Hiroyuki Ebara**[1]
[1]Kansai University, Yamate, Suita, Osaka, Japan

Abstract— *In a previous paper, we proposed a rescue support system for victims buried in an earthquake disaster by constructing an ad-hoc network using home-server smart homes. However, this system has the following two problems: i) it cannot ensure sufficient density of home servers for a WLAN communication range, ii) the system does not consider areas in which home servers cannot be used such as in parks and factories, for example. In this research, we propose a new method using a delay tolerant network (DTN) technique. In this method, rescuers with mobile devices relay information between disconnected networks by walking around during rescue activities. For a performance evaluation, we performed simulation experiments using a map of Abeno-ku, Osaka. From our results, we show that the proposed method increases the information acquisition rate, and the network can be maintained. In addition, we quantitatively show the penetration of the smart home needed for our system.*

Keywords: *ad-hoc* network, delay tolerant network(DTN), smart home, emergency rescue, earthquake

1. Introduction

In Japan, earthquake disasters are frequent. Problems during an earthquake disaster include communication blackouts and damaged infrastructures which cause traffic jams due to building collapse. Because of these problems, security companies and public institutions such as the fire department, often experience delays in their rescue activities. In the Great Han-Shin Awaji Earthquake, the survival rate within 24 hours was about 75 %, but only 15 % in 72 hours [1]. Making quick rescue activities is essential because the survival rate decreases with the passage of time.

In [2], we proposed a smart home network built with *ad-hoc* networks using home servers for smart homes, and a rescue support system for buried victims by making a rescue request map using this network in an earthquake disaster. The smart home manages various systems in the same way as home servers realizing a comfortable home environment through sensing. In the smart home network, home servers contain a wireless LAN (WLAN) and battery functions. Thus, this network will work even in the case of infrastructure blackouts and outages in the area because each home server forms an *ad-hoc* WLAN network. To use this network, a home server detects the presence of buried victims by information of their presence in collapsed homes and buildings, and sends neighboring home servers this information. Each home server makes a rescue request map based on this information. The rescue request map displays information of victims on the map. In addition, rescuers get this map from near home servers from rescuers with mobile devices. Therefore, we can identify the position of victims and rescue them quickly.

The smart home networking system (we previously devised), however, has a few problems. First, we have to ensure sufficient density of home servers for the WLAN communication range, and introducing this service into rural area is difficult. Therefore, this system is useful only in urban residential areas, and then only with a low penetration. Second, we consider places such as parks, factories, schools, and wide load trucks, not available to home servers. Thus, we proposed to set repeaters to aid communication between home servers in [2], but such repeaters are highly expensive.

In this research, we propose mobile device rescuers that can bring relay information to communicate between disconnected home servers. Mobile devices are introduced as a data exchange method in a delay tolerant network (DTN). The DTN communication system can transfer data with a long delay, but with some confidence even in environments of interruption and disconnection for communication during an earthquake disaster. The 'carry and forward' technique commonly used with DTN can exchange information between nodes. In a smart home network, this technique can relay information among disconnected home server groups because rescuers with mobile devices walk around and obtain information during a rescue activity. In this way, we can solve the problem of communication between disconnected home servers without the repeaters.

2. Delay Tolerant Network

In Epidemic Routing for Partially-Connected *Ad Hoc* Networks [3], techniques have been developed to allow message delivery in cases where a connected path from a source to a destination is not available in mobile *ad-hoc* networks. The authors show that Epidemic Routing achieves eventual delivery of 100 % of messages with reasonable aggregate resource consumption through an implementation in the Monarch simulator. Epidemic routing is generally used with DTN routing such as [4].

Delay Tolerant Networks (DTNs) [5] [6] are designed to overcome limitations in connectivity due to conditions such as mobility, poor infrastructure, and short-range radios. In fact, there are experimental projects such as the TIER [7] and

the KioskNet [8] due to internet connection in sparsely populated areas without communicational infrastructures. However, missed contact opportunities among nodes decrease throughput and increase delay in the network. By using capacity Enhancement with Throwboxes in DTNs [9], the authors of this article have proposed the use of Throwboxes to enhance network capacity in mobile DTNs. Furthermore, this capacity increased the transmission opportunities as well as throughput between nodes. The authors performed an extensive evaluation of their algorithms by varying both the underlying routing and the mobility models.

One type of research about the DTN routing technique is Data Routing for DTN Environments According to Data Size and Deadline [10]. In this research, the authors propose a technique to enable asynchronous communication between two points that cannot be used for infrastructures by the transport of data using a mobile device with which the user can move around. This proposed method uses the carry and forward techniques. In [10] the authors assume that each node introduces a small battery-powered server called an Infobox. Thus, they also assume that the Infobox and the mobile device are narrow-area wireless communication functions (WiFi, Bluetooth etc.), with enough storage, computing power, and memory to run the DTN. The novelty of this study [10], is not only improvement in the data arrival rate and shortening of the communication delay, but also consideration of the data size and the transmission deadline. Because the time a user has to communicate between nodes is limited in a real environment, users are not able to exchange all the data in time. Therefore mobile devices change the priority of the data to be sent by importance of data. This proposed method [10] can send and receive the higher value data and improve performance. In this proposed method, the authors performed simulation experiments in the Manhattan area. They show that the data arrival rate that considers the importance of data is higher than in other methods.

3. Smart Home Network with Delay Tolerant

In this section we give an overview of the smart home network and rescue support system, and propose a new method to improve connection in the smart home network. For more information about the smart home network and rescue support system, see [2].

3.1 Overview of Smart Home Network

In the smart home network, the home server operates a smart home system in the case of normal (non-emergency situations), and constructs *ad-hoc* networks by wireless functions between neighboring home servers in the case of a disaster. The smart home system shown Figure 1 represents a system that realizes a secure home environment in terms of monitoring, consumer electronics operations by sensing, and security.

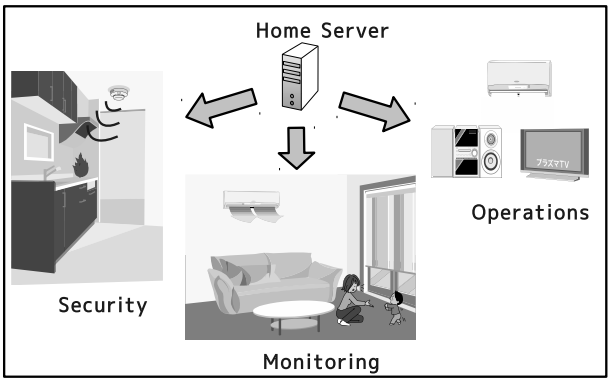

Fig. 1: Example of services by the smart home.

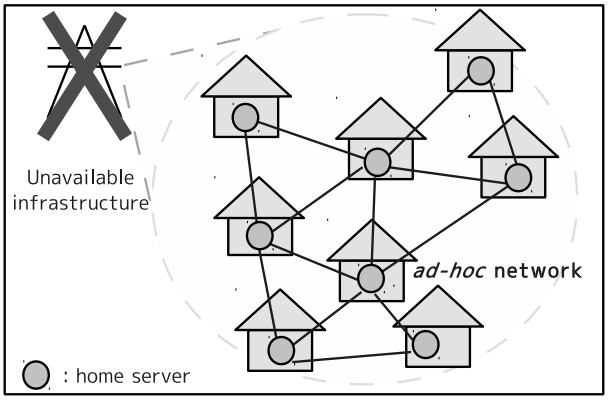

Fig. 2: Construction of *Ad-hoc* networks.

The smart home network uses Earthquake Early Warning (EEW) that exists in 2 types [11]. One type is for advanced users and another is for the general public. We use both EEWs in the smart home network, and we call the EEW for advanced users the first EEW, and the second type for the general public, the second EEW.

We describe the behavior the smart home network in an earthquake disaster. Receiving the first EEW, each home server checks connections between neighboring home servers. Receiving the second EEW, each home server sends and shares information (such as home rescue etc.) using infrastructures such as the Internet. When a blackout occurs after an earthquake, each home server connects and communicates with neighboring home servers to maintain the system, as shown in Figure 2. Thus, each home server needs a battery to run the system while electricity supply stops.

3.2 Overview of the Rescue Support System

It is very important for rescuers to rescue buried victims in an earthquake. However, such rescue operations to identify

Table 1: The amount of data needed to create a rescue request map.

information	amounts [bit]
rescue request information	1
home information	4
information of various sensors	7
complete rescue information	1
coordinate information	51

the location of buried victims are often difficult. In fact, the way rescuers now often find victims is by hearing the rescuers when they call for help. In this research, home servers create a rescue request map to quickly identify the location of buried victims.

The type of information needed to create a rescue request map is as follows:

- Rescue request information - a direct rescue request
- Home information - the number of people in a home
- Information of various sensors - the sensing signals of several sensors in the smart home system
- Information of disconnected home servers - home servers disconnected from the network by some abnormal reason emergencies, for example
- Complete rescue information - information to be sent by mobile devices after the rescuer rescues the victim
- Coordinate information - positional information of the home server

Deciding the amount of data for each piece of information needed to create a rescue request map is necessary. In Table 1 we show the amount of data needed to create a rescue request map. Rescue request information and complete rescue information need 1 bit (switching ON/OFF); home information needs 4 bits because the number of people in home is usually less than 15. The information about various sensors requires up to 7 bits, which can be used for up to 7 sensors. Coordinate information requires 51 bits because of GPS information. The longitude is 25 bits, and the latitude is 26 bits in the coordinate information. From Table 1, we assume the information required to create a rescue request map that needs at the minimum 8 Bytes.

We describe next how a home server creates a rescue request map. Home servers send information to create a rescue request map to each other, and share this information. Based on this information, each home server creates a rescue request map, and checks connections between neighboring home servers. If a home server updates information or receives new information, the home server sends it to a neighboring home server. The home server doesn't send duplicated information. The rescuer with mobile devices can get a rescue request map from the home servers, as shown in Figure 3.

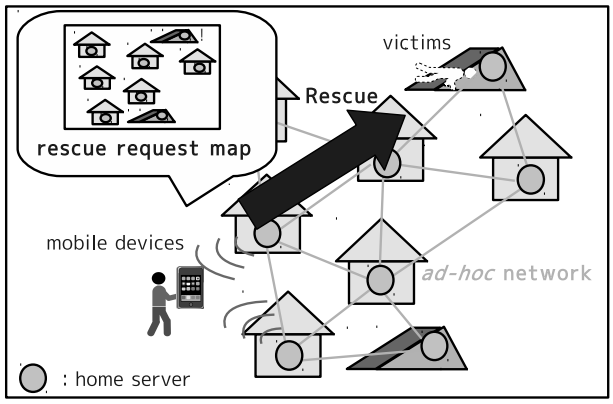

Fig. 3: Getting a rescue request map.

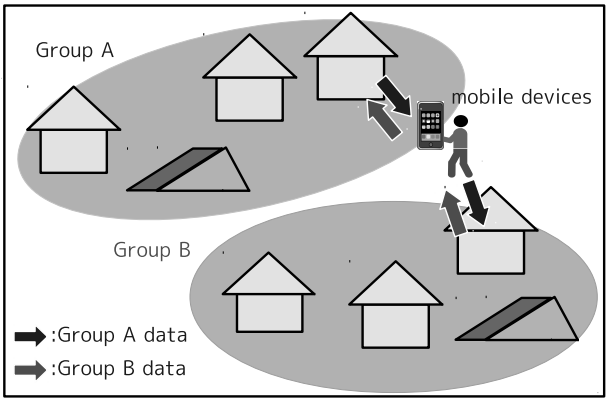

Fig. 4: Example of the mobile device relay.

3.3 Mobile Device Relay

To achieve the smart home network, we should consider two major problems. First, because the communication range of WLAN is small, the home server cannot connect to neighboring home servers. Second, cities have large areas such as mentioned before in which the home server cannot be used. Not putting a home server in these areas, causes several small home server groups. These problems cause a reduction in the connection rate if the smart home network is introduced. Therefore, we propose the mobile device relay to communicate between disconnected home servers in the smart home network, as shown Figure 4. Mobile devices have a data exchange method used in DTN, called a 'carry and forward' technique, so mobile devices can save information to create a rescue request MAP and pass it to other home servers. If a rescuer with mobile devices gets information to create a rescue request map from one home server group and moves to another home server group, the mobile devices can communicate with the home server group and share information between home server groups.

We propose an algorithm for sending and receiving information of a rescue request map for the proposed method as

follows:

Step1) When the rescuer with a mobile device moves with in the communication range of a home server, the mobile device sends rescue request map information to the home server.

Step2) If information the home server receives is new, the home server obtains this information.

Step3) If the home server has information the mobile devices do not have, the home server sends this information to the mobile device.

3.4 Assumptions necessary for Achieving the Proposed Method

To achieve the proposed method, it is necessary to consider several assumptions, described below.

3.4.1 Home Server

The home server has several functions in the smart home network as follows:

- Each home server has WLAN (IEEE 802.11) communications.
- Each home server can save all information to create a rescue request map.
- Each home server sends the differences in information to create a rescue request map.
- Each home server broadcasts between home servers, and broadcasts to mobile devices.

3.4.2 Mobile device

The mobile device of a rescuer has several functions as follows:

- Each mobile device has WLAN (IEEE 802.11) communications.
- Each mobile device gets information to create a rescue request map once.
- Each mobile device broadcasts to home servers (No transportable mobile devices).

The carry and forward technique needs to set a transmission deadline to avoid network congestion and waste of bandwidth. Nonetheless, rescuers with mobile devices do not discard information to create a rescue request map during the rescue activity. In addition, the size of information to create a rescue request map is small because it is less than the multiplication value of 8 Bytes by the number of home servers sharing information. Therefore, we do not need to worry about the transmission deadline for information to create a rescue request map, but only need to update new information sent to the home server.

In our proposed method, the mobile device can communicate with home servers, but cannot communicate with other mobile devices, called message passing communication. Using passing communication, mobile devices must always have an active communication function, which wastes the battery. Therefore, we assume that the mobile device only communicates with home servers.

Table 2: Parameters in simulations.

items	parameters
simulation area	Osaka Abeno-ku
simulation range	1 km^2
communication protocol	WLAN (IEEE 802.11)
communication range	15 m and 30 m
the number of households	8000
simulation time	15 minutes - 2 hours
measurement range (arrival rate)	300 m

3.4.3 Battery

When a large earthquake occurs, electricity supply is stopped because of damage to infrastructure functioning. Because the home server needs to supply it's own power, the home server has a large battery, or private power generation such as solar power. In addition, the home server is required to work for a minimum of three days. The sensor in the smart home and in the mobile device also needs to have enough battery to last for three days. We think, however, that battery capacity will increase through future technological development. Thus, we assume home servers, sensors, and mobile devices will have enough power supply to achieve the proposed method.

3.4.4 Movement of Rescuer

We assume rescuers move anywhere in areas in our simulation. Rescuers move freely in areas when mobile devices do not get the position of the victim. In our research, we assume that the free action of the rescuer follows a self-avoiding random walk [12] [13]. However, we propose that rescuers move a random distance up to one-tenth of the map in the same direction; otherwise, the random walk would be stuck in one place. When the mobile device gets the position of the victim, a rescuer can move there. If rescuers finish the rescue by finding the victims, then the rescuers can move freely again.

3.4.5 Communication Range of Home Server and Mobile Device

In our research, we assume that the communication range of the home servers and mobile devices is the same. We also assume that the communication range is equal in a circle. We assume that the communication range for WLAN is up to 30 m because we measured this range in [2].

4. Performance Evaluation

To show the effectiveness of the proposed method, we performed simulation experiments on an actual map. The simulator is implemented in Java.

Fig. 5: Map of simulation area in Abeno-ku.

4.1 Setting of Simulations

Table 2 shows the parameters in our simulations. We assume the simulation model is the residential area of Abeno-ku, Osaka, and the simulation area is within the range of 1 km square. The map of the simulation area is from the Geographical Survey Institute (GSI) [14]. The location of the home servers and the communication range are with respect to pixels[1]. The number of households in the simulation area is obtained from the number of households divided by the area of Abeno-ku. The penetration rate is obtained from the number of home server installations divided by the number of households in the simulation area.

Figure 5 shows the actual map of the simulations. The map is divided in monochrome by residential areas and not residential areas (home servers can be installed in the white spaces, but not in the black). The black areas represent places such as parks and factories as mentioned previously.

We simulate the information acquisition rate each of home servers and mobile devices in a simulation area. The information acquisition rate shows the rate of the information which the home server can get from others. We also simulate the arrival rate of a home server information in this area. This rate is the information acquisition rate measured the certain range with a focus on a home server, and this is because home servers should communicate in a narrow range to avoid large amount of information. We assume the certain range (the measurement range) is 300 m from preliminary experiments, as shown Table 2. Note that both the communication range and the measurement range are radiuses of a circle. If a mobile device communicates between disconnected home servers, both of the rates are added. In the simulation, the information acquisition rate for one home server (a single rate) is obtained from the number of other home server information divided by the number of households. The arrival rate for a single rate is obtained from the number of other home server information divided by the number of home servers in the measurement range. Then, we obtain the information acquisition rate and the arrival rate by taking average of a single rate in all home servers.

[1]Range of 1 pixel is 1.2 m (speed of people).

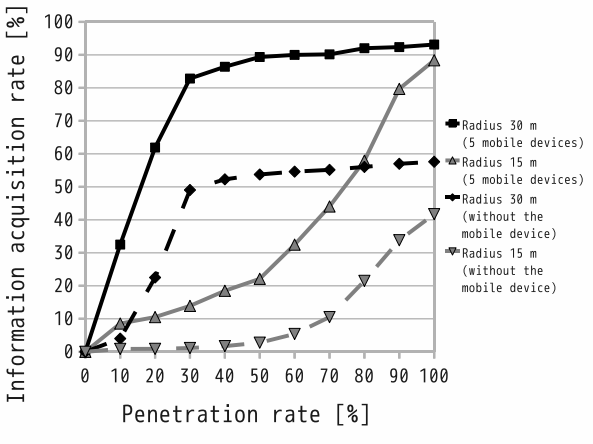

Fig. 6: Characteristics of the information acquisition rate for the home servers.

We do the simulation a hundred times, and then take the average.

4.2 Results of Simulations

We describe the simulation results about the information acquisition rate for home servers and mobile devices. Moreover, we also describe the result about the arrival rate of the home server information.

Figure 6 shows the information acquisition rate for home servers in the smart home network. The horizontal axis represents the penetration rate, and the vertical axis the information acquisition rate. The result of no mobile devices measures only the home server, which is the connection rate (the connection rate is obtained from the maximum number of home servers connected to each other divided by the number of households). The result of 5 mobile devices is due to the proposed method. In the proposed method, the number of rescuers is 5 and simulation time is 1 hour. From Figure 6, we can see that the information acquisition rate (the connection rate) without the mobile device for both 15 m and 30 m was less than 60 % even if the penetration rate was 100 %. Because the area in which home servers cannot be put is too large, several small home server groups are needed for this area. However, the information acquisition rate of the proposed method (with 5 mobile devices) is significantly improved compared to without the mobile device. Moreover, this system needs about a 50 % penetration rate to get over a 90 % connection rate in a communication range of 30 m for each 1 hour.

Figure 7 and Figure 8 shows the information acquisition rate of the mobile device relay for both home servers and mobile devices in the smart home network. The horizontal axis represents the simulation time, and the vertical axis the information acquisition rate. We simulate the penetration rate of the home server as 50 % and the communication range

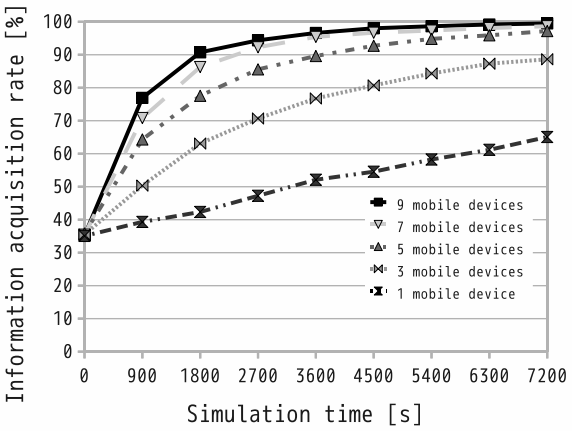

Fig. 7: Characteristics of the information acquisition rate for home servers by the simulation time.

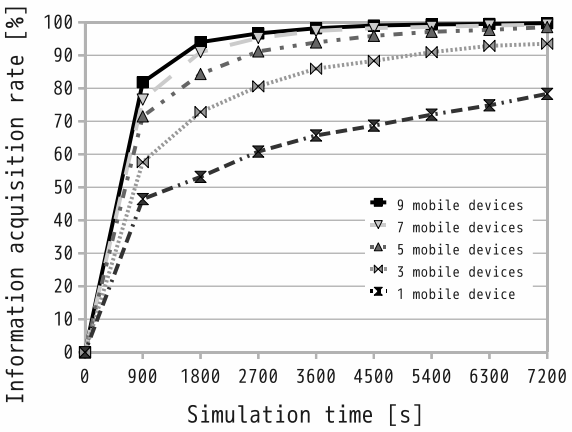

Fig. 8: Characteristics of the information acquisition rate for mobile devices by the simulation time.

as 30 m, and simulation time is 2 hour. From both Figure 7 and Figure 8, the more the simulation time increases, the more information acquisition rates increase. Especially, the result of both 7 and 9 mobile devices is over a 95 % within 1 hour, we consider this value is enough to maintain the smart home network.

Figure 9 shows the arrival rate for the home server information in the certain range with a focus on a home server as 300 m. The horizontal axis represents the simulation time, and the vertical axis the arrival rate. We simulate the penetration rate of the home server as 50 %, and simulation time is 1 hour. From Figure 9, the more the simulation time increases, the more arrival rates approach 100 % in a communication range of 30 m within 1 hour. Moreover, the larger the number of mobile devices, the earlier arrival rates approach 100 %.

The connection rate, therefore, is improved by our proposed method especially with in the communication range of 30 m. In this range we showed a performance good enough to provide the system with connection rate of at least 90 %. We simulated the communication rate equally in a circle. However, we need to consider that the communication range isn't equal in a circle because of the difference in height of the terrain and the placement of obstacles in reality.

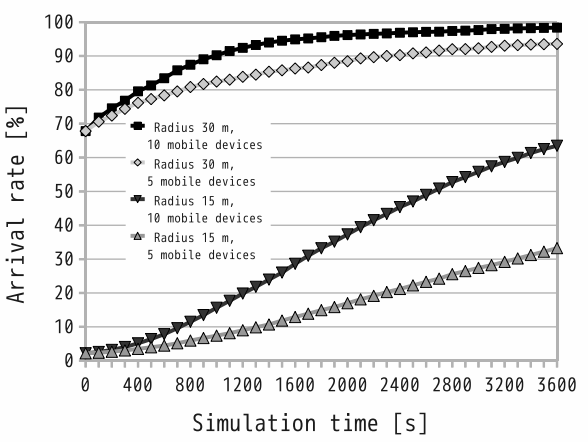

Fig. 9: Characteristics of the arrival rate for the home server information.

5. Conclusion

It is very important for victims to be rescued within 72 hours because this is generally how long victims can survive without help. To do this, rescuers must identify the location of buried victims. We proposed a rescue support system that creates a rescue request map. In our research, we proposed a method for a mobile device relay to communicate between disconnected home servers in the smart home network during an earthquake disaster. We showed that our proposed method is effective by performing an evaluation of the information acquisition rate.

We are currently implementing a communication environment to achieve a smart home network and a rescue support system.

***Abstract*—We are doing researching and development of an intelligent lighting system to provide desired brightness to a desire place. To realize individual lighting environments, this system needs the influence level of each lighting and each illuminance sensor. Also, by measuring the influence level that dynamically, this system can cope with dynamic illuminance sensor relocations (user relocations). If this system don't consider illuminance sensor relocations, this system can turn off lightings of little influence. Therefore, this system leads to energy saving. However, It is impossible to be successful at both illuminance sensor relocations and turning off lightings (improvement of energy efficiency). To solve this problem, this paper proposes a new lighting control algorithm which estimates illuminance sensor positions based on distances from turned-on lightings. It will enable the lighting system to learn the change in user or desk positions, and turn off those lightings which affect users very slightly. we conducted an experiment to simulate a real office. As a result, we indicate that the algorithm can realize the illuminance level desired by users while further saving energy consumption.**

I. Introduction

With the development of information technology and hardware, many electronic appliances such as televisions, air conditioners and fans, now incorporate an intelligent system which controls the operation of the appliance to suit environmental conditions, reducing the need of human operation.

Against such backdrop, intelligent controls are being introduced also for lighting systems from the aspect of saving energy consumption. One example of such systems is the "Energy-Saving Lighting Control System Linked to Access Control" by Mitsubishi Electric Corporation[1]. This system has infrared sensors built into lighting fixtures to detect user position coordinates and controls the luminous radiation of variable-light lighting fixtures. In this way, it can bring the light from the lighting system only to areas where a user is present and prevent excess light to save energy consumption. This system, however, uses an approach that controls each lighting fixture and does not consider providing a given brightness (illuminance) at a given point.

On the other hand, it has been reported that, to realize a better office environment, providing an illuminance optimized for each worker's task is effective for raising worker productivity[2]. One lighting solution which can realize individualized illuminance levels in an office environment is a task-ambient lighting system[3]; but in Japanese offices, task-ambient lightings are rarely adopted. This is because typical office buildings are equipped with ceiling lighting fixtures which provide a uniform illuminance, and most companies are unwilling to pay extra costs for adding task-ambient lightings. Considering these, there is a need of a lighting control system which provides light optimized for each office worker using only ceiling lighting fixtures.

Against this backdrop, the authors have proposed an intelligent lighting system which can provide brightness as required by users at any given points specified by users, depending only on ceiling lighting fixtures[4], [5]. The intelligent lighting system is composed of lighting fixtures, a lighting control devices, illuminance sensors (one person holds one illuminance sensor), and an electrical power meter. With this intelligent lighting system, each user specifies a target illuminance level for an individualized illuminance sensor placed on the desktop, then the system will follow a lighting pattern which realizes the target illuminance level while minimizing energy consumption using an optimization method. One should also note that this intelligent lighting system does not consider turning off part of lightings in the office to cope with dynamic changes in environmental conditions such as user relocations and change

in desk positions.

The intelligent lighting system has proven successful in our laboratory experiments[6]. Toward the commercialization of our intelligent lighting systems, currently verification experiments are underway in several offices in Tokyo and Fukuoka[7]. In the experiment, it was found that users hardly changed desk positions in these offices. Under such circumstances, we introduced a lighting control algorithm which turns off lights in places requiring no brightness to further improve the energy efficiency.

On the other hand, there are many "non-territorial" offices where users can move or change desk positions rather frequently. In view of this, this paper proposes a new lighting control algorithm which estimates illuminance sensor positions even after they are relocated. It will enable the system to cope with user relocations and desk position changes, while turning off those lightings which hardly affect users.

In this study, an operational experiment simulating a real office environment was conducted to verify the effectiveness of the proposed system.

II. INTELLIGENT LIGHTING SYSTEM

A. Construction of Intelligent Lighting System

An intelligent lighting system realizes an illuminance level desired by the user while minimizing energy consumption by changing the luminous intensity of lightings. The intelligent lighting system, as indicated in Fig.1, is composed of lights equipped with microprocessors, portable illuminance sensors, and electrical power meter, with each element connected via a network.

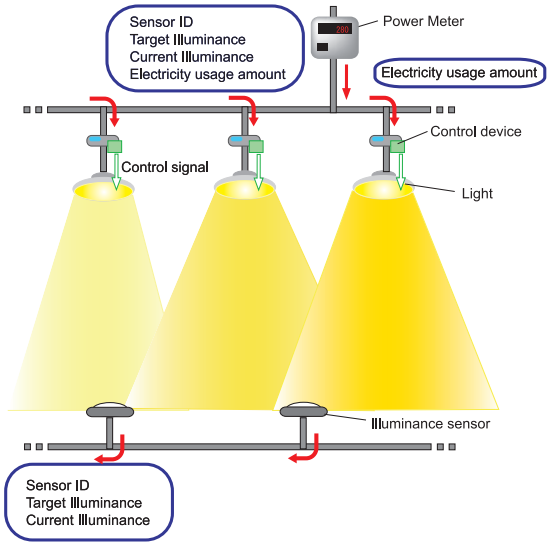

Fig. 1. Configuration of intelligent lighting system

B. Adaptive Neighborhood Algorithm using Regression Coefficient(ANA/RC)

The control algorithm is a critical element for the control of an intelligent lighting system. The speed of convergence to the target illuminance as well as its accuracy depends largely on the lighting control algorithm. As the best algorithm presently available for lighting control, we have proposed an Adaptive Neighborhood Algorithm using Regression Coefficient (ANA/RC)[8], which was developed by adapting the Stochastic Hill Climbing method (SHC) specifically for lighting control purposes.

In ANA/RC, the design variable is the luminous intensity of each lighting: the algorithm aims to minimize the power consumption while keeping the illuminance at the target level or above. It further enables the control system to learn the effect of each lighting on each illuminance sensor by regression analysis and, by changing the luminous intensity in response, enables a quick transition to the optimum intensity.

The following is the flow of control by ANA/RC:

1) Each lighting lights up by initial luminance.
2) Each illuminance sensor transmits illuminance information (current illuminance, target illuminance) to the network. The electrical power meter transmits power consumption information to the network.
3) Each lighting acquires the information from step 2), and conducts evaluation of objective function for current luminance.
4) Neighborhood is determined, which is the range of change in luminance based on factor of influence and illuminance information.
5) The next luminance within the neighborhood is randomly generated, and the lighting lights up by that luminance.
6) Each illuminance sensor transmits illuminance information to the network. The electrical power meter transmits power consumption information to the network.
7) Each light acquires the information from step 6), and conducts evaluation of objective function for next luminance.
8) The system performs regression analysis based on the luminous intensity data from each light and illuminance data from each illuminance sensor to determine the regression coefficient (influence level).
9) If the objective function value is improved, the next luminance is accepted. If this is not the case, the lighting returns to the original luminance.
10) If any of the lightings has been at the minimum lighting luminous intensity for a certain time with only a small influence level, the system turns it off (applicable only when there is no illuminance sensor relocation) .
11) Steps 2) through 10) constitutes one luminous intensity value search operation, which is repeated.

A search operation process (requiring about 2 seconds) consists of steps 2) through 10) above: by iterating this process, the system continues to learn how the lighting affects the illuminance sensor measurement until it realizes the target illuminance with minimum power consumption. Furthermore, by using the influence level found in step 8) as a basis for the evaluation and generation of the next illuminance value, the

system can quickly optimize illuminance.

Next, we will see the objective function used in this algorithm. The purpose of the intelligent lighting system is to achieve each user's desired illuminance, and to minimize energy consumption. Thus, it can be understood as an optimization problem in which each light optimizes its own luminance. Following from this, the luminance of each light is considered a design variable, under the constraint of the user's target illuminance, in resolving the problem of optimization to minimize energy consumption. For this reason, the objective function is set as in Eq. (1).

$$f = P + w\sum_{i=1}^{n} g_i \quad (1)$$

$$g_i = \begin{cases} (It_i - Ic_i)^2 & I_* \leq |It_i - Ic_i| \\ 0 & otherwise \end{cases} \quad (2)$$

P: Power consumption, w: Weight
Ic: Current illuminance, It: Target illuminance
n: Number of users
I^*: Threshold on illuminance difference

The objective function was derived from amount of electric power P and illuminance constraint g_j. Also, changing weighting factor w enables changes in the order of priority for electrical energy and illuminance constraint. The illuminance constraint is decided so that a difference between current illuminance and target illuminance within a threshold, as indicated by Eq. (2). The threshold value is set as a 50 lx.

Since this intelligent lighting system uses an autonomous distributed-control algorithm, particular cases of installation may use either distributed control or centralized control.

III. VERIFICATION EXPERIMENTS IN REAL OFFICE ENVIRONMENTS

From around 2009 onward, we have conducted experiments to verify the effectiveness of the intelligent lighting system in several offices in Tokyo and Fukuoka.

In an intelligent lighting system, to cope with user relocations and change in desk positions, even those lightings which hardly affect users need to be kept on at a minimum luminous intensity level. However, in the offices where our experiments were conducted, workers' desk positions were basically fixed and user relocations were rare. Hence, to further improve the system's energy efficiency, we have introduced a control mechanism which turns off lightings at points requiring no light <item (10) listed in 2.1> in these offices.

In this system, for each illuminance sensor, the IDs of several lightings around it are registered on a database, which are chosen based on the levels of influence of lightings to the sensor. By using the data, each lighting can be controlled optimally and turned off when appropriate. However, this method cannot cope with illuminance sensor relocations.

Meanwhile, not a few offices now use a non-territorial office design, in which workers have no fixed personal desks. In non-territorial offices, users may choose any desk position and user relocations are easy. If the control method which may turn off some lights is introduced in this type of office with a dramatically changing environment <item (10) listed in 2.1>, then the system will not be able to optimize lightings once a user relocation occurs, because it will be impossible to calculate the level of influence by a turned-off lighting onto the relevant illuminance sensor.

One solution to this problem may be to require users to notify the system of every user relocation: then the system turns on all lightings that have been turned off and calculate the influence levels of each lighting to relevant illuminance sensors and update the database. But in a real office, turning on all lights that have been off every time a worker relocates may disturb other workers in the office. In addition, users take time to notify the system that they relocate.

Hence, we propose a new lighting control algorithm for the system to automatically detect a user relocation and turn on only those lights which have a high level of influence over the relocated user.

IV. LIGHTING CONTROL ALGORITHM BASED ON ESTIMATED ILLUMINANCE SENSOR POSITIONS

A. Basic Idea of the Proposed Method

This study proposes a new lighting control algorithm which can cope with illuminance sensor relocations when some lightings have been turned off. In the study, regression analysis is performed based on the luminous intensity data from lightings which are on and the illuminance sensor data after the relocation, then the new sensor position is estimated based on their influence levels. After that, the lighting closest to the estimated sensor position is identified. If that lighting is off, the system can calculate the influence level by turning it on. This will enable the system to cope with user relocations while minimizing discomforts on other office workers. Moreover, the relocated user does not need to take the trouble of notifying the system of the relocation.

To realize this, the following control steps are added to the intelligent lighting system control algorithm:

1) The system detects an illuminance sensor relocation.
2) Regression coefficients for turned-on lightings and the relocated illuminance sensor are calculated.
3) Based on the regression coefficients obtained from step 2), the distances from turned-on lightings to the relocated sensor are calculated.
4) Based on the calculated distances, the position coordinates of the relocated illuminance sensor are estimated.
5) Based on the position coordinates of lightings and the estimated position coordinates of the relocated illuminance sensor, the system finds the lighting closest to the sensor and turns it on if it is off.

Illuminance sensor relocations are detected based on the amount of changes in the illuminance level. When a change in illuminance occurs which cannot be explained from changes

in the luminous intensities of adjacent lightings alone, the system assumes it to be a sensor relocation. Unlike our former intelligent lighting systems, position coordinates of each lighting need to be known because relocated sensor positions are estimated from its distances to lightings. Also, for each illuminance sensor, at least three of those lightings which have high level of influence onto the sensor should be on at any point of time. This is to enable the system to estimate the position of a relocated sensor based on the distances from those lightings which are on. Once the position coordinates of the relocated illuminance sensor are estimated, the number of lightings to be turned on is determined more than three.

Using the method described above, the system can turn off those lightings which hardly affect users while coping with user relocations and desk position changes.

B. Estimating Distances Based on Regression Coefficients

To estimate distances from turned-on lightings to a relocated illuminance sensor, regression analysis is used. Regression analysis is a method to derive a regression equation to explain the causality relation between change in the explanatory variable L and change in the observed value I, which is shown in this case by Eq. (3):

$$I = \sum_{i=1}^{n} r_i \times L_i + \beta \quad (3)$$

I: Illuminance, r: Regression coefficient
L: Luminous intensity, β: Constant
n: Number of lightings

In an intelligent lighting system, regression analysis is performed using explanatory variable L which is the luminous intensity of a lighting, and an observed value I which is the illuminance measured by an illuminance sensor, to calculate the regression coefficient r. The regression coefficient r, which explains the regression equation, is the level of influence by the lighting to the illuminance sensor. Based on this regression coefficient r, the distance between the lighting and the illuminance sensor is estimated.

The relation between luminous intensity L and illuminance I is expressed by Eq. (4) [9], where illuminance I is in inverse relation with the square of the distance d from the light source. Also, the relation between the distance d from the light source and the regression coefficient r expressed by Eq. (3) is expressed by Eq. (5).

$$I = \frac{L}{p^2} \quad (4)$$

$$\Leftrightarrow \quad d^2 = \frac{L}{I} = \frac{1}{r}$$

$$\Leftrightarrow \quad d = \frac{1}{\sqrt{r}} \quad (5)$$

r: Regression coefficient, I: Illuminance
L: Luminous intensity
d: Distance from the light source

Eq. (5) shown above indicates that the regression coefficient r in the intelligent lighting system indicates an estimation of distance d from the light source (distance between the lighting and the illuminance sensor).

Thus, an experiment was conducted to verify the distances between lightings and illuminance sensors and their relation with regression coefficients. In the experiment, 15 neutral white fluorescent lamps (Panasonic FHP45EN) and 4 illuminance sensors were installed as shown by Fig.2, and between each lighting and each illuminance sensor, the distance and the regression coefficient were calculated.

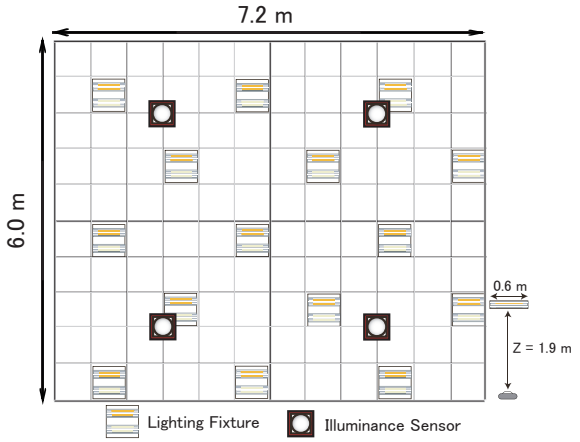

Fig. 2. Experimental environment to obtain regression coefficients

Fig.3 shows the distances between lightings and illuminance sensors and respective regression coefficients.

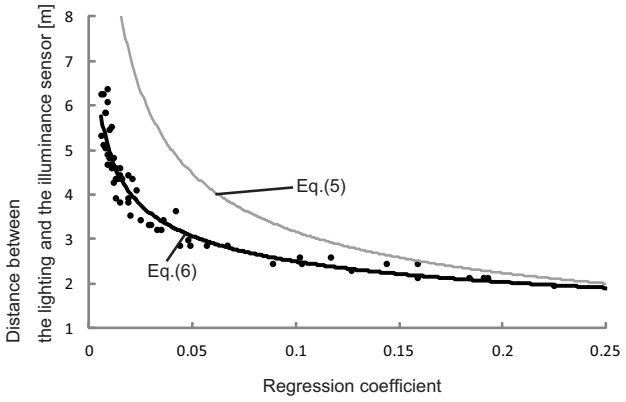

Fig. 3. Relation between the regression coefficient and distance

Fig.3 compares the regression coefficients obtained from the experiment were with the Eq. (5). The result indicates that when the distance between the lighting and illuminance sensor is shorter, the disparity is smaller; when the distance is larger, the disparity is greater. This is because Eq. (4) does not take account of the lighting fixture's radiation characteristics. Fig.4 shows the luminous intensity distribution curve curve for the fluorescent lamp (Panasonic FHP45EN) used in the experiment.

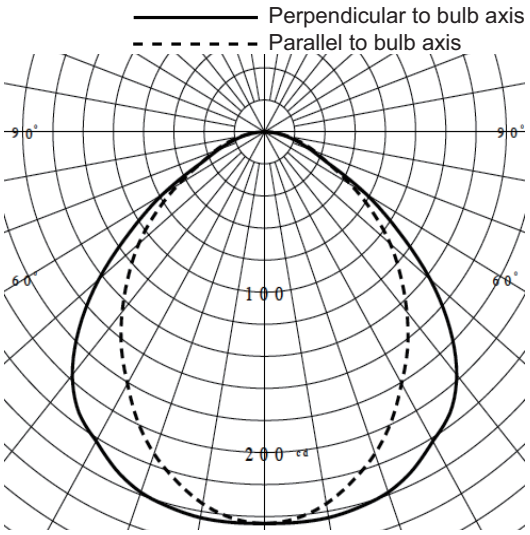

Fig. 4. Luminous intensity distribution curve(FHP45EN)

Luminous intensity distribution curve is a polar plot representing the luminous intensity as a function of angle about a light source. From Fig.4, one can see that the illuminance on the illuminated plane decrements more when the angle between the lighting fixture and the illuminated plane is larger. In the experimental results shown by Fig.3, the angle is larger when the distance between the lighting and the sensor is larger. Hence, the greater the distance is, the more largely the resulting regression coefficient falls below Eq. (5). Therefore, it is necessary to derive a model taking into account the lighting fixture's radiation characteristics.

In the proposed method, a mathematical model was derived, which estimates the distance based on the regression coefficient obtained through the experiment as shown by Fig.3 using the least square method. The derived mathematical model is shown by Eq. (6).

$$d = 1.8044 \times r^{-3.221} \tag{6}$$

r: Regression coefficient
d: Distance between the lighting and the illuminance sensor

Under this environment, the radiation characteristics of the lighting fixture is taken into account by using Eq. (6), to reduce the error in estimating the distance using the regression coefficient.

C. Estimating an Illuminance Sensor Position

Based on the method described in the section above, we can estimate the distance between a turned-on lighting and a relocated illuminance sensor. Based on the estimated distance, the position of the relocated illuminance sensor is estimated using Eq. (7) below.

$$d_i = \sqrt{(X - x_i)^2 + (Y - y_i)^2 + (Z - z_i)^2} \tag{7}$$

d_i: Distance between the turned-on lighting and the illuminance sensor
X, Y, Z: Position coordinates of the relocated illuminance sensor
x_i, y_i, z_i: Position coordinates of the turned-on lighting
i: Number of turned-on lightings

Now because the unknown values are the position coordinates (X, Y, Z) of the relocated illuminance sensor, a unique solution will be found by writing three or more equations. However, for a lighting that is turned off, it is impossible to estimate the distance because there is no way to calculate a regression coefficient concerning any illuminance sensor. Considering this, the system is designed to keep at least three lightings of relatively high influence levels always turned on per illuminance sensor to enable the estimation of position coordinates of relocated illuminance sensors.

Using the method described above, the position of a relocated illuminance sensor is estimated and three or more lights in its vicinity are turned on. This enables the system to calculate the regression coefficient for a lighting near the relocated illuminance sensor which had been turned off.

V. Operational Experiment

A. Overview of the Operational Experiment

To verify the effectiveness of the proposed method, an operational experiment was conducted for 30 minutes changing luminous intensity of the lighting in 2-second steps (900 steps). For the experiment, 15 lighting fixtures were installed as shown by Fig.5 to simulate a workplace with 3 users (using 3 illuminance sensors). For illuminance sensors A, B and C, the desired illuminance level was set at 300, 400 and 500 lx respectively. The lighting fixtures used were neutral white fluorescent lamps (Panasonic FHP45EN) which had a variable lighting luminous intensity range between a minimum of 30 % and a maximum of 100 %.

In the experiment, when the illuminance value is within the range between +6 % and -8 % of the desired level, the desired illuminance level is deemed to be achieved.

The operational experiment was conducted using the following two patterns to compare the system's performance with a conventional intelligent lighting system as well as to verify the energy saving effect of the new method.

- An operational experiment using our conventional lighting control algorithm (conventional method)
- An operational experiment using a control algorithm incorporating the proposed method (proposed method)

In the operational experiment, after 250 steps, the illuminance sensor A (at illuminance setting point A) is relocated to the new position shown by Fig.5. When an illuminance sensor relocation is detected using the proposed method, the relocated sensor position is estimated using illuminance and luminous intensity data over 60 steps.

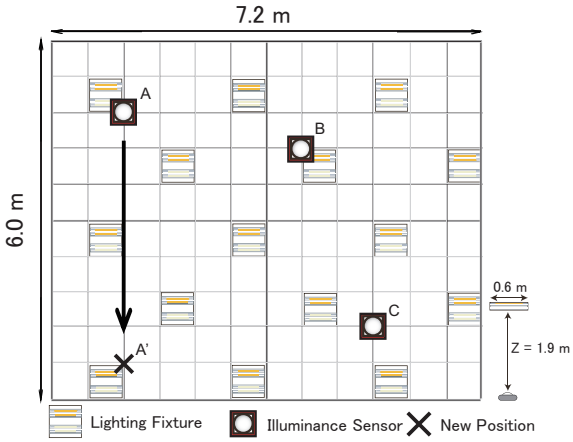

Fig. 5. Experimental environment

B. EXPERIMENT RESULTS AND DISCUSSIONS

We checked whether the system realized the desired illuminance level at each illuminance setting point in each of the conventional method and the proposed method. Fig.6 shows the historical illuminance levels from the conventional method and Fig.7 shows those from the proposed method.

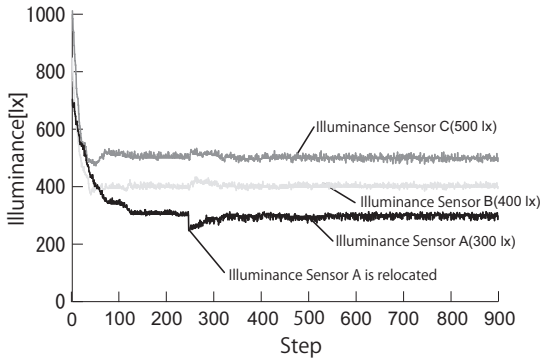

Fig. 6. History of the illuminance data (conventional method)

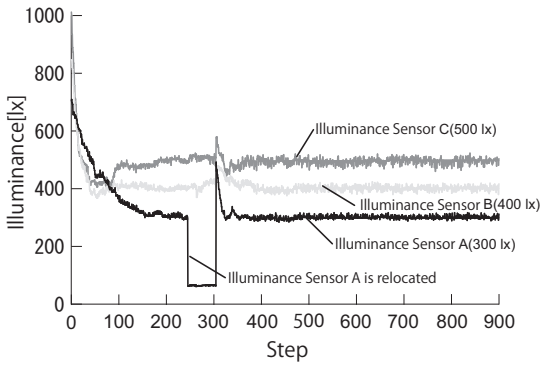

Fig. 7. History of the illuminance data (proposed method)

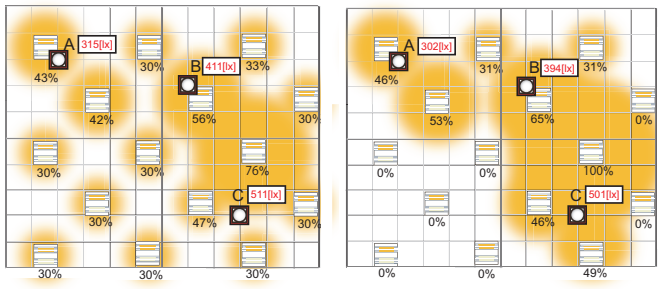
Fig.6 and Fig.7 show that in both methods the system realized desired illuminance level at each illuminance setting point. It is shown also that both methods successfully coped with the relocation of illuminance sensor A.

Next, to verify the energy saving effect, the status of each lightings before the sensor relocation at the point of 200th step is shown in Fig.8.



(a)Conventional method (b)Proposed method

Fig. 8. Status of lightings (at the point of 200th step)

From Fig.8-(a) showing the status of lightings in the conventional method, we can see that lightings near each illuminance setting point are turned on at a high luminous intensity level while those distant from an illuminance setting point are turned on at a low luminous intensity level. To cope with sensor relocations, however, all lightings need to be kept on at least at a low luminous intensity level. Meanwhile, from Fig.8-(b) showing the status of lightings in the proposed method, we can see that the lightings near each illuminance setting point are turned on at a high luminous intensity level while those distant from an illuminance setting point are turned off.

Then illuminance sensor A is relocated at the point of 250th step. In the proposed method, after detecting the relocation, the system calculates influence levels concerning turned-on lightings to estimate the new position. Fig.9 shows the estimated and actual position coordinates of relocated illuminance sensor A.

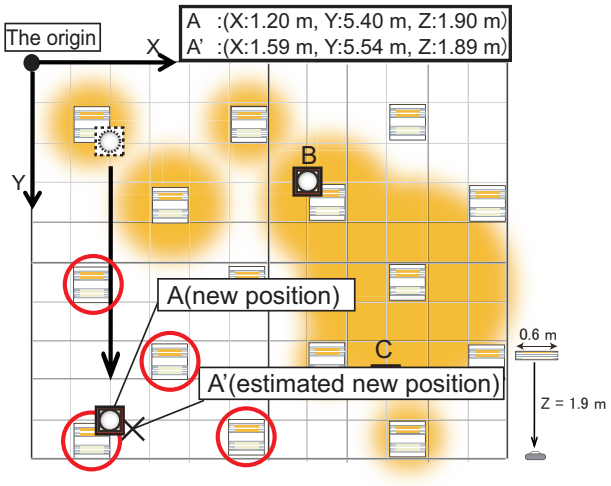


Fig. 9. Status of lightings at the point of 310th step (proposed method)

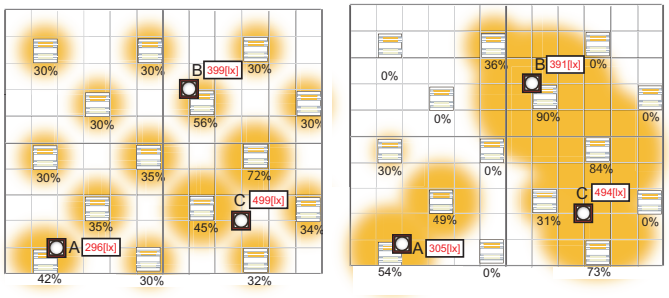
Fig.9 shows that the proposed method is able to estimate the position of illuminance sensor A after relocation. This means that by turning on the four lightings (lightings in circles shown in Fig.9 closest to the estimated sensor position, the regression coefficients for the lightings presumed to be most influential can be calculated.

Finally, Fig.10 shows the status of lightings after sensor relocation (at the point of 500th step).



(a)Conventional method (b)Proposed method

Fig. 10. Status of each lightings (at the point of 500th step)

Fig.10-(a) shows that in the conventional method, the energy consumption levels of some lightings were lowered after detecting a sensor relocation. But anyway, even lightings of little influence were not turned off but kept on. On the other hand, in the proposed method shown by Fig.10-(b), those lightings expected to have a high influence level are turned on and regression coefficients are calculated. Then based on the calculated regression coefficients, lightings of little influence are turned off to realize a greater energy saving effect than in the conventional method.

From the results of the experiment, it has been demonstrated that the proposed method can also realize the illuminance levels as desired by users while saving energy consumption.

C. Comparison of Power Consumption Results

This section compares the power consumption by the lightings between the conventional method and the proposed method. Fig.11 shows the historical records of power consumption by the lightings controlled by the conventional method and the proposed method.

From Fig.11, we can see that the proposed method consumes about 30 % less power than the conventional method. As a result, it has been demonstrated that the proposed method realizes a performance equivalent to the conventional method while further reducing energy consumption.

VI. CONCLUSION

Ever since 2009, we have been conducting verification experiments for our intelligent lighting systems at several offices in Fukuoka and Tokyo. Since most of these offices employ a fixed desk system, we introduced an algorithm which turns off lightings of smaller influence levels assuming no user relocations. However, in offices where users often move, once some lightings are turned off, it becomes impossible

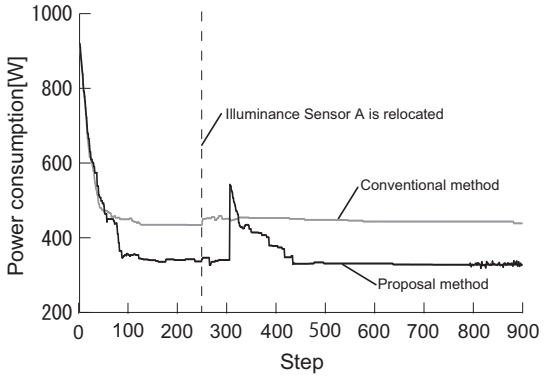


Fig. 11. Historical power consumption by two methods

to measure the levels of influence of those lightings on illuminance sensors.

To solve this problem, we have proposed in this study a new lighting control algorithm which can cope with illuminance sensor relocations by estimating sensor positions using data from turned-on lightings. To verify the effectiveness of the proposed method, an operational experiment was conducted using 15 lighting fixtures and assuming 3 users simulating a real office environment. The experiment demonstrated that the proposed system realizes a performance equivalent to the conventional intelligent lighting system while reducing power consumption.

Abstract— *We are going to investigate and design a healthcare navigation system that consists of sensor devices for human's vital sign, a mobile terminal for transferring the vital data to the cloud, and a cloud computing environment for intelligential processing of the vital data. In this paper, we present a tool for the mobile terminal, i.e. a smartphone, which displays user's biological stress levels. Although the tool is a part of our healthcare navigation system, it does not require the computation resource of the cloud because the stress levels, LF/HF, are enough computable on the processor of the current smartphone in real time. LF/HF is an index of sympathetic nervous activity calculated with the heart rate data obtained from heartbeat sensors. The LF/HF values are displayed in a form of bar graph at user's current location on the Google map of the smartphone. The location information is easily obtained from the GPS of the smartphone. Using the tool, the user can see his/her current stress levels as bar graph on the Google map in real-time. Namely, the tool provides users with their spatiotemporal biological stress levels in real time.*

Keywords: RR interval, WHS-1, smartphone, googlemap, LF/HF

1. Introduction

Over the past 20 years, the CPU performance, the HDD capacity, and the internet bandwidth have improved 1,000 times, 20,000 times, and 15,000 time, respectively. As a result, cloud computing is available among the world. With the rapid expansion of the computation resource, the idea of life computing is aborning. Unlike existing scientific computing, life computing supports our human life. The demand is exceeding the demand of scientific and engineering calculations. We are just going to investigate and design a healthcare navigation system. We believe that this healthcare system will be a major field of life computing. Healthcare computing consists of sensor devices for human's vital sign, a mobile terminal for transferring the vital data to the cloud, and a cloud computing environment for intelligential processing of the vital data. Then this system sends appropriate and useful recommendation about healthcare to the user. In this healthcare navigation system, a mobile terminal gets the vital data from sensor devices to transfer them with applying appropriate pre-processes to the cloud. It is sometimes possible to directly provide the user with information about his/her health condition at the mobile terminal without using computation resource of the cloud. In this paper, we develop a tool for a mobile terminal, i.e. a smartphone, which displays LF/HF that is a method to measure stress levels in real time as a part of our healthcare navigation system. The LF/HF values are displayed in a form of bar graph at user's current location on the Google map of the smartphone. Frequency analysis is applied to time series data for heart rate variability. Its power spectral includes LF that is low frequency and HF that is high frequency. The ratio of LF to HF is used for an index of stress levels (sympathetic nervous activity). Extreme stress causes various physical harms. It is helpful for us to reduce stress for spending healthy life. The tool does not require any computation resource of the cloud because LF/HF are enough computable on the current smartphone in real time. The location information is easily obtained from the GPS of the smartphone.

Instant Heart Rate produced by Azumio[1] and Period tracker[2] produced by GP Apps are examples of existing healthcare services. The former can measure heart rate by using camera equipped with most smartphones. The application measures pulse waves by pressing the camera with a finger. When user inputs the start date of menstruation, the latter can predict the next menstruation and next ovulation date. In these services, user consciously provides his/her vital data for these services. These services influence user's daily life owing to the device size. A healthcare system needs to measure at all times for predicting user's condition accurately. However, the size of the heart rate sensor which is used in this paper is 40.8*37.0*8.9 cubic millimeter and weight is only 13 grams including a battery cell. This sensor can be put on user's body directly at all times. User only has to put on the heart rate sensor to send vital data. This sensor does not influence user's daily life. The tool which we present here notifies user of his/her stress levels without sending user's vital data to the cloud.

In the case that just time and LF/HF are displayed, it is difficult to predict what situations cause stress. Not only time and LF/HF but also other information is required to solve

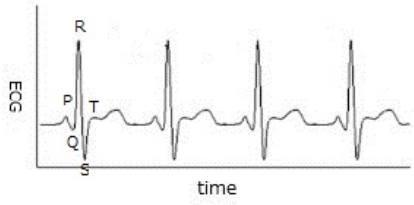

Fig. 1: Heart rate data

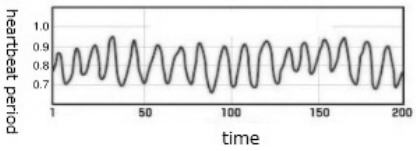

Fig. 2: Time series data of heart rate variability

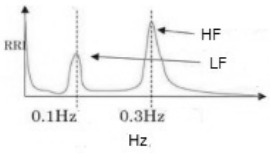

Fig. 3: Frequency analysis

this problem. One of the factors that give stress is location information. Getting stressed or relaxed may depends on the surrounding. The action at the notable time can be predicted from the location information. In this tool, the association of the location information and LF/HF can be predicted in what situations cause stress. It helps to reduce stress for spending healthy life.

The rest of the paper organized as follows. In section 2, LF/HF which is an index of sympathetic nervous activity is described. In section 3, we explain the requirement specification and the implementation of the tool. In section 4, we show some examples of the execution of the tool.

2. Heart rate data

This section explains the heart rate sensor used to take the heart beat and the calculation method for LF/HF as the index of the stress used in this paper.

2.1 Calculation of LF/HF

As shown in Fig.1, various shapes of waves such as P, Q, R, S, and T waves are included in each heart rate. The RR interval is an interval of R waves that is the biggest peak wave in each heart rate. It is known that the RR interval is synonymous with the heart rate, and always changes constantly.

Fig. 4: heartbeat sensor

As for the evaluation of the autonomic nervous function, the index of the frequency domain obtained by the spectral analysis is used [3][4][5]. Figure 2 shows time series data of heart rate variability. The horizontal axis and the vertical axis are time and RR interval, respectively. Figure 3 shows frequency analysis of time series data of heart rate variability. Its power spectral includes LF which is low frequency and HF which is high frequency. LF is related to the change of blood pressure and influenced by both parasympathetic and sympathetic nervous system. HF is related to breathing variation and influenced by parasympathetic nervous system. The sympathetic nervous system promotes the shrinking of the blood vessel, the increase of the heart rate, and the reaction of the muscular tension etc., so that it reacts to the change in the situation quickly, and the stress like uneasiness, fear, and anger, etc. has been received. Parasympathetic nervous system promotes responses which include the decrease of the heart rate, decreased blood pressure, and muscle relaxation, etc. Sleeping and getting relaxed, parasympathetic nervous system works.

The index of the sympathetic nervous system is calculated with the ratio of LF to HF. HF decreases while LF appears when a stress is received. When parasympathetic nervous system becomes active, HF increase. Therefore, getting stress and relaxed make LF/HF large and small, respectively.

LF/HF is calculated with time series data of heart rate variability. The time series data of heart rate variability is applied to linear interpolation or spline interpolation to get equal interval samples. Power spectrum of sampling data is calculated using Fourier transform or an autoregressive model. LF and HF are set to area of 0.05Hz - 0.15Hz and 0.15Hz - 0.40Hz, respectively.

2.2 Heart rate sensor

Figure 4 shows WHS-1 manufactured by union tool corporation [6] that is the heart rate sensor we use. This sensor detects and calculates the RR interval. It is possible to use it without interfering in user's daily life by putting directly on the skin with an electrode pad because the size is so small (40.8*37.0*8.9mm), and the weight is very light (only 13 grams) including a battery cell. WHS-1 also includes an

acceleration sensor and a temperature sensor as well as the heart rate sensor so that it detects the change of user's body movement and measures his/her body surface temperature.

WHS-1 supports two types of data transmissions. One method is sending data to a PC using wireless communication. The other method is sending data to a PC using a flash memory. In the case of wireless communication, it can also output the heart rate waveform instead of the RR interval.

In the case of outputting RR interval, heart rate signal, which are measured by an electrode attached to the sensor, is sampled at 1,000Hz. Then RR interval is calculated by predicting the interval between R waves which are found in the heart rate waveform. A flash memory with16MB saves almost one week RR intervals data.

3. Displaying LF/HF in real time

In our future healthcare navigation system, vital data is transferred to the cloud via a smartphone. A smartphone can effectively utilize the information from the sensor device. In this paper, LF/HF is calculated with the vital data, and GPS equipped with the smartphone is used. We develop a tool that displays LF/HF values on the map at the user's location in real time. In this section, we explain the requirement specification and the implementation issues of the tool.

3.1 Requirement specification

The stress might be received in unconsciousness to cause deconditioning as a result while we learn the condition of our daily life by knowing the changing of LF/HF values. However, this is just an understanding when to have caused the stress and the relaxation. Since it is difficult to know which situation has caused the stress, not only time but also other information are necessary. By using time and other information, we can predict the factors which bring down the stress. As such extra information, location information is easily given with GPS, for example. The LF/HF value and the location information help us predict our condition at that time. Then the relation between our stress and our daily life is clarified. In the proposed tool, the LF/HF value should be displayed on the map at user's current location.

Figure 5 shows the correlation of each function. LF/HF value is calculated and displayed by numerical characters every 10 seconds. Moreover, the value is shown with a bar graph at user's present location on the Google map of a smartphone every 60 seconds. When user swipes on the screen, the map works with the swipe. When user touches on the screen, a zoom item is displayed and the map can be zoomed in or out. When the menu button is pushed, the MyLocation item, the Reset item, and the On/Off item are displayed. When the MyLocation item is selected, the present location is displayed at the center of the screen. When the Reset item is selected, the LF/HF bar graph displayed on the screen is deleted. When the On/Off item is selected, the bar graph is displayed or hidden on the screen. The specification to achieve the above-mentioned functions is as follows.

1) The LF/HF value is displayed in digits every 10 seconds.
2) The LF/HF bar graph is put at the present location on the Google map every 60 seconds.
3) User's movement information on speed, distance, altitude, and traveling direction, etc. are displayed.
4) Swipe of the map
5) Zoom of the map
6) In the case of the expanded map, it switches from the bar graph to the label.
7) The present location is obtained.
8) The LF/HF value is display or hidden.
9) The displayed LF/HF value can be deleted.
10) The mobile terminal and the sensor are communicated with Bluetooth.

In function 1), the LF/HF value that presents stress level is displayed and updated every 10 seconds so that user can confirm the LF/HF every 10 seconds.

In function 2), user can confirm the change of his/her stress level by looking at the displayed LF/HF bar graph every 60 seconds. The more heart rate data, the more accurate LF/HF is calculated. When the LF/HF value is displayed as numerical characters, it is difficult to confirm the change of the LF/HF value viscerally. To solve this problem, a form of bar graph is adopted. A series of bars along user's move makes the user confirm the change of the LF/HF value viscerally. User can understand what situation causes a stress by confirming the change of the LF/HF value which is drawn at user's current location on the Google map at that time.

It is known that exercise influences LF/HF. So the relation between exercise and LF/HF is effectively predictable by giving the information of user's exercise. In function 3), exercise information such as speed, distance, elevation and direction are displayed.

In function 4), when user swipes the screen, the Google map moves accordingly. The user can see the LF/HF value of any location by using swipe.

In function 5), the Google map can be zoomed in or out. When the wide range is displayed, the change of the LF/HF value can be roughly confirmed. On the other hand, when a small range is displayed, the relation between the place and the LF/HF value can be observed in detail. When two or more bar charts are displayed by the large scale, the LF/HF value is not confirmed easily. Then, in function 6), it switches to the label from the bar chart to the integer portion of the LF/HF value.

In function 7), user's current location is put at the center of the screen using the GPS of the smartphone so that he/she confirms his/her location any time.

In function 8), user can display or delete the LF/HF bar graph/numeric characters. When he/she wants to see just the

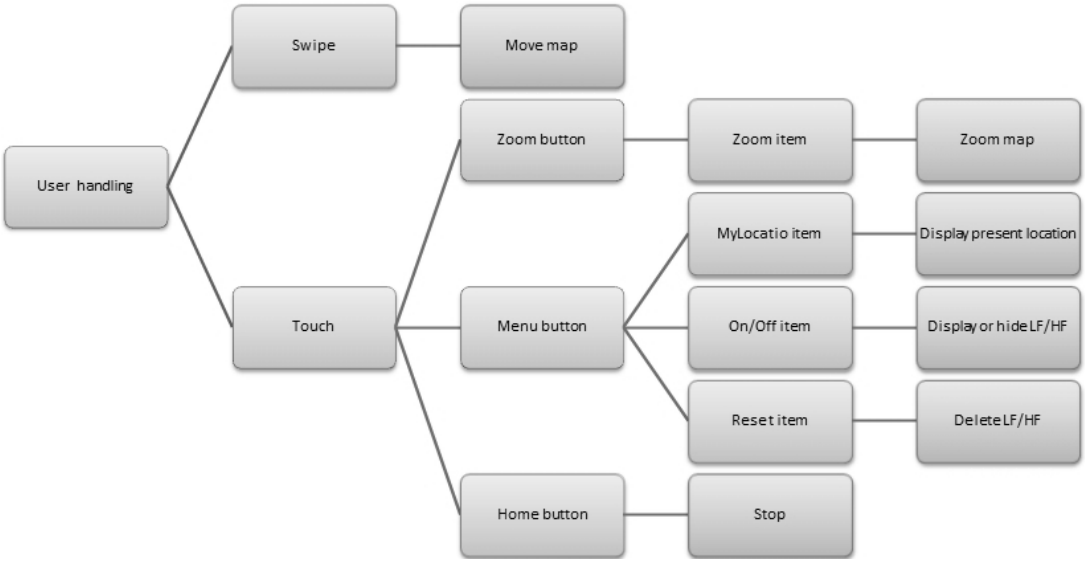

Fig. 5: correlation of each functions

Google map, the display of the LF/HF value may make the screen hard to see.

Function 9) is used for deleting the record of the LF/HF value data. When a lot of the LF/HF value data is recorded, various functions might not be able to be operated smoothly. Function 9) is used to prevent such cases.

The tool we present in this paper is executed on a mobile terminal emulator on a PC, and does not use the Bluetooth communication. Since this is a hardware restriction, we will easily support the Bluetooth communication very soon using a real mobile terminal.

3.2 Implementation

When our tool is invoked, user's current location is displayed by using GPS on the Google map. Then, it starts reading the heart rate data from WHS-1. The LF/HF value is displayed and updated by digit in the upper part of the screen every 10 seconds. In addition, the current location is displayed at the center of the screen, and user's moving information of speed, distance, altitude, and direction are displayed, too. The LF/HF bar graph is put on the Google map to be updated with an interval of 60 seconds. The acquisition of the current location, the calculation of LF/HF, and the explanation of GUI are presented as follows.

3.2.1 Acquisition of user's current location

The GPS of the smartphone is used to acquire user's (namely smartpone's) current location. The application makes use of Google Map API [7]. Google Map API provides Maps API and Maps Javascript API that are widely used for smartphones. In this paper, we adopt Maps API because Maps API Key is necessary to control the Google Map. When the location information is required, an API called Location-based Service that enhances GPS functions is used in smartphones. The GPS acquires the location information by way of LocationManager. The getSystemService method obtains LocationManager, and begins to acquire the location information of latitude, longitude, altitude, direction, and speed, etc. The update notification for the location information is set by the requestLocationUpdate method, and sent to the LocationListener interface. Function 7) is implemented with these APIs.

For the requirement specification regarding to the location information (Function 3)), an object of the Ctiteria class is sent to the Provider as a parameter. The distanceBetween method calculates the distance from the starting point to the current point.

3.2.2 LF/HF calculation implementation

In this subsection, we explain the implementation issues for calculating LF/HF. X and Y are provided for time and the RR interval, respectively. Then, a spline interpolation is applied to the sampling data with an equal interval. The power spectrum is calculated from the sampling data with the equal interval by a Fourier transform. The areas of LF and HF are 0.05Hz - 0.15Hz and 0.15Hz - 0.40Hz, respectively.

Heart rate data is sent from WHS-1 every 3 heart beats. Then the received data is stored in a circular buffer, which is implemented with an array and modulo operations for the array index. Using the circular buffer, the data which become unnecessary is overwritten with new data to avoid consumption of memory. As is easily expected, the more heart rate data, the more accurate LF/HF is calculated. We investigate the tradeoff between the circular buffer size and

the LF/HF accuracy to decide the buffer size for 60 seconds data. The initial LF/HF is calculated with the data of first 60 seconds. After the first calculation, LF/HF is calculated every 10 seconds using the last 60 seconds data, which occupies the circular buffer. Each new 10 seconds data is overwritten to the oldest 10 seconds data.

In this way, LF/HF is obtained every 10 seconds, so function 1 is satisfied. In addition, LF/HF is also obtained every 60 seconds, so Function 2) is satisfied.

3.2.3 GUI

In the screen of the smartphone, the information of LF/HF, speed, distance, elevation and direction is displayed on the upper part. Since the information is updated every 10 seconds, Function 3) is satisfied. The Google map is displayed below the information area. The MyOverlay class is used to draw a bar graph of LF/HF at the current location on the Google map, and Function 2) is satisfied.

The Google map moves at the same time as user swipes. When user swipes, the touching point moves with user's finger. User can move the Google map to confirm the LF/HF value anywhere. Namely, Function 4) is achieved.

The SetBuiltInZoomControls method is used for the expansion and reduction of the Google map to satisfy Functions 5) and 6). The LF/HF value is expressed as digit label or bar graph depending on the scale of the Google map. The digit label is the current LF/HF value while the length of the bar graph is the LF/HF value at that point. In the case LF/HF is expressed as bar graph on the small scale of the Google map, the LF/HF value is not confirmed easily. Moreover, in the digit label on the large scale map, the change of the LF/HF values is not confirmed easily. The onZoomListener method is needed to solve this problem.

The onCreateOptionsMenue method is used for setting menu buttons equipped with smartphones. When the menu button is pushed, menu items which include MyLocation, Reset and On/Off are displayed. When user select an item, the Item.getItemId method judges which item is selected. The selected item is processed by the onOptionsItemSelected method. When the Mylocation item is selected, the current location is obtained to be displayed in the center of the screen. When the Reset item is selected, the record of the LF/HF values is deleted. When the On/Off item is selected, the LF/HF value is displayed or hidden. In this way, Functions 7)-9) are satisfied.

4. Example of behavior

In this section, we explain the performance of our tool that is an Android application. The tool is developed with Java SE Development Kit, Android SDK, and Eclipse. Java SE Development Kit is used for developing Java applications. Android SDK is for the development of Android applications by Java. Eclipce is an integrated development environment. The heart rate data is obtained from WHS-1.

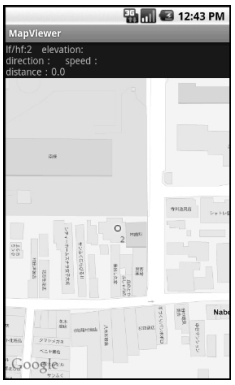

Fig. 6: The screen of the tool at 60 seconds after the invocation

(a)initial state (b)result

Fig. 7: swipe

In this paper, we use heart rate data which is preliminarily obtained from heart rate sensor and display the LF/HF bar graph at arbitrary location. We believe it is enough to investigate whether Function 1)-9) are achieved.

Invoking the tool, the screen after 60 seconds is shown in Fig. 6. Each LF/HF is calculated and updated every 60 seconds. Since the LF/HF bar graph is put at current location, user can predict the correlation between stress and location information. The LF/HF value shown in Fig. 6 is calculated with the data of the initial 0-60 seconds. In the upper part of the screen, LF/HF, altitude, speed, direction, and moving distance are displayed and updated every 10 seconds.

Figure 7 shows the change of the screen by swipe. Figure 7(a) is the initial state. When the screen is swiped from right to left, the screen moves left according to the swipe. Figure 7(b) shows the result of the swipe. Using swipe, user can confirm his/her LF/HF vale at any location.

In Fig. 8, when user touches the screen, the zoom item is displayed. Figure 8(a) is the initial state. When the plus icon in the zoom item is selected, the Google map is zoomed in. Figure 8(b) is the zoomed screen by the plus icon. On the other hand, when the minus icon in the zoom item is

(a)initial state

(b)reesult

Fig. 11: Reset button

selected, the Google map is zoomed out. The LF/HF values are shown as bar graphs on figure 8(a) while the LF/HF values are shown as the digit label as on figure 8(b). The toggle for the bar graph and the digit label is the zoom scale of the Google map. The LF/HF bar graph changes to the LF/HF digit label when the zoom scale exceeds the pre-defined value. The length of the bar graph presents the LF/HF value at that point. On the small Google map, two or more bar graphs represent the change of the LF/HF values viscerally. User can understand where his/her stress arises. On the other hand, the digit label presents the integer part of the LF/HF value at that time. On the large Google map, user's past and present locations are displayed in detail. The user understands the relation between the LF/HF value and his/her moving path. Therefore, the switch of the bar graph and the digit label is useful to understand what situation causes his/her stress.

Figure 9 shows the screen applied by the MyLocation item. When the menu button of the smartphone is pushed, the menu item is displayed at the bottom of the screen as shown in Fig.9(a). In the menu item, the MyLocation item, the On/Off item, and the Reset item are included. When the MyLocation item is selected, the current location is acquired to be displayed at the center of the screen. In Fig.9(a), the current location is not displayed. When the MyLocation item is chosen, the current location is displayed at the center of the screen as shown in Fig.9(b). User can confirm his/her current location at any time.

Figure 10 shows the screens where the On/Off item is used. When the On/Off item in the menu item is selected, the LF/HF bar graphs are displayed or hidden. Fig.10(a) shows the screen with the LF/HF bar graphs. Using the On/Off item, the LF/HF bar graphs are hidden as shown in Fig.10(b), and user can take a detail look at the Google map without the LF/HF bar graphs. When the LF/HF bar graphs are hidden, the LF/HF value is calculated every 10 seconds. Using the On/Off item, the LF/HF bar graphs appear again.

Figure 11 shows the screens where the Reset item used. When the Reset item is selected, the LF/HF bar graphs as shown in Fig.11(a) are deleted. Then, the LF/HF bar graphs begin to be displayed. When a lot of LF/HF bar graphs are displayed, various functions might not be able to be operated smoothly. This item is used to avoid this problem.

5. Conclusions

In our ongoing healthcare navigation system, vital data from sensor devices are sent to a portable terminal such as smartphone to process the data including error correction. The processed vital data are sent to a cloud for intelligent processes. In this paper, we showed that it is possible to show some of user's conditions to the user without cloud resource, but with just a smartphone.

In this paper, we presented a tool for a mobile terminal that displays the LF/HF value in real time as an index of user's stress level. The LF/HF value is calculated by using heart rate data obtained from a heart rate sensor WHS-1, and displayed at user's current location in the Google map. Some physical conditions cause various slumps by an excessive stress. User can understand what situation causes his/her stress by using the location information and the LF/HF values. When the source of stress is detectable, user can easily improve his/her daily life. It leads to the environment improvement to find the reason of stress brought on by location such as noise.

In this tool, the LF/HF value is immediately calculated every 10 seconds. To confirm the change, the LF/HF bar graph is drawn on the Google map. The information of speed, distance, elevation and direction is displayed to predict the relation between the exercise and the LF/HF value effectively. The Google map can be zoomed in/out, and swiped freely. The LF/HF value is shown in a form of bar graph to understand the relation between user's location and LF/HF value in the small scale Google map, and the LF/HF value is shown in the digit label in the large scale. The user can confirm his/her current location at any time. When user wants to look at the Google map, the LF/HF value can be hidden. To operate various functions smoothly, the LF/HF value record can be deleted. In this paper, we develop a prototype to show the actual execution.

For our future work, it is necessary to include other information such as user's acceleration and some environment information such as weather. The information helps user predict his/her situation more precisely. Another method to calculate the stress level with electro-oculogram is needed to improve the accuracy of the stress level.

Abstract— *In this paper, we propose two methods to train students' spatial reasoning capacity using AR (Augmented Reality). The first method supports students for rotating spatial objects more easily with two AR markers. One marker is used for questions, on which several blocks and a landmark (with a shape of a chick) are displayed. The other marker is used for answers, on which blocks are moved freely. The layout of the blocks toward the chick is selected on the marker. The second method includes limitation of rotation on the marker using some Arduino based hardware. The second method supports students for rotating spatial objects partially. To validate the effect of the trained and resultant spatial reasoning capacity, we perform an experiment using the first method. The analysis results explain the spatial object recognition accuracy increases using the AR learning. To validate the effect of rotation angles, we perform other experiments using the second method. The analysis result shows the rotation angle of sixty degrees is the best for the training of spatial reasoning capacity.*

Keywords: Augmented Reality, Spatial reasoning capacity, Mental rotation, Arduino

1. Introduction

The spatial reasoning capacity is an ability to recognize objects in three-dimensional space. Objects' locations and conditions, which are shapes, angles and sizes, are recognized quickly and accurately by this capacity. Even non-existent objects are always imaged using the spatial reasoning capacity, too. Visual images can be controlled by cognitive operations in the same way for real objects.

Compulsory education includes the learning of spatial objects in some ages although the learning of the spatial objects has been decreased according to lighter curriculum promoted by the Ministry of Education in Japan. In the second grade of elementary school, children learn spatial objects for the first time as compulsory education [1]. First, children learn the basic objects, which are cubes and rectangular solids. These objects are shown in learning materials such as textbooks with a plane surface. Consequently, if they do not have spatial reasoning capacity so much, it is difficult to learn abecedarian arithmetic. In such case, they cannot understand spatial objects in junior high school. Moreover, selected specific general planes and equations for lines are given in mathematics of high school regardless of their intelligibility of spatial objects.

Children in old days mainly used to play with three-dimensional objects, such as building blocks, cat's cradle, puzzle links and plamodels. On the other hand, children in nowadays mainly plays in a plane, i.e. video games, rather than in the three-dimensional world. Spatial reasoning capacity is improved by strong awareness in the three-dimension space, for example, playing with three-dimensional objects. Opportunities of spatial reasoning learning have decreased in terms of play and education in general. Hence, special education for spatial reasoning capacity is needed in childhood.

In this paper, we propose some methods to train students' spatial reasoning capacity with using AR. In the AR environment, virtual objects are displayed even in floating and can be moved freely. Students with low spatial reasoning capacity can effectively learn by rotating an AR marker. To validate the effects of the trained and resultant spatial reasoning capacity, we perform some experiments and analyze them to model the learning phases.

The rest of the paper is organized as follows. In section 2, we propose two methods to train students' spatial reasoning capacity using AR. In section 3, the effect of the trained and resultant spatial reasoning capacity is validated. In section 4, the effect of rotation angle to the improved spatial reasoning capacity is validated to be represented by a model expression.

2. Rotating blocks using AR

In this section, two methods to train spatial reasoning capacity are proposed. These methods support easy spatial object rotation for improving spatial reasoning capacity. We first explain the construction of an AR supporting environment. Then, we propose the first method to train spatial reasoning capacity and the second method with physical limitation of rotation.

2.1 Construction of an AR supporting environment

In this paper, we adopt AR to provide free spatial objects movement with displaying the corresponding virtual objects for students. In the AR space, the acquisition of virtual object location is generally performed by the following two ways.

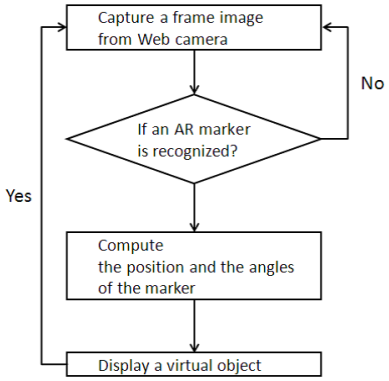

Fig. 1: Construction of the AR environment

One is by using GPS (Global Positioning System). The other way uses an AR marker on which an asymmetry figure is printed. AR markers are freely movable, and virtual objects on the AR markers are redisplayed according to their movement. Since we are interested in training spatial reasoning capacity, we use the marker based AR that provides the free movement of virtual objects for students.

The marker based AR supporting environment for spatial reasoning capacity is constructed as shown in Fig.1. First, a frame image of video stream from a Web camera is captured to be displayed. Next, an AR marker is recognized in the captured image. Then, the position and the angles of the marker are computed. Finally, a pre-defined virtual object is displayed at the position with the angles. The AR marker receives events from user via keyboard to change the position and the angles of the virtual object.

2.2 Rotating virtual objects in the marker based AR supporting environment

In this subsection, we present a method to train students' spatial reasoning capacity with rotating virtual blocks in the above AR environment. This method requires two AR markers: for questions and for answers. On the question marker, several blocks, a landmark (with a shape of a chick) and box frames are displayed. Figure 2 shows an example where two blocks and a landmark are displayed as a question. Up to 2^3 blocks can be placed in the box frame. The number of blocks is selected using the keyboard. The layout of blocks is changeable in random. The landmark can be placed on the four directions. The box frame is always displayed. The possible number of questions is $2^8 * 4 = 1,024$.

On the answer marker, numbers of 1 to 4 are written. First, only the box frame is visible on the answer marker. A block is placed on the answer marker according to the keyboard input. The keyboard input is chosen from key 1 to 4. When a key is pressed, a block is placed on the same number of the answer marker. Figure 3 shows examples of the key entries. When key 1 is pressed once, a block is displayed on

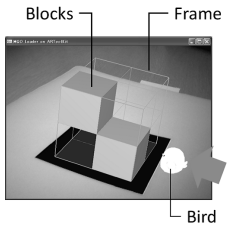

Fig. 2: A question marker

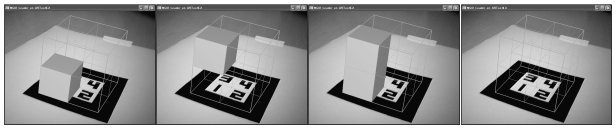


(a) (b) (c) (d)

Fig. 3: Block placement ((a):One Click, (b):Two Clicks, (c):Three Clicks, (d):Four Clicks)

(a) Correct (b) Incorrect

Fig. 4: Answer markers

the bottom as shown in Fig.3(a). When the key is pressed twice, the block moves up as shown in Fig.3(b). When the key is pressed three times, two blocks are displayed on the bottom and the top as shown in Fig.3(c). When the key is pressed four times, the two blocks disappears and the key entries are canceled as shown in Fig.3(d).

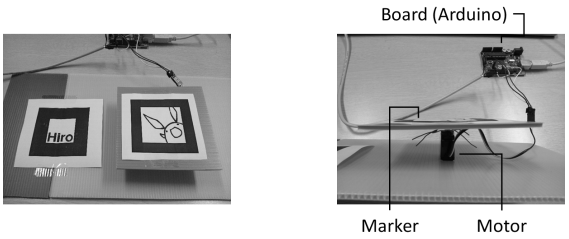
Figure 4 shows two examples of answers. The layout of the blocks toward the landmark is selected on the answer marker. The correct and the incorrect layouts of blocks are Fig.4(a) and (b), respectively. When the correct layout is given, the color of the displayed blocks is changed.

These blocks move synchronously with the marker. This method is applied to varous rotations of blocks. When a given question is hard to be solved, the marker can be rotated physically with the displayed blocks so that the question becomes easier.

2.3 Improved version of the AR environment

The method described in subsection 2.2 does not take the rotation angle of the AR marker in account, and blocks can be observed from any direction. In this subsection, we improve the first method so that it provides analysis functions for the relationship between the angle and the learning efficiency of students.

The improvement to the AR environment is given by



(a) Top view (b) Side view

Fig. 5: Views of AR markers installed with the moter

restricting the rotation of the AR marker supported by some hardware module. The hardware module consists of a fixed board (a plastic cardboard), a servo motor RB-001 and an Arduino Uno [3] based substrate. Arduino Uno is used as an A/D converter, which controls the servo motor, and is connected to the host PC via USB interface. Figure 5 shows an answer marker and a question marker installed with the motor. Figure 5(a) and 5(b) show the top and the side view, respectively.

We show the procedure to control the question marker.

Step-1) Power down the motor
Step-2) Compute the angle of the question marker
Step-3) When the angle of the marker does not reach to a given threshold, go back to Step-2)
Step-4) Start serial communication
Step-5) Power up the motor
Step-6) Push back the marker
Step-7) Power down the motor and go back to Step-2)

In Step-1), the question marker can be rotated freely since the motor is off. In Step-2), to compute the angle of the marker, we get the marker coordinate (X_m, Y_m, Z_m) and the camera coordinate (X_c, Y_c, Z_c). The two coordinates are expressed as

$$\begin{bmatrix} X_c \\ Y_c \\ Z_c \\ 1 \end{bmatrix} = \begin{bmatrix} r_1 & r_2 & r_3 & t_x \\ r_4 & r_5 & r_6 & t_y \\ r_7 & r_8 & r_9 & t_z \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} X_m \\ Y_m \\ Z_m \\ 1 \end{bmatrix}, \quad (1)$$

where t_x, t_y and t_z are translation elements. $[r_1, r_4, r_7]^\top$, $[r_2, r_5, r_8]^\top$ and $[r_3, r_6, r_9]^\top$ mean directional vectors of x-, y- and z-axis, respectively. Eulerian angles are computed with the directional vectors to be used for the marker angle. In Step-3), the marker angle is compared with a given threshold, which restricts the rotation of markers. When the marker angle reaches to the threshold, serial communication between the host PC and Arduino via USB is started in Step-4). At this point, Arduino is notified of the marker angle violation. So it turns on the motor in Step-5), and controls the motor so that the marker angle does not exceed the threshold in Step-6). When the marker angle becomes less than the threshold, Arduino turns off the motor and wait for the next marker angle violation in Step-7).

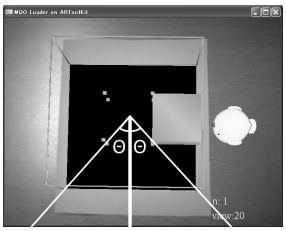


Fig. 6: A view of the angle limitation for a question marker

Figure 6 shows a view of the angle limitation for a question marker. The location of the landmark is set to the right direction of the marker unlike in subsection 2.2. The angle limitation is defined as θ ($0 \leqq \theta \leqq 90$).

3. An experiment to validate the effect of the AR learning

To validate the effect of the trained and resultant spatial reasoning capacity, we perform an experiment using the method described in subsection 2.2. The method is implemented with ARToolKit [4] to provide an AR space. Objects in the AR space are displayed by using OpenGL [5].

According to Piaget's stage of cognitive development [6], four cognitive stages, which are a sensorimotor stage, a pre-operational stage, a concrete operational stage and a formal operational stage, are observed. The sensorimotor stage is the period of zero to two years old, where a hidden object can be recognized and the permanence of an object is acquired. The pre-operational stage is the period of two to seven years old, where limited intelligence is developed to symbolize objects so that make-believe games are played. On the other hand, thinking is done without logic. The concrete operational stage is the period of seven to twelve years old, where considerable intelligence is developed through logical and systematic manipulation of objects. Finally, complete intelligence, which is as competent as adults, is established in the formal operational stage at the age of twelve. The spatial reasoning capacity is developed by training. Since objects, which are generated in the method in section 2.2, are examined and logicized, children in concrete operational stage should be targeted. Therefore, in this experiment, we chose fifth grade pupils of an elementary school. The pupils are in the age of ten to eleven. In the fifth grade, there are 37 boys and 36 girls.

We start the experiment with the hypothesis that the method using AR does not affect the spatial reasoning capacity. The hypothesis is rejected later in this section.

The conditions of the AR learning are classified into three groups. The first group uses the method in Fig.2, namely "*with frame*". The second group uses the question marker "*without frame*". The effect of box frames shown in Fig.2 is validated by comparing these two groups. Finally, the group

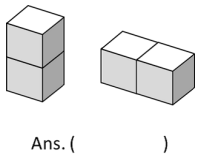

Fig. 7: An example of tests

Fig. 8: A view of the AR learning

of "*without learning*" does not contain the AR learning phase to validate the effect of AR learning.

The experimental procedure is shown as follows.

Step-I) Paper test 1 (5 min.)
Step-II) AR learning (15 min.)
Step-III) Paper test 2 (5 min.)

In Step-I), the preliminary spatial reasoning capacity is measured using test 1. Figure 7 shows an example of paper tests. The right-and-left objects are compared and the pupils determine if these objects are same or different. There are 80 questions in each paper test. The paper test 1 is to be completed within 5 minutes. Note that it is not necessary to answer all the 80 questions. In Step-II), the AR learning is performed in 15 minutes. The pupils of the "*without learning*" group wait 15 minutes without the AR learning. In Step-III), the spatial reasoning capacity is measured using paper test 2 in common with paper test 1. The effect of the AR learning is expected to be validated by this paper test when it is confirmed that Step-I) affects Step-III). These two paper tests are distributed at random.

In this experiment, laptop computers, AR markers and Web cameras are used for the AR learning. The AR markers are freely movable. Figure 8 shows a view of the AR learning.

We analyze the results of the experiment. The spatial reasoning capacity is to recognize the overview of objects in the three-dimensional space quickly and accurately. The spatial object recognition speed is measured with the response rate (the rate of the response time in all questions). In addition, the spatial object recognition accuracy is measured with the accuracy rate. Figure 9 and 10 show the average response rate and the average accuracy rate, respectively. ANOVA (ANalysis Of VAriance) is used to uncover the attributions and interaction effects. Table 1 shows the result of the two-way ANOVA. Here, F shows the proportion of within-group variance to between-group variance. p shows significance probability. * shows significance level. t is calculated with $\frac{\overline{X}-\mu}{\sqrt{U/n}}$, where n is the number of samples, $\overline{X}$ is the sample average, U is the sample unbiased estimate of variance, and μ is the population mean. One attribution is the conditions for learning (learning with frame, learning without frame, and no learning). Another attribution is "*before and after*" (Step-I) and Step-III)).

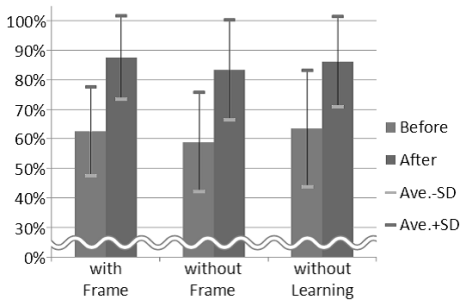

Fig. 9: The response rate

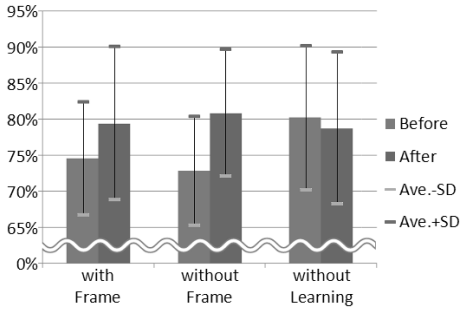

Fig. 10: The accuracy rate

Table 1: Two-way ANOVA

		A response rate	An accuracy rate
Condition	$F(2,70)$	0.54	0.76
	p	0.59	0.47
before and after	$F(1,70)$	189.37	14.82
	p	$< .001$****	$< .001$****
Interaction	$F(2,70)$	0.17	8.09
	p	0.84	$< .001$****

Significant level $p < .001$****

In the result of the response rate, "*before and after*" learning differs significantly ($F(1,70) = 189.37$, $p < .001$****). Therefore, the spatial object recognition speed has the possibility to be improved by the tests. In the result of the accuracy rate, "*before and after*" learning differs significantly ($F(1,70) = 14.82$, $p < .001$****). Interaction between "*before and after*" learning and the learning conditions also differ significantly ($F(2,70) = 8.09$, $p <$

Table 2: The result of a post-hoc test for "*before and after*" learning

An accuracy rate	$F(1,70)$	p
with frame	8.14	$< .01$**
without frame	22.08	$< .001$****
without learning	0.78	0.38

Significant level $p < .01$**, $p < .001$****

Table 3: The result of a post-hoc test for learning conditions

An accuracy rate	$F(2,140)$	p
before	4.13	$< .05$*
after	0.32	0.73

Significant level $p < .05$*

Table 4: The result of a post-hoc test in "*before*" learning

An accuracy rate			t	p
without learning	-	*without frame*	2.76	$< .01$**
without learning	-	*with frame*	2.12	$< .05$*
with frame	-	*without frame*	0.64	0.53

Significant level $p < .05$*, $p < .01$**

.001****). Therefore, the interaction should be evaluated. The results of the simple main effect test are shown in Tab.2 and Tab.3. Significant difference is found in "*before and after*" learning within the "*with frame*" ($F(1,70) = 8.135$, $p < .01$**) and the "*without frame*" ($F(1,70) = 22.083$, $p < .001$****). So the AR learning affects the accuracy rate among "*with frame*" and "*without frame*".

The learning of "*before*" differs significantly ($F(2,140) = 4.13$, $p < .05$*) in the learning conditions. The result of multiple comparisons in the learning conditions of the accuracy rate is shown in Tab.4. The relationship between "*without learning*" and "*without frame*" shows significant difference ($t = 2.76$, $p < .01$**), and the relationship between "*without learning*" and "*with frame*" shows significant difference, too ($t = 2.12$, $p < .05$*). Therefore, it turns out that the group of "*without learning*" contains more examinees with high spatial reasoning capacity. Namely, the hypothesis is rejected. Thus, the effectiveness of the attribute "*with frame*" and "*without frame*" is validated.

As the result of the ANOVA, it is confirmed that the response rate is improved. However, the response rate is improved with any conditions and does not differ significantly. It means that the improvement is not affected so much by the AR learning but the habituation to the tests. Therefore, the spatial object recognition speed is not affected by the AR learning. The accuracy rate is improved by "*before and after*" AR learning. In the case of the accuracy rate, both of "*with frame*" and "*without frame*" are improved while the effect of the box frame is not observed. Thus, the AR learning affects the spatial object recognition accuracy.

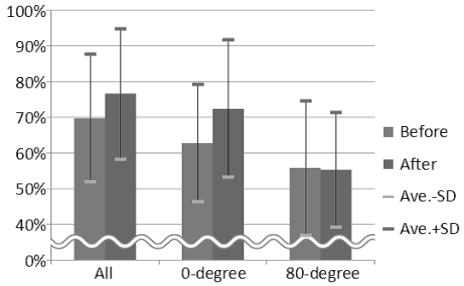

Fig. 11: The response rate in the improved version

4. Experiments for AR marker learning with angle rotation

To study the relationship between rotation angle and the learning efficiency of examinees, we perform other experiments as described in subsection 4.1. In this section, we first investigate the difference between the cases of fixed angle and variable angles for the AR marker by experiment. Then, we explain the experimental results to show the effect of the learning with rotating the AR marker.

4.1 Learning with limited angles

In this subsection, we perform an experiment to investigate the difference between the cases of fixed angle and variable angles. For the experiment, we have 42 examinees who are female students of our university. We start the experiment with the hypothesis that rotation angle does not affect the spatial reasoning capacity using the method of section 2.3. The hypothesis is rejected later in this section.

The experimental procedure is the same as in section 3. Therefore, just different parts are shown as follows. In step II), the method of section 2.3 is used. The conditions of the AR learning are separated into three groups to investigate the angle rotation effect. The three groups are as follows.

- "*all*" (zero, twenty, forty, sixty and eighty degrees)
- "*0-degree*"
- "*80-degree*"

The first group "*all*" has limitations of rotation angles (θ in Fig.6) from zero (cannot rotate) to eighty degrees by twenty degrees. The second group "*0-degree*" is fixed θ zero degree. Finally, the group "*80-degree*" is fixed θ eighty degrees.

We analyze the results of the experiment. Figure 11 and 12 show the average response rate and the average accuracy rate, respectively. Table 5 shows the result of the two-way ANOVA. One attribution is the conditions for learning (learning all, learning with 0-degree, and learning with 80-degree). Another attribution is "*before and after*" (Step-I) and Step-III)).

As the result of the response rate, "*before and after*" learning differs significantly ($F(1,39) = 12.60$, $p < .001$****). Interaction between "*before and after*" learning and the

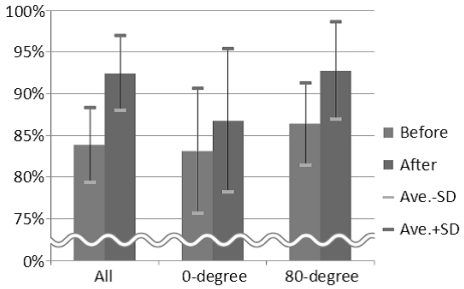

Fig. 12: The accuracy rate in the improved version

Table 5: Two-way ANOVA

		A response rate	An accuracy rate
Condition	$F(2,39)$	3.86	2.57
	p	$< .05$*	0.09
before and after	$F(1,39)$	12.60	50.85
	p	$< .001$****	$< .001$****
Interaction	$F(2,39)$	4.12	2.74
	p	$< .05$*	0.08

Significant level $p < .05$*, $p < .001$****

Table 6: The result of a post-hoc test in "*before and after*" learning

A response rate	$F(1,39)$	p
all	6.89	$< .05$*
0-degree	13.91	$< .001$****
80-degree	0.04	0.84

Significant level $p < .05$*, $p < .001$****

learning conditions also differ significantly ($F(2,39) = 4.12$, $p < .05$*). Therefore, the interaction should be evaluated. The results of the simple main effect test are shown in Tab.6 and Tab.7. Significant difference is found in "*before and after*" learning within "all" ($F(1,39) = 6.89$, $p < .05$*) and "*0-degree*" ($F(1,39) = 13.91$, $p < .001$****). So the rotation angle seems to affect the response rate in "*all*" and "*0-degree*".

The learning of "*after*" differs significantly ($F(2,78) = 5.61$, $p < .01$**) in the learning conditions. The result of multiple comparisons in the learning conditions of the response rate is shown in Tab.8. The relationship between "*all*" and "*80-degree*" shows significant difference ($t = 3.16$, $p < .01$**), and the relationship between "*0-degree*" and the "*80-degree*" shows significant difference, too ($t = 2.55$, $p < .05$*). Therefore, it turns out that the group of "*all*" gets considerable learning effects rather than "*0-degree*". Namely, the hypothesis is rejected from the fact that the learning flow affects the spatial reasoning capacity. Thus, the effect of the attribute "*all*" and "*0-degree*" is validated.

In the result of the accuracy rate, "*before and after*" learning differs significantly ($F(1,39) = 50.85$, $p < .001$****).

Table 7: The result of a post-hoc test for learning conditions

A response rate	$F(2,78)$	p
before	2.14	0.12
after	5.61	$< .01$**

Significant level $p < .01$**

Table 8: The result of a post-hoc test in "*after*" learning

A response rate			t	p
All	-	*80-degree*	3.16	$< .01$**
All	-	*0-degree*	0.61	0.54
0-degree	-	*80-degree*	2.55	$< .05$*

Significant level $p < .05$*, $p < .01$**

Therefore, the spatial object recognition accuracy has the possibility to be improved regardless of any rotation angle.

As the result of the ANOVA, the response rate is improved by the "*before and after*" AR learning. In this case, both of "*all*" and "*0-degree*" are improved from the view point of the rotation angle effect. Since this method is to have examinees to image object rotation with ninety degrees, "*80-degree*" is too much support for such object rotation in mind. Thus, the rotation angle affects the spatial object recognition speed. Furthermore, the accuracy rate is improved with any conditions and does not differ significantly. It means that the improvement is not affected so much by the rotation angle but the AR learning itself. Therefore, the spatial object recognition accuracy is not affected by the rotation angle.

4.2 Learning with various angles

In this subsection, we perform another experiment to study the effect of the AR learning with rotating the AR marker. The examinees are 16 female students of our university. The experimental procedure is shown as follows.

Step-i) Paper test 1 (5 min.)
Step-ii) Paper test 2 (5 min.)
Step-iii) Rotate the AR marker by θ in a random manner
Step-iv) AR learning (3 min.)
Step-v) Paper test 3 (5 min.)
Step-vi) Terminate, if all angles are selected
Step-vii) Go to step-iii)

In Step-i), the preliminary spatial reasoning capacity is measured using test 1. The test is the same as in section 3. In Step-ii), the spatial reasoning capacity after the test 1 is measured using test 2. In Step-iii), the AR marker is rotated by zero, twenty, forty, sixty and eighty degrees in a random order only once. In Step iv), the AR learning is performed using the method of section 2.3 for 3 minutes. In Step-v), the spatial reasoning capacity after the learning is measured using test 3. In Step-vi), when all the five angles are examined, the procedure is terminated. Otherwise it returns to Step-iii). The total time for the procedure is $5 + 5 + (3 + 5) * 5 = 50$ minutes.

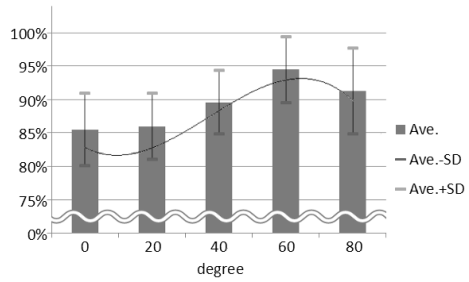

Fig. 13: The relationship between the rotation angle and the accuracy rate

Table 9: Multiple comparisons of angles

Degree			t	p
0	-	80	3.25	$< .005$***
20	-	80	2.98	$< .005$***
40	-	80	0.93	0.36
60	-	80	2.05	$< .05$*

Significant level $p < .05$*, $p < .005$***

We analyze the results of the experiment to investigate which rotation angle is the most effective. To investigate the relationship between the rotation angle and the accuracy rate, a regression analysis is performed. Figure 13 illustrates the average accuracy rate and a regression model [7]. This model is expressed as follows.

$$y = -0.12 * 10^{-5}x^3 + 0.13 * 10^{-3}x^2 - 0.22 * 10^{-2}x + 0.86$$

The effect of learning does not change from zero to twenty degrees. The accuracy rate increases for twenty to sixty degrees. Then the accuracy rate shows a gradual decline for eighty degrees. As pointed out in section 4.1, "*80-degree*" is too much support for such object rotation in mind.

In this experiment, "*80-degree*" improves the accuracy rate rather than "*0-degree*". However, "*0-degree*" improves the accuracy rate rather than "*80-degree*"in section 4.1. This result contradicts the result in section 4.1. Therefore, we examine a one-way ANOVA test. One attribution is the rotation angle. In the results of the one-way ANOVA, the relationship among five rotation angles shows significant difference ($F(4, 56) = 8.99$, $p < .001$****). Therefore, a post-hoc test should be examined. The relationship between "*80-degree*" and other angles in the results of the multiple comparison is shown in Tab.9. There are significant difference between "*80-degree*" and "*0/20-degree*". In the experiment in section 4.1, other angles have no effect with "*80-degree*". However in this experiment, the list of the learning is randomly generated, and the other angles are confirmed to be affected. Since the learning of "*0-degree*" does not support the rotation, the learning itself is difficult. Hence, we conclude that the learning of "*0-degree*" is an unsuitable angle.

As the result of the analysis, it turns out that the AR learning with sixty degrees as the limitation of angle is the most effective method.

5. Conclusions

In this paper, we proposed new methods to train students' spatial reasoning capacity using AR. In the AR environment, virtual objects are displayed even in floating and can be moved freely. Students with low spatial reasoning capacity can effectively learn by rotating an AR marker. In the first method, if the rotation of a virtual object in mind is hard, the AR marker can be rotated by arbitrary angle physically. The second method has physical limitation of the rotation.

To validate the effect of the trained and resultant spatial reasoning capacity, we perform an experiment using the proposed method. As the result of the ANOVA, the accuracy rate is improved by "*before and after*" AR learning. In the case of the accuracy rate, both of "*with frame*" and "*without frame*" are improved while the effect of the box frame is not observed. Thus, the AR learning affects the spatial object recognition accuracy.

To study the relationship between rotation angle and the learning efficiency of examinees, we performed two experiments. First, we performed an experiment to investigate the difference among the cases of fixed angle and variable angles. As the result of the ANOVA, the response rate is improved by the "*before and after*" AR learning. In this case, both of "*all*" and "*0-degree*" are improved from the view point of the rotation angle effect. Second, we performed an experiment to study the effect of the AR learning with rotating the AR marker. The effect of the AR learning does not change from zero to twenty degrees. The accuracy rate increases for forty to sixty degrees. Then the accuracy rate shows a gradual decline for eighty degrees. From the result of the analysis, it turns out that the AR learning with sixty degrees as the limitation of angle is the most effective method.

In our future work, we plan to develop an AR tool to train spatial reasoning capacity for understanding 3D objects from opened-up cubes.

Abstract *Queuing network techniques are effective for evaluating the performance of computer systems. We discuss a queuing network technique for computer systems with multiple memory resource requirements. When a job arrives from outside the network, it occupies one of the memory resources and executes CPU and I/O processing in the network occupying the memory. When the job completes the CPU and I/O processing, it releases the memory and leaves the network. However, because the memory resource is considered to be a secondary resource for the CPU and I/O equipment, and because the queuing network model of computer systems with memory resources is an open one, we cannot calculate its exact solutions.*

We propose here an approximation technique for calculating the performance measures of computer systems with multiple memory resource requirements using the queuing network technique. This technique involves dividing a network into two parts; one is a "processing part" in which a job executes CPU and I/O processing, and the other is a "memory part" that indicates how the memory resources are used by jobs. By dividing the network into two parts, we can prevent the number of network states from increasing and can approximately calculate the performance measures of the network. We evaluated the proposed approximation technique using numerical experiments.

Keywords *performance of computer systems, central server model, memory resource, memory resource requirements*

1. Introduction

Queuing network techniques are effective for evaluating the performance of computer systems. In computer systems, two or more jobs are generally executed at the same time, which causes delays due to conflicts in accessing hardware or software resources such as the CPU, I/O equipment, or data files. We can evaluate how this delay affects the computer system performance by using a queuing network technique. Some queuing networks have an explicit exact solution, which is called a product form solution [1]. With this solution, we can easily calculate the performance measures of computer systems, for example the busy ratio of hardware and the job response time. However, when the exclusion controls are active or when a memory resource exists, the queuing network does not have a product form solution. To calculate an exact solution of a queuing network that does not have a product form solution, we have to construct a Markov chain that describes the stochastic characteristics of the queuing network and numerically solve its equilibrium equations. The number of unknown quantities in the equilibrium equations is the same as the number of states of the queuing network. Since the number of states of the queuing network drastically increases when the number of jobs or the amount of hardware in the network increases, the number of unknown quantities in the equilibrium equations also drastically increases. Therefore, we cannot numerically calculate the exact solution of the queuing network. Moreover, when the queuing network is an open model where jobs arrive from or depart for the outside of the network, the number of states of the network can become infinite (the number of jobs can be infinite.), and we cannot actually calculate an exact solution.

We discuss the queuing network technique for computer systems with memory resources. When a job arrives from outside the network, it occupies a portion of the memory resources and executes CPU and I/O processing in the network with the memory. When the job completes CPU and I/O processing, it releases the memory and leaves the network. Therefore, memory can be considered as a secondary resource for the CPU and I/O equipment. When a queuing network includes a secondary resource, it does not have product form solutions. Moreover, since the queuing network technique of computer systems with memory resources is an open model, we cannot calculate its exact solutions.

We propose an approximation technique for calculating the performance measures of computer systems with multiple memory resource requirements. We previously reported the results for a single job type case [6]. In this

paper, we extend the results of [6] and discuss them for the case when there are multiple memory resource requirements and multiple job types (each of which is called a job class). Similarly to the single job class in [6], we divide the network into two parts in order to prevent the number of states of the Markov chain from increasing. One part is called the "processing part," in which jobs execute CPU and I/O processing, and the other is the "memory part," which indicates how the memory resources are used by the jobs. As with the behavior of CPU and I/O processing, the memory usage behavior also differs for each job class, such as how much memory is allocated to the job. When there is a single job class, both the processing and memory parts have a product form solution, but when there are multiple job classes, only the processing part has a product form solution. Therefore, it is not sufficient to divide the queuing network into two parts; an approximation is also needed to analyze the memory part.

Dividing the model into primary and secondary resources is a two-layer queuing network techniques [3][4]. Our proposed technique is also a two-layer technique for computer systems with memory resources.

2. Model Description

The processing part is equivalent to the ordinary central server model with multiple job classes. In this model, K job classes exist, and each of them is numbered k =1, 2, … , K by affixing a k. The processing part consists of a single CPU node and multiple I/O nodes. We denote M as the number of I/O nodes. The I/O nodes are numbered m =1, 2, … , M by affixing m, and the CPU node is numbered m =0 by also affixing m. The service rate of job class k at the CPU node is μ_0^k, and the service rate of job class k at an I/O node m is μ_m^k. The service time at each node is a mutually independent random variable subject to common exponential distributions. Jobs are scheduled on a first come first served (FCFS) principle at all nodes. At the end of CPU processing, a job probabilistically selects a I/O node and moves to it, or completes CPU and I/O processing and departs from the network. The selection probability of I/O node m of job class k is p_m^k (k =1, 2, ... , K; m =1, 2, ... , M), and the completion probability of job class k is p_0^k (k =1, 2, ... , K). Therefore, $\sum_{m=0}^{M} p_m^k = 1$ (k =1, 2, ... , K).

Memory resources are added to this ordinary central server model (Figure 1). We denote S_k as the number of memory resources for job class k. A job from job class k arrives from the outside at random at an arrival rate λ_k. The

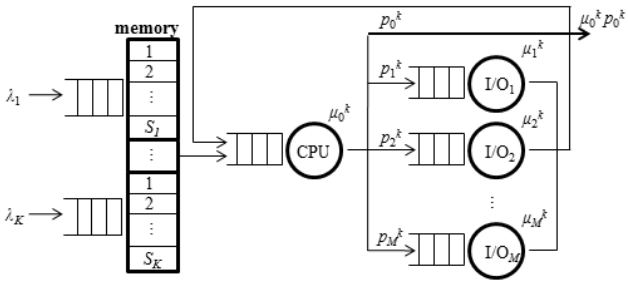

Fig. 1 Central server model with multiple memory resource requirements

job requests and acquires a memory resource before entering the processing part. If all the memory resources for job class k are occupied when the job of job class k arrives, the job joins the memory-waiting queue and waits for one of the memory resources to be released by another job. When the job completes CPU and I/O processing, it releases the memory resource and leaves the network. Because the job has to occupy a memory resource upon entering the processing part, the number of jobs occupying a memory resource is always equal to the number of jobs in the processing part. Therefore, at most S_k jobs of job class k can enter the processing part. That is, the maximum job multiplicity of job class k in the processing part is S_k. The number of jobs of job class k in the processing part is denoted by n_k (= 0, 1, 2, ... , S_k). By replacing "CPU → outside transition" with "CPU → CPU transition," the processing part is modified to a closed central server model in which the number of jobs is constant (Figure 2). In this closed model, when "CPU → CPU transition" occurs, the job terminates and a new job starts. Therefore, the mean job response time is the mean time between two successive "CPU → CPU transitions." This means job response time can be considered as a job lifetime.

3. Approximation Model

To obtain the exact solution of the central server model with memory resource requirements, we have to describe the entire model with a single Markov chain for each job class. However, this causes the number of states of the Markov chain to drastically increase when the number of nodes and the number of jobs in the network increase. By dividing the central server model into two parts (processing part and memory part), and describing each part with two Markov chains, we can prevent the number of states of the model from increasing (Figure 2). We set the following notations.

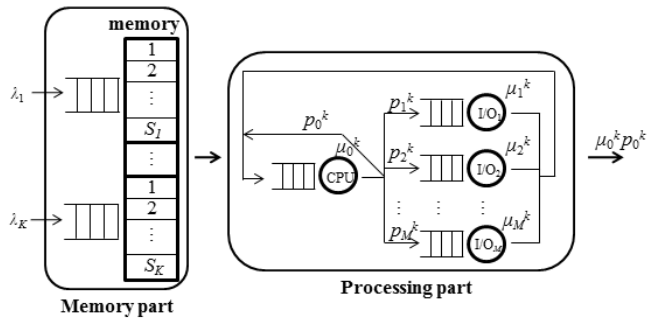

Fig. 2 Concept of approximation

We set the following notations.

τ_{km} : total mean service time at node-m in a job lifetime of job class k (S_k, k=1, 2, ... , K; m =0, 1, ... , M)

$\boldsymbol{n}^* = (n_1, n_2, \dots, n_K)$
: vector of number of jobs (n_k =0, 1, 2, ... , S_k)

n_{km} : number of jobs in job class k at node-m (m =0, 1, ... , M)

$\boldsymbol{n} = (n_{10}, n_{11}, \dots, n_{1M}, n_{20}, n_{21}, \dots, n_{2M}, \dots, n_{K0}, n_{K1}, \dots, n_{KM})$
: state vector of the processing part

$$\boldsymbol{F}(\boldsymbol{n}) = \{\boldsymbol{n} \mid \sum_{m=0}^{M} n_{km} = n_k,\ n_{km} \geq 0 \ (m = 0, 1, \dots, M)\}$$

(n_k =0, 1, 2, ... , S_k, k =1, 2, ... , K)
: set of all feasible states of the processing part when the number of jobs of job class k is n_k

$P_s(\boldsymbol{n})$: steady-state probability of state $\boldsymbol{n}$

The processing part is equivalent to the ordinary central server model with multiple job classes, and therefore, the Markov chain describing the processing part has a product form solution. Then the steady-state probability $P_s(\boldsymbol{n})$ is represented by the following formula [1][2].

$$P_s(\boldsymbol{n}) = \frac{\prod_{k=1}^{K}\prod_{m=0}^{M} \tau_{km}{}^{n_{km}}}{\varphi(n_1, n_2, \cdots, n_K, M)}$$

where $\varphi(n_1, n_2, \cdots, n_K, M) = \sum_{n \in F(n)} \prod_{k=1}^{K}\prod_{m=0}^{M} \tau_{km}{}^{n_{km}}$ is the normalizing constant of steady-state probabilities when the number of jobs of job class k in the processing part is n_k (k =1, 2, ... , K). From these steady-state probabilities, we can calculate the mean job response time $T_{\boldsymbol{n}}{}^k$ of job class k in the processing part, when the number of jobs is n_k (k =1, 2, ... , K), as follows.

$$T_n{}^k = \frac{n_k \cdot \varphi(n_1, \cdots, n_k, \cdots, n_K, M)}{\varphi(n_1, \cdots, n_k - 1, \cdots, n_K, M)}$$

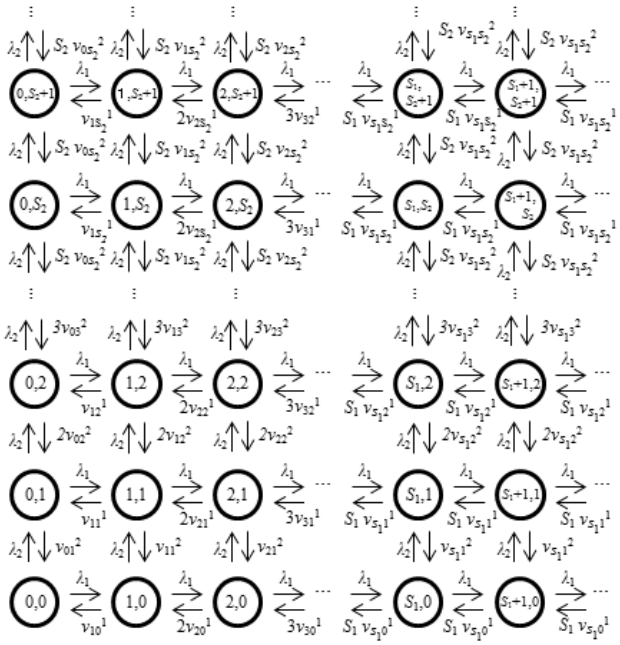

Fig. 3 State Transition diagram (two job classes)

The memory part can be considered as an M/M/S_k queuing model with S_k servers (k =1, 2, ... , K). In an ordinary M/M/S_k queuing model, the service rate at a server is constant, regardless of the number of guests in the service. In the memory part, however, the service rate changes depending on the number of occupied memory resources. The mean job response time $T_{\boldsymbol{n}}{}^k$ of job class k (k =1, 2, ... , K) in the processing part, when the number of jobs in the processing part is $\boldsymbol{n}^* = (n_1, n_2, \dots, n_K)$, is equal to the mean time of occupied memory. Since the service rate from the processing part $v_{\boldsymbol{n}}{}^k$ is denoted as $v_{\boldsymbol{n}}{}^k = \frac{1}{T_{\boldsymbol{n}}{}^k}$, $v_{\boldsymbol{n}}{}^k$ depends on the number of occupied memory resources n_k. The state transition of the M/M/S_k queuing model (k =1, 2) is shown in Figure 3, where the memory service rates change depending on the number of occupied memory resources. This is a two-dimensional birth-death process. The equilibrium equations with the steady-state probability $Q_{\boldsymbol{S}}(\boldsymbol{n}^*) = Q_{\boldsymbol{S}}(n_1, n_2)$, when the number of memory resources is $\boldsymbol{S} = (S_1, S_2)$ and the number of occupied memory resources is $\boldsymbol{n}^* = (n_1, n_2)$, are as follows (similar to the case with higher dimensions).

$$(\lambda_1 + \lambda_2) \cdot Q_{\boldsymbol{S}}(0, 0) = v_{10}{}^1 \cdot Q_{\boldsymbol{S}}(1, 0) + v_{01}{}^2 \cdot Q_{\boldsymbol{S}}(0, 1)$$

$$(\lambda_1 + \lambda_2 + n_1 v^1_{n_1 0}) \cdot Q_{\boldsymbol{S}}(n_1, 0) = \lambda_1 \cdot Q_S(n_1 - 1, 0) + (n_1 + 1)\, v^1_{n_1+1\,0} \cdot Q_{\boldsymbol{S}}(n_1 + 1, 0) + v^2_{n_1 1} \cdot Q_{\boldsymbol{S}}(n_1, 1)$$

(n_1=1, 2, ... , $S_1 - 1$)

$$(\lambda_1+\lambda_2+ S_1\nu^1_{S_1 0})\cdot Q_S(n_1, 0) = \lambda_1\cdot Q_S(n_1-1, 0) + S_1\nu^1_{S_1 0}\cdot Q_S(n_1+1, 0) + \nu^2_{n_1 1}\cdot Q_S(n_1, 1) \quad (n_1= S_1, S_1+1, ...)$$

$$(\lambda_1+\lambda_2+n_2\nu^2_{0n_2})\cdot Q_S(0, n_2) = \lambda_2\cdot Q_S(0, n_2-1) + \nu^1_{1n_2}\cdot Q_S(1, n_2) + (n_2+1)\nu^2_{0n_2+1}\cdot Q_S(0, n_2+1) \quad (n_2 =1, 2, ..., S_2-1)$$

$$(\lambda_1+\lambda_2+S_2\nu^2_{0n_2})\cdot Q_S(0, n_2) = \lambda_2\cdot Q_S(0, n_2-1) + \nu^1_{1n_1}\cdot Q_S(1, n_2) + S_2\nu^2_{0S_2}\cdot Q_S(0, n_2+1) \quad (n_2 =S_2, S_2+1, ...)$$

$$(\lambda_1+\lambda_2+n_1\nu^1_{n_1n_2}+n_2\nu^2_{n_1n_2})\cdot Q_S(n_1, n_2) = \lambda_1\cdot Q_S(n_1-1, 0) + \lambda_2\cdot Q_S(0, n_2-1) + (n_1+1)\nu^1_{n_1+1n_2}\cdot Q_S(n_1+1, n_2) + (n_2+1)\nu^2_{n_1n_2+1}\cdot Q_S(n_1, n_2+1) \quad (n_1 =1, 2, ..., S_1-1;\ n_2 =1, 2, ..., S_2-1)$$

$$(\lambda_1+\lambda_2+S_1\nu^1_{S_1n_2}+n_2\nu^2_{n_1S_2})\cdot Q_S(n_1, n_2) = \lambda_1\cdot Q_S(n_1-1, 0) + \lambda_2\cdot Q_S(0, n_2-1) + S_1\nu^1_{S_1n_2}\cdot Q_S(n_1+1, n_2) + (n_2+1)\nu^2_{n_1n_2+1}\cdot Q_S(n_1, n_2+1) \quad (n_1 =S_1, S_1+1, ...;\ n =1, 2, ..., S_2-1)$$

$$(\lambda_1+\lambda_2+n_1\nu^1_{n_1n_2}+S_2\nu^2_{n_1S_2})\cdot Q_S(n_1, n_2) = \lambda_1\cdot Q_S(n_1-1, n_2) + \lambda_2\cdot Q_S(n_1, n_2-1) + (n_1+1)\nu^1_{n_1+1n_2}\cdot Q_S(n_1+1, n_2) + S_2\nu^2_{n_1S_2}\cdot Q_S(n_1, n_2+1) \quad (n_1 =1, 2, ..., S_1-1;\ n_2=S_2, S_2+1, ...)$$

$$(\lambda_1+\lambda_2+S_1\nu^1_{S_1n_2}+S_2\nu^2_{n_1S_2})\cdot Q_S(n_1, n_2) = \lambda_1\cdot Q_S(n_1-1, n_2) + \lambda_2\cdot Q_S(n_1, n_2-1) + S_1\nu^1_{S_1n_2}\cdot Q_S(n_1+1, n_2) + S_2\nu^2_{n_1S_2}\cdot Q_S(n_1, n_2+1) \quad (n_1 =S_1, S_1+1, ...;\ n_2 =S_2, S_2+1, ...)$$

The transition diagram of the two-dimensional birth-death process is shown in Figure 3. However, the steady-state equation does not have a product form solution. Therefore, some approximation is required to solve it.

When a single job class and a single memory resource exist in the model, it can be described with a one-dimensional birth-death process. Its transition diagram is shown in Figure 4, and the steady-state equation is as follows:

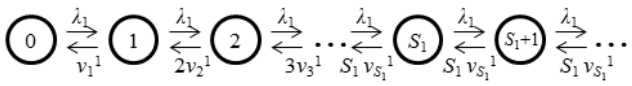

Fig. 4 State Transition diagram (single job class)

$$\lambda_1\cdot Q_S(0)=\nu_1{}^1\cdot Q_S(1)$$

$$(\lambda_1+ n_1\ \nu^1_{n_1})\cdot Q_S(n_1) =\lambda_1\cdot Q_S(n_1-1) + (n_1+1)\ \nu^1_{n_1+1}\cdot Q_S(n_1+1) \quad (n_1 =1, 2, ..., S_1-1)$$

$$(\lambda_1+S_1\nu^1_{S_1})\cdot Q_S(n_1) =\lambda_1\cdot Q_S(n_1-1)+) + S_1\nu^1_{S_1}\cdot Q_S(n_1+1) \quad (n_1 =S_1, S_1+1, ...)$$

Solutions for the steady-state equation are in the following product form.

$$Q_S(n_1) = Q_S(0)\cdot\frac{1}{n_1!}\prod_{i=1}^{n_1}\left(\frac{\lambda_1}{\nu^1_i}\right) \quad (n_1=1, 2, ..., S_1-1)$$

$$= Q_S(0)\cdot\frac{1}{S_1!S_1^{\,n_1-S_1}}\prod_{i=1}^{S_1}\left(\frac{\lambda_1}{\nu^1_i}\right)\cdot\left(\frac{\lambda_1}{\nu^1_{S_1}}\right)^{n_1-S_1} \quad (n_1=S_1, S_1+1, ...)$$

In this formula, for the state transition of i =1, 2, ... , S_1-1, multiply by factor $\frac{\lambda_1}{i\cdot\nu^1_i}$ while for the state transition of i = S_1, S_1+1, ... , multiply by factor $\frac{\lambda_1}{S_1\cdot\nu^1_{S_1}}$. For two-dimension case, we consider routes from lattice point (0, 0) to (n_1, n_2) shown in Figure 3, and for the state transition to the right direction along a route, multiply by factor $\frac{\lambda_1}{i\cdot\nu^1_i}$ (i =1, 2, ... , S_1-1) or $\frac{\lambda_1}{S_1\cdot\nu^1_{S_1}}$ (i =S_1, S_1+1, ...), while for the state transition in the upward direction, multiply by factor $\frac{\lambda_2}{j\cdot\nu^2_j}$ (j =1, 2, ... , S_2-1) or $\frac{\lambda_2}{S_2\cdot\nu^2_{S_2}}$ (j =S_2, S_2+1, ...). Thus, the coefficient of $Q_S(n_1, n_2)$ related to $Q_S(0, 0)$ is represented as the multiplication based on the route from (0, 0) to (n_1, n_2). Since there are multiple routes from (0, 0) to (n_1, n_2), the

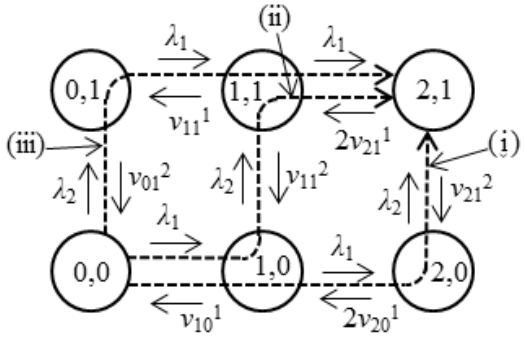

Fig. 5 Calculating State Probability along routes to (2, 1)

coefficient of $Q_S(n_1, n_2)$ related to $Q_S(0, 0)$ is approximately represented as the average of the multiplication based on all routes. For example, since there are three routes from $Q_S(0, 0)$ to $Q_S(2, 1)$ then,

$$Q_S(2,1) = Q_S(0,0) \times \frac{1}{3} \cdot \left\{ \left(\frac{\lambda_1}{\nu_{10}^1}\right)\left(\frac{\lambda_1}{2\cdot\nu_{20}^1}\right)\left(\frac{\lambda_2}{\nu_{21}^2}\right) \right. \quad \text{..... (i)}$$

$$+ \left(\frac{\lambda_1}{\nu_{10}^1}\right)\left(\frac{\lambda_2}{\nu_{11}^2}\right)\left(\frac{\lambda_1}{2\cdot\nu_{21}^1}\right) \quad \text{.... (ii)}$$

$$\left. + \left(\frac{\lambda_2}{\nu_{01}^2}\right)\left(\frac{\lambda_1}{\nu_{11}^1}\right)\left(\frac{\lambda_1}{2\cdot\nu_{21}^1}\right) \right\} \quad \text{.... (iii)}$$

Here (i)(ii)(iii) are the terms that were calculated on the basis of the corresponding routes of the broken lines in Figure 5. Similarly to the case above, we can approximately calculate the state probability of a queuing network with multiple memory resource requirements when K >2.

4. Numerical Experiments

We evaluated the proposed approximation technique through numerical experiments. We used the following parameters.

1. Number of memory resources: (S_1, S_2)=(2, 2), (3,3), (4, 4)
2. Arrival rate: λ_1=0.0 -- 21.0, λ_2 =1.0, 4.0
3. Number of I/O nodes: M =2
4. Total service time at each node
   τ_{10}=1.0, τ_{11}=τ_{12}=0.5
   τ_{20}=1.0, τ_{21}=τ_{22}=1.0
   where τ_{km} is the total service time of job class k at node m.

Figures 6 and 7 show the mean job response times of job classes 1 and 2 as T_1, T_2 respectively, when λ_2 is fixed at 1.0 and 4.0, and λ_1 changes from 0.0 to 21.0. In these graphs, T_k (S_1, S_2) is the mean job response time of job class k when the numbers of memory resources of job classes 1and 2 are S_1, S_2 respectively. Similarly to the case of a single job class, the mean job response time for both job classes increases monotonically in a convex curve. As the arrival rate λ_1 increases and λ_2 is fixed (the load of only job class 1 increases), the mean response time of both job classes 1 and 2 increases. We can see that the mean response time of job class 2 is increasing higher than that of job class 1, and the reason for this is presumed to be that job class 2 has a longer I/O time than job class 1.

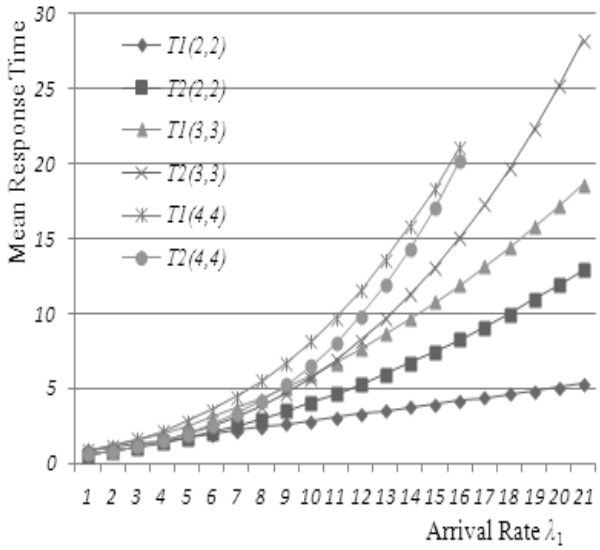

Fig. 6 Mean Job Response Time (λ_2=1.0)

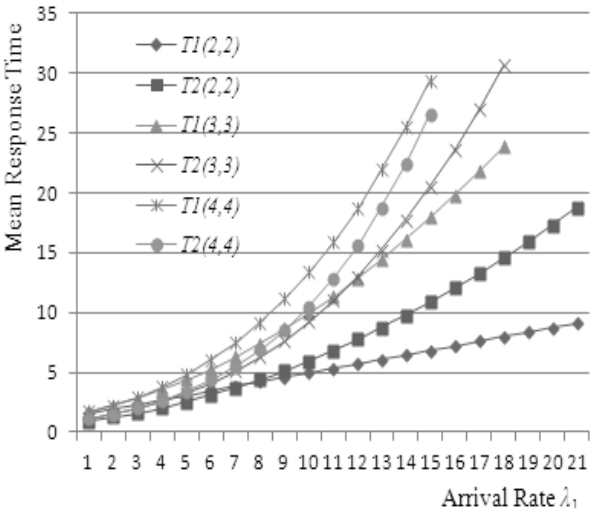

Fig. 7 Mean Job Response Time (λ_2=4.0)

5. Conclusion

We proposed an approximation technique for evaluating the performance of computer systems with multiple memory resource requirements using a queuing network and analyzed its performance measures through numerical experiments. The concept of the approximation is based on separately analyzing the processing part and the memory part of the queuing network model.

The numerical experiments clarified the characteristics of the mean job response time.
In the future we plan to examine the accuracy of the proposed approximation technique by comparing it with exact solutions or simulation results.

GPU Acceleration of BCP Procedure for SAT Algorithms

Hironori Fujii[1] **and Noriyuki Fujimoto**[1]
[1]Graduate School of Science Osaka Prefecture University
1-1 Gakuencho, Nakaku, Sakai, Osaka 599-8531, Japan

Abstract— *The satisfiability problem (SAT) is widely applicable and one of the most basic NP-complete problems. This problem has been required to be solved as fast as possible because of its significance, but it takes exponential time in the worst case to solve. Therefore, we aim to save the computation time by parallel computing on a GPU. We propose parallelization of BCP (Boolean Constraint Propagation) procedure, one of the most effective techniques for SAT, on a GPU. For a 2.93GHz Intel Core i3 CPU and an NVIDIA GeForce GTX480, our experiment shows that the GPU accelerates our SAT solver based on our BCP-embedded divide and conquer algorithm 6.7 times faster than the CPU counterpart*

Keywords: Satisfiability problem, Boolean constraint propagation, GPGPU, CUDA

1. Introduction

The satisfiability problem (SAT for short) [1] is a problem of determining if a given boolean expression (usually in the conjunctive normal form) can be true by assigning some boolean values into the boolean variables in the expression. Formally, SAT is defined as follows:

- Let $V = \{V_1, V_2, \cdots, V_n\}$ be a set of n boolean variables.
- Let $C = \{C_1, C_2, \cdots, C_m\}$ be a set of m *clauses* where
  - $C_j = (L_{j_1} \vee L_{j_2} \vee \cdots \vee L_{j_{k_j}})$
  - $L_i \in \{V_p, \neg V_p\}$
- Question: Is there assignment to the variables in V such that $C_1 \wedge C_2 \wedge \cdots \wedge C_m = \text{true}$?

where $\neg$ is a logical not operator, $\vee$ is a logical or operator, $\wedge$ is a logical and operator. L_i is called a *literal* which is either affirmation or negation of a boolean variable. SAT problem such that clauses are of exactly three literals is called 3SAT. Any SAT instance can be transformed to a 3SAT instance with the same solution. Therefore, without loss of generality, for simplicity, our SAT solver accepts 3SAT instance only.

SAT is widely applicable and one of the most basic NP-complete problems. This problem has been required to be solved as fast as possible because of its significance, but it takes exponential time in the worst case to solve. Recent SAT algorithms can solve problem instances with several million variables in a few hours. SAT algorithms can be categorized into complete-type and incomplete-type. Complete-type algorithms can identify whether any given problem instance is satisfiable or unsatisfiable. In contrast, incomplete-type algorithms can not identify unsatisfiability but satisfiability. Many of common complete-type algorithms can be categorized into so-called DPLL algorithm [2], [3]. DPLL algorithm performs BCP(Boolean Constraint Propagation) procedure, which is a dominant part of the algorithm. BCP procedure occupies 80% to 90% of the whole execution. On the other hand, Davis et al. proposed a method [4] to accelerate BCP procedure by parallel processing with an FPGA. Davis et al. parallelized only BCP procedure for their method to be applicable to various DPLL algorithms. With Xilinx Virtex 5 LX110T and 3.6GHz Intel Pentium 4, Davis et al. experimentally showed that zChaff [5], [6], [7] with FPGA accelerated BCP procedure runs 5 to 16 times faster than the zChaff with the CPU only.

This paper proposes parallelization of BCP procedure on a GPU, rather than an FPGA. Similar to Davis et al.'s method, the proposed method can be used with various DPLL algorithms. However, we adopt divide-and-conquer algorithm [14] (3SAT-DC for short) with BCP procedure as our SAT solver used in the experiments in this paper. 3SAT-DC is complete-type. For a 2.93GHz Intel Core i3 CPU and an NVIDIA GeForce GTX480, our experiment showed that the GPU accelerates our SAT solver based on our BCP-embedded divide and conquer algorithm 6.7 times faster than the corresponding CPU implementation.

The remainder of this paper is organized as follows. Section 2 briefly reviews DPLL algorithm, BCP procedure, and SAT-DC. Section 3 presents the proposed algorithm. Experiments to show the performance of the proposed algorithm are reported in Section 4. Section 5 briefly surveys the related works. Section 6 gives some concluding remarks and future works. Due to the limited space, this paper include no description on CUDA. Readers unfamiliar with CUDA GPU architecture are recommended the literature [8], [9], [10], [11], [12], [13].

2. Preliminaries

2.1 DPLL Algorithm

Basically, DPLL algorithm finds an optimal solution by checking all the patterns of boolean value assignment to the variables in a given boolean expression while discarding hopeless sets of patterns without checking them. One of the methods to identify a hopeless set of patterns is

BCP procedure. Listing 1 shows a pseudo code of DPLL algorithm with BCP procedure. DPLL algorithm performs BCP procedure every *decision phase* which heuristically determines the value of a variable. Other features of DPLL algorithm are not used in the proposed method, and therefore not described in this paper. See the literatures [2], [3] for more detail of DPLL algorithm.

2.2 BCP Procedure

BCP procedure consists of "implication" process and "conflict" process. The *"implication" process* finds a literal whose value is consequently determined by other literals in the same clause, and then repeat this process until no such a literal is found. The *"conflict" process* finds a clause with all literals false. Listing 2 shows a C code of BCP procedure. In the following C codes, literals and clauses are respectively stored in arrays named "atom" and "clause". The number of literals and clauses are hold in variables named "numatom" and "numclause". Value of a literal is true, false, or unknown, which are represented as 1, -1, and 0 respectively. BCP procedure repeatedly calls function BCPEngine (line 7 in Listing 2) until no more implication occurs or conflict is detected. Listing 3 shows a C code of function BCPEngine. After "implication" process, BCPEngine scans all clauses to detect implication or conflict in $O(m)$. If every literal in a clause is false, then BCPEngine finishes after updating flag variable "conf" to indicate that conflict occurs (line 5 to 8 in Listing 3). Otherwise, BCPEngine performs "implication" process. If exactly one literal is unknown (line 11 to 13 in Listing 3) and any other literal is false, then BCPEngine detects implication and assigns the value which makes the unknown literal true into the corresponding element of array "atom" (line 20 to 22 in Listing 3). Then, BCPEngine pushes the index value of the modified element of array "atom" to array "implicated" and increments the stack pointer "sp" (line 23 in Listing 3). Finally, BCPEngine updates flag variable "imp" to indicate the detection of implication (line 24 in Listing 3).

2.3 3SAT-DC

Listing 4 shows a pseudo code of 3SAT-DC where the parameter "f" of function "3SAT-DC" is a given logical expression and notation "f(x=propositional constant)" represents the logical expression such that "f" is simplified by substituting the constant to propositional variable "x" . 3SAT-DC is a recursive procedure for a clause with the minimum unknown literals at that time. The time complexity of 3SAT-DC is $O(m1.84^n)$ [14].

3. The Proposed Algorithm

3.1 An Overview

BCP procedure is inherently sequential because it consists of iterations of $O(m)$ time. Therefore, we parallelize only each iteration on a GPU and performs the other part on a CPU. To do so, we partition m clauses. Listing 5 shows a pseudo code of the proposed CPU code for DPLL algorithm with parallelized BCP procedure. After partitioning given clauses, DPLL algorithm with parallelized BCP procedure searches a solution while transferring data on the current status of search to memory on a CPU or a GPU every decision. The difference between serial DPLL algorithm in Section 2.1 and the parallel version is addition of clause partitioning in line 2 of Listing 5.

3.2 Clause Partitioning

We partition clauses into groups in order to parallelize BCP procedure. Each group is processed by a thread block. Hence, we partition clauses into groups the same number of clauses for load balance. The maximum number of active thread blocks is eight times the number numMP of multiprocessors. Hence, we set the number numsubclause of clauses in a group at (numclause + numMP * 8 - 1) / (numMP * 8). Due to this, the number of groups is at most the maximum number of active thread blocks.

3.3 Parallelized BCP Procedure

This section describes how to parallelize the serial BCP procedure in Section 2.2.

3.3.1 Calling from a CPU

Listing 6 shows a CUDA C code of the proposed parallelized BCP procedure called from line 5 in Listing 5. The differences between the serial BCP in Listing 2 and the parallel version are:

- Status data are packed into the same array as many as possible.
- Data transfers between a CPU and a GPU are inserted before and after do-while statement and kernel function call.

The reason why status data are packed into the same array is to reduce the number of cudaMemcpy execution. The overhead of cudaMemcpy invocation is heavy. Therefore, memory transfer time can be reduced by reduce the nuber of the invocations. In the proposed CUDA C code, flag variables "conf" and "imp" are packed into array "flag". Also, stack pointer "sp" and array "implicated" are packed into array "sp_implicated". Due to these packings, the whole execution time is reduced to about 90%. The proposed CUDA C code transfers array "atom" and "sp_implicated" before and after executing parallelized BCP procedure (line 7 to 10 and 18 to 21 in Listing 6). However, if no conflict occurs, the latter transfer is not performed to avoid excess transfer. After executing kernel function BCPEngine, variable "flag" is transfered (line 15 in Listing 6).

Listing 1: A pseudo code, focusing on BCP procedure, of DPLL algorithm

```
preprocess to detect trivial unsatisfiability
while(1){
  Decision
  while (BCP() == conflict) { if (no more backtrack) return FALSE; backtrack }
}
```

Listing 2: Serial BCP procedure

```
int BCP(int numclause, int (*clause)[3], int *atom)
{
  int conf = 0, imp;
  do {
    imp = 0; BCPEngine(numclause, clause, atom, &conf, &imp);
  } while (!conf && imp);
  return conf;
}
```

Listing 3: Serial BCP Engine

```
void BCPEngine(int numclause, int (*clause)[3], int * atom, int *conf, int *imp)
{
  *conf = 0; *imp = 0;
  for (int i = 0; i < m; i++) {
    if (clause[i][0] * atom[abs(clause[i][0])] >= 0) goto F;
    if (clause[i][1] * atom[abs(clause[i][1])] >= 0) goto F;
    if (clause[i][2] * atom[abs(clause[i][2])] >= 0) goto F;
    *conf = 1; return;
F:
    int numUnknown = 0; int idxUnknown;
    if (atom[abs(clause[i][0])] == 0) { numUnknown++; idxUnknown = 0; }
    if (atom[abs(clause[i][1])] == 0) { numUnknown++; idxUnknown = 1; }
    if (atom[abs(clause[i][2])] == 0) { numUnknown++; idxUnknown = 2; }
    if (numUnknown == 1) {
      // There is exactly one literal of unknown value in clause[i]
      if (clause[i][0] * atom[abs(clause[i][0])] > 0) continue;
      if (clause[i][1] * atom[abs(clause[i][1])] > 0) continue;
      if (clause[i][2] * atom[abs(clause[i][2])] > 0) continue;
      // Any other literal is false
      int litUnknown = clause[i][idxUnknown];
      int val = (litUnknown > 0) ? TRUE : FALSE;
      atom[abs(litUnknown)] = val;
      implicated[sp++] = abs(litUnknown);
      (*imp)++;
}}}
```

Listing 4: A pseudo code of 3SAT-DC

```
3SAT–DC(f)
{
  if (f == FALSE) return FALSE;
  min_c = a clause with minimum number of literals;
  if( min_c == an empty clause ) return TRUE;
  if( min_c == (x) ) return 3SAT–DC( f(x = true) );
  else if( min_c == (x or y) )
    return 3SAT–DC( f(x = true) ) || 3SAT–DC( f(x = false, y = true));
  else /* min_c==( x or y or z ) */
    return 3SAT–DC( f(x = true) ) || 3SAT–DC( f(x = false, y = true))
             || 3SAT–DC( f(x = false, y = false, z = true));
}
```

Listing 5: A pseudo code of the proposed CPU code for DPLL algorithm with parallelized BCP procedure

```
1 preprocess to detect trivial unsatisfiability
2 partition clauses into groups
3 while(1){
4   Decision
5   while (BCP() == conflict) {
6     if (no more backtrack) return FALSE
7     backtrack
8   }
9 }
```

Listing 6: A CUDA C code of the proposed parallelized BCP procedure

```
1  #define BLKSZ 64
2  int BCP_GPU(int numatom, int *atom, int s, int *sp_implicated, int *d_subset,
3              int *d_orderedClause, int *d_atom, int *d_flag, int *d_sp_implicated)
4  {
5    int flag[2];  // flag[0]:conf, flag[1]:imp
6    cudaMemset(&d_flag[0], 0, sizeof(int));  // conf = 0;
7    cudaMemcpy(d_atom, atom, sizeof(int) * (numatom + 1),
8               cudaMemcpyHostToDevice);
9    cudaMemcpy(d_sp_implicated, sp_implicated, sizeof(int) * (numatom+1),
10             cudaMemcpyHostToDevice);
11   do {
12     cudaMemset(&d_flag[1], 0, sizeof(int));  // imp = 0;
13     BCPEngine<<< s, BLKSZ >>>( d_subset, d_orderedClause,
14                                d_atom, d_flag,d_sp_implicated);
15     cudaMemcpy(flag, d_flag, sizeof(int)*2, cudaMemcpyDeviceToHost);
16   } while (!flag[0] && flag[1]);  // conf == 0 && imp != 0
17   if(!flag[0]){  // no conflict
18      cudaMemcpy(atom, d_atom, sizeof(int) * (numatom + 1),
19                 cudaMemcpyDeviceToHost);
20      cudaMemcpy(sp_implicated, d_sp_implicated, sizeof(int) * (numatom+1),
21                 cudaMemcpyDeviceToHost);
22   }
23   return flag[0];  //return conf;
24 }
```

3.4 Kernel Function BCPEngine

Listing 7 shows the CUDA C code of the proposed kernel function BCPEngine. The number of thread blocks is the number s of groups. The number of threads in a thread block is predefined constant BLKSZ. The arguments subset and orderedClause represent partitioned groups together. Each element of orderedClause holds a clause. Clauses in the same group are consecutively stored in array orderedClause. The head index of elements of each group is stored array "subset". The type of orderedClause is int[4] rather than int[3]. Since every clause of 3SAT instance has exactly three literals, int[3] is sufficient to hold each clause. However, the proposed kernel stores each clause into int[4] with padding in order to enable coalesce access.

The kernel function BCPEngine works as follows. As preparation, the number "size" of clauses in the group assigned to each thread block is calculated (line 4 in Listing 7). Also, pointer "orderedClause" is moved so as to point at the head clause of the assigned group (line 5 in Listing 7). Hence, in the lines below line 5, each thread block can access the assigned group via orderedClause[0..size-1]. The processing for each clause is almost same as the serial BCPEngine in Listing 3, but there are four different points. First, flag "conflict" is checked before each clause is processed and if conflict is detected then each thread is finished (line 8 in Listing 3). Second, each clause is loaded into variable "c" of type int4 to realize coalesced access (line 10 in Listing 3). Third, detection of simultaneous implication by multiple threads is processed by CUDA atomic functions (line 27 to 30 in Listing 7). If multiple threads detect implications for the same variable and attempt to assign the variable different values, then conflict should be detected as shown in line 31 in Listing 7. However, even if line 31 is deleted, no problem occurs because it will be detected as conflict at the next invocation of BCPEngine. Preliminary experiments show that the code without line 31 is faster by a few percent. Therefore, we deleted line 31. Fourth, implication flag variable on global memory is not updated immediately. Instead, each thread updates myImplication

flag variable on a register at each iteration and finally updates implication flag variable once (line 34 in Listing 7).

3.4.1 Cache Configuration

The proposed kernel function in Listing 7 never use shared memory. Instead, it relies on cache memory of Fermi architecture. Fermi GPUs can configure size of shared memory and L1 cache memory either 16KB/48KB or 48KB/16KB. Our current implementation never use shared memory. Therefore, we set the size of L1 cache memory at 48KB.

4. Experiments

This section compares the performance of the proposed CUDA program with a CPU program that performs the same computation. We measured the execution time (average of 10 trials for each test) of not only BCP procedure but also whole execution of 3SAT-DC with BCP procedure. We embedded invocations of BCP procedure just before recursive calls in line 6, 8, 10, and 11 in Listing 4, which correspond to Decisions. Furthermore, we set up the maximum number BCPMAX of invocations of BCP procedure. If our SAT solver executed BCP procedure BCPMAX times, we stopped our SAT solver and measured the execution time at that time. If our SAT solver found a solution or exhausted the search space before BCP procedure was executed BCPMAX times, the execution time at that time is measured. We fixed the number of threads in a thread block at 64 because preliminary experiments showed the number is better.

For each test, a single core of 2.93 GHz Intel Core i3 and NVIDIA GeForce GTX480 was used. The OS used is Windows7 Professional SP1 with NVIDIA graphics driver Version 285.62. For compilation, Microsoft Visual Studio 2008 Professional Edition with optimization option /O2 and CUDA 3.2 SDK were used.

4.1 Performance and Problem Size

In this section, we compare the performance of GPU with that of CPU for various problem sizes. The used problem instances were generated by Motoki's 3SAT instance generator G3 (n,m) [15], [16] (G3 for short). G3 generates a boolean expression that has exactly one solution with high probability. In general, to solve 3SAT instance with many (a few) solutions is easy (hard).

Figure 1, 2, and 3 show a performance comparison between CPU and GPU with problem instances generated by G3. As for Figure 1 and 2, x-axis is the number of variables and y-axis is the execution time in second. Figure 1 shows performance for relatively small instances with BCPMAX 50000. Figure 2 shows performance for relatively large instances with BCPMAX 10000. Figure 3 shows the speedup ratios in case of Figure 1 and 2. As for Figure 3, x-axis is the number of variables and y-axis is speedup ratio. Our GPU solver runs faster with an increase of the problem size (i.e., the number of variables). Although GPU is slower than CPU for small problems, it is reversed for 2500 variables. The best GPU performance is about 4.5 times than CPU for 50000 variables. For more than 50000 variables, the performance of GPU tends to decrease with an increase of the problem size.

4.2 Performance and the Number of BCP Procedure Done

In this section, we fix problem size and compare the performance of GPU with that of CPU for various values of BCPMAX. We randomly selected 10 instances from SAT11 Competition [17] with category RANDOM, 50000 variables, and 210000 clauses.

Figure 4 shows the result. The x-axis shows the name of instance file name and the y-axis is speedup ratio. The speedup ratio is improved with an increase of BCPMAX. Even if BCPMAX is 1000, GPU is 1.5 times faster than CPU in average. The best performance (6.7 times speedup) of GPU is obtained when BCPMAX is 10000. For BCPMAX larger than 10000, the performance improvement is negligible.

5. Related Works

As far as we know, there exist five existing research on SAT algorithm parallelized on a CUDA GPU, as shown below.

In [18], Meyer et al. proposed a complete-type method to parallelize 3SAT-DC like us. However, they did not use BCP procedure. Instead, they proposed a problem partitioning method to parallelize divide-and-conquer itself and their own heuristic for Decision phase.

In [19], McDonald et al. proposed an incomplete-type method to parallelize WalkSAT algorithm with clause learning. Their parallelization method is to run many threads such that each thread executes serial WalkSAT algorithm with pseudo random sequence different any other thread.

In [20], Gulati et al. proposed a complete-type method named MESP (MiniSAT enhanced with SurveyPropagation). They experimentally showed speedup ratio of 2.35 in average with 2.67GHz Intel i7 CPU and NVIDIA GeForce 280GTX GPU.

In [21], Wang et al. proposed an incomplete-type method of a celler genetic algorithm with random walk local search.

In [22], Deleau et al. proposed an incomplete-type method such that SAT instance is represented by a 0-1 matrix and 0-1 matrix multiplication is used to search a solution for a given SAT instance.

6. Conclusion and Future Work

This paper has proposed a method to parallelize BCP procedure for SAT algorithm and has implemented a CUDA GPU program based on the proposed method. Experimental

Listing 7: A CUDA C code of the proposed parallelized BCP procedure

```
__global__ void BCPEngine(int *subset, int (*orderedClause)[4],
                          int *atom, int *flag, int *sp_implicated)
{
   int size = subset[blockIdx.x + 1] - subset[blockIdx.x];
   orderedClause += subset[blockIdx.x];
   int myImplication = 0;
   for (int i = threadIdx.x; i  < size; i += blockDim.x) {
     if (flag[0]) return;  // Another thread detected conflict
     int c[4];
     *((int4 *) c) = *((int4 *) orderedClause[i]);
     if (c[0] * atom[abs(c[0])] >= 0) goto F;
     if (c[1] * atom[abs(c[1])] >= 0) goto F;
     if (c[2] * atom[abs(c[2])] >= 0) goto F;
     flag[0] = 1;  // conf = 1;
     return;
F:
     int numUnknown = 0; int idxUnknown;
     if (atom[abs(c[0])]==UNKNOWN) {numUnknown++; idxUnknown=0;}
     if (atom[abs(c[1])]==UNKNOWN) {numUnknown++; idxUnknown=1;}
     if (atom[abs(c[2])]==UNKNOWN) {numUnknown++; idxUnknown=2;}
     if (numUnknown == 1) {  // exactly one literal of unknown value in orderedClause[i]
       if (c[0] * atom[abs(c[0])] > 0) continue;
       if (c[1] * atom[abs(c[1])] > 0) continue;
       if (c[2] * atom[abs(c[2])] > 0) continue;
       int litUnknown = c[idxUnknown];
       int val = (litUnknown > 0) ? TRUE : FALSE;
       int old = atomicCAS(&atom[abs(litUnknown)], UNKNOWN, val);
       if (old == UNKNOWN) {myImplication++;
                            sp_implicated[atomicAdd(&sp_implicated[0],1)]
                            = abs(litUnknown);}
       //else if (old != val) { flag[0] = 1; return; }
       }
     }
     if(myImplication) flag[1] = 1;  //  imp = 1;
  }
}
```

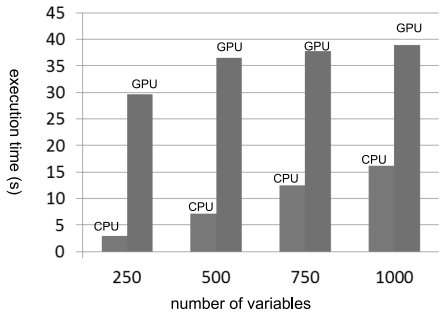

Fig. 1: A performance comparison between CPU and GPU (small instance)

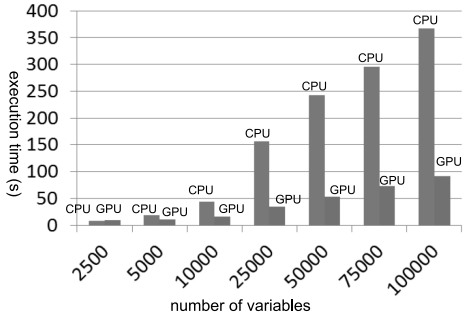

Fig. 2: A performance comparison between CPU and GPU (large instance)

results show that the proposed GPU SAT solver runs maximum 6.7 times faster than the corresponding CPU solver. One of future works is to realize more speedup by improving clause partitioning method and so on.

Exploring Multi-level Parallelism for Large-Scale Spiking Neural Networks

Vivek K. Pallipuram, Melissa C. Smith, Nimisha Raut, and Xiaoyu Ren
Holcombe Department of Electrical and Computer Engineering, Clemson University, Clemson, SC 29634, USA

Abstract**—** *Several biologically inspired applications have been motivated by Spiking Neural Networks (SNNs) such as the Hodgkin-Huxley (HH) and Izhikevich models, owing to their high biological accuracy. The inherent massively parallel nature of the SNN simulations makes them a good fit for heterogeneous computing resources such as the General Purpose Graphical Processing Unit (GPGPU) clusters. In this research, we explore multi-level parallelism offered by heterogeneous computing resources for large-scale SNN simulations. These simulations were performed using a two-level character recognition network based on the aforementioned SNN models on NCSA's Forge GPGPU cluster. Our multi-node GPGPU implementation distributes the computations to either CPU or GPGPU based on task classification and utilizes all the available multi-level parallelism offered to ensure maximum heterogeneous resource utilization. Our multi-node GPGPU implementation scales up to 200 million neurons for the two-level network and achieves a speed-up of 355x over an equivalent MPI-only implementation.*

Keywords **–** GPGPU cluster, Neural Networks, Performance, Scalability, Multi-level Parallelism

1 Introduction

Spiking Neural Networks (SNNs) are very popular in the neuroscience community for modeling the mammalian brain to understand its functional and operational principles. The ability of spiking neurons to reproduce most of the neuronal properties with high accuracy makes them amenable for brain related studies [1]. Biologically inspired SNNs are now popular in other fields such as pattern recognition [2], artificial intelligence [3], and smart control of power grids [4]. Among several SNN models, the Izhikevich model [5] and the Hodgkin-Huxley (HH) model [6] are considered to be highly biologically accurate [1]. The Izhikevich model is the most recent and computation efficient model, whereas the HH model is the oldest and highly computation intensive model.

With the advent of General Purpose Graphical Processing Units (GPGPUs) in the field of high performance computing, the current trend is to extract concurrency from heterogeneous computing resources such as GPGPU clusters. The current state-of-the-art heterogeneous systems are composed of several thousands of compute nodes, where each node is equipped with multiple CPU cores in conjunction with one or more GPGPU accelerators. Since GPGPUs have been established in the literature as viable architecture choice for SNN simulations [7, 8], GPGPU clusters are lucrative options for large-scale SNN simulations and related studies. Although these heterogeneous systems can provide substantial performance for massively parallel simulations, much of their computing resources are often under-utilized due to poor tuning strategies. To achieve optimal utilization of the heterogeneous resources, it is imperative to perform efficient load-balancing between the CPU cores and GPGPU devices, which requires exposing all available parallelism in the application and effective memory and bandwidth utilization.

With the above as motivation, in this research, we investigate multi-level parallelism for large-scale massively parallel SNN simulations. These simulations were performed using a two-level character recognition network based on [2]. The two-level network capable of recognizing 48 alpha-numeric characters was developed using the Izhikevich and HH models. The two-level network was mapped on the *National Center for Super-Computing Applications* (NCSA) 32-node Forge GPGPU cluster and scaled to over 200 million neurons. The focal contributions of this work are:

1) Exploration of multi-level parallelism for spiking neural networks in the form of GPGPU+MPI+OpenMP implementations.
2) Demonstration of optimal load-balancing between the CPU cores and GPGPUs.
3) Scaling of the two-level network beyond the single-node capability.
4) Scalability and performance analysis on the Forge cluster.

Our heterogeneous parallel implementations were able to achieve significant application speed-ups, as high as 355x for the computation intensive HH model and 4x for the computation efficient Izhikevich model over equivalent MPI-only implementations on the Forge cluster. The performance of the two SNN models was found to depend on the computation-to-communication requirements of the SNN models.

The rest of the paper is organized as follows. Section 2 provides a brief background on the two SNN models, the two-level network, and an overview of the GPGPU architecture. Section 3 discusses related work. Section 4 details the experimental set-up and network mapping. Section 5 presents the results and analysis, and the paper is concluded in Section 6 with conclusions and suggestions for future work.

2 Background

2.1 Spiking neural networks

Over the last 50 years, several models [9] have been proposed that capture the spiking mechanism within a neuron. In this paper, we examine two of the most biologically accurate spiking neuron models for implementation on the GPGPU cluster. In what follows, we give a brief chronological overview of these two popular SNN models, namely the Hodgkin-Huxley and Izhikevich models.

The Hodgkin–Huxley (HH) model is considered to be the most accurate and the most important model in the neuroscience community till date. As mentioned in [1], the model involves 4 equations and 10 parameters describing various neuron current activation and deactivation. The model takes 120 flops per 0.1 ms time-step and hence 1200 flops/1 ms for the update. In our research, we have used 0.01 ms time-step for the neuron update.

In [5], Izhikevich developed a simple and very computation efficient spiking neuron model that has similar accuracy as the HH model. Izhikevich successfully reduced the complex HH model equations to a 2-D system of ordinary equations. Izhikevich's model requires only 13 flops per neuron update and still sufficiently reproduces a majority of neuronal properties. The equations are found in [5]. In our research, we have used a 1 ms time-step (13 flops/1 ms update) for neuronal dynamics update for the Izhikevich model.

The time-steps used in our research for the models discussed are in the valid range of time-steps that are deemed sufficient for reproducing biologically relevant neuron dynamics [1].

Table I provides the Flops/Byte ratio for the two models, which is pertinent to the performance analysis of the two models. The Flops/Byte ratio is an algorithm specific value and is defined as the ratio of the number of floating-point operations required for a complete neuron update (level-1 and level-2) to the overall bytes requested (all model parameters, firing vector and block firing vector) for all of the neuron updates [8].

Table I. Flops/Byte ratio for the two models

Model	Flops/neuron required for the complete neuron update	Flops/Byte ratio
HH	246	9.84
Izhikevich	13	0.9997

2.2 The two-level network

The two-level character recognition network used in this research is based on [2] and the network used to test the models is shown in Figure 1. The task of the network is to detect images from a training data set of 48 images. The level-1 neurons act as an input collection layer and the level-2 neurons act as output collection layer. Each neuron in level-1 corresponds to a pixel in the input image; hence the number of neurons in the input level is equal to the total number of pixels in the test image. The number of neurons in the output layer, level-2, is equal to the number of images in the database. When an input image is presented to level-1, each neuron evaluates its membrane potential based on the pixel level presented and the neuron model chosen. This process is referred to as the *evaluation of neuron dynamics*. If the pixel is "on," a constant current is supplied to the neuron for membrane potential evaluation. The input current equation for a level-2 neuron is:

$$I_j = \Sigma w(i,j) f(i) \qquad (1)$$

In (1), I_j is the net input current to the neuron j in level-2, $w(i,j)$ is the weight of the synapse connecting neuron i in level-1 and the neuron j in level-2. A neuron in any level is said to have "fired" if its membrane potential crosses the threshold value for the selected neuron model. The research presented in this paper accelerates the recognition phase of the network by implementing all of the level-1 neurons on the GPGPU devices, while the level-2 neurons (input current accumulation and dynamics) are implemented on the host processors as will be discussed later in Section 4.

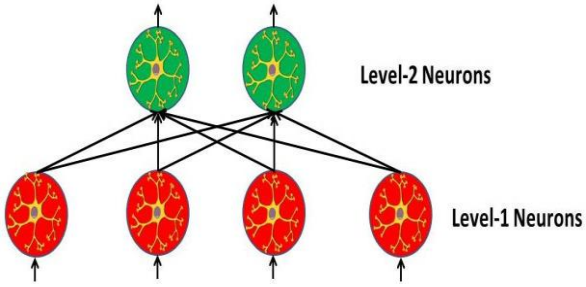

Figure 1. Two-level character recognition network

2.3 The GPGPU architecture

The Compute Unified Device Architecture (CUDA) programming framework views the GPGPU architecture as an array of streaming multi-processors (SMPs). Each multi-processor contains a set of scalar processors (referred to as CUDA cores), a double-precision (DP) unit, shared memory for thread cooperation, and texture addressing and texture fetch units. While a single thread is executed on a CUDA core, a group of threads called a *thread block*, is executed on the SMPs. Threads in a thread block can synchronize with each other using shared memory. The Fermi architecture has brought a lot of innovation versus previous Nvidia architectures: 512 CUDA cores organized as 16 SMPs with 32 cores each sharing a L2 cache. The SMPs have two sets of 16 CUDA cores, 4 special function units for transcendental functions, 16 load/store units, a hefty register file, and a configurable 64 KB L1 cache/shared memory. The GPGPU device has the capability of supporting 6 GB of GDDR5 DRAM memory. The Fermi-based Tesla M2070

used in this research can theoretically offer 1.03 tera-flops of single-precision floating-point performance and 515 giga-flops of double-precision floating-point performance. More information on the GPGPU architecture and CUDA framework can be found in [10] and [11], respectively.

3 Related work

Several research activities have been motivated by the idea of modeling the neocortex. In [12], the authors have studied the mammalian brain neocortex in detail and were successful in simulating a rat-size cortex in 42% of real-time and a cat-size cortex in 23% of real-time on a 442 node Dell Xeon cluster. Their neuron model is in the integrate-and-fire (I&F) category, which according to Izhikevich, is insufficient for accurately reproducing neuronal properties [1]. In [13], the authors successfully used Izhikevich's model to simulate a cat-size cortical model with 10^9 neurons and 10^{13} synapses using a BlueGene/P machine with 147,456 processors and 144 TB of main memory. The authors claim that their simulation scale is roughly 1–2 orders of magnitude smaller than the human cortex and 2–3 orders of magnitude slower than real-time.

Alternative computing architectures such as GPGPUs are now being investigated for biologically realistic simulations. In [7], the authors implemented Izhikevich's random network on Nvidia's GTX-280 with 1 GB memory and achieved a speed-up of 26x over an equivalent software implementation for a 100K neuron network simulation. Their work discusses mapping strategies on the GPGPU to efficiently utilize the memory bandwidth and parallelism.

In [14], the authors investigated GPGPU cluster based implementations of the HH and Izhikevich models using a two-level network based on [2]. They reported GPGPU speed-ups of 24.6x and 177x for the Izhikevich and HH models, respectively over a 2.4 GHz dual-core AMD opteron processor. Their 16 GPGPU-based MPI implementation on a 32-node Tesla S1070 NCSA cluster was successful in scaling the network up to 150 million neurons and achieved 17910 ms runtime for the HH model.

Although our two-level network and experiments are similar to [14], our work is different in the following ways. In [14], the authors perform the level-1 neuron dynamics, level-2 current accumulation, and level-2 neuron dynamics calculations on the GPGPU device. In [14], the authors also claim that the image detection operation (checking if any of the level-2 neurons fired) is inherently serial, therefore it can be performed on the CPU host. As will be highlighted in Section 4, the implementation in [14] is not efficient since the level-2 dynamics calculation is fairly small (only 48 neurons in level-2), performing this operation on the GPGPU device is not warranted and renders the CPU resources under-utilized. Additionally, the evaluation of level-2 neuron currents on the GPGPU device requires the transfer of the large weight matrix to the GPGPU device memory, which is wasteful of the host-device bandwidth and device memory as explained in [15]. Our GPGPU-based MPI implementation achieves optimal load-balancing between the CPU cores and GPGPU devices by implementing the level-1 neuron dynamics on the GPGPU devices and level-2 neuron calculations (current accumulation and dynamics) on the host processors as will be discussed in Section 4. In addition, our work exploits parallelism across multiple levels of the heterogeneous architecture in the form of a complete GPGPU+MPI+OpenMP based implementation.

4 Experimental setup and network mapping

4.1 Experimental setup

NCSA's Forge GPGPU cluster was used in this research for the large-scale SNN simulations. The 153 tera-flop cluster is composed of 36 Dell PowerEdge C6145 servers; each server is connected to six Fermi-based Tesla M2070 GPGPUs via three PCI-e Gen2 X16 slots. Each server is equipped with two 2.4 GHz AMD Opteron Magny-Cours 6136 processors, eight cores each. The network interconnect is comprised of InfiniBand QDR. Our implementations were developed using CUDA 4.0 and OpenMPI 1.4.3 on Red Hat Enterprise Linux 6.

4.2 SNN network mapping

In this sub-section, we first provide the details of network mapping for the single-GPGPU implementation that is subsequently extended to a GPGPU-based MPI implementation.

As discussed in section 2.2, level-1 is the most computation intensive layer of the network since the number of neurons is equal to the number of pixels in the input image; therefore these operations are performed on the GPGPU device. Each GPGPU thread evaluates the dynamics of a single level-1 neuron. Therefore, the number of GPGPU threads created is equal to the number of level-1 neurons. The GPGPU device then provides the host processor with the level-1 neuron firing information, the *global firing vector*, which is used by the host processor to obtain the level-2 neuron currents and dynamics. The level-2 computations (current accumulation and dynamics) are implemented on the host processor since the level-2 neuron computations constitute less than 5% of the total computation overhead and, implementing the level-2 dynamics on the GPGPU would require the transfer of the weight matrix to the GPGPU device memory. Hence any computational improvement obtained by implementing level-2 neuron dynamics will be insufficient to amortize the communication overhead involved in transferring the large weight matrix to the GPGPU device. The single-GPGPU implementation was optimized with memory level, instruction level, and execution configuration level optimizations as mentioned in [15].

The host-device bandwidth was further optimized using a *block firing vector* concept introduced in [8]. The block firing vector is implemented in the device shared memory to avoid transferring the global firing vector in each algorithmic time-step. The block firing vector is similar to the global firing vector but instead acts as a collection of flags for thread blocks. Since the threads are collected in thread blocks of size: *blocksize*, the block firing vector is *blocksize* magnitude smaller than the global firing vector, and hence can be transferred from the device to host in each time-step with minimal overhead. If at any time-step the block firing vector contains information of a firing event, only then will the entire global firing vector be transferred from the device to host and then read by the host. Figure 2 illustrates the block firing vector concept.

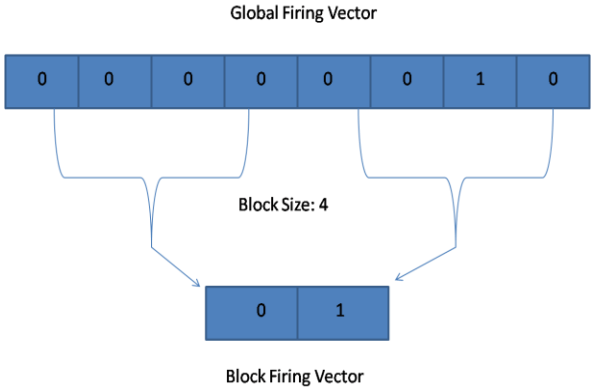

Figure 2. The concept of block firing vector

The single-GPGPU implementation is then extended to a GPGPU-based MPI implementation. The MPI ranks were assigned in node-packing fashion, meaning the ranks are packed into nodes. The nodes were configured with a maximum of six MPI processes per node. This configuration allows for 1:1 CPU core-to-GPGPU ratio at each node and potentially reduces long distance inter-node communication. The GPGPU devices were allotted to the CPU cores using modulo rule where an MPI process with rank *n* is coupled with the GPGPU device number, *n modulo 6* [16]. Future work will investigate the impact of other CPU core-to-GPGPU ratios on application performance.

The GPGPU-based MPI orchestration is as follows. The MPI rank 0 acts as the master process that scatters the level-1 neuron inputs to all other processes. The level-1 neuron parameters are initialized to the SNN model specific constant values at each MPI process, and hence require no MPI communication. Each CPU-GPGPU pair works as an independent unit where the GPGPU device evaluates the partial level-1 neuron dynamics and the host processor evaluates the partial level-2 currents using the firing vector obtained from its designated GPGPU device. The partial level-2 currents from each MPI process are then accumulated at MPI rank 0 where the complete level-2 neuron dynamics are evaluated and the image detection decision is made. The level-2 neuron computations on the hosts were accelerated using OpenMP. Figure 3 elucidates the orchestration of the GPGPU-based MPI implementation discussed in this sub-section.

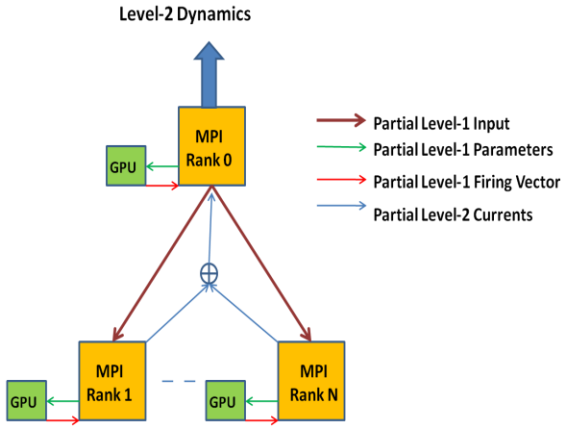

Figure 3. GPGPU-based MPI orchestration

5 Results and analysis

In this section, we present the results for the GPGPU-based MPI implementation of the two-level network developed using the HH and Izhikevich SNN models. We discuss the application runtime values, show the overall runtime breakdown in terms of GPGPU time, CPU time, and communication time for a 32 CPU Core-GPGPU device pair cluster configuration, and compare the GPGPU-based MPI implementation with an equivalent MPI-only implementation. A single CPU Core-GPGPU device pair shall henceforth be referred to as a host-device pair. For the two SNN models, the cluster configuration was varied from 2 up to 32 host-device pairs. We first present the results for the computation intensive HH model followed by the results for the Izhikevich model.

5.1 Hodgkin-Huxley model

The statistical-average runtime values for different cluster configurations versus the network size using the HH model are given in Table II. These runtimes correspond to those measured by the master process, MPI rank 0, which distributes the tasks and makes the final image detection decision. The implementation successfully scaled the two-level network to 200 million neurons using a configuration of 32 host-device pairs with a statistical-average runtime of 2416 milliseconds. The dashes in the table indicate that the problem will not fit in the GPGPU device memory resulting in a configuration failure for that particular neural network size.

Table II. HH model: Statistical-average runtime values (in ms)

Cluster Configuration	Network Size (in millions)			
	9.73	51.8	92.16	207.36
2	1256	-	-	-
4	742	3516	-	-
8	486	1928	3396	-
16	412	1168	1990	-
32	356	784	1195	2416

As seen in Table II, the scalability of the implementation improves with the increase in network size. We define the runtime *improvement ratio* as the ratio of runtimes of two successive cluster configurations for a given network size. For a network size of 9.73 million neurons, the runtime improvement ratio is 1.7 for 2 vs. 4 host-device pairs, 1.5 for 4 vs. 8 host-device pairs, 1.2 for 8 vs. 16 host-device pairs, and 1.15 for 16 vs. 32 host-device pairs. However, for a large neural network size, 51.8 million neurons, the improvement ratios are better with values 1.8, 1.65, and 1.5 for 4 vs. 8, 8 vs. 16, and 16 vs. 32 host-device pairs, respectively. The above scaling behavior is expected since the amount of computations per GPGPU device decreases with the host-device pair scaling. Consequently, for smaller network sizes, the GPGPU computations are not sufficient to amortize the necessary CPU computations and MPI communications.

Figure 4 further supports the scalability explanation given above. The figure provides the overall runtime broken into: GPGPU time (kernel time and host-device transfer time), CPU time (level-2 currents and dynamics), and MPI communication time for a 32 host-device pair configuration versus the network size. For a small network configuration of 13 million neurons, CPU time dominates the GPGPU time owing to a relatively small number of computations per GPGPU device. As the network size increases, the number of computations per GPGPU device increases significantly, thereby making the GPGPU time dominant with respect to the overall runtime.

Figure 5 provides the speed-up of the GPGPU-based MPI implementation over an equivalent MPI-only implementation. The 32 host-device pair configuration was able to achieve a speed-up of 281.8x over the equivalent MPI-only implementation for the largest SNN network size. Table III provides the speed-up values for many of the intermediate network sizes tested. As shown in Figure 5 and Table III, the speed-up over the equivalent-MPI implementation increases with the increase in network size for all of the cluster configurations. The increase in speed-up is due to the amortization of CPU and MPI communication times by the GPGPU computations due to the increased number of GPGPU computations required by the increasing network size. The speed-up values are particularly large for the HH model due to its high Flops/Byte ratio requirements (see Table I). This supports the claim that applications with high Flops/Byte ratios are highly suited for GPGPU-based implementations [8].

Further inspection of Figure 5 and Table III reveals that for a fixed network size, the speed-up of the GPGPU-based MPI implementation over the equivalent MPI-only implementation falls as the number of processors increases. As explained previously, a significant number of computations are required to fully utilize the compute capabilities of the GPGPU device; hence large cluster configurations observe lower speed-ups for smaller network sizes.

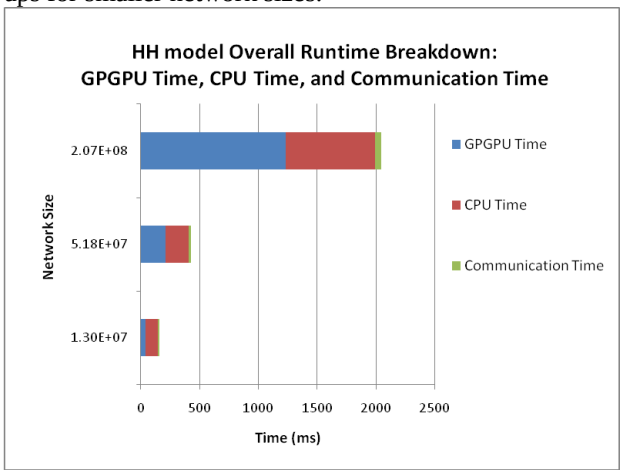

Figure 4. HH model: Overall runtime breakdown for 32 host-device pair configuration

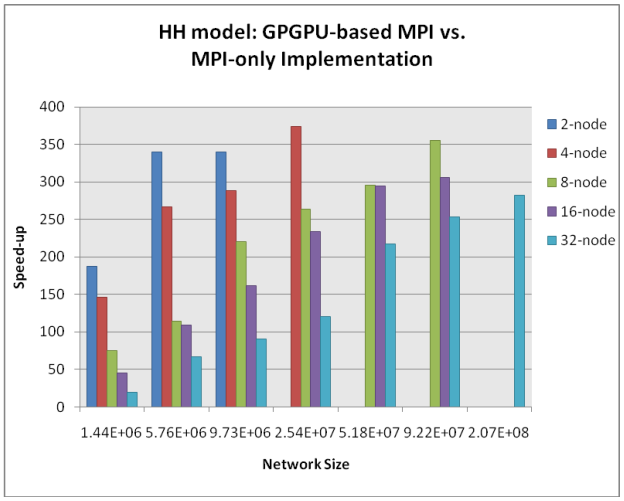

Figure 5. HH model: GPGPU-based MPI vs. MPI-only implementation

Table III. HH model: GPGPU-based MPI vs. MPI-only implementation

Cluster Configuration	Network Size (in millions)			
	1.44	**9.73**	**25.4**	**92.2**
2	187x	340x	-	-
4	146x	288x	374x	-
8	75x	220x	264x	355x
16	44x	162x	233x	306x
32	20x	90x	120x	253x

5.2 Izhikevich model

The statistical-average runtime values for different cluster configurations versus the network size using the Izhikevich model are given in Table IV.

Table IV. Izhikevich model: Statistical-average runtime values (in ms)

Cluster Configuration	Neural Network Size (in millions)			
	9.73	**51.8**	**921.16**	**207.36**
2	180	-	-	-
4	142	928	-	-
8	118	952	725	-
16	96	363	453	938
32	96	491	253	498

Unlike the high Flops/Byte ratio HH model, strong scaling is not observed for the low Flops/Byte ratio Izhikevich model as seen in Table IV. In addition to the lower number of computations in the Izhikevich model (see Table I); the fall in the number of computations per GPGPU device further impedes the scaling performance. Figure 6 provides the overall runtime breakdown for the 32 host-device pair configuration in terms of CPU time, GPGPU time, and communication time.

As seen in Figure 6, the CPU time continues to dominate the kernel time as the network size increases, leading to sub-optimal performance for the Izhikevich model. The continued domination of the CPU time is due to the increased level-2 current computations as the network size increases. Although computations per GPGPU device also increase with the increase in network size, the increase is marginal due to nominal number of computations in the Izhikevich model.

Figure 7 and Table V present the performance comparison of the GPGPU-based MPI implementation and MPI-only implementation. The 32 host-device pair configuration attained a speed-up of 2.87x versus the 32-processor MPI-only implementation. As seen in Table V, the increase in speed-up with the increase in network size is marginal for all cluster configurations examined. The explanation for the fall in the speed-up with the increase in cluster configuration for fixed network size is the same as was given for the HH model.

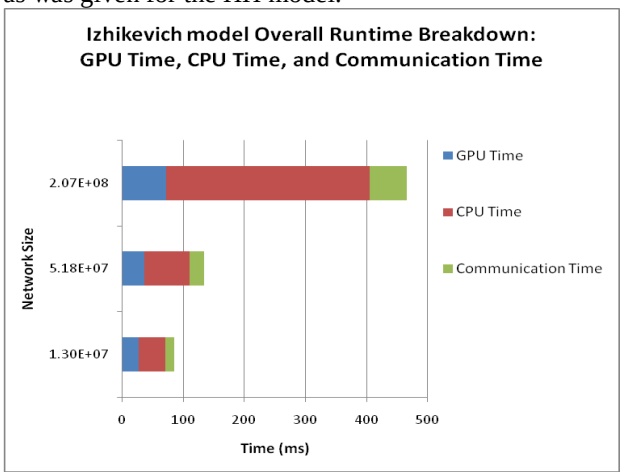

Figure 6. Izhikevich model: Overall runtime breakdown for 32 host-device pair configuration

The Izhikevich model is an interesting case for GPGPU-based MPI implementation. Although the application itself is massively-parallel, it involves only a nominal amount of computations. Therefore, the GPGPU computations do not amortize the increased CPU computation and MPI communication overhead as the SNN network size increases. As mentioned in this sub-section, the level-2 current evaluation for the Izhikevich model increases significantly with the SNN network size. One possible improvement is to implement the level-2 current evaluation on the GPGPU device for larger network sizes. The task would not only require meticulous handling of the GPGPU device memory for the inherent reduction operation involved, but also accommodation of the large weight matrix (48 * Network Size) in the GPGPU device memory. The Izhikevich model explored in this research serves well to highlight the importance of an optimal application-to-accelerator cluster match. It is claimed that applications should not only expose sufficient parallelism, but should also yield enough computations to fully utilize the compute capabilities of heterogeneous clusters. Nonetheless, our GPGPU-based MPI implementations produced performance advantages versus the equivalent MPI-only implementations as shown in this section.

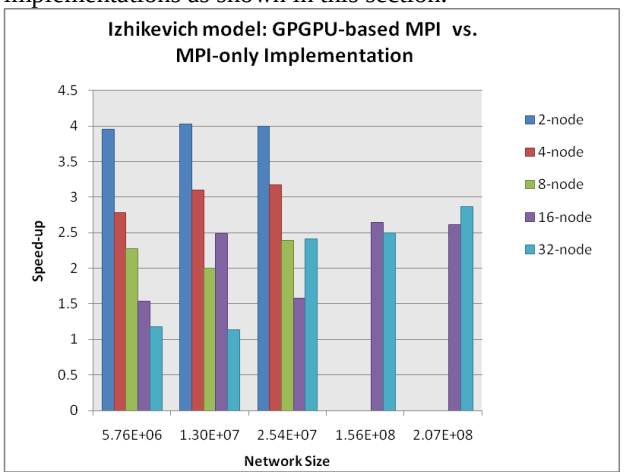

Figure 7. Izhikevich model: GPGPU-based MPI vs. MPI-only implementation

Table V. Izhikevich model: GPGPU-based MPI vs. MPI-only implementation

Cluster Configuration	Neural Network Size (in millions)			
	5.76	13	25.4	156
2	3.9x	4.0x	4.0x	-
4	2.8x	3.0x	3.2x	-
8	2.3x	2.0x	2.4x	-
16	1.5x	2.5x	1.6x	2.7x
32	1.2x	1.1x	2.4x	2.5x

6 Conclusions and future work

In this research, we explored the multi-level parallelism offered by heterogeneous GPGPU clusters for large-scale SNN simulations in the form of a complete GPU+MPI+OpenMP implementation. A GPGPU-based MPI orchestration was presented that allows for optimal heterogeneous resource utilization for large-scale SNN simulations. The two-level network based on the HH and Izhikevich SNN models successfully scaled to 200 million neurons using a 32 host-device pair cluster configuration. In addition to providing significant speed-ups, as high as 355x over an equivalent MPI-only implementation, the GPGPU-based MPI implementation for the HH model scaled well with the SNN network size. Although, our GPGPU-based MPI implementation for the Izhikevich model performed slightly better than the MPI-only implementation, sub-optimal scaling was observed with increasing SNN network size. The results for the Izhikevich model implementation highlighted the

importance of an optimal application-to-accelerator cluster match for maximum application performance. It is claimed that applications should not only expose sufficient parallelism, but should also yield enough computations to fully utilize the compute capabilities of the heterogeneous cluster resources.

As future work, we plan to explore other cluster configurations with different CPU Core-to-GPGPU device ratios per node and investigate the performance of such configurations for large-scale SNN simulations. The future work also includes the development of performance prediction models for heterogeneous clusters that optimally matches the applications with appropriate heterogeneous cluster configurations. As encouraged by the large-scale simulation efforts presented in this research, we also plan to explore GPGPU cluster based smart control of power grids that employs biologically inspired SNNs as massively parallel computation engines.

Abstract— *One of the main consequences of current HPC systems heterogeneity is that different levels of parallelism should be considered in all phases of parallel application development. Therefore, support tools and, in particular, performance analysis and tuning tools, must also be adapted to manage heterogeneity. A significant step forward in this adaptation consists of developing specific strategies to automatically improve the performance of the parallel regions of the application being executed in each computing element. We propose a methodology to systematically develop performance optimization strategies for specific application patterns taking into consideration hardware characteristics. These performance optimizations are intended to be applied by means of the management code provided by most high level libraries. This study describes the methodology developed and shows how it can be used to expose performance factors that can be dynamically tuned on an OpenMP application.*

Keywords: OpenMP, performance analysis, dynamic tuning

1. Introduction

Performance on multicore systems does not depend only on the processor frequency, but mainly on the number of cores, so, intuitively more cores means higher performance. However, cores have shared hardware resources and performance also depends on how concurrency and contention are managed, making it more difficult to meet performance goals.

Nowadays hardware architectures have such heterogeneity that programming frameworks/languages have to take into consideration many possible configurations, going from multicore processors based on a shared memory hierarchy, to manycore proposals based on cores interconnected with mesh on-chip network (Tilera[1]) and dedicated hardware accelerators (GPUs). Nowadays, processor architecture designs tend towards an increasingly higher number of cores in the same processor. The way parallel programming frameworks (defined in a comprehensive way, i.e., including libraries, languages and so on) are going to manage those cores involves a high complexity.

There is a widerange of programming frameworks for multi/many core architectures depending on the implemented programming model. In addition, other models like MPI, have implementations that take advantage of the shared memory hierarchy for communicating processes in the same node. However, shared memory architecture of most multicore systems is usually managed by frameworks implementing the shared memory programming model, such as OpenMP [2], Cilk [3], and so on. Consequently, developing parallel applications is becoming more and more difficult because of heterogeneous architectures and corresponding heterogeneous programming frameworks. Logically, this complexity is also reflected in the performance analysis and tuning process of these applications.

Therefore, due to the growing heterogeneity of multicore systems and the configurability of the parallel programming frameworks, a way for improving the applications' performance is to dynamically adjust the applications' requirements to the characteristics of each hardware architecture using the code provided by the parallel programming framework.

OpenMP is one of the most widely spread APIs for multiplatform shared-memory parallel programming in C/C++ and Fortran. The management of parallelism is made through a library that can be adapted for deploying performance strategies. To adjust the runtime execution, it is possible to use dynamic instrumentation tools, such as Pin[4] or Dyninst[5].

We propose a methodology, that considering an application, an architecture, and a runtime manager, would determine the implication of performance factors, such as loop management, data imbalance, thread imbalance, and so on; and that will help to provide dynamic strategies that can be applied to those factors.

Dynamic tuning is a complex undertaking, particularly since many performance factors and mitigation strategies are not independent. This paper is focused in discussing a methodology for developing these strategies, the defining elements that have been considered, and its objectives. In addition, a complete example of its use is included for a particular application.

To achieve these objective, this works has been structured as follows. Related work is presented in Section 2. Section 3 describes the methodology. This is followed by the methodology applied to a case of study in Section 4 and in Section

5 is described the dynamic tuning tool developed for the performance factor exposed on the case of study. Finally, conclusions are detailed in Section 6.

2. Related work

Dynamic instrumentation is used in performance analysis environments to tune applications at runtime. As an example, MATE[6] performs automatic dynamic tuning by inserting code into the application through the Dyninst library. This framework uses externally provided strategies for taking tuning decision, but it is specific for distributed memory systems and there is no implementation for multicore.

Wicaksono et al.[7] demonstrates the functionality of a collector-based dynamic optimization framework called DARWIN that uses collected performance data as feedback to affect the behavior of the program through the OpenMP runtime. It is able to take different actions, such as modifying the number of threads, adjusting core frequency, or accessing a specialized malloc library transforming the source code, or modifying instructions in the binary. This framework has been evaluated in a ccNUMA platform, therefore, the main performance problems are related to scalability due to data locality between nodes and false sharing detection. However, this global approach does not consider hybrid systems (MPI+OpenMP) where the OpenMP problems are local to the node. Our methodology is oriented to nodes, by considering that, nowadays, most scientific applications use hybrid programming models and improving a local execution will benefit the overall performance.

Other works such as Stephen Olivier et al.[8] and A.Duran et al.[9], are focused on performance issues related to task managing. The first discusses task managing work-stealing algorithm, where it is necessary to define the appropriate number of tasks to be stolen from a remote queue, as well as the performance results achieved on several architectures. While the second proposes a cut-off strategy for limiting the space required to deploy tasks. Various strategies are evaluated to reduce the number of created tasks, and consequently the creation overhead is reduced.

In addition, the utilization of different compilers could be determinant for tasks based applications performance, as shown in an evaluation for different compilers supporting task parallelization is shown in Stephen Olivier and Jan Prins[10].

Up to date, most scientific applications in OpenMP are data parallel. Consequently, we consider that dynamic performance tuning has to take into consideration both, performance related to task and data parallelism, and we have developed our methodology in accordance to this consideration.

3. Methodology

The objective of the proposed methodology is to define models and tuning strategies associated to performance factors in multicore systems. A performance factor is a latent performance problem that can arise in a specific context. The performance factors depend on the application patterns, the high level library, and hardware characteristics.

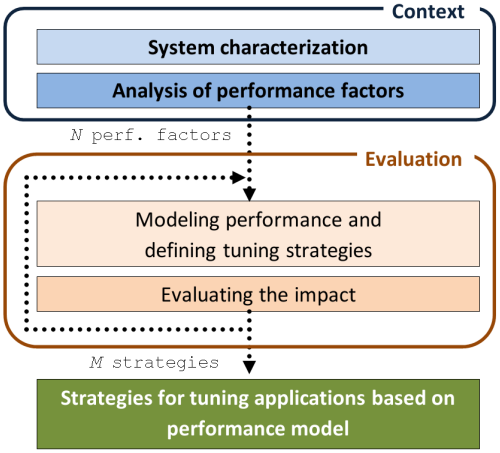

Fig. 1: Methodology for generating dynamic tuning strategies in multicore systems

The methodology has to provide, for each performance factor: what should be measured, the performance model, and the strategies for automatically tuning the application. Fig. 1 shows that the context of the methodology is defined on the first two stages. The first is a characterization of the application, the manager library, and the hardware. Then, this characterization has to provide insight on related performance factors that are affecting the application's performance. This is done generating hypotheses of performance factors.

Afterwards, the next stages are developed for an evaluation on a specific context, trying to achieve the most general solution for a performance factor. Therefore, to find a valid performance model strategy for a performance factor, the methodology has to iterate in order to evaluate different context configurations to validate the proposed strategy.

The general context is presented in the next subsections and summarized in Fig. 2.

3.1 System characterization

As mentioned before, it is necessary to take into consideration the application pattern, and the manager library and hardware specific characteristics.

Latent performance factors may arise when context changes. To observe context implications, it is necessary to analyze static and dynamic information at different levels.

Static information has to be provided from context specification, such as applications configuration (data input parameters, pattern, parallel library), and systems libraries (parallelization paradigm, scheduling parameters), and architecture specification (number of cores, memory hierarchy, and so on).

Dynamic information can be analyzed through micro benchmarking. This information provide context's behavior and some of its low level characteristic, such as system's GFlops on computation bound performance analysis, evaluation of performance for different affinity configurations, and so on.

3.1.1 Application

Scientific programs can be classified by its pattern design (Master/Worker, Pipeline, SPMD), but at thread level those patterns could not present specific performance factors. Moreover, there are more appropriated characteristics in threaded applications such as iterativity, recursivity, computation bound, memory bound, and so on. These properties can better represent the characteristics and related performance factors of a threaded application.

Performance factors at application level are usually coarse-grained, and performance strategies can hardly be generalized. Thus, the detection of these patterns may allow the use of dedicated strategies. For example, some iterative patterns generate thread imbalance by working with umbalanced data. It is possible, to estimate data input patterns, on the first iterations of an application, in order to try to balance the rest of the execution. However, this is a coarse grained strategy heavily linked to the pattern and hardly generalizable.

As an experimental testbed, we use scientific kernels present in different OpenMP benchmarks as NAS Parallel Benchmark[11] and BOTS[12] (Barcelona OpenMP Tasks Suite) that are representative of some communication and computing patterns observed in scientific multicore applications.

3.1.2 Manager library

One of the most widely used programming model implementation is OpenMP, as a superset of threads library. In its last specification it allows data and task parallelism. Thus, the performance factors can be splitted into the specific context of the data parallelism common performance factors related to loop directives, affinity definition, synchronization elements and parallel constructs; and in the case of task parallelism the performance factors are related to scheduling policies (centralized or decentralized), task granularity, number of tasks, and creation overheads.

Some of those performance factors can be measured with specific benchmarks such as the EPCC[13] micro benchmark suite, that allows for studying of OpenMP performance comparisons between different OpenMP implementations.

3.1.3 Hardware

It is important to have an initial knowledge of our hardware system configuration. The hardware performance factors are mainly related to computing capabilities and memory architecture.

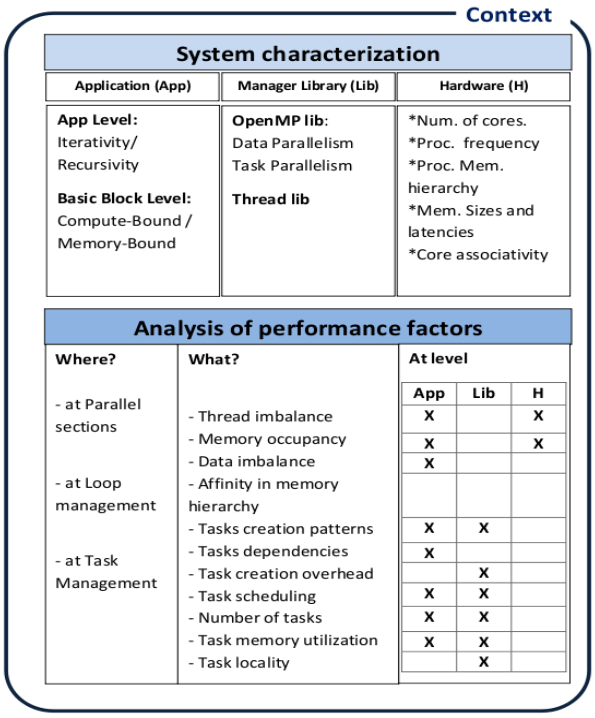

Fig. 2: Context characteristics development template

To analyze the hardware characteristics it is possible to evaluate the dynamic behavior by using benchmark tools. The computing capabilities can be measured with a compute-bound application that can provide metrics such as GFlops. Also, measuring memory issues through benchmarking can provide an insight of the memory architecture. Some benchmark application use threads, therefore, it can be significant to evaluate the system for different numbers of threads and different affinity configurations.

3.2 Analysis of performance factors

The analysis of an application has to provide the inherent problems that can arise at execution time. In order to find the dynamic application problems it must be evaluated for different contexts. A problem can arise, or its impact can affect performance, depending on the architecture, the runtime manager, and the application configuration. When a performance factor is detected it has to be isolated, as much as possible, to identify its sources.

A first step is to identify where the latent performance factor is located, generally associated to parallelized code. The performance issues in OpenMP applications are present on parallel sections, loop regions, and task regions. Each of which are managed by specialized functions of the dynamic library.

The analysis of performance factors, defined into a context, provides a knowledge base. Presumably, the strategies applied for an application could be applied for other similar applications in the same context.

The following performance factors have been classified to be considered by a dynamic tuning tool, in order to feasibly apply dynamic tuning strategies.

1) Thread imbalance; can arise at application level due to data dependencies, synchronization points, and also because of different latencies on core memory access. It is possible to dynamically adjust the number of computing elements and vary the affinity definition, or the scheduling policy, in order to minimize the imbalance.
2) Memory occupancy; threads accessing memory can cause memory contention for the increase of replacements at shared cache level, generating performance degradation. A bad definition at application level can origin this performance factor. The performance degradation can be decreased dynamically by adjusting the number of racing threads.
3) Data imbalance; differences in the amount of data assigned to each thread can cause imbalance. This performance factor is implicit to the application. However, adequate dynamic strategies can be applied for data partitioning and allocation, or data reordering, that have demonstrated to improve performance in some cases.
4) Affinity in memory hierarchy; when an application is executed on an architecture, a mismatch between the application configuration and computing elements sharing memory resources can originate performance degradation. Trying to take advantage of collaborating threads and memory re-utilization sometimes can cause a false-sharing condition. Analyzing the behavior of the application and assigning collaborative threads to the appropriate hierarchy levels will promote collaborative computation.
5) Task management; there are an extense variety of performance factors in the task parallel model. Tasks, as executing units, are also affected by the same performance factors that in the data parallel model. Furthermore, due to its highly dynamic nature, they also present specific performance factors such as those originated at application level due to creation pattern or task dependencies; as well as at library level due to task creation overhead, task scheduling policies, the amount of tasks created, and memory utilization per task. Some strategies can be applied, such as adapting dynamically the granularity of the task level parallelism, and adjusting the scheduler behavior to be aware of the application and hardware requirements.

3.3 Modeling performance and defining tuning strategies

A performance model identifies what is observed, and why is the problem originated. To define a performance model it is necessary to know the details of the performance factor, such as measurable causes (e.g. configuration values, thresholds, memory occupancy) and probable causes (e.g. data imbalance, false sharing). Generating a complex performance model is sometimes counterproductive because the dynamic analysis and data collection generates overhead.

It is also necessary to propose and evaluate the feasibility of applying previously defined strategies to tune the application, such as modifying the number of threads, the scheduling of loops, the distribution of tasks, and so on.

3.4 Evaluating the impact

The applied strategy has to be evaluated. Initially it can be implemented with manual instrumentation. The expected performance gain has to consider that the monitoring, the dynamic analysis, and the tuning strategies are generating overhead. Furthermore, it is necessary to provide certainty that the strategy can be dynamically instrumented.

The methodology has to iterate the performance factor evaluation, until the strategy coverage is considered appropriate. Understanding that, the performance factor could be relevant and the strategy could improve performance for other applications, another hardware system, or another manager library.

4. Tuning the number of threads: Case Study

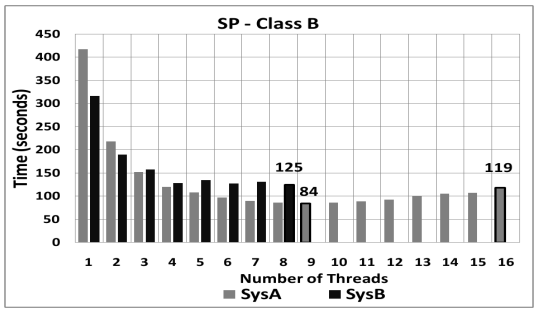
This section shows the application of the methodology on the Scalar Pentadiagonal solver (SP) application of the NAS Parallel Benchmark suite on two different architectures.

This case of study presents an existing performance factor in SP application. By following the methodology stages, the performance factor is detected in the analysis stage, a strategy is proposed to effectively tune the application, and finally, the impact of the strategy is evaluated.

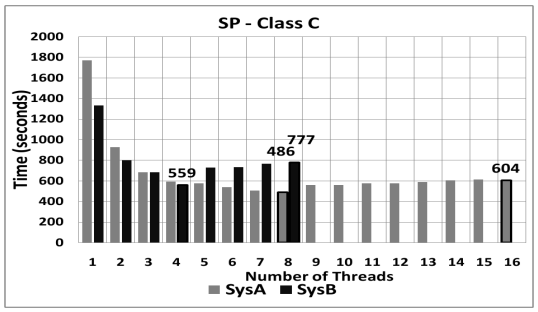
4.1 System characterization

The system characterization provides an insight on the specific context and has been determined following the template in Fig. 2.

- **Application**: SP benchmark of NPB-3.3.1 (OpenMP version), running class B and C configurations. Problem size for Class B is 102 elements and for Class C is 162 elements per matrix dimension. Both classes are configured with 400 iterations. For this application only data parallelism is used.
- **Manager library**: GNU libgomp 4.5.2, which implements the OpenMP 3.1 specification.
- **Hardware**; the following hardware platforms are available to evaluate the application.
  - SysA; SMP system with 2x AMD Opteron 6128 @ 2GHz processors with 8 cores; total amount of 16 cores and 32GB of main memory. Shared cache L1 of 64KB per core pair, Cache L2 of 512KB



(a) SP Class B execution times



(b) SP Class C execution times

Fig. 3: NAS SP Class C and Class D in SysA(16 cores) and SysB(8 cores)

shared by core pairs and shared 5MB of Cache L3 by groups of 4 cores.

– SysB; SMP system with 2x Intel Xeon E5430 @ 2,6GHz processors with 4 cores; total amount of 8 cores and 16GB of main memory. Dedicated Cache L1 of 32KB and Cache L2 shared by core pairs. Enabled hardware counters.

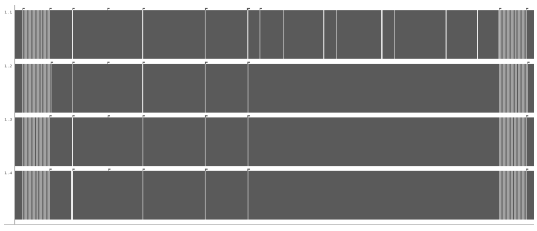
4.2 Analysis of performance factors

The NAS benchmarks have been characterized by executing them in different hardware platforms. There is a set of configurations to be evaluated, by using different data input types (NAS Classes) and by evaluating the benchmarks for different numbers of threads.

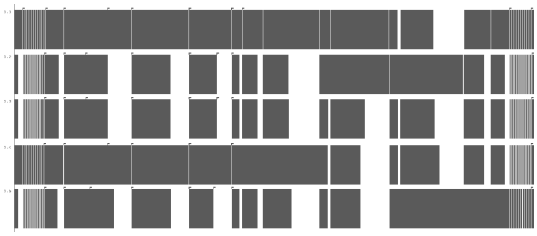
Result on Fig. 3(a) and Fig. 3(b) show a performance issue related with the ideal number of threads to be configured to achieve the best performance. This is because a performance factor is limiting the scalability.

Fig. 3 shows the results for different configurations in both systems. The evaluation of different data sizes and iterations represented by classes B and C into the hardware platforms SysA with 16 cores, and SysB with 8 cores. In all cases it can be seen that using half of the possible threads is achieving the best scalability.

To analyze the origin of the performance degradation, which appears when configuring more than half of the possible threads, it is necessary to compare critical configurations in detail. This analysis, described below is performed on SysB Class C.



(a) System B (4 threads) - 1 SP iteration



(b) System B (5 threads) - 1 SP iteration

Fig. 4: Paraver trace detail for one's SP application iteration on SysB

Table 1: SysB ClassC execution time (sec.) and cumulative percentage (relative to total time T_{ref}) of use for the weightiest parallel regions (x,y and z_solve, and rhs).

	Number of threads							
P.Reg	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*
x_sol	175	87	60	**46**	85	88	103	**120**
y_sol	199	100	70	**53**	87	90	99	**106**
z_sol	224	112	79	**60**	94	96	105	**113**
rhs	537	327	331	**277**	328	342	330	**315**
T_{ref}	1331	797	683	559	725	732	765	777
%	85.2	82.8	79.3	78.3	81.8	81.9	83.2	84.4

Paraver [14] trace visualizer is used for a deeper analysis to compare the execution of 4 threads (559 seconds) and 5 threads (725 seconds) in the architecture SysB. Fig. 4 shows a thread imbalance because a repetitive pattern is observable for 10 iterations in the 4 thread configuration, an undetermined behavior appears for the 5 thread configuration. The dark blocks represent execution and the light blocks represent synchronization, scheduling, and idle states. Thread imbalance performance factor is shown for each iteration in the 5 threads configuration case. The thread imbalance can be measured in detail to find its cause.

The profile shows that the summarized imbalance for 4 threads total execution represents the 1%, and it is increased to 14% for 5 threads. ompP [15] provides the cumulative time spent in every OpenMP parallel region (P.Reg). By analyzing in detail the call graph, to refine the granularity analysis Table. 1 presents the overall percentage for the 4 main parallel regions. The performance degradation between the 4 thread execution in comparison with the 8 thread execution, of x_solve(160%), y_solve(100%), z_solve(88%) and the rhs(13%), is quite significant.

Thread imbalance is located mainly in four parallel re-

Table 2: x_solve parallel region on SysB ClassC for one iteration execution. Where T_{it_n} is the time for n-iteration and T_{ref} is the measured time for 400 iterations.

P.Reg	**Number of threads**							
x_solve	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*
$\%C_{L2}$	1	1	1	1	**7**	**11**	**14**	**16**
T_{it_1}	0.45	0.25	0.16	0.13	0.22	0.22	0.27	0.3
T_{it_400}	180	100	64	52	88	88	108	120
T_{ref}	175	87	60	46	85	88	103	120

gions and, as it is shown in Fig. 4(a) when comparing the same class in different architectures, it is dependant on the system architecture. Therefore, an analysis of parallel regions have to consider hardware implications.

To analyze in detail the origin of the hardware performance factor, a representative function has been instrumented with PAPI [16] to obtain information from hardware counters (L2 cache misses percentage $\%C_{L2}$) for 1 iteration. The results on Table. 2 for the function x_solve show that the percentage of accesses to main memory increases significantly when the last level cache is shared between cores. This indicates that the threads are racing for memory in the highest level of cache, and consequently generating a significant overhead. Consequently, the amount of data generated for the classes B and C are exposing a performance factor related to memory occupancy, taking into consideration the core associativity from the hardware architecture.

The performance factor in the x_solve parallel region is originated by memory occupancy, when threads are sharing L2 cache modules the cache overhead degrades performance.

To conclude the analysis stage and to set an specific context for impact evaluation, the performance factors found in the analysis stage are, thread imbalance (summarized imbalance of 14% in 5 thread configuration), due to different memory access latencies, and a heavier performance factor due to memory bottleneck. As shown in the memory occupancy located at L2 cache in SysB for the x_solve function, which achieves 46 seconds in a 4 threads configuration compared with the 120 seconds for 8 threads configuration.

4.3 Modeling performance and defining tuning strategies

The performance factors exposed in the previous stage have been statically measured through the function execution time, and memory hardware counters. However, it is known that these metrics can be dynamically obtained by instrumenting the application using timers and the PAPI API.

The number of threads can be dynamically tuned by instrumenting the application and inserting in the appropriated point the *omp_set_num_threads(VALUE)* OpenMP function, that allows explicitly to define the number of threads to be created in the subsequent parallel regions.

Taking advantage of this previous knowledge, an initial coarse grained strategy is presented,

The SP application is iterative and those iterations are balanced because they execute in the same time. Then, it is possible to execute the N initial iterations with different configurations to acquire a prior knowledge of the performance. Next, the best configuration parameter is selected to tune the application for the remaining iterations. The SP NAS benchmarks are configured for 400 iterations in classes B a C. The number of iterations for N, used to acquire the best configuration, must be as small as possible.

The performance model proposed is based on selecting the number of threads configuration with the minimum time obtained in the characterization phase.

The strategy has been implemented and executed on SysB, the initial number of threads is configured to the maximum number of available cores, the measurement point is located at the beginning of the iteration. Finally, when the characterization phase is finished, the number of threads variable is tuned to the best selected configuration to achieve the minimum time for the remaining iterations.

4.4 Evaluating the impact

The evaluation of the strategy on SysB is as follows, the average execution time for the instrumented application is 562 seconds, which represents only an overhead of 0.5% compared to the 559 seconds of the original execution with 4 threads.

For this case of study the strategy has been implemented in the application source code. The overhead generated by instrumentation is less than 2 seconds.

Furthermore, the analysis of performance factors have shown that at basic blocks level there are other performance factors based on memory occupancy located at cache level 2 in SysB (evaluated for x_solve function), and also, a natural thread imbalance due to different core associativity of executing threads that achieve different memory access latencies in cores. Therefore, it is necessary to continue with the evaluation phase to define a strategy that achieves a higher impact on the application's performance.

5. Applying the dynamic tuning strategy

With the aim of demonstrating that dynamic tuning on OpenMP is feasible and to analyze the tuning overheads, we have implemented the strategy described in Section 4.

The strategy is implemented as a wrapper to libgomp library. The strategy has been applied by adding the control logic to the entry and exit points of the parallel regions, because parallelism on SP is defined by parallel regions and parallel loops with static scheduling. At low level compilation, those transformations have the same entry and exit point. Therefore, the tuning strategy has been implemented by hijacking libgomp function calls and replacing them with

the monitoring, analysis and tuning functions schematized below.

```
GOMP_parallel_start(params){
  if (characterization_Phase){
    config_Params = generate_Config();
    Start_Timer();
    real_GOMP_parallel_start( config_Params )
  }else{
    real_GOMP_parallel_start( tuned_Params )
  }endif  }

GOMP_parallel_end (){
  real_GOMP_parallel_end()
  if (characterization_Phase){
    Stop_Timer();
  }else{
    if(last_charact_phase( iter_Counter ))
       tuned_Params = time_Analysis();
  iter_Counter++;  }
```

The SP benchmark has been evaluated in different statically characterized architectures. The implemented solution is obtaining the best possible configuration by monitoring only the 5% of total number of iterations. The performance achieved in comparison with the original execution is presented in the table 3.

Table 3: Execution time (sec.) for the dynamic tuning strategy and execution without tuning for classes B and C. The tuning strategy uses 5% of total iterations for the characterization stage.

Class	Tune	SysB.	SysA.	Class	Tune	SysB.	SysA.
B	Dyn.	128	86	C	Dyn.	586	485
B	-	125	119	C	-	777	604
Speedup		0.97	1.38	*Speedup*		1.32	1.24

The strategy has been applied at iteration level. However, it is important to take into account the granularity of the tuning strategy to evaluate this strategy with real applications because it is possible to apply the strategy acting at parallel region level, achieving even greater performance improvements.

6. Conclusions

In this work, we have shown that, due to the growing heterogeneity of multicore systems, a way for improving the applications' performance is to dynamically adjust the applications' requirements to the characteristics of each hardware architecture using the code provided by the parallel programming framework.

A methodology has been proposed, with the aim of detecting performance factors, which can arise as performance problems depending on the context. The methodology must allow to detect performance factors on applications, moreover, for each detected performance factor it helps to define a performance model, the monitoring parameters, and tuning strategies that will allow to develop a dynamic strategy.

The methodology has been applied for a case of study based on the benchmark SP from the NAS PB suite. A performance factor has been presented, which is based on memory occupancy. Monitoring elements have been shown, which are reporting effectively the existence of the performance problem. Following the methodology, a strategy to dynamically tune the application has been implemented and evaluated, achieving a good performance in comparison with by default configuration.

The future work includes evaluating the strategy with a real application, and developing applied strategies for the rest of performance factors mentioned into the methodology.

Abstract— *In communication libraries for recent supercomputers, decisions of appropriate implementations are becoming difficult by increasing size and complexity of them. Especially, because of the wide variety of the rank allocation and the improvability of the collisions, traditional static method cannot choose the appropriate technology for the given situation. As a dynamic technique for choosing implementation technologies, this paper introduces a method that selects a suitable algorithm of collective communications at runtime. At the first invocation of a collective communication, this method predicts the performance of each algorithm from the information about the rank allocation, the network topology and the routing policy. Then it discards the algorithms that are predicted much slower than others. After that, it examines each algorithm at each invocation of the collective communication to find the fastest one empirically. Results of some preliminary experiments showed the efficiency of the proposed method.*

Keywords: Collective Communication, Performance Model, Runtime Optimization

1. Introduction

In high-performance computing, communication libraries are playing an important role. To fulfill the strict requirement on performance with limited resources, they change the implementation technologies of some functions according to the situation. For example, most of the libraries prepare at least two protocols, Eager or Rendezvous, for transferring messages, and chooses one of them with a consideration of the tradeoff between the performance and the memory usage. Similar techniques are used for choosing algorithms for collective communications or deciding sizes of segments in pipelined communications. Previously, these choices of implementations have been done statically, in which they are selected according to the thresholds provided before execution. In most cases, benchmarks on some possible combinations of parameters, such as the number of ranks and the size of messages, are used to decide these thresholds [8], [9].

However, as the sizes and the complexities of computer systems for high-performance computing are increased significantly, such static strategy has become insufficient to enable efficient usage of the systems. One of the reasons is simply because the parameters to be considered has become large in number and wide in range. In addition to that, especially for communication libraries, usage of cost-efficient topologies of interconnect networks, such as Fat Tree, Mesh or Torus, has increased the difficulty on appropriate choice. On these topologies, there are some additional issues that affect the performance significantly, such as the collisions among independent messages, and the distance between the sender and the receiver. This means, even when the number of ranks and the size of the message are the same, best implementation technology can be different according to the situations only known at runtime, such as relative locations of ranks. Therefore, demands for the techniques to choose suitable implementations at runtime are increasing [1], [10].

In this paper, as one of them, a method is proposed for choosing the appropriate algorithm of collective communications at runtime. Collective communications, such as broadcasts, reductions and all-to-all exchanges, are popularly used in parallel programs of computational sciences to achieve productivity and performance portability. There have been many algorithms introduced for each of these collective communications. The method proposed in this paper is a combination of two approaches, performance prediction and performance measurement. At first, it gathers the information about the allocations of ranks, and applies them to the performance models of the available algorithms along with the information about the topology and the routing policy of the system to predict the time for completing the communication with them. By comparing the results, algorithms that are predicted to be significantly slower than others are discarded from the candidates. Then, each of the remained algorithms is examined one at each call of the collective communication to gather the empirical performance data. After all algorithms are examined, the fastest algorithm is chosen to be used for the rest of the calls. In this paper, this method is applied for Alltoall communication on a system with Fat Tree topology. The effect of the method is examined with some experiments.

2. Alltoall communication

As previously mentioned, collective communications are patterns of communications among a group of ranks to

copy, reduce or exchange data. This paper applies our method of runtime algorithm selection method to one of those communications called Alltoall, which is frequently used in Fast Fourier Transform or in matrix transposing. This communication involves every rank interchanging data among all the ranks at the end of the operation. Since each rank needs to send different data for each receiver, this is one of the most network-intensive collective communications used in parallel programs.

There have been many algorithms of Alltoall introduced to achieve better performance. For example, Simple Spread algorithm basically posts all receives and all sends, starts the communications, and waits for all communications to finish. Each rank proceeds with the communication sequentially and the order of the communications for node i is as follows: $i \rightarrow i+1$, $i \rightarrow i+2$, ..., $i \rightarrow (i+p-1) mod p$. This parallel algorithm is achieved using the non-blocking communication, such as MPI_Isend and MPI_Irecv in MPI(Message Passing Interfase). This means that the rank returns immediately after a function call. Thus, consecutive communications can overlap. However, it may cause severe collisions on a rank at which many messages have arrived at the same time.

To avoid such collisions, there are some algorithms that divide the entire communications in phases. For each phase, the targets of communications are carefully chosen so that each rank sends data to different rank. Ring algorithm, for example, uses the phase number as the distance of the target, while the Pairwise algorithm uses exclusive-or on the rank number and the phase number to decide the ranks to exchange data. These algorithms can be further classified by the method how they synchronize the phases. In one implementation, barrier synchronization is called before each phase, while there is another implementation that calls a barrier only once at the beginning of the algorithm. Another approach uses a light barrier in which senders wait for acknowledgement messages from receivers before sending data, like rendezvous protocol.

On the other hand, Bruck algorithm packs data for different receivers in one message to reduce the number of phases. At first, it rotates the data blocks on the rank i by a distance of i blocks both at the beginning and at the end of the algorithm rank. Then it sends messages in $\log(p)$ steps. In each step k, each rank sends to $(myrank + 2k)$ and receives from $(myrank - 2k)$, where $myrank$ represents the id of the rank. Since it requires redundant message transfer, this algorithm is mainly used for small message sizes.

These algorithms are only a part of the introduced ones for Alltoall communication. The relative speed of each algorithm depends not only on the traditional parameters such as the size of the message and the number of ranks, but also other factors such as the topology of the system and the location of ranks. The relative speed among algorithms changes according to not only traditional parameters such as the size of the message and the number of ranks, but also the topology of the system and the location of ranks. Therefore, static strategy cannot find the appropriate algorithm for given situation.

3. Effect of the Rank Allocation on the Performance of Collective Communication Algorithms

This section examines the effect of the rank allocation on the relative performance of the algorithms of collective communications by an experiment.

As the environment of the experiment, RICC (RIKEN Integrated Cluster of Clusters) at RIKEN is used. Each compute node of RICC consists of two processors of Intel Xeon X5570 2.93GHz and 12GB of memory. Each processor has four cores, and the processes are mapped to the cores one by one.

Compute nodes are connected by InfiniBand with Fat-Tree topology. It has two spine switches, and both are connected to all leaf switches. Figure 1 shows the topology, and the routing policy of the interconnect network of RICC. Each leaf switch is connected to each spine switch with two links, which means, there are four links in total from leaf to spine. The total number of compute nodes is 1024. 20 nodes are connected to each of the 51 leaf switches, and four nodes are connected to one. Each compute node has a unique number. As shown in the figure, contiguous numbers are attached to the nodes in a leaf switch; compute nodes on the 0th leaf switch have numbers from 0 to 19, those on the 1st leaf switch have 20 to 39, and so on. On the other hand, four links to spine switches are numbered from 0 to 3. At the transfer of a message to the node in other leaf switch, the node number of the target is divided by four, and the remainder is used as the number of the link to be used for sending the message upwards from leaf to spine, as well as downwards from spine to leaf.

On such topology, the balance of the usage ratio of the links depends on the rank allocation. Therefore, in this experiment, 128 ranks are allocated in five patterns as shown below to see the effect of the unbalanced usage on the performance of the collective communication algorithms.

Pattern 0:

> In each of 32 leaf switches, four ranks are allocated on the compute nodes with the node number of the multiple of four from the one with the smaller

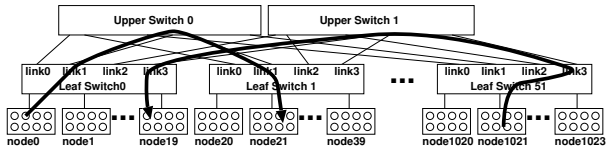

Figure 1: Topology and Routing Policy of the Network of RICC

number. That means in the 0th switch, four ranks are allocated on node 0, 4, 8 and 12, while in the 1st switch, another four ranks are allocated on node 20, 24, 28 and 32, and so on. With this pattern, at each leaf switch, four ranks share one link from, and to the spine switch.

Pattern 1:

In each of 32 leaf switches, four ranks are allocated on the compute nodes with the node number of the even number from the one with the smaller number. That means in the 0th switch, four ranks are allocated on node 0, 2, 4 and 8, while in the 1st switch, another four ranks are allocated on node 20, 22, 24 and 28, and so on. With this pattern, at each leaf switch, each two ranks share one link from, and to the spine switch. With this pattern, at each leaf switch, each two of four ranks share one link from, and to the spine switch.

Pattern 2:

In each of 32 leaf switches, four ranks are allocated on the compute nodes sequentially from the one with the smaller node number. That means in the 0th switch, four ranks are allocated on node 0, 1, 2 and 3, while in the 1st switch, another four ranks are allocated on node 20, 21, 22 and 23, and so on. With this pattern, each rank exclusively use one link from, and to the spine switch.

Pattern 3:

In each of 16 leaf switches, eight ranks are allocated on the compute nodes sequentially from the one with the smaller node number. With this pattern, at each leaf switch, each two of eight ranks share one link from, and to the spine switch.

Pattern 4:

In each of eight leaf switches, 16 ranks are allocated on the compute nodes sequentially from the one with the smaller node number. With this pattern, at each leaf switch, each four of 16 ranks share one link from, and to the spine switch.

Figure 2 and 2 show the elapsed time of each algorithm with the message size of 16KB and 1MB, respectively. Horizontal axis is the pattern number.

In the figure 2, the performance of the algorithm Bruck varies with the pattern. With pattern 0 and 4, the time with Bruck is more than two times longer than the time with the fastest algorithm. On the other hand, with pattern 2, the time with Bruck is almost the same with the fastest one. This is because of the difference of the message size transferred. When the number of ranks is P, Bruck repeats communication with message size 16KB * P/2 for $\log_2 P$ times, while other repeat 16KB message transfers for P-1 times. Therefore, change of the available bandwidth with the pattern has affected severer on Bruck than others. In addition to that, the reason for the difference of the performance

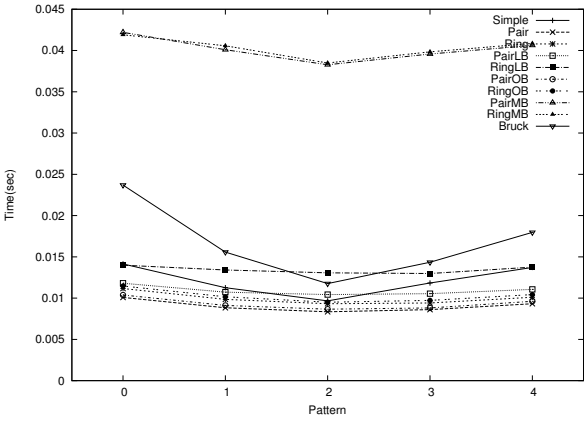

Figure 2: Elapsed time of each algorithm with each pattern(16KB)

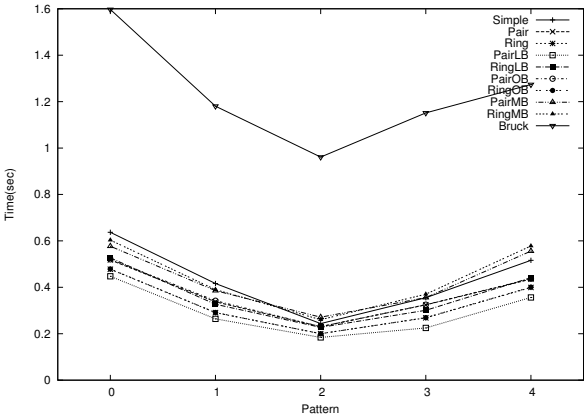

Figure 3: Elapsed time of each algorithm with each pattern(1MB)

between pattens 0 and 4, or patterns 1 and 3 is because the number of communications across leaf switches differs. In the figure 3, on the other hand, other algorithms also show the similar variation of performance with Bruck.

These results denote that the performance of algorithm changes significantly according to the relative locations of ranks. In addition to that, the effect of the rank allocation to the performance differs for each algorithm. Therefore, choice of the algorithm should be done with the consideration of the relative positions of ranks in the network topology.

4. Runtime Algorithm Selection of Collective Communication in Consideration of the Rank Allocation

4.1 Overview of the Method

The method proposed in this paper selects the algorithm according to the rank allocation as follows:

1) Before the execution of the program:
   Gather the information about the topology and the routing policy of the interconnect network of the system. Prepare performance models of each algorithm based on the information.
2) At the beggining of the execution:
   Acquire the information about the rank allocation.
3) At each call of a function of collective communication:
   If it is the first call of the function with the specified parameters, apply the rank allocation information to the performance models to estimate the time with each algorithm. Then, discard algorithms with the predicted time longer than the threshold from the candidate. This threshold is a relative value from the time of the algorithm that is predicted to be the fastest. The ratio of the time used in the experiments of this paper is 2.0.
   For each call, until all of the candidate algorithms are examined, use one algorithm for one call to complete the communication, and record the measured time.
   If sufficient number of measurements are done for each algorithm, choose the fastest one as the best algorithm, and use the best algorithm for the remaining calls.

In this method, the process for predicting performance of algorithms must be designed and implemented in consideration of the topology and the routing policy of the system. This paper introduces an example of the process of performance prediction for Alltoall communications on the Fat-Tree topology of RICC.

On the other hand, as the empirical technique for choosing the best one from the remaining algorithms, STAR-MPI [1] by Faraj, et al. is used. This method consists of two phases, Learning and Probing. In the Learning phase, one of the candidate algorithms is used for each call of the collective communication to measure the execution time with it. After repeated calls, when sufficient measurements are done on each algorithm, this phase is finished, and the fastest one is chosen to be used for the following the Probing phase. In this phase, the execution time of the chosen algorithm is measured for each call. If the time changed significantly from the previous measurement, it uses the second one.

4.2 Performance Prediction of Alltoall Algorithms on a Fat-Tree Topology

This section describes the performance prediction method for Alltoall algorithms on a Fat-Tree topology. In this method, the average bandwidth is estimated according to the topology and the allocations of ranks.

First of all, the estimation of the average bandwidth is done by considering the effect of collisions occur when each rank communicates with all the other ranks. A collision occurs when more than one communications share the same link with the same direction at the same time, The method proposed in this paper assumes that, when a collision occurs, the bandwidth of the link is shared evenly by each of the communications that caused it. Therefore, the average bandwidth of a link is estimated by dividing the base bandwidth of the link without collision, by the expected number of communications that use the link in the same direction.

In calculating this expected number on the link that connects leaf switches and spine switches, the way of calculation depends on the direction of communications. As for the upward direction, a link from a leaf switch to one of the spine switches is shared by communications that have the same value of the remainder after the division of the node number of the target by four. On the other hand, communications to the compute nodes in a leaf switch that share the same remainder of dividing the node number of the target by four share the same link from a spine switch in the downward direction. In this paper, the effects of the collisions in these two directions are assumed to be almost the same. Therefore, only the downward directions are considered to calculate the average bandwidth.

As the parameters for estimating the average bandwidth, N_{node} denotes the number of nodes, P_n is the number of ranks in a node, N_{LS} is the number of leaf switches, LS_i is the i-th leaf switch, UL_{ij} is the j-th link from LS_i to the spine switches, N_i is the number of nodes in LS_i, and NUL_{ij} is the number of nodes in LS_i with the remainder of dividing the node number by four is j. In addition to that, the base bandwidth of the communications in a node, in a leaf switch and across leaf switches is assumed to be the same value B.

The average bandwidth is estimated for each of the types of communications. For the communications between two ranks in a node, they assumed to be no collision, and the average bandwidth remains as B. On the other hand, for communications between two nodes in a leaf switch, one link from a node to the leaf switch is assumed to be shared by all ranks in the node. Therefore, the average bandwidth is calculated to be B/P_n.

For communications across leaf switches, as described above, the expected number of communications that share the same link is used to calculate the average bandwidth. For the link UL_{ij}, the expected number of ranks in LS_i that shares the link at the same time is calculated as follows:

$RCV_{ij} = 1 + (NUL_{ij} * P_n - 1) * (N_{node} - N_i) * P_n/(N_{node} * P_n - 1)$

The weighted average of these estimations of available bandwidth by using the ratio of the occurrence of each type of communication as the weight, is calculated in the following fomula.

$BRij = \frac{P_n - 1 + N_i - 1 + (N_{node} - N_i) * P_n / RCV_{ij}}{N_{node} * Pn - 1} * B$

BR_{ij} is calculated for each i, j with $0 \leq i < N_{LS}$, $0 \leq j < 4$, and the minimum value B_{min} is used as the average bandwidth of the system. This value is applied to the performance models of algorithms to predict the execution

time of collective communication with them. Table 1 shows the models of the algorithms of Alltoall used in this paper.

Table 1: Performance models of Alltoall

Algorithm	Model
Simple Spread	$(P-1)*L+(P-1)*M/B_{min}$
Ring	$(P-1)*(L+M/B_{min})$
Ring with One Barrier	$(P-1)*(L+M/B_{min})+(L*log_2P)$
Ring with MPI Barrier	$(P-1)*(L+M/B_{min})+(L*(P-1)*log_2P)$
Pair with Light Barier	$(P-1)*(L+M/B_{min})+L*(P-1)$
Pair	$(P-1)*(L+M/B_{min})$
Pair with One Barrier	$(P-1)*(L+M/B_{min})+(L*log_2P)$
Ring with MPI Barrier	$(P-1)*(L+M/B_{min})+(L*(P-1)*log_2P)$
Ring with Light Barier	$(P-1)*(L+M/B_{min})+L*(P-1)$
Bruck	$L*log_2P+P*M*log_2P/(2*B_{min})2$

These models use Hockney model as the basic model for point to point communication. In this model, time for each point to point communication is estimated as $L + M/B$ where M is the size of the message, and L and B are the latency and the bandwidth of the network respectively. This is one of the simplest algorithms. There have been some other models, such as LogP [2], LogGP [3] and PLogP (Parameterized Log-P) [4] that are proposed to achieve better correctness of the estimation. For example, PLogP represents the change of the bandwidth for different message sizes. Applying these models to the model of algorithms is remained as the future works.

In the implementation of Alltoall in this paper, L and B of the system are measured before executing the program. A benchmark program that repeats point-to-point communications is used for this measurement. In addition to that, the information about the topology, such as the number of links between leaf switch and spine switch, and the policy of routing are also collected before execution to construct the formula for calculating B_{min}.

On the other hand, the information of rank allocation is achieved at the beginning of the program. This information is applied to the formula to estimate the performance of each algorithm. From the results of this estimation, the algorithms that are predicted to be sufficiently slower than others are discarded from the candidates for the following Learning phase. The experiments in this paper used the threshold of time for discarding algorithms as the time two times longer than the fastest one. This threshold will be examined carefully with consideration of the accuracy of the prediction, in a future work.

5. Experiments

5.1 Overview

To examine the effect of the proposed method, experiments are done on a program called Alltoall Benchmark in the sample codes of STAR-MPI. This program is written in C with MPI, and repeats Alltoall communications for 200 times. The environment of the experiment is RICC. In the experiment, 10 jobs are submitted for each pair of a message size and a number of ranks.

On RICC, jobs are managed by a scheduler that is called Meta Job Scheduler. This scheduler prepares only one job pool, instead of job queues. The users specify the resource requirements at the submission of a job, such as the number of ranks, the size of memory and the estimated execution time. Then the scheduler uses these pieces of information to map the ranks of the job to the scheduling table of compute nodes. Nodes start execution of ranks according to the table. Since there is no job queue or node block, the scheduler can map ranks of jobs to the nodes without considering their locations. Therefore, with this policy, the number of idle nodes can be reduced, which can cause the throughput to be increased significantly.

This flexibleness on allocating ranks causes unstableness of the performance of communications. With this situation, existing static methods for choosing algorithms of collective communications cannot find the appropriate one. On the other hand, runtime selection techniques, such as the one proposed in this paper or STAR-MPI, are able to find suitable algorithms for given situations.

5.2 Results

Figure 4, 5 and 6 show the average times of alltoall communications with 16KB of message size on 1 rank $times$ 32 nodes, 4 ranks $times$ 32 nodes and 8 ranks $times$ 32 nodes, respectively. Horizontal axis is the job number. Each curve of the figures shows the average time with the method proposed in this paper (DYN GROUP), the method of runtime algorithm selection that measures all available algorithms (DYNþ£Őąþ£ŐąNOGROUP), and with the algorithms, Bruck (Bruck), Pairwise (Pair), Pairwise with Light-Barrier (PairLB), Pairwise with MPI-Barrier (PairMB), Pairwise with One-Barrier (PairOB), Ring (Ring), Ring with Light-Barrier (RingLB), Ring with MPI-Barrier (RingMB) and Ring with One-Barrier (RingOB).

As shown in the figures, performances of both DYN GROUP and DYN NOGROUP are close to the fastest algorith in most of the cases. These results indicates that both runtime selection methods could find the fastest algorithm. The overhead of each method is shown as the gap from the time of the fastest one. The major part of the overhead is the time for examining slow algorithms.

Figure 7 and 8 show the ratio of the time of DYN GROUP over DYN NOGROUP, for different number of ranks. In all

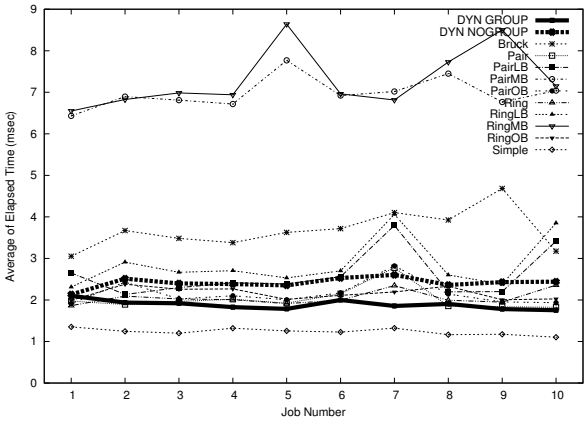

Figure 4: Average Time of Alltoall at each Job (16KB, 1 rank × 32 nodes)

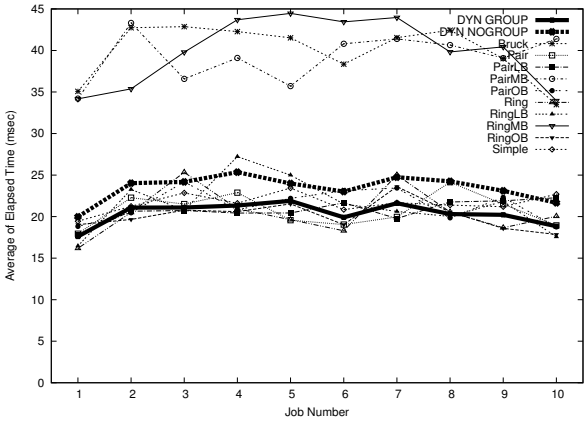

Figure 5: Average Time of Alltoall at each Job (16KB, 4 rank × 32 nodes)

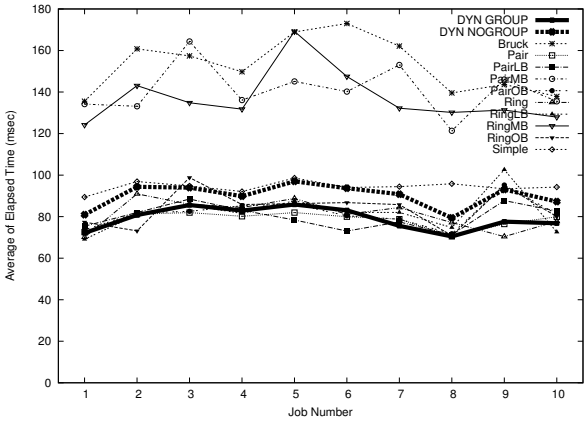

Figure 6: Average Time of Alltoall at each Job (16KB, 8 rank × 32 nodes)

the cases, DYN GROUP was faster than, or as fast as DYN NOGROUP. This is the effect of reducing the number of candidate algorithms at runtime. The reason of the significant effect on smaller message sizes is because most of the available algorithms are for middle or large sizes.

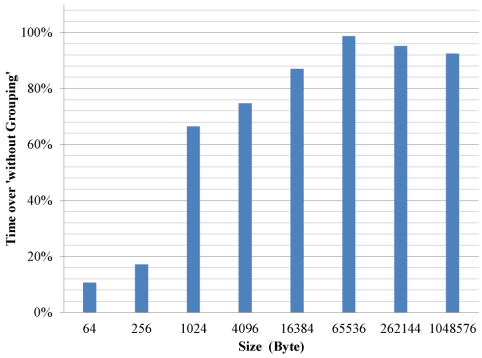

Figure 7: Ratio of the Time with and without Discarding Slow Algorithms (4 ranks × 32 nodes)

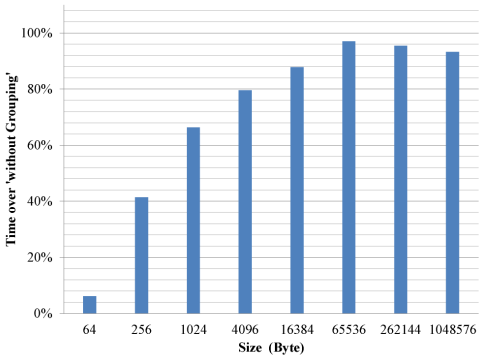

Figure 8: Ratio of the Time with and without Discarding Slow Algorithms (8 ranks × 32 nodes)

5.3 Accuracy of the performance prediction

This section examines the accuracy of the performance prediction introduced in this paper. As an example, Table 2 compares the predicted time with the average of the measured time of each algorithm in the case with 1 rank × 32 nodes.

The predicted time is less than a half of the measured time. Therefore, the prediction is not accurate enough. In the experiment, the proposed method has discarded two algorithms, Pair_mpi_barrier and Ring_mpi_barrier because they are predicted to be more than two times slower than the fastest one, Simple. However, the measured times shows that Bruck was also more than two times slower than Simple.

Therefore, the performance is expected to be gained if the prediction becomes more accurate. For example, us-

Table 2: Measured and Predicted Time of the Algorithms

Algorithm	Measured Time (ms)	Predicted Time (ms)	Remained or Discarded
Simple	1.352	0.606	remain
Pair	1.974	0.606	remain
Ring	1.865	0.606	remain
Pair_light_barrier	2.650	0.776	remain
Ring_light_barrier	2.310	0.776	remain
Pair_one_barrier	1.912	0.661	remain
Ring_one_barrier	1.989	0.661	remain
Pair_mpi_barrier	6.432	2.366	discard
Ring_mpi_barrier	6.551	2.366	discard
Bruck	3.053	1.150	remain

ing more detailed performance models, such as LogGP or Parametrized LogP, may solve this problem.

6. Related Works

Several algorithms for improving the performance of collective communications have been proposed for decades [5], [6]. More recently, some researchers have focused their efforts on taking advantage of existing algorithms in order to find techniques for selecting the most efficient algorithm for any given system/workload configuration. For example, Abdul Hamid, et al. have proposed an analysis of algorithm selection for optimizing collective communication with MPICH for Ethernet and Myrinet networks [8]. Instead of using the same thresholds for any MPICH installation on any parallel computer, they have investigated a way to find the optimum change-over points for different systems. Still their approach is a static optimization that could not be applicable on unstable situations by all means. Thus, Faraj, et al. have proposed STAR-MPI [1]. Their solution for tackling the best-performing algorithm selection problem uses dynamic profiling empirical data coupled with a static algorithm grouping method based on the performance results of different network platform systems. In addition, the authors also mentioned that the number of candidate algorithms can cause severe overhead, and performance models of those algorithms can be a clue to reduce their number. Nishtala, et al. have implemented a method of runtime algorithm selection on GASNet [10]. This method reduces the number of candidate algorithms by using performance models of them. However, since this method does not consider the effect of rank allocations, the estimation of the performance is not precise enough. In addition to that, this method measures the execution times of all candidate algorithms at the first call of the collective communication, overhead of the method is significant.

We have proposed an idea about combining both performance prediction and runtime measurement for choosing algorithms at runtime [11]. In this method, latencies and bandwidths are measured at the beginning of the program. Because the available number of measurement is limited to achieve low overhead, this method cannot consider the effect of rank allocation sufficiently.

7. Conclusions

A method for choosing an appropriate algorithm of a collective communication at runtime was proposed. This method used information about the network topology, the routing policy and the rank allocation to reduce the number of candidate algorithms examined at runtime. As an example of this method, Alltoall communication function was implemented for Fat-Tree topology of RICC. Experiments showed that the proposed method could find an appropriate algorithm with low overhead.

As the future works, functions for other collective communications and other topologies will be constructed.

USING INTELLIGENT AGENTS FOR PERFORMANCE TUNING OF BIG DATA PARALLEL APPLICATIONS

Sherif Elfayoumy
School of Computing, University of North Florida, Jacksonville, FL, USA

Abstract - *Clusters of workstations are widely used to carry out big data applications. Applications running on these architectures may not produce the anticipated speedup because of imperfect load distribution. Developing intelligent application support tools that help improving performance by adjusting performance parameters is of great importance for the big data applications. A new architecture is presented in this paper to tune the performance of big data parallel applications with minimal effort from the application programmer and designer. This architecture is based on using intelligent agents to automatically and adaptively decide on load distribution with a focuses on image processing applications. This architecture is comprised of several features that are well-suited to heterogeneous environments, including: a flexible image partitioning scheme that assigns tasks in proportion to workstation's computational capabilities, an overlapping task assignment scheme that allows load balancing operations to be carried out with minimal communications overhead.*

Keywords: Big Data; Intelligent Agents; Performance Tuning; Parallel Computing.

1 Introduction

Many of today's applications are resource intensive with steadily increasing computational demands due to processing unprecedented amounts of data. As applications and data modality become more complex, new generations of hardware and software architectures are needed to serve the increasing demands of these applications. Achieving high-performance usually involves efforts on both hardware configurations and software architectures. The following sections introduce modern high performance computing architectures and the different classifications of intelligent agents as the core of next generation software.

Many hardware architectures have been developed through the last two decades to support high performance computing ranging from vector and superscalar processors to supercomputers and parallel computers. Supercomputers of commodity components are recognized today as one of the most efficient computer architectures that can provide an economical alternative for organization with big data processing needs [1]. Generally, clusters of workstations follow the distributed memory MIMD architecture, and usually achieve the required parallelism using direct message passing, or using software emulators to coherently share distributed memories [2]. This architecture has many advantages such as, no bus contention and no cache coherence. Commonly, processors exchange data by passing messages, which may result in some drawbacks such as increased latency and interruptions caused to the receiving processor to handle the received messages. Recognizing the concept of locality in designing parallel algorithms is recommended to minimize the number of messages traversing the interconnection network [2].

Performance instrumentation, prediction, analysis, and tuning play important roles in the design, development, and evaluation of big data applications. In parallel environments, the performance parameters space is much larger than that of the sequential case; consequently, dealing with performance in parallel environments tends to be more complex. The alternative of simulating various performance parameters is time consuming and for many large applications it may be impossible to accomplish in a reasonable amount of time. Numerous scattered efforts have concentrated on developing specific tools to help users instrument, analyze, predict, and tune the performance of their parallel and distributed applications using broad range of approaches. Most of these tools are run-time, using performance data gathered by instrumenting the application [5, 6, 7]. Unfortunately, for many reasons very few of these tools are actually being used [8]. A definition of the features needed to exist in performance analysis tools is provided by Reed et al. [9]. They emphasize that optimizing the behavior of complex parallel applications requires performance analysis tools to evolve, and replace postmortem analysis with real-time, adaptive optimization, and supporting high modality visualization. These new tools combined with big data application forms new paradigms of software architectures and we believe intelligent agents can be in the core of such tools.

Most of the performance problems in parallel applications are caused by imperfect load distributions. Developing intelligent agents to continuously monitor the load distribution and autonomously attempt to redistribute the load in a more balanced fashion should improve the overall application performance. Load-balancing techniques are distinguished by the timing of the load-balancing operations. Dynamic load balancing (run time) offers the most flexible and challenging load-balancing type because they provide for flexible scheduling policies that consider varying computing climates.

The problem of dynamically balancing load is typically divided into the following five phases: load evaluation, profitability determination, work transfer calculation, task selection, and task migration. Before load balancing is performed, it is necessary to establish that a load imbalance exists. A good load evaluation not only makes a good determination of the system load, but also does so with

minimal overhead measurement techniques. The load evaluation should also maintain some type of estimates associated with individual tasks to determine which tasks should be transferred to which workstation to balance the computation in the best possible way. Once it has been determined that a load imbalance exists, the cost of the imbalance should be contrasted with the cost of rebalancing. If the cost of the imbalance exceeds the cost of performing load balancing, then we should perform some load balancing. This comparison of the cost of imbalance vs. the cost of load balancing is the profitability determination.

The third phase involves the consideration of the measurements taken in the first two phases, to determine the work transfers necessary to balance the load. These considerations are used to generate a work transfer set. This set is the set of tasks that, once migrated, will rebalance the processing load. Next, in the task selection phase, we must select a set of tasks for exchange or transfer that will fulfill the work transfer set computed in the previous phase. When considering tasks for exchange or transfer, communication locality and task size should be considered. Thus, we should consider the cost of moving a task over a link, and the size of the transfer, since larger tasks will take longer time to migrate than smaller tasks. The final step in load balancing is to actually perform the exchange or transfer of tasks from one workstation to another. This step must be done carefully and correctly to ensure continued communication integrity and algorithm/program correctness. Additionally, if cost is not considered in this final phase, an excessive number of tasks can be transferred or exchanged, and the migration of these tasks will negatively influence system performance.

Due to the vast and varied number of parallel algorithms and the class of problems to which they are applied, there is no single dynamic load-balancing methodology that produces optimal results for all unbalanced workloads. Therefore, dynamic load-balancing strategies must not only be tailored to individual parallel run-time environments, but also tailored to the class of problems on which they operate. For these reasons, our solution is focused on big data applications, particularly those that process images.

A dynamic load-balancing approach for heterogeneous computing environments, DynamicPVM, was presented by Overinder [1]. DynamicPVM can offer speedups of 1.17 in light to medium load situations. While this approach can work in heterogeneous environments, tasks can only be migrated between similar architectures, which prevents it from becoming a true heterogeneous load-balancing approach. Furthermore, DynamicPVM utilizes frequent checkpoints in load-balancing operations causing computations to stall on all workstations during balancing operations.

Zaki and Parthasarathy presented several customized approaches to dynamic load-balancing [2]. The classes of applications that Zaki and Parthasarathy proposed customized approaches for include: matrix operations and TRFD from the Perfect Benchmark suite. Their work clearly demonstrates the effective use of differing strategies for different applications. However, all of the strategies they presented were developed for a homogeneous mix of workstations, rendering their results inappropriate for heterogeneous environments. Furthermore, each of their strategies relied upon synchronization points to perform load-balancing operations. These synchronization points can be a source of performance degradation on faster workstations that must wait on slower workstations to reach the synchronization point, making them even less suited to heterogeneous environments where performance capabilities offered by individual workstations can vary significantly.

Bozyigit presented a dynamic load-balancing scheme for heterogeneous networks of workstations that utilizes the previous execution histories of tasks to partition the current workload in such a manner as to minimize the need for rebalancing operations during computations [3]. While this method is suited to heterogeneous networks of workstations, rapidly varying load situations during computations remain unbalanced, resulting in sluggish load-balancing operations.

A comprehensive approach to dynamic load-balancing was presented by Watts [4]. This approach incorporates several features including: a diffusion algorithm that allows for balancing decisions to make trade-offs between work transfer and overall run time, and flexible task selection mechanisms that allows task movement to be governed by task size and communication costs. This approach has two serious drawbacks. First, the relative capabilities of each workstation are not considered when making load balancing decisions, making this approach poorly suited to heterogeneous environments. Second, this approach fails to balance the individual components that comprise the system load, which yields a low overall efficiency.

Most dynamic load-balancing strategies for rectifying load imbalances involve the migration of tasks from heavily-loaded workstations to lighter-loaded workstations. Hamdi and Lee presented a unique method for load balancing image-processing applications: instead of redistributing the tasks, they proposed the redistribution of the data [5]. This method would seem to incur large communication; however this approach is well suited to big data parallel applications such as image processing. Hamdi and Lee's approach is successful in rebalancing light and medium load imbalances, but offers poor performance when a large load imbalance exists between workstations. Furthermore, their approach partitions tasks into equal-size pieces for computation. This approach is not well suited to heterogeneous environments where the capabilities offered by individual workstations may vary significantly.

Hui presented a dynamic load-balancing system called DELAY [6]. DELAY incorporates a useful feature for dynamically load-balancing tasks executed on loosely-coupled architectures such as NOWs: the delay between load

measurement and reporting is considered when making load-balancing decisions. DELAY's scheduler prevents new tasks from being scheduled on a given workstation once the number of active jobs executing on it reaches a given threshold. DELAY requires the user to provide information regarding the relative capabilities of each workstation, making this approach poorly-suited not only to large networks of workstations, but also rapidly changing load scenarios.

Most of the investigated approaches are either limited to homogeneous environments, or are specifically tailored to a class of applications not congruous to image processing. Furthermore, these load-balancing approaches are designed not only to deal with unbalanced workloads resulting from non-uniform algorithms, but also load scenarios that change gradually and infrequently [5]. Practically, heterogeneous clusters of workstations can have load situations that vary frequently and dramatically.

2 Intelligent Agents

Software agents have evolved from multi-agent systems (MAS), which in turn form one of three broad areas, which fall under distributed artificial intelligence (DAI). The other two DAI areas are distributed problem solving (DPS) and parallel artificial intelligence (PAI). Hewitt [10] proposed the concept of the self-contained, interactive and concurrently executing object, which he termed *"actor"*. He defined an actor as "a computational agent that has a mail address and a behavior. Actors communicate by message passing and carry out their actions concurrently". Several definitions have been proposed to define an intelligent agent, although some of them are very specific to certain types of agents. Nwana [11] defines an agent as referring to a component of software/hardware that is capable of acting exactingly in order to accomplish tasks on behalf of its user. Despite the variety of definitions, there is general agreement that a good agent should possess most of the following features: intelligence, autonomy, taskability, awareness, a*ctiveability, flexibility, t*rustworthiness, adaptability, collaboration, and learning [12]. Nwana [11] has listed several dimensions to classify agents according to the features they exhibit, such as mobility, architecture, primary attributes, and role. Mobility is defined as the agents' ability to move around the network, so an agent can be classified as either mobile or static. According to architecture, agents are classified into three well known different classes of architectures, namely, the deliberative, reactive, and hybrid architectures. A minimal list of three primary attributes is developed. This list includes autonomy, learning, and cooperation. An agent may exhibit one or more of these primary attributes. Finally, the role that should be played by the agent is the last dimension for classifying agents. Examples of agents' classes in this dimension include, but not limited to, control agents and information agents that manage huge amounts of information such as the Internet search engines.

There are several more attributes to classify agents, but they are considered secondary to those mentioned. Out of the above classification, seven types of agents are identified: 1) collaborative agents, 2) interface agents, 3) mobile agents, 4) information/Internet agents, 5) reactive agents, 6) hybrid agents, and 7) smart agents [11]. Also, some applications combine agents of two or more of the above-mentioned categories. These agents are referred to as heterogeneous agent systems. The next section introduces an agent-based approach for parallel computing.

3 Agents-based Architecture

Although the primary motivation for using parallel computing platforms to carry out big data applications is their speedup potential, this potential is often difficult to realize in practice. Since many algorithms and development techniques can be used to build these applications, many system and performance parameters are involved. This causes difficulties in achieving the anticipated speedup without careful analysis and tuning of performance parameters. One objective of this research is to develop a new paradigm for adaptive performance tuning of big data parallel applications that is based on intelligent agents (performance agents).

The performance agent monitors the application behavior during run time, and adapts and tunes performance parameters' values (PPVs). The goal is for this performance agent to interact (collect, analyze, and decide) with the application as if it is an expert human user, so that performance is always improved, or at least not degraded. A general model for this approach is depicted in figure 1. The performance agent regularly receives the PPVs of each logical process (LP), and then it starts analyzing these values. Usually, the performance agent adapts and tunes these PPVs and finally sends the new values back to the corresponding logical processes. If the performance agent decided that no changes could improve the performance at this time, the application would continue using the same PPVs. Unfortunately, this may be difficult to achieve because many performance parameters are correlated, and this operation is expected to be time consuming. Thus, the agent uses heuristic techniques to find PPVs that lead to better performance.

This research recommends that a performance agent should exhibit intelligence, autonomy, adaptability, collaboration, and reusability. Also, it should act on behalf of the human user to make performance-enhancing adjustments to PPVs, thus showing intelligence. Although the agent can make independent decisions (autonomy), it can accommodate adjustments made by the user, thus showing adaptability. Moreover, a parallel application can have more than one agent. Each of these agents should perform a single job, such as a performance agent or a visualization agent. However, agents are not supposed to either overlap or compete. They can cooperate and exhibit collaboration. This performance agent needs to be generic such that it can be used with different parallel and distributed applications with different

topologies and underlying architectures, thus displaying reusability. Briefly, this paradigm is based on employing a performance agent that exhibits the above-mentioned features, to continuously improve the parallel applications performance.

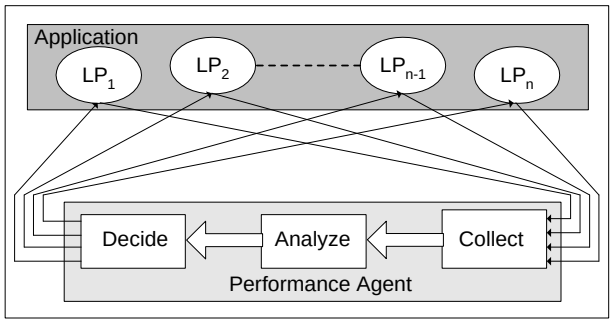

Figure 1. General Model

The architecture presented in this paper extends the approach presented by Hamdi by providing developing agents that are capable of balancing the load of processing a stream of images through the use of a flexible image partitioning scheme. Agents provide an adaptive load-balancing scheme by managing overlapping regions of computation. This architecture consists of one manager process agent, and a set of worker process agents. The manager process is responsible for queuing of the incoming image stream, image partitioning, transmitting data to workers, receiving completed computations from workers, and saving the processed images to disk. The manager process agent is responsible for balancing the load. The manager process flow diagram is depicted in Figure 2.

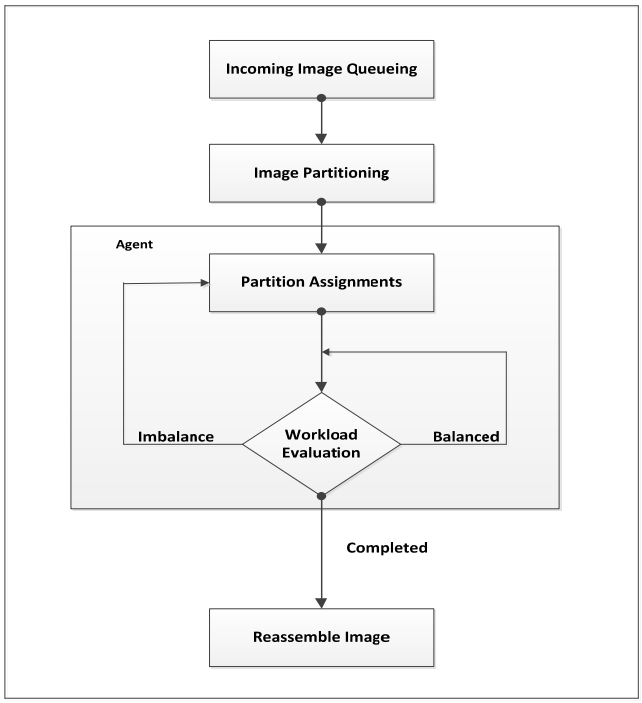

Figure 2: Manager Process Flow Diagram

Each worker process receives image data from the manager to process, processes image data, communicates local load information to the manager, and transmits processed image data back to the manager process. The worker process flow diagram is depicted in Figure 3.

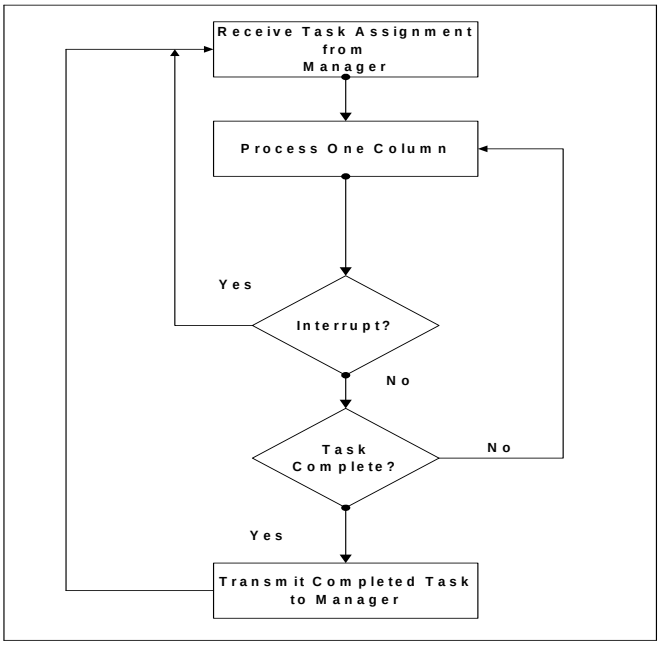

Figure 3: Worker Process Flow Diagram

This dynamic load-balancing architecture is designed for heterogeneous clusters of workstations, and first consideration was given to the load measurement scheme. In a heterogeneous environment, a load measurement scheme that eliminates the comparison challenges due to performance peculiarities of varying CPU and hardware architectures is desired.

3.1 Load Management

Hamdi proposed the use of the number of pixels processed at a worker to be a good load measurement [5]. This technique is adopted in our architecture for several reasons. First, count of pixels processed is a scalar value that presents no comparison challenges due to differing architectures. Second, a faster worker will be indicated by a large number of pixels processed when compared to other workers in the cluster. Additionally, the number of pixels processed is a load measurement that can be made by each worker with minimal impact on worker performance. Thus, we not only have a means of load measurement that presents no comparison challenges, but also whose measurement imposes little load on a worker.

3.2 Collection of Load Information

The manager process sends load interrupts to all worker processes. The frequency at which this occurs is to be determined experimentally. Upon receipt of a load interrupt, a worker transmits a vector containing the number of pixels it

has processed since the last load interrupt it received, and two additional scalar values that will be discussed later, to the manager. A worker resets its local pixels processed counter after it has transmitted its load measurement so that load measurements remain current, and do not reflect an execution history that is not commensurate with the current worker load situation.

3.3 Task Partitioning

Since the manager process in this architecture must collect load information from each worker process, the partitioning scheme should use this load information to assign tasks to workers in proportion to their historical contribution to the overall system throughput.

Assuming that we have n workers, let ℓ_i denote the load for worker *i*, where 0<=i<n-1. Recall that information is a scalar, the number of pixels processed. We compute the system throughput, or cumulative workload, in pixels processed per system time quantum (CW) using the following summation: load

$$CW = \sum_{i=0}^{n-1} \ell_i$$

The manager determines the percentage of columns in the image assigned to worker i,(A_i) by solving the proportion:

$$A_i = \frac{\ell_i}{CW}$$

Thus, each worker receives an image partition sized in proportion to its contribution of the current system throughput in pixels processed. In this way, image data is distributed in proportion to each worker's capabilities.

The manager process uses column wise block striping to partition incoming images. Each worker is assigned a partition based upon A_i. Next, we define a task vector that contains several scalar variables that the manager will transmit to each worker to describe the details of its next work assignment. The manager determines the leftmost and rightmost columns that worker i will be responsible for processing, designated LB_i and RB_i respectively. To offer reduced-cost load rebalancing operations, this architecture will transmit some columns in the image to two neighboring workers. By doing this, we eliminate data transmission requirements in remapping operations. With the existence of this "overlap" of image data, some load imbalances can be corrected with a reassignment of LB_i and RB_i on adjacent workers. The manager determines the amount of overlap that is transmitted to a given worker by first calculating the difference between the most and least-loaded workers in the cluster. We compute the degree of the largest imbalance (L_i) as:

$$LI = \max_{0<i<n}\{L_i\} - \min_{0<i<n}\{L_i\}$$

Next, the manager calculates the ratio of the imbalance (RI) to the current system throughput using: RI = LI/CW. The value of RI is used by the manager to help predict how much of an imbalance may need to be corrected during the next computation. The manager then calculates the number of columns to transmit as overlap (CO) to the workers using: CO = RI x width of image. Now that the manager has determined the number of columns that constitute the overlap transmitted to the workers, the manager must then determine how much of the overlap to distribute to each worker. The manager has already partitioned the non-overlapping data using A_i. Thus, the manager assumes that a lightly-loaded worker is more likely to assume responsibility for calculating more data in the overlap region to correct a future load imbalance. The manager uses A_i and CO to determine the number of overlap columns O_i to send to worker i using: $O_i = A_i$ x CO. The manager not only needs to calculate this data for later use during load-balancing operations, but also communicates this data to each worker. So, two new variables are added to the task vector previously introduced: LD_i and RD_i. LD_i and RD_i represent the leftmost and rightmost columns that worker i has sufficient data to process. The manager calculates the values of LD_i and RD_i for each worker using:

$$LD_i = LB_i - \frac{O_i}{2} \quad \text{if } 0<i<n-1$$

$$RD_i = RB_i + \frac{O_i}{2} \quad \text{if } 0<i<n-1$$

$$LD_i = LB_i \text{ and } RD_i = RB_i + O_i \text{ if } i = 0$$

$$LD_i = LB_i - O_i \text{ and } RD_i = RB_i \quad \text{if } i = n-1$$

After calculating each of these values for a given worker i, the manager process sends a task vector to each worker containing these calculated values. To maximize the possible benefit of utilizing the overlap in scenarios where a load imbalance exists, each worker will begin processing the columns farthest from the overlap region, with computations proceeding towards the local overlap region.

3.4 Load Evaluation and Balancing

As stated previously, the manager process periodically interrupts each worker involved in a computation to obtain load information. This load information is used to determine if a load imbalance exists, if it is profitable to correct the imbalance, and what steps should be taken to rebalance the load. After collecting l_i from each worker, the manager recomputes CW. The manager then computes the current ratio of throughput (Z_i) for each worker using: $Z_i = l_i/CW$. The manager then compares the values of Z_i to A_i for each worker i. By doing this, the manager can determine if the assignment ratio(A_i) is either too large or too small for a given worker's contribution to the computational workload based on Z_i. To make the determination that a load imbalance is large enough to warrant rebalancing, the manager sets a threshold (T), below which no rebalancing take place. Rebalancing decisions are based upon the following inequality: if ($|A_i - Z_i| > T$) perform rebalancing at worker i. Rebalancing is performed to satisfy the following inequality: $|A_i - Z_i| < T/2$. The right-hand

side of the inequality is divided by two so that the manager can make gradual changes to the distribution of work. The manager performs rebalancing by adjusting the values LB_i and RB_i for workers involved in the load imbalance. Specifically, faster workers are directed to take responsibility for one-half of their remaining overlaps adjacent to a slower worker, and slower workers are directed to forfeit responsibility for one-half of their remaining columns contained in the overlap with a faster adjacent worker. The manager accomplishes this by determining the new values of LB_i and RB_i using:

$$RB_{i-1} = RB_{i-1} + \left\lceil \left(\frac{RB_{i-1} - RD_{i-1}}{2} \right) \right\rceil$$

$$LB_{i+1} = LB_{i+1} - \left\lceil \left(\frac{LB_{i+1} - LD_{i+1}}{2} \right) \right\rceil$$

$$LB_i = RB_{i-1} \qquad RB_i = LB_{i+1}$$

Each worker maintains a local task vector that contains two additional entries: LP_i and RP_i. LP_i and RP_i are the leftmost and rightmost columns that worker i has already processed. These additional variables are used by the worker to manage the processing of the columns in the partition it receives from the manager, and to ensure that a worker does not attempt to compute columns outside its assigned partition. Additionally, these are the two additional values contained in the vector returned to the manager after the receipt of a load interrupt.

4 Conclusion

This agent-based paradigm has many strengths indicating support of system heterogeneity, minimal dependence on the application, reusability, and ease of use and development. The application programmer needs only to decide on the application performance parameters and metrics, insert instrumentation code in the application, and define the relations between the different performance parameters. The last task may not be an easy job in complex big data applications, so it is recommended that some heuristic techniques be used, which would be based on the application.

Abstract— *Improving the performance of MPI applications on Multicore cluster is a huge challenge and even more, when we execute applications with high data synchronicity as is presented in SPMD paradigm. The different communications links of these clusters have to be managed properly if we wish to enhance performance metrics such as: efficiency, speedup and application scalability. In this sense, this work presents an approach that allows us to give an efficient solution for improving the strong and weak scalability under a defined efficiency for SPMD applications on Multicore clusters. This solution is focused on managing the communication heterogeneities using an analytical model, a mapping and a scheduling technique. The objectives are based on finding the maximum strong scalability point and determining how the problem size has to be increased in order to maintain an execution time constant while the number of core are expanded. The results obtained have demonstrated that using our method we can achieve improvements around 18% in the strong scalability. Also using our method, we have determined the ideal problem size, when we increase the number of core (weak scalability) and results show an small error of around (+/-) 4% in efficiency.*

Keywords: Strong and Weak Scalability, Performance, Efficiency

1. Introduction and Motivation

The efficiency and scalability are two key concepts when we are evaluating the performance in parallel applications. However, both performance metrics are seriously affected when we use heterogeneous execution environments such as Multicore clusters. These clusters are defined as heterogeneous because they integrate a hierarchical communication architecture, which can affect the performance. Therefore, if we consider the current use of multicore cluster and the communication heterogeneity in parallel computing, then, we have to design suitable strategies which allow parallel applications to be tuned with the aim of improving the application performance.

Also, the current integration of multicore nodes in high performance computing (HPC) has brought the inclusion of more parallelisms within nodes, enabling greater computing capacity within the node [1]. However, these capacity can be affected when we execute parallel applications due to parallel processes have to exchange information with others processes which can be located in the same node or in other node. These communications can be performed using the diverse communication paths, which are included in the hierarchical communication architecture. For this reason, communications have to be managed properly because they can present different speed and bandwidth, which may cause degradation and imbalance problems [2][3]. These problems can seriously affect when we use a pure MPI (message-passing interface) application with high data synchronicity.

Under this focus, one of the parallel paradigm, which is very affected by the communication heterogeneities is the Single Program Multiple Data (SPMD). This paradigm executes the same program in all MPI processes but uses different set of tiles to compute and communicate [4]. These tiles need to exchange information with neighboring tiles during a set of iterations. For this reason, when applications are designed under this paradigm, and these are mapped into multicore clusters, the programmer must consider the communication heterogeneity and how these can affect the performance.

Despite of these communication issues, we have to take into consideration that the multicore environments bring a huge computational capacity. For this reason, this work is focused on improving the performance of parallel application using a combination of different performance metrics such as efficiency, speedup and scalability (strong and weak).

Hence, the main objective of this work is based on how to design a method to manage the communication heterogeneity of multicore cluster in order to increase the SPMD application scalability under a defined efficiency. This method will allow us to determine the ideal number of cores that are needed in order to obtain a linear scalability using a constant problem size (strong scalability) while the efficiency is maintained over a defined threshold, and also, this method will permits us to determine how to maintain an isoefficiency system, where we can increase the number of processing elements (cores) and problem size while the execution time remains approximately constant (weak scalability).

On multicore clusters the tiles are computed in a similar time due to the homogeneity inside the core but the communication time of tiles can be performed using different communication paths and their communication times can be

†This paper is addressed to the PDPTA conference.

totally different. In some cases, the differences between each link for a defined packet size can include up one and a half order of magnitude in latency. These variances are translated into inefficiency, which decreases performance metrics of SPMD applications.

As a first approach to manage the inefficiency, we have created a method, which manages the communication latencies using characteristics of application (e.g communication and computation ratio). This method is organize in four phases characterization, tile distribution model, mapping and scheduling and the main objective of this method is to find the maximum speedup while the efficiency is maintained over a defined threshold [5]. Taking advantage of this method, we have adapted it with the aim of controlling the hierarchical communication architecture with the objective of finding the maximum scalability point for both strong and weak scalability under a defined efficiency.

In this sense, we have introcuded the concept of supertile (ST). An ST is a unit which integrates a set of tiles where these tiles are divided in two types internal and edge. The main idea of these STs is to create a structure, which is assigned one per core. These STs manage the communication heterogeneity and also eliminate communication wasting time of parallel execution. This method takes advantage of the communication time assigning more computation tiles and hiding the communication effects. The division of STs among internal and edge allow us to apply an overlapping technique, where is overlapped the internal computation time while the edge communication is performed. The ST size is calculated considering the slowest communication path, allowing us to manage the communication between all links in the hierarchical communication architecture.

Then, this method is divided in two direction: the first one is to obtain the problem size and determine the ideal number of core which allow us to find the maximum strong scalability point under a defined efficiency threshold and the second direction is based on increasing the problem size according to the ST size allowing us to obtain a linear weak scalability. Both uses of the ST and the advantages obtained will be demonstrated in the experimental evaluation.

Finally, this paper is structured as follow: the related works are described in section 2. Section 3 presents of the hierarchical communication architecture and the performance effects over SPMD applications. Section 4 exposes the method for improving the application scalability and section 5 illustrates the performance evaluation. Section 6 draw the main conclusions and future works.

2. Related Works

Improving the performance of applications on multicore clusters has been widely studied. One method was developed by Liedbrock [6] which defines a manner to calculate a performance model of hybrid applications. This method was based on studying the scalability and fidelity of application on a specific multicore cluster. Another method for placed efficiently MPI process was designed by Mercier et al [7] where they studied how to establish an adequate placement policy for improving the performance. Another method was developed by Vikram [8]. This method seeks to improve the performance on multicore using mapping and scheduling strategies, using the management of communication links. On the other hand, our method attempts to enhance the performance of SPMD application on multicore through the combination of scalability and efficiency. The goal is to obtain the maximum speedup under a defined efficiency.

However, developing strategies for improving performance on heterogeneous communications environments is a challenge as was demonstrated by Oliver [9]. In this sense, there are works that are focused on proposing solution for managing the internal communication of the multicore node [10][11]. In this sense, our methodology takes advantage of the mapping scheduling and overlapping techniques in order to to create a novel method which improves the efficiency, speedup and scalability of the SPMD applications.

3. Heterogeneus Communication links and their performance effects

One important problem of executing SPMD application on Multicore is related to tiles have to exchange their information each iteration with the aim of calculating values for next iteration and this communication can create imbalaces issues that affect the performance. Also, the different communication patterns can vary according to the objective of the SPMD applications. In some cases, the communications can be executed in two, four, six, etc. bidirectional communications. These communications pattern are established at the beginning of the SPMD application and are kept until the application finishes.

Also, SPMD applications used to apply our method have to be designed under the characteristics of static, local and regular, where static, defines the communication pattern and this cannot vary during the execution, local communication, that determines the neighboring communication and it is maintained in all the execution, regular, because communications are repeated for several iterations and finally n-dimensional grid applications (however this characteristic has been evaluated using applications until 3 dimension). There are different kind of benchmarks and applications of diverse fields that accomplish all these characteristics. One example of benchmark can be detailed the NAS parallel benchmark in the CG, BT, MG, SP [12], all these benchmark have been designed for 2D and in some case for 3D grid problem size. Also, there are examples of real applications especially simulation problem such as fluid dynamics, heat transfer, etc.

A real example of this phenomena can be detailed in figure 1, where is execute a (LL-2D-STD-MPI) application of the

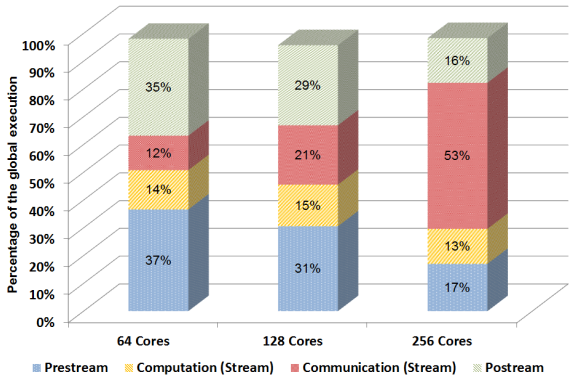

Fig. 1: Functions decomposition of LL-2D-STD-MPI.

mplabs suite over a juropa cluster [1] and results show the impact of communications over the total execution. In this case, for 64 core the impact of communication is around of 12,42% of total execution. However, when we increase the number of core to 256 for the same problem size the communication is around 52,59%. This example illustrates a clear impact of the communications on the application, where more than a half of application is communicating and hence the scalability and efficiency get worse.

Under this scenario, we can propose a method that allows us to manage the communication using the Supertile (ST) definition, where a ST is a structure composed by internal and edge tiles with the aim of allowing us to compute the edge tiles and then to overlap the edge communication with the internal computation. The problem of finding the optimal ST size is formulated as an analytical problem, in which the ratio between computation and communication of the tile has to be founded with the objective of determining the ideal size that maintain a close relationship between internal computation and edge communication. The ST size is calculated with two objectives: the first is to find the maximum strong scalability point under a define efficiency and second is to increase the problem size according to the ST size in order to maintain the execution time constant, when we increase the number of cores(weak scalability).

4. Method for improving the application scalability

This methodology is focused on managing the different communication latencies which are presented on multicore clusters due to the hierarchical communication architecture. The main idea is to develop a method that allows us to hide the communication effects that affect seriously the SPMD application. This method is integrated by four phases: characterization, tile distribution model, mapping and scheduling and all these phases allow us to obtain an efficient and a faster parallel execution [5].

[1]Cluster located in Julich Supercomputing center and it has 2248 computing nodes with 8 cores each node (17984 cores

As a first approach this method was designed to find the maximum speedup while the efficiency is maintained over a defined threshold, however, this method calculates the supertile size, which an import key for the scalability analysis. In this sense, our method has been updated with the aim of using the ideal number of cores and ST size that permit us to accomplish the objectives stated before.

4.1 Characterization phase

This phase is focused on performing an application and environment analysis with the aim of obtaining the application parameters which are used to calculate the analytical model. The main idea is to find a nearest relationship between the machine and the SPMD application. The parameters are classified in three groups: the application parameters, parallel environment and the defined efficiency.

The parameters determined allow us to establish the communication and computational ratio time of a tile inside of the hierarchical communication architecture. This relationship will be defined as $\lambda(p)(w)$, where p determine the link where the communication of one tile to another neighboring tile has been performed and w describes the direction of the communication processes (e.g. Up, right, left or down in a four communications pattern). This ratio is calculated with equation Eq. 1, where $Commt(p)(w)$ determines the time of communicating a tile for a specific p link and the Cpt is the value of computing one tile on a core. This characterization process has to be done in a controlled and monitored manner.

$$\lambda_(p)(w) = CommT(p)(w)/Cpt \quad (1)$$

4.2 Tile distribution Model

The analytical model for predicting the strong and weak scalability begins by considering the problem size and the number of cores that execute the application. For this reason, equation 2 represents an easy manner to calculate the ideal number of cores, where is divided the problem size (defined by M^n) by the ideal supertile size (K^n) [2], where n is the application dimension(e.g 1,2,3, etc). In this case, we are working on the strong scalability, where we define a problem size fix and we increase the number of core [13][14].

$$Ncores = M^n/K^n \quad (2)$$

Beside of the strong scalability, the equation 2 allows us to determine the behaviour of the weak scalability, where the number of cores and the problem size are expanded [15][16]. This equation is used to calculate the problem size M^n through the multiplication of the $Ncores$ by the supertile size K^n. However, to calculate both scalabilty we have to know the value of K, which depends on the overlapping strategy. In this sense, the equation 3 represents

[2]The supertile consist in a structure designed to allows us to overlap and hide the communication effects

the execution of an SPMD application using the overlapping strategy, where is first calculated the edge tile computation time $EdgeComp_(i)$ and then we add the maximum value between internal tile computation $IntComp_(i)$ and edge tile communication $EdgeComm_(i)$. This process will be repeated for a set of iteration $iter$. A first approach of this model can be found in [17]. However, the previos model was defined only for a specific number of dimension, and in this case we have defined for a n dimesnsional SPMD application and for studying strong and weak scalability.

$$Texe_{(i)} = \sum_{i=1}^{f} EdgComp_{(i)} + Max\begin{pmatrix} IntComp_{(i)} \\ EdgeComm_{(i)} \end{pmatrix} \quad (3)$$

$$EdgComp_{(i)} = (K^n - (K-2)^n \quad (4)$$

$$IntComp_{(i)} = (K-2)^n \quad (5)$$

$$EdgeComm_{(i)} = K^(n-1) * Max(CommT_{(p)(w)} \quad (6)$$

From the foregoing, the next step is to find the value of K considering the overlapping strategy between intenal computation and edge communication. The equation 7 shows how both values(internal computation and edge communication) can be equalized with the aim of finding the value of K. However, the edge communications are in function of the $CommT$. For this reason, we need to equalize the equation in function of Cpt. This is achieved using the equation 1. Having both internal computation and edge communication in function of Cpt, the next step is to find the value of K, replacing all the values in equation 7. Depending on the dimension of the SPMD application, we can obtain for example an cuadratic equation, cubic equation, etc.

$$K^{(n-1)} * max(\lambda_{(p)(w)} * Cpt) = ((K-2)^n/effic) * Cpt \quad (7)$$

4.3 Mapping phase

The main purpose of this phase is to apply a distribution of ST in the execution core. The ST assignations are made applying a core affinity which allows us to allocate the set of tiles according to the policy of minimizing the communications latencies (cite). This core affinity permits us to identify where the processes have to be allocated and how the ST have to be assigned to each core. However, the ST assignations should maintain the initial considered allocation used in the characterization phase.

This phase is divided in three key points. The first point performs a logical processes distribution of the MPI processes. The second function is to apply the core affinity, and the last one is the division and distribution of the STs. The mapping has to divide the tiles in order to create the ST considering the value of K obtained by the analytical model. It's important to understand that an incorrect distribution of the tiles can generate different application behaviors.

4.4 Scheduling phase

The main function is to assign a execution priority assignment to each tile with the aim of applying the overlapping strategy. This process establishes the highest priorities for tiles which have communications through slower paths and slower priority to internal tiles. This phase peforms an overlapping strategy, which is the main key of our method.

5. Performance Evaluation

In order to evaluate the maximum strong scalability under a defined efficiency and how the problem size and the number of cores (weak scalability) have to be increased with the aim of maintaining an execution time constant, we have used different multicore clusters composed by 16-17664 cores. However, this article has been validated using a large scale system which is setup with 2208 nodes with 2 intel Xeon X5570 nehalem-EP quad core processor (17664 cores), 24 GB of ram memory by node, 8 MB of l2 cache and infiniband interconnection network. This clustes is called JUROPA and it is located in the julich supercomputing center. Also, this methodology has been validated with different set of benchmarks and applications, but in this case we have used two examples of application of fluid dynamics integrated in the MPlab suite (LL-2D-STD-MPI and ZSC-2D-STD-MPI). Both versions are two dimensional problems and they accomplish the characteristics defined of local, regular and static.

The first application LL-2D-STD-MPI is integrated by 3 main modules: prestream, stream and poststream. The prestream and poststream are computation functions, where there are not any communication, while the stream function integrates the communication exchanging process between neighboring tiles. An example of this decomposition is illustrated in figure 2, where we can observe the impact of each function and the effect over the execution time. This example shows the relationship for a defined problem size of 2000x2000 using 1000 iterations (size that will be used for both applications). As can be detailed, the functions prestream and poststream maintain the same proportion of the execution time, while the stream begin to increase, when the number of core increases and the communication starts to introduce a strong impact over the execution (this was illustrated in figured 1). The communication in this case is around 53% of the total execution time for a 256 cores.

Another example is illustrated in figure 3, where is analyzed the ZSC-2D-STD-MPI application which integrates two exchanging functions called collision and stream. Both functions increase the inefficiency, while the number of cores is increased due to the communications. In this case, the impact of communication is increased while the number of cores is expanded (Fig. 3), where half of the time, the application is communicating when execute with 256 cores.

This scenario allows us to apply our method with the aim of improving the performance for both strong and weak

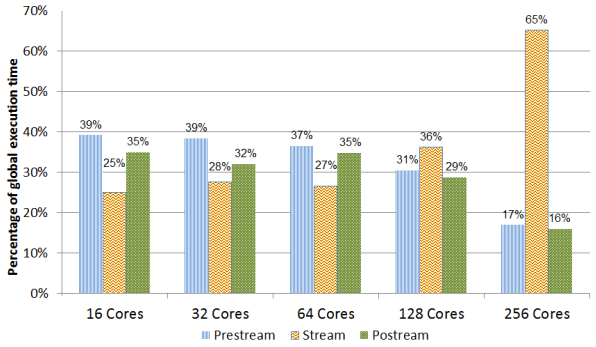

Fig. 2: LL-2D-STD-MPI application behavior.

Table 1: Tile distribution model and Supertile Calculation

Application	Problem Size	Effic	ST size	N Cores
LL-2D-STD-MPI	7200	90%	318	513
ZSC-2D-STD-MPI	7015	95%	155	2048

scalability. The first step is to characterize the application and the environment with the objective of finding the communication and computation ratio. In this sense, the tables included in figure 4 shows the ratio obtained using all the communication links in the juropa cluster and for both applications. Also, figures 2 and 3 illustrates the latency values, which can vary according to the communication level and also, they allow us to determine the slowest communication path.

The next step is to determine the ideal value of the ST, which will be used to both strong and weak scalability analysis. In this sense, we have defined the problem size and the desired efficiency, which we wish to apply our method. Using both problem size and efficiency together to the characterization values, we can calculate the ideal supertile which maintains the maximum strong scalability under a defined efficiency. These values can be detailed in table 1 and are calculated using the equations 2 and 7.

The first validation is related to the objective of determining the ideal number of cores that are needed in order to obtain a linear scalability using a constant problem size (strong scalability), while the efficiency is maintained over a defined threshold. This number of cores has been shown

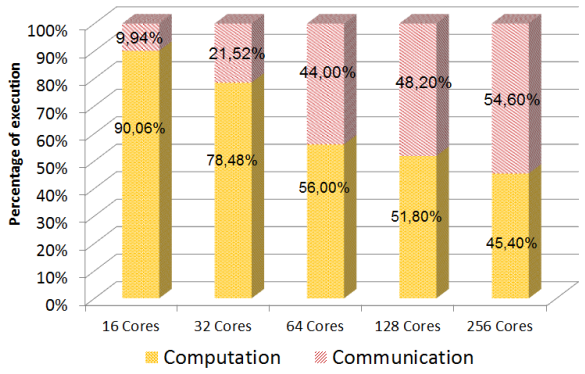

Fig. 3: ZSC-2D-STD-MPI application behavior.

Fig. 4: Communication and computation characterization

in table 1. Using these values, we have analyzed the scalability and efficiency of both applications. These have been performed evaluating the speedup and efficiency parameters using and not using our method with the aim of evaluating the improvements obtained using our method. Also, we calculated the theoretical behavior of applications according to the overlapping strategy between internal computation and the edge communication defined in our method.

In this sense, the figure 5 shows the behavior of speedup and efficiency of LL-2D-STD-MPI application, where the theoretical values calculated using our model have a similar growth until the ideal number of cores calculated for a defined problem size. Likewise, the application using the methodology has a close behavior than the theoretical with a small error rate around +/- 5% until the ideal number of cores and ST calculated in table 1. From that point, the error begins to increase motivated to the communication congestions. In this case, the edge communication times are greater than the internal computation and therefore, the

efficiency is seriously affected. Also, as can be illustrated in figure 5, the application without using our methodology begins to decrease considerably from 256 cores because the communication are not managed and they generated delays between each iteration that affect the scalability.

When we analyses both performance metrics with the objective of determining the maximum strong scalability under a defined efficiency, we can see in the table inside the figure 5, that speedup grows in both version. However, the efficiency has been defined in a threshold of 90% and this condition is nearly accomplished in the 512 cores for the application using our method. The efficiency and speedup improvements between the version using our method and not using our method are around 18%. This value is found when we divide the (speedup or efficiency) obtained using our method between the (speedup or efficiency) achieved without applying our method.

In similar manner, the figure 6 illustrates the behavior of ZSC-2D-STD-MPI application. the version using our method is above the threshold of efficiency until the number of cores ideal calculated with the model (Table 1). Otherwise is presented in the version that not use our method where efficiency is bellow the threshold from 64 cores. In this example, the error rate between the theoretical value and the value obtained using the version with our method is around 3,5 %. Also, the efficiency and speedup of the version without applying our method starts to decrease considerably from 1024 cores, while the version using our method begins to decrease from 4096 cores. In addition, can be detailed in figure 6 that speedup increases until 4096 core for both cases but the efficiency constraints defines the ideal number of cores that has to be used in order to find the maximum

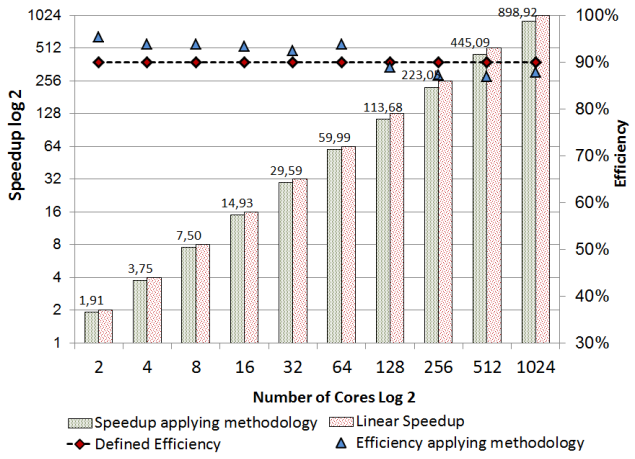
Fig. 6: ZSC-2D-STD-MPI strong scalability analysis.

strong scalability under a defined efficiency.

As demonstrated in this first validation, the maximum strong scalability under a defined efficiency is found near to the value calculated with our method. Our method calculates the ST and from this ST size estimates the ideal number of cores need to achieve the combination of both metrics.

On the other hand, the next validation is focused on demonstrating how to maintain an isoefficiency system, where we can increase the number of processing elements (cores) and problem size while the execution time is maintained approximately constant (weak scalability). In this sense, we start of the ST definition and we increase the problem size using as a reference the supertile size and the number of cores. In a similar manner, we have considered the initial value for the LL-2D-STD-MPI application (table 1). In this case, the ideal value of the supertile is 318 squared. Therefore, if we wish to obtain a constant execution time when we increase the number of cores and the problem size, we have to create the same amount of ST that execution cores in order to assign one ST per core and also, each ST has maintain the same size calculated through the model with the aim of maintaining the overlapping strategy and thus, we can maintain the performance of the system.

Then, the figure 7 shows an example of increasing the problem size and the number of cores proportionally to the ST size and the results illustrate how the execution time is approximately maintained with a small error for the worst case of 5%. This clearly is demonstrated with the values of table inside figure 7 where the problem size is increased and the execution time is approximately constant and the application efficiency is maintained around the threshold value. In this case the efficiency ranges between (+/-) 4% of the efficiency threshold defined, these values depend on the



Cores	Coord(X,Y)		Problem Size (X,Y)		Execution Time	Efficiency	*Speedup*
2	2	1	636	318	3.4042	95.28%	1.91

1024	32	32	10176	10176	3.6949	87.79%	898.92

Fig. 7: LL-2D-STD-MPI weak scalability analysis.

number of cores and the problem size used.

This last analysis allows us to validate that our method can maintain an execution time constant while the ST is maintained. This phenomenon is motivated that the ST is created under the consideration of the overlapping strategy and the main objective of this strategy is to hide the effects of communications and therefore increases the performance of the application. This method is possible to be applied due to the deterministic behavior of the SPMD applications.

6. Conclusion and Future works

This work has described an efficient method to improve the strong and weak scalability under a defined efficiency of SPMD applications executed on multicore clusters. In this sense, we have used a methodology which defines four execution phases (characterization, tile distribution model, mapping and scheduling) and allows us to determine the ideal number of cores and the supertile size need to maintain a relationship between efficiency and speedup. The examples described in the performance evaluation have demonstrated that using the supertile size and the number of core obtained through the analytical model, we can obtain the maximum strong scalability point with a small error which can vary between (+/-4%) depending of the SPMD application tested and the multicore system used.

Moreover, the weak scalability analysis has demonstrated that if we increase the problem size according to the relationship of the supertile size, we can maintain the efficiency and speedup conditions. In this sense, the weak scalability allows us to determine the ideal problem size for a specific number of cores, that is, our method seeks that the application can be adapted as best possible to the parallel environment with the aim of obtaining a linear scalability. Hence, maintaining the condition of the overlapping between the edge communication and internal computation of the ST, we can obtain an execution with a small error, as was evidenced in the experimentation. The future work is focused on applying our method in hybrid parallel execution (Multicore and GPU), where another communication level is included.

Performance Comparison Between Cg-based and CUDA-based Matrix Multiplications

Luke West† **and Jong Kwan Lee**
Dept. of Computer Science, Bowling Green State Univ., Bowling Green, OH 43403, U.S.A.

Abstract— *In this paper, we compare the performances of Cg-based and CUDA-based GPU programming APIs. In particular, their performances on squared matrix multiplications are considered. We also discuss other aspects of these widely-used GPU programming APIs. This work can help gain insight on various applications that involve matrix multiplication that are better suited for a specific GPU programming API.*

Keywords: GPU Computing, Cg Programming, CUDA Programming, Matrix Multiplication

1. Introduction

While microprocessors based on a single CPU drove rapid performance increases and cost savings in computing applications for many decades, programmable graphics processing units (GPUs), driven by the insatiable market demand for real time and high-definition 3D graphics, have been the primary high performance parallel computing tool in recent years; GPUs have become extremely powerful parallel computing units with multi-threaded many-core processors that can process not only graphical operations, but also other general-purpose operations.

Utilization of such GPUs has been considered in many research areas. For instance, there have been many attempts to apply GPU-based processing in visualization. Some of these studies involved the development of fast and accurate rendering algorithms using volumetric datasets (e.g., [16], [15]). GPU-based processing has also been applied to computer vision (e.g., [6]). Scientific simulation is another area where GPU processing is often considered (e.g., [14], [12]). Many of these research efforts and applications benefit from exploiting data parallelism on GPUs.

In this paper, we compare the performance of two widely-used GPU programming models–Cg (C for graphics) [8] and CUDA (Compute Unified Device Architecture) [9]– for squared matrix multiplication. (Other GPU programming models include OpenGL Shading Language (GLSL) and High Level Shading Language (HLSL) for DirectX.) This work can help gain insight on various applications involving matrix multiplications that are better suited for a specific GPU programming API. We are unaware of any prior reports on Cg and CUDA performance comparison.

Next, some background information on Cg and CUDA is discussed.

Since 2002, the arrival of the fourth and current generation of GPUs, GPUs supported programmable vertex and fragment shaders. GPU shaders denote the GPU's streaming processing units that perform predefined graphical operations, as well as user-defined operations (including non-graphical operations), in parallel without directly exposing their parallel processing operations to the programmer. When utilizing GPUs for general-purpose applications, tasks that are typically processed on a CPU can be mapped to a GPU and *processed along the GPU pipeline*. A GPU pipeline is the sequence of graphical processing stages that operate in parallel and in a fixed order on a GPU. A typical GPU pipeline is shown in Figure 1 (i.e., the five GPU stages are inside the red box). Here, we note that in applications employing programmable GPUs, fragment shaders are typi-

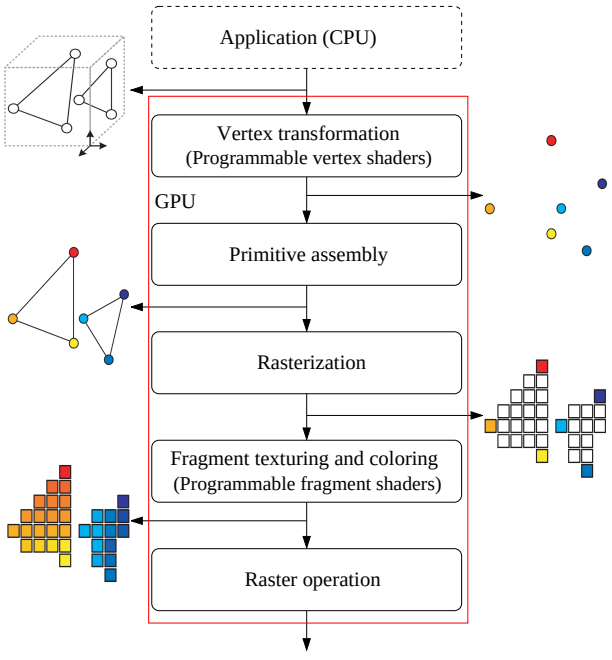

Fig. 1: GPU Pipeline (adapted from [3], [8]) considered for Cg API

†Corresponding Author, Email: lukew@bgsu.edu

cally relied upon more heavily than vertex shaders. One main reason is that there are more fragment shaders than vertex shaders on a typical programmable GPU. In addition, the memory access on fragment shaders is more straightforward than it is on vertex shaders. (For example, the outputs of the vertex shader must pass through all the other pipeline stages before accessing the memory [11]; thus, direct memory access is not straightforward on the vertex shaders.)

Cg is one widely-used GPU programming API that enables programming of the type of GPU discussed above. It is a modified version of the C programming language that includes some new data types that create a more suitable programming environment when utilizing GPUs through the GPU pipeline. Here, we note that some of the later programmable GPUs (e.g., Nvidia GeForce 8 Series and later) have an additional programmable logic unit known as the geometry shader. Geometry shaders are used after the vertex transformation stage and before the primitive assembly stage in the GPU pipeline. This enables generation and elimination of geometry primitives on the fly on the GPUs. However, since the Nvidia GeForce 8 Series GPUs, the concept of shaders has evolved into multi-threaded, unified GPU processors.

While many computing applications have used Cg in GPU computing, this trend changed when CUDA [9] was released in 2007. CUDA provides a new general-purpose parallel programming interface for the GeForce 8 Series (G80) and its successor GPUs. In particular, CUDA-based programs no longer run through the GPU pipeline (i.e., there is no need to perform general-purpose computations within the graphics pipeline); thus, programmers do not need to learn the graphics pipeline to utilize GPUs in their applications.

Figure 2 (a) shows a CUDA-enabled GPU architecture. As shown in the figure, it is organized into an array of highly threaded streaming multiprocessors (represented by the green cells). CUDA-based programs utilize these multiprocessors to exploit data parallelism for extremely high parallel computing performance. In particular, these multiprocessors available on GPU can create and execute thousands of threads simultaneously. For example, the GeForce 200 series GPU can support up to 1024 threads per processor, which sums up to about 30,000 threads in total. We note that CUDA-enabled GPUs also provide a very high memory bandwidth (e.g., G80 supports 86.4 GB/s of memory bandwidth). One key advantage of CUDA over Cg is its ability to use GPU's shared memory for much faster data access. (Modern GPUs have a large amount of global memory and a relatively small amount of shared memory. The global memory is slow whereas the shared memory is fast.) In Figure 2 (b), the latest CUDA compute architecture, the FERMI [10], is shown. FERMI architecture provides not only an increased number of multiprocessors, but also improved performance for double precision computations, true cache hierarchy, more shared memory, faster context switching, and faster atomic operations.

2. Related Work

Next, some prior work in matrix multiplication is briefly discussed.

The complexity of the standard matrix multiplication using three nested loops is $O(n^3)$. Strassen [1] first reported that the standard matrix multiplication was not the optimal solution. The report presented another way to perform matrix multiplication (i.e., the Strassen's algorithm [1]) that recursively partitioned the matrices into smaller blocks and then performed multiplications. This recursive algorithm's complexity is $O(n^{2.81})$. Another fast matrix multiplication algorithm is the block matrix multiplication algorithm [13] which utilizes memory coherency in matrix multiplication.

There have also been GPU-based matrix multiplication studies. Some of these were based on Cg (e.g., [4], [2]) and some recent studies were based on CUDA (e.g., [17], [7]). However, to our knowledge, there has not been any report that presented a performance comparison of Cg-based and CUDA-based matrix multiplication.

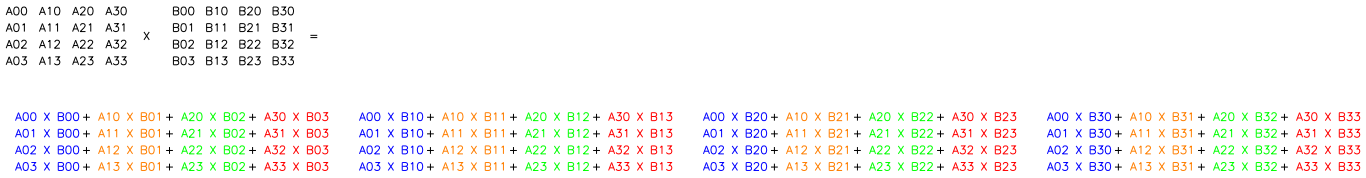

Fig. 3: Illustration of Two 4×4 Cg-based Matrix Multiplication

3. GPU-based Matrix Multiplication

In this section, the Cg-based and CUDA-based squared matrix multiplications used in this paper are described.

Our Cg-based matrix multiplication utilizes the fragment shaders by using textures on GPUs. (A texture on the GPU can be considered similar to an array on the CPU [11].) Specifically, each matrix on the CPU is mapped to a GPU texture. Then, using a simple querying of texture elements, the Cg program iteratively performs the matrix multiplication. In particular, each iteration takes one set of matrix elements from each of the two input matrices, computes the product of the values, and stores the result. Figure 3 illustrates this iterative process of matrix multiplication for two 4×4 matrices. In the figure, the elements of both input matrices (i.e., A and B) are denoted as AXY and BXY, where X and Y denote the column and row indices, respectively. In the Cg program, the multiplication operations are performed in the order of blue, orange, green, and red element multiplications in each iteration. The GPU's fragment shaders perform the multiplications in parallel. The Cg-based code is shown in Figure 4.

The CUDA-based matrix multiplication we consider here is based on the CUDA-based matrix multiplication in [5]. Similar to Cg-based matrix multiplication, input matrices are mapped to the GPU's memory. Then, each thread (among thousands GPU threads) computes one element in the product matrix. For very large matrices, the *tiling* is employed. Tiling divides the matrices into smaller sub-matrices and performs the matrix multiplication. In addition, for faster memory referencing, the GPU's shared memory is also used.

```
void _cg_mat_mul( in float2 coords: WPOS,
                  uniform samplerRECT texA,
                  uniform samplerRECT texB,
                  uniform float mSize,
                  out float matC : COLOR0 )
{
    float matA, matB;
    float2 ACoords, BCoords;

    for(float i=0; i<mSize; i++)
    {
       ACoords = float2(i+0.5, coords.y);
       matA = texRECT(texA, ACoords);

       BCoords = float2(coords.x, i+0.5);
       matB = texRECT(texB, BCoords);

       matC = matC + matA*matB;
    }
}
```

Fig. 4: Cg-based Matrix Multiplication Code

4. Experimental Results

We compared the processing times of the Cg-based and CUDA-based squared matrix multiplications using six different matrix sizes (i.e., 256^2, 512^2, 1024^2, 2048^2, 4096^2, and 8192^2) on two different PCs (running Linux) that have different GPUs. Trimmed average timings were used for matrix multiplication processing time measurements.

The first (Type 1) PC has a 2.8 GHz Intel Core i7 CPU with 12 GB of RAM and dual 1.8 GB Nvidia GeForce GTX 285 GPUs. The GTX 285 GPU has 240 CUDA processors and supports a memory bandwidth of 159 GB per second. The second (Type 2) PC has a 3.4 GHz Intel Core i7 CPU with 16 GB of RAM and one 1.5 GB Nvidia GeForce GTX 480 GPU. The GTX 480 GPU has 480 CUDA processors and supports a memory bandwidth of 177.4 GB per second. We note that only GTX 480 GPU is a FERMI GPU.

Table 1 shows the processing times of CPU-based, Cg-based, and CUDA-based squared matrix multiplications on Type 1 PC (with dual GeForce GTX 285 GPUs). Here, the block matrix multiplication algorithm [13] was used for the CPU-based matrix multiplication. As shown in the table, the Cg-based and CUDA-based matrix multiplications executed much faster than the CPU-based version. In addition, the CUDA-based version was faster than the Cg-based version.

In Table 2, the GPU-based matrix multiplications on Type 2 PC (with a Geforce GTX 480 GPU). As shown in the table, the CUDA-based version executed faster than the Cg-based version.

Figure 5 summarizes our performance comparisons. In Figure 5 (a), the speedups of the Cg-based and CUDA-based matrix multiplications over the CPU-based matrix multiplication is shown. As shown in the table, while the Cg-based version was about 10 times faster for the 256^2 case and about 340 times faster for the 8192^2 case, the performance of CUDA-based version was better (e.g., 100 times faster for the 256^2 case and about 500 times faster for the 8192^2 case). In Figure 5 (b), the performance comparisons of Cg and CUDA (i.e., Cg processing times over CUDA programming times) on two different GPUs are shown. As shown in

Table 1: Processing Times (in seconds) on Type 1 PC (dual GTX 285 GPUs): CPU-based, Cg-based, and CUDA-based Squared Matrix Multiplications

Matrix Size	CPU	Cg	CUDA
256^2	0.03	0.003	0.0003
512^2	0.31	0.015	0.002
1024^2	3.19	0.094	0.015
2048^2	25.56	0.668	0.129
4096^2	205.5	5.182	1.032
8192^2	4146.4	12.103	8.276

Table 2: Processing Times (in seconds) on Type 2 PC (GTX 480 GPU): Cg-based and CUDA-based Squared Matrix Multiplications

Matrix Size	Cg	CUDA
256^2	0.004	0.0002
512^2	0.013	0.001
1024^2	0.065	0.009
2048^2	0.448	0.073
4096^2	3.397	0.582
8192^2	9.334	4.852

the table, the CUDA-based version executed faster than the Cg-based version on both GPUs. Specifically, the CUDA-based version was about 10.0, 7.5, 6.3, 5.2, 5.0, and 1.5 times faster using the GTX 285 GPUs and about 20.0, 13.0, 7.2, 6.1, 5.8, and 1.9 times faster on the GTX 480 GPU, for 256^2, 512^2, 1024^2, 2048^2, 4096^2, and 8192^2 matrix multiplications, respectively. Use of the shared memory in CUDA-based version was one of the key factors for this better performance.

5. Conclusion and Discussion

In this paper, we considered two of the most widely-used GPU computing APIs (i.e., Cg and CUDA) and compared their performances for squared matrix multiplication. To our knowledge, this work is the first report to compare the Cg and CUDA performance. A simple Cg-based matrix multiplication code is also presented.

For the matrix multiplications, while both Cg and CUDA outperformed the CPU-based processing, CUDA-based was 1.5–20.0 times faster than Cg-based version. The relative CUDA performance was better for smaller matrix sizes than for the large matrix sizes. For example, the CUDA-based version was 10–20 times faster for 256^2 matrices while it was only 1.5–1.9 times faster for 8192^2 matrices. Here, we note again that the CUDA-based version utilized the GPU's shared memory. CUDA-based version without using the shared memory was about 3.5–6.6 times slower than CUDA-based version with the shared memory. For large matrix sizes

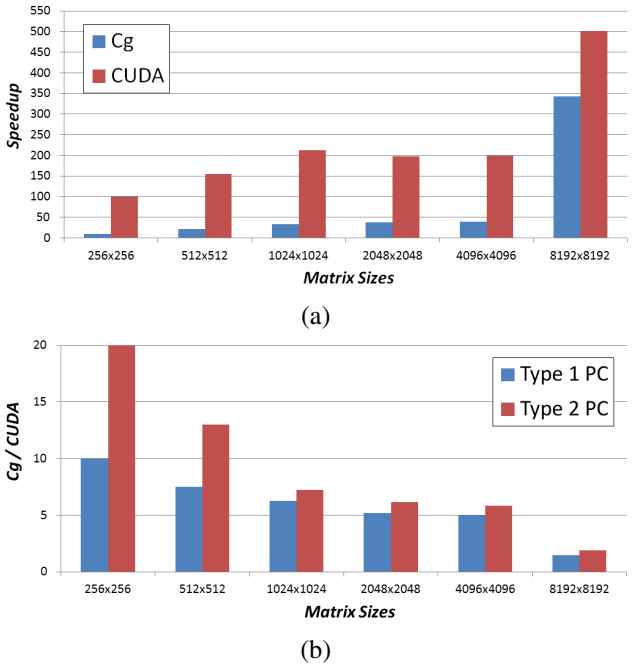

Fig. 5: Performance Comparisons: (a) Speedups of GPU-based versions (vs. CPU-based version) and (b) Cg and CUDA Performance Comparisons (Cg processing time/CUDA processing time) on Type 1 PC (dual GTX 285 GPUs) and on Type 2 PC (GTX 480 GPU)

(e.g., 4096^2 and 8192^2), the CUDA-based version without using shared memory was even slower than the Cg-based version. Shared memory usage is not supported in Cg-based programs.

For the programmers who are familiar with the GPU pipeline, the Cg API is easy to understand. For matrix multiplication, Cg-based code was shorter than that of the CUDA-based code. Here, we note that using Cg-based matrix multiplication for very large matrices, tiling is also needed since there is a limit on the GPU texture size on GPUs. For programmers who are not familiar with the GPU pipeline, it is difficult to write Cg programs. Programmers with some parallel processing experience find it easier to write high performance programs using the CUDA API than the Cg API.

We have also found that debugging is much easier using the CUDA-based API. There is no debugging tool support provided for the Cg API. The programmers have to transfer values through the GPU pipeline to the CPU, then display and check the values manually using Cg API. For the CUDA-based API, the programs can be executed in device emulation mode. In this mode, threads are executed sequentially on the CPU and other debugging tools (e.g., break points) are also supported.

These different aspects of Cg and CUDA APIs reported

in this paper can assist scientists in choosing which GPU programming API to use for their high performance applications.

Acknowledgment

1 Introduction

Multi-core platforms become ubiquitous nowadays. Even laptops contain multi-core processors now. There are multiple cores in a chip or socket or die. A computing node contains multiple chips. For example, Intel X5472 consists of dual die quad-core CPUs manufactured on a 45 nm process. Multi-core platforms are rapidly increasing and the number of cores on these platforms. Moreover, many users of High Performance Computing, HPC, adopt the multi-core platforms. How to enjoy the benefits of parallel computing on the multi-core platforms plays a key role in HPC.

With the increasing complexity of modern multi-core processors, the problem of distributing a software application across different cores to maximize the utilization of the computing power becomes more and more difficult. Different programming patterns big influence the program performance. Two common programming patterns of parallel program are Message Passing Interface [1], MPI, and OpenMP [2]. MPI had widely used to parallel program on traditional parallel platforms and PC Cluster since 1994. Scientists have obtained a great help on MPI programming pattern in the last few decades. Even it enters multi-core platforms ear. Naturally it is in the wake of overheads, such as message passing inside a node and duplicate memory location.

OpenMP programming pattern is implemented for high efficient computing on Symmetrical multiprocessor system, especially on a multi-core platform. It adopts a fork-and-join execution model, that is, it is thread level parallelism. The behavior of compute is in system bus level and threads are able to share a memory space, but it is limited by scale. The version 2.5 of standard was released in 2005. Most of the compilers (Fortran or C or C++) support the functions of "directive", runtime libraries, and environment variables. Moreover, the version 3.0 of standard, which contains "task" parallelism implementations, was released in May 2008.

We intuitively think the hybrid MPI/OpenMP computing that MPI mainly handles inter message passing, while OpenMP focus on intra computing. But it inherits diverse hardware characteristics, such as the number of multi cores in a die, the number of die in a node, the bandwidth of memory and system bus, how many cores shared resources, and so on. In general, there are two hybrid programming paradigms on multi-core platforms. One is like this model, while the other model is that one adopts a "Parallel Region" directive of OpenMP and master thread to handle the message passing.

We adopt Himeno Benchmark [3], which performs computations of 19-points stencil, to evaluate the performance on different programming patterns of parallel program on NCHC (National Center for High-Performance Computing) platforms, "GPU Cluster", which contains 16 of Intel X5472, and NCHC ALPS hereafter. [4] depicts that the "Stencil" computation, such as Himeno Benchmark, is limited by the bandwidth of memory based on Roofline Model. It is conceivably improved the performance of parallel programs based on Thread Level Parallelization only.

Firstly, we evaluate the performance of Himeno Benchmark on 8 cores in a node on GPU Cluster on different compilers. We implement the hybrid MPI/OpenMP programming patterns on Himeno Benchmark and come out these results on hybrid mode and pure MPI mode on different mapping patterns of 8 nodes (64 Cores) of GPU Cluster. We will present the results of Himeno Benchmark and High Performance Linpack, HPL[5], for CPU binding on NCHC ALPS. We also illustrate the Roofline model on NVIDIA GT200. We hope the results can give some useful information to the user of HPC.

2 Test beds and software

We adopt two test beds, NCHC GPU cluster built in 2010 and upgraded in 2011 and NCHC ALPS built in 2011. We implement MPI/OpenMP hybrid for Himeno Benchmark and evaluate the performance on both platforms. HPL is employed for CPU binding on NCHC ALPS.

2.1 NCHC GPU Cluster

GPU Cluster contains 16 of Intel X5472, which consists of dual die quad-core CPUs manufactured on a 45 nm process. The motherboard adopts Tempest i5400XT (S5396) and Intel 5400 Chipset as shown in Figure 1. Figure 2 shows the logic picture, system bus and bandwidth of memory.

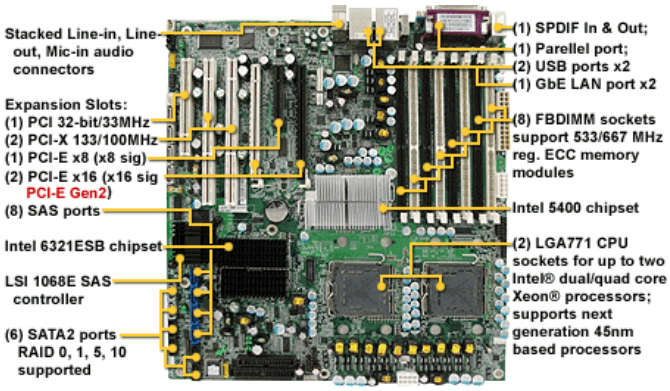

Figure 1. Motherboard of GPU Cluster

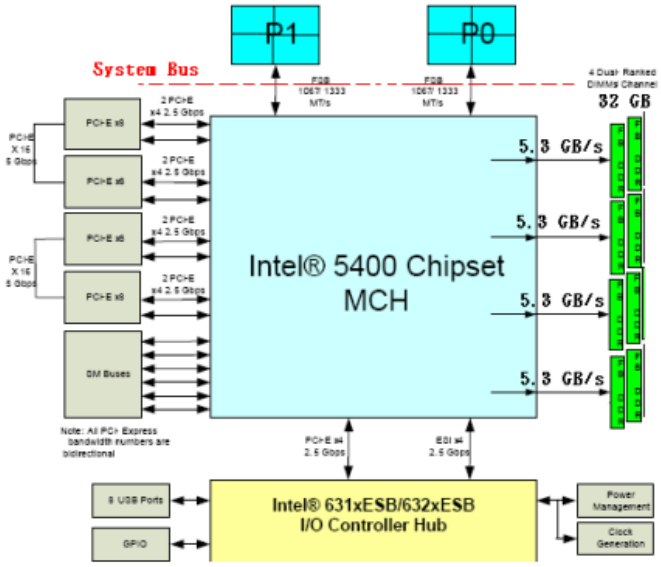

Figure 2. Intel 5400 Chipset

A computing node contains 32 GB RAM and a DDR Infiniband connected together. We adopt OpenSuSE 11.0 as Operation System, OS, different compilers, its version and its compiler option as Intel 11.0 (**`ifort -openmp -O3 -fast`**), PGI 9.0 (**`pgfortran -mp -O3 -fast`**), and GNU 4.3.2 (**`gfortran -fopenmp -O3`**), and MPI middleware as OpenMPI 1.2.8.

2.2 NCHC ALPS

The hardware of computing nodes on NCHC ALPS consists of 600 of Acer AR585 as shown in Figure 3. They are connected together with Qlogic InfiniBand in 4x QDR (40Gb) and the bandwidth throughput of this system achieves 51.8 Tbps. In logic point of view, the system comprises 8 computing clusters, which consists of 4 of AMD Opteron 6174 inside 12 cores running at 2.2 GHz, that is, 48 cores a node sharing 128 GB RAM in 4-memory-controller non-uniform memory access architecture, and 1 large memory cluster that includes 4 of AMD 6136, which comprises 8 core running at 2.2 GHz, that is, 32 cores a node sharing 256GB RAM. There are 25,600 computing cores of AMD Opteron 6100 in this system and the maximal Linpack achieves at 177 TFlops and at 42th place in Top500 list in June 2011 [6].

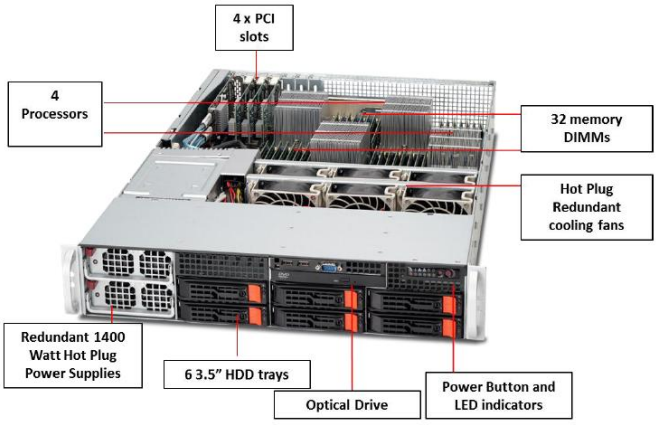

Figure 3. The architecture of Acer AR585

This system adopts the Novell SuSe Linux Enterprise 11 SP 1 for its operation system. The parallel file system is Lustre. Platform LSF is for job scheduler and queuing system. Message passing interface libraries are installed such as Platform MPI, OpenMPI, mvapich, and so on. The debug tool is Allinea DDT, Distribut Debugging Tool. There are four compilers in this system: Intel, PGI, Open64, and GNU. Intel MKL and AMD ACML, AMD Core Math Library, inherit this system for math libraries.

2.3 Himeno Benchmark

To solve the pressure commonly adopts Poisson equation solver in computational fluid dynamic, such as incompressible Navier-Stokes equations solver. The Poisson equation is shown as Figure 4 and the kernel computing of Himeno Benchmark. Use central finite difference and Jacobi iteration. To calculate the value of a point requires reading 18 points of neighbors, named it as "19-Points Stencil". It performs 34 of floating-point operations and uses 14 of three-dimensional matrices per iteration. The computational intensity achieves 0.6 *Flop/Byte* on a problem size of 1024×512×512 in single precision compute (required around 14*GB*) sequentially.

Poisson Equation: $\Delta p = \rho$

$$\frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} + \frac{\partial^2 p}{\partial z^2} + \alpha \frac{\partial^2 p}{\partial x \partial y} + \beta \frac{\partial^2 p}{\partial x \partial z} + \gamma \frac{\partial^2 p}{\partial y \partial z} = \rho$$

$$\frac{p_{i+1,j,k} - 2p_{i,j,k} + p_{i-1,j,k}}{\Delta x^2} + \frac{p_{i,j+1,k} - 2p_{i,j,k} + p_{i,j-1,k}}{\Delta y^2}$$
$$+ \frac{p_{i,j,k+1} - 2p_{i,j,k} + p_{i,j,k-1}}{\Delta z^2}$$
$$+ \alpha \frac{p_{i+1,j+1,k} - p_{i-1,j+1,k} - p_{i+1,j-1,k} + p_{i-1,j-1,k}}{4\Delta x \Delta y}$$
$$+ \beta \frac{p_{i+1,j,k+1} - p_{i-1,j,k+1} - p_{i+1,j-1,k} + p_{i-1,j,k-1}}{4\Delta x \Delta z}$$
$$+ \gamma \frac{p_{i,j+1,k+1} - p_{i,j+1,k-1} - p_{i,j-1,k-1} + p_{i,j-1,k-1}}{4\Delta y \Delta z} = \rho_{i,j,k}$$

Figure 4. Himeno Benchmark

2.4 The High Performance Linpack, HPL

The High Performance Linpack[5], HPL, employs the LU decomposition to solve a dense $N \times N$ system of linear equation in a floating point workload of 2/3 N^3+2N^2. HPL utilizes LU factorization with row partial pivoting to solve a dense linear system while using a two-dimensional block-cyclic data distribution for load balance and scalability.

3 Methodology

We implement two hybrid models, which both models will be described in detail in next Section, for Himeno benchmark in Fortran 90 and evaluate the performance on NCHC GPU Cluster first. The results are performed for GPU version on NCHC GPU Cluster, too. Moreover, we establish a Roofline model for GT200.

Since NCHC ALPS inherits the non-uniform memory access, NUMA, and consists of 48 cores and 8 of NUMA servers as shown in Figure 5, we expect the limit of system bus and memory bandwidth. In order to get the best performance, we adopt the CPU binding for memory use efficiently. First we find the rank pattern via HPL and evaluate the performance. Next, we compare the performance of CPU binding with those for other models via Himeno benchmark. The performances of Himeno benchmark via different compilers are shown, too.

4 Results

We follow 95% confidence to evaluate the results and employ the ganglia and "top" command to monitor the status of the system for dedicated usage.

4.1 NCHC GPU Cluster

We show that the performance of this program at 3.35 *GFlops*, 2.85 *GFlops*, and 2.57 *GFlops* on 8 cores a node via Intel, PGI, and GNU, respectively. It is expectable. Intel compiler gets more benefit of intrinsic computation involving Streaming SIMD Extensions than the others. The performance score of Intel compiler slightly surmounts the peak performance of 3.20 *GFlops*. Commercial PGI compiler shows the performance based on standard computational pattern. The score is lower than the peak performance. The public GNU compiler obtains the worst performance in three compilers.

We implement two hybrid MPI/OpenMP parallel programming patterns: First Model (Hybrid Model 1) is that MPI handles inter message passing between nodes, while OpenMP handles intra computation between 8 cores a node. Its advantage is that the data and program flow are clear. That is, the program is able to be divided into some sub-program blocks, which many sub-program blocks perform heavy operation, while few sub-program blocks perform message passing between nodes. The downside is that all threads are idle on message passing. Amdahl's law points that it big decreases the parallel performance!

The other model (Hybrid Model 2) is that one use a parallel region involves all operations and message passing, which master thread performs message passing between nodes. The race conditions become more and more. The program structure and data flow becomes complicated, too. That is, a programmer requires more human time to better performance. It is opportunity to get parallel efficiency in hidden overhead of message passing carefully. The first model shows 15.0 *GFlops* on 8 nodes with Intel compiler and OpenMPI 1.2.8, while the second model shows 22.50 *GFlops*. It is expectable that the last model presents better performance than those on the first model. We very surprise that different programming patterns can improve 7.5 *Gflops*!

Though MPI 2 has new features of communicator management and OpenMP 3.0 increases the task parallelism, we don't unfortunately perform our overlap version between computation and massage passing (**MPI_THREAD_MULTIPLE**) on our test beds. We adopt MPI 1.2 standard and OpenMP 2.5 to implement our hybrid MPI/OpenMP parallel programming pattern as end-users. The second model of hybrid MPI/OpenMP parallel programming patterns with Intel compiler and OpenMPI 1.2.8 are evaluated on GPU Cluster. Therefore, MPI can perform diverse MPI task mapping, for example a node has 1×1×8, 1×8×1, 8×1×1, 1×2×2, and so on. That is, the data decomposition is 1-dimension in z- or y- or x-direction or 2-dimension in y- and z-direction.

Like MPI mapping, hybrid MPI/OpenMP parallel programming pattern contains large amount of combination of MPI and thread. We evaluate all mapping on combinations of MPI Processes and threads to get interest results. First of all, we define "1×2×4×8" as x-, y-, and z-directions of MPI Processes and the number of threads a MPI Process, that is, x-, y-, and z-directions use 1, 2, 4 MPI Process, respectively, and a MPI Process uses 8 threads. The special case "4×4×4×1" means pure MPI programming paradigm, because of a thread used a MPI process. Table 1 shows the partial (better) results in *GFlops* on 8 nodes (64 cores in total) on different programming paradigms. To our surprise, the pure MPI programming paradigm (4×4×4×1) outperforms!

This is because that the Intel compiler abundantly enjoys the benefit of the hardware, such as SSE intrinsic. Hybrid programming paradigm doesn't have enough room for thread level parallel. Our experience via PGI compiler, pure MPI obtains 19.18 *GFlops* vs. Hybrid model achieves 20.99 *GFlops*. Our opinion is confirmed. The other reason is hardware limitation, such as, obstruction of memory bandwidth. We adopt the Phillips's results presented in Cluster 2009 conference to establish a Roofline Model for GT200 as shown in Fig. 5. The performance of CUDA version of Himeno Benchmark achieves at 767 *GFlops!*

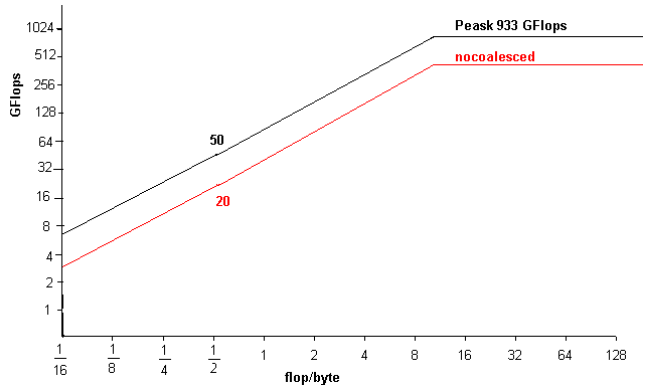

Figure 5. Roofline model on GT200

4.2 NCHC ALPS

For our clear description, we define the notations, **Intel**, **Op64**, **GNU**, and **PGI**, in Table 1. The compiler option is "**Ofast**" for Op64 and GNU, while it is "**fast**" for Intel and PGI.

Table 1. Notations

Notation	Compiler	MPI
Intel	Intel 12.0	openMPI 1.4.3
Op64	Open64 4.2.5	openMPI 1.4.4
GNU	gcc 4.6.2	openMPI 1.4.4
PGI	PGI 11.10	openMPI 1.4.4

We adopt N=1000 for HPL using two cores to obtain the best CPU bind mapping 0-3. We adopt the mapping for **CPU bind** model hereafter and use GNU compiler with AMD acml5.1.0 single thread. Table 2 shows the maximal Linpack in *GFLOPS* for different N=80000 vs. N=100000 with/out CPU bind on 48 core a node. CPU bind model outperforms.

Table 2. Maximal Linpack in *GFLOPS* for different N with/out CPU bind

N	CPU bind	Not CPU bind
80000	286.7	278.0
100000	287.9	274.7

Table 3 depicts the performance of Himeno benchmark in *GFLOPS* for different compilers for $1024 \times 512 \times 512$ problem size in $3 \times 4 \times 4$ partition pattern with/out CPU bind on 48 cores a node. As we expected, CPU bind model outperforms. It is very interesting for CPU bind that PGI outperforms on NCHC ALPS, instead of Intel! It is different from those performed on NCHC GPU Cluster. When we do not use bind processor, Intel outperforms like those on NCHC GPU Cluster. It is because that PGI shows slightly better than Intel for memory affinity on NCHC ALPS.

Table 3. Performance of Himeno benchmark in *GFLOPS* for different compilers for 1024×512×512 problem size in 3×4×4 partition pattern with/out CPU bind

Compiler	CPU bind	Not CPU bind
PGI	36.69	17.02
Intel	35.93	20.12
Op64	31.77	16.22
GNU	20.44	12.12

Table 4 depicts the performance of Himeno benchmark in *GFLOPS* for different partition patterns for 1024×512×512 problem size with/out CPU bind on 48 cores a node. As we expected, CPU bind model outperforms, again. It is very interesting for CPU bind that the three-dimensional partition pattern, $4 \times 4 \times 3$, cannot enjoy the benefits of parallel computing, while the two-dimensional partition pattern, 8×6×1, outperforms. It is different from those on NCHC GPU cluster again.

Table 4. Performance of Himeno benchmark in *GFLOPS* for different partition patterns for 1024×512×512 problem size in with/out CPU bind

partition patterns	CPU bind	Not CPU bind
48×1×1	26.08	9.25
1×48×1	29.25	14.20
1×1×48	27.82	11.53
8×6×1	40.85	26.12
6×8×1	40.24	26.15
6×1×8	36.67	19.54
3×4×4	36.69	17.02
4×3×4	34.79	27.57
4×4×3	40.09	22.30

Table 5 shows the performance of Himeno benchmark in *GFLOPS* for different processor binds for 1024×512×512 problem size in 8×6×1 partition pattern on 48 cores a node.

Rank model, which we define the processor mapping by myself, outperforms. The model that binds each MPI process to a core show comparable results to those on Rank model. The other model, which it binds each MPI process to a processor socket, performs worse results. Every core performs around 60% of workload based on "**top**".

Table 5. Performance of Himeno benchmark in *GFLOPS* for different processor binds for 1024×512×512 problem size in 8 ×6×1 partition pattern on 48 core a node

partition patterns	GFLOPS
Rank model	40.85
Bind each MPI process to a core	40.07
Bind each MPI process to a processor socket	14.75
Not bind processes	26.12

5 Conclusion

We implement two hybrid MPI/OpenMP models for Himeno Benchmark and evaluate the performance on NCHC GPU Cluster and NCHC ALPS. Intel compiler outperforms on NCHC GPU Cluster, while PGI compiler outperforms on NCHC ALPS for CPU bind! It is because that Intel compiler gets more benefit of intrinsic computation involving Streaming SIMD Extensions on Intel platform than PGI and GNU. Moreover, it does not have enough room for thread level parallel via hybrid MPI/OpenMP. Consequently, The pure MPI parallel programming paradigm on 4×4×4 partition pattern outperforms on NCHC GPU Cluster!

Himeno Benchmark and High performance linpack can enjoy the benefits of parallel computing for CPU binding on NCHC ALPS from our various evaluations. The two-dimensional partition pattern, 8×6×1, with PGI compiler outperforms for Himeno Benchmark on NCHC ALPS. Our defined rank model outperforms for Himeno Benchmark and High performance linpack on NCHC ALPS. We establish a Roofline Model for GT200, too.

Acknowledgment

We would like to thank NVIDIA Co. for supporting CUDA version of Himon Benchmark. We are grateful to the National Center for High-Performance Computing for computer time and facilities.

Abstract— *In this paper we critically take a look at what the 3rd generation Intel Core processor brings to high performance computing. We compare four generations of Intel CPU based systems and present a performance review of these four platforms. We compare four families of Intel CPU based systems utilizing a single socket platform across a number of HPC benchmarks and micro-benchmark focused on different performance criteria, compare the results and discuss the implications for HPC.*

Keywords: 3rd generation Intel Core i7-3770K processor; benchmarking; multicore; performance evaluation.

1. Introduction

The 3rd generation Intel Core processor family (codename: Ivy Bridge) is tick product in the Intel's "tick-tock" design methodology. This new CPU does not only represent typical shrink to new 22 nm manufacture process but also improve performance of the integrated graphic module as well improving power-management capabilities.

The new graphic unit is completely redefined and provides new level of experience and performance for video and graphics applications. In this paper we will not focus on graphics aspect of performance as we targeted the HPC applications where floating-point performance is the main criteria.

The 3rd generation Intel Core processor family is based on the same micro-architecture philosophy as its predecessor. This is the second generation of CPU products with AVX support and second CPU with integrated graphics processor unit (GPU) in a monolithic chip.

The first members of the 3rd generation Intel Core processor family have been designated for mobile and desktop products and the server version of Ivy Bridge will be introduced afterwards. Power consumption as well as performance per watt characteristic was first design choices for Ivy Bridge. The first priority was to reduce power. After power savings, Intel design team focused more effort on improving the graphics unit.

Although the first members of the 3rd generation Intel Core processor family are focused on the desktop and mobile markets some of the technology implemented is also expected to be very applicable for the HPC segment.

This study compares 4 configurations of systems: one based on the Intel Core 3rd generation processor second on Intel Core 2nd generation processor family the third system is based on Intel Core i7-970 Processor and the fourth one Intel Core i7-870 Processor based system.

The present study uses High Performance Computing Challenge benchmarks, NAS Parallel Benchmarks and micro-benchmark to measure performance at the subsystem level.

To the best of our knowledge, this is first paper to conduct:

- Analytical and extensive performance evaluation and characterization of a system based on the Intel Core 3rd generation processor, using HPCC and NPB suite.
- Complete comparison of Intel Core 3rd generation processor based system with a system based on Intel Core 2nd generation processor family and another systems based on Intel Core i7-970 Processor (codename: Gulftown) and one Intel Core i7-870 Processor (codename: Lynnfield).
- Performance evaluation of Turbo Mode implemented in the Intel Core 3rd generation processor.

To answer the research questions, we have organized the paper in the following way. Section 2 presents architecture and system configuration for all platforms and deeply describes the microarchitecture of Intel Core 3rd generation processor. In section 3 we discuss system performance and analyze results from running benchmarks. Section 4 contains a summary and conclusions of the study.

2. Architecture and Configuration of the Systems

In our study the 3rd generation Intel Core i7-3770K processor is running on new Intel DX79SI desktop board based on Intel X79 chipset with 8GB of system memory (4x2GB DDR3-1600MHz) with Optimal memory configuration. The 2nd generation Intel Core i7-2600 processor based system utilizes the Intel desktop board DP67BA with 8GB system memory (4x2GB DDR3-1333MHz) populating all available DIMM slots. The six cores based system utilizing Intel Core i7-970 processor is based on Intel desktop board DX58SO with 6GB system memory. This platform has 3 memory channels and we utilized all 3 channels with 2GB (1 DIMM 2GB per channel, DDR3-1066MHz). The quad core system

based on Intel Core i7-870 processor uses Intel desktop board DP55WB with 8GB (4x2GB 2 DIMMs per channel DDR3-1333MHz).

All platforms have deployed enterprise Intel SSD X25-E hard disk drive. Operating system installed is in all the platforms the same: RedHat Enterprise Linux 6 kernel ver. 2.6.32-71.el6.x86_64. In all platforms the new version of the Intel software tool kit has also been installed. The Intel Composer XE 2011 includes Intel Compiler 12.0.0.084 as well as the Intel Math Kernel Library (MKL) 10.3. The new compiler and libraries offer advanced vectorization support, including support for Intel AVX and include Intel Parallel Building Blocks (PBB), OpenMP, High-Performance Parallel Optimizer (HPO), Interprocedural Optimization (IPO) and Profile-Guided Optimization (PGO). All performance tools and libraries provide optimized parallel functions and data processing routines for high-performance applications and in addition contain several enhancements, including improved Intel AVX support.

2.1 CPU characteristic

The 3rd generation Intel Core processor family has been manufactured on 22nm Hi-k metal gate silicon technology and has 1.48 billion transistors for quad-core version. This is the increase from 995 million transistors implemented on Sandy Bridge. Die size of new Ivy Bridge is 23% smaller than quad core version of Sandy Bridge. The 3rd generation Intel Core i7-3770K processor die size has an area of 170mm2 and the 2nd generation Intel Core i7-2600 processor has a die size roughly 220mm2. Majority of this new 500 millions of transistors are taken by new graphics unit as CPU‘s part of the chip is almost unchanged from that implemented in Sandy Bride.

Nevertheless same modification has been made on to the cache and memory interface such as memory hashing and reuse of cache line.

The Ivy Bridge has also new next-page prefetcher able to fetch cache lines ahead of use it on.

The new floating-point data type has been also introduced. This half precision (16-bit) floating-point data type provides 2x more compact data representation than the single precision floating-point (32-bit) format, but sacrifices data range and accuracy. This type of data is widely used in graphics and imaging applications and reduces dataset size and memory bandwidth consumption.

Next modification made on the core level is new divider. Ivy Bridge introduces a partly pipelined implementation of the divide unit, which is reducing the latency and increasing the throughput of the divide and square root instructions.

Some forms of register-to-register MOV instructions are executed in Ivy Bridge microarchitecture do not consume resources of execution unit. Using these MOV instructions remove instruction latency and frees up the execution unit for other operations running on the machine, improving application performance.

Table 1: Processors characteristic.

Processor type	3rd gen. Intel Core i7-3770K	2nd gen. Intel Core i7-2600	Intel Core i7-970	Intel Core i7-870
Technology (nm)	22	32	32	45
Code name	Ivy Bridge	Sandy Bridge	Gulftown	Lynnfield
Cores per socket	4	4	6	4
Turbo Mode	Yes	Yes	Yes	Yes
Intel HT	Yes	Yes	Yes	Yes
Core Freq. (MHz)	3500	3400	3200	2930
Max Turbo Freq. (MHz)	3900	3800	3460	3600
L1 cache size	32 KB Inst	32 KB Data	per core	
L2 cache size		256 KB	per core	
L3 cache size	8MB	8MB	12 MB	8 MB
Integrated memory controller	Yes	Yes	Yes	Yes
Memory channels	2	2	3	2
Memory type supported	DDR3 1333/	DDR3 1066/	DDR3 800/	DDR3 1066/
(MHz)	1600	1333	1066	1333
Core performance (GFLOPS)	28	27.2	12.8	11.7
Memory Bandwidth (GB/s)	25.6	21	25.6	21
CPU Peak Performance (GFLOPS)	112	108.8	76.8	46.8
Core Turbo performance (GFLOPS)	31.2	30.4	13.8	14.4
Peak Turbo CPU performance (GFLOPS)	121.6	112	80	51.2
TDP (W)	77	95	130	95

For reduction of power Ivy Bridge development team implements DRAM and I/O power gating mechanism. This allows turning off the DRAM interface when it is not in use.

Ivy Bridge has a number of other system enhancements such as support for up to three monitors, dynamic (no reboot required) overclocking control and DDR3LV memory support. The DDR3LV DRAM uses a 1.35V memory module voltage of versus 1.5V for regular DDR3 DRAM this cuts power by 20%.

In this study four generations of the CPUs have been evaluated: the 3rd generation Intel Core i7-3770K processor versus its predecessors the 2nd generation Intel Core i7-2600, six core Intel Core i7-970 and quad Intel Core i7-870. The architecture summary of all processors has been summarized in Table 1.

All CPUs are based on the same microarchitecture foundation but the 3rd and 2nd generations Intel Core processor family have brought enhancements not only in to the instruction set like AVX but also modification in microarchitecture of the core.

3. System Performance

The main focus of this section is to present a comparison of 4 platforms based on CPUs described above. The two first platforms are utilizing AVX enabled CPUs. The last two platforms are utilizing Intel Core CPUs first Intel Core i7-970 processor and second one Intel Core i7-870 processor. These platforms are only limited to the SSE 4.2 instruction set but exploit more cores and different micro architecture implementation.

In this study for evaluation of CPU performance we use a matrix to matrix multiplication micro-benchmark, HPC Challenge Benchmark (HPCC) and NAS Parallel Benchmarks (NPB). Theoretical performance of all tested platform has been summarized in Table 1.

Single core theoretical performance for all platforms is in the range from: 11.7 GFLOPS to 28 GFLOPS. The 139% performance improvement accomplished by Intel 3rd generation Intel Core i7-3770K processor with AVX enabled is mainly achieved due to AVX. For Intel Turbo Boost Technology single core performance we have theoretical performance of 31.2 GFLOPS for Intel 3rd generation Intel Core i7-3770K and 13.8 GFLOPS for Intel Core i7-970, 14.4 GFLOPS for Intel Core i7-870 and 30.4 GFLOPS for Intel 2nd generation Intel Core i7-2600. The difference is 126% between Intel Core i7-970 and Intel 3rd generation Intel Core i7-3770K. The difference in obtained results with Intel Turbo Boost Technology is determined by the different scheme and characteristic of turbo mode implementation. The 3rd and 2nd generations of Intel Core CPUs because of turbo mode allows increased frequency about 4 steps (4 x 100 MHz) for a single core and for Intel Core i7-970 it is 2 steps but (2 x 133MHz) and Intel Core i7-870 can do 5 steps 133MHz each so it increases clock up to 3600MHz. Calculated theoretical performance of all cores, will give 108.8 GFLOPS and 112 GFLOPS for Intel 2nd generation Intel Core i7-2600 and Intel 3rd generation Intel Core i7-3770K respectively. For Intel Core i7-870 we have 46.8 GFLOPS and 76.8 GFLOPS for Intel Core i7-970. Consequently theoretical performance with Intel Turbo Boost Technology will give 121.6 GFLOPS for Intel 3rd generation Intel Core i7-3770K, 112 GFLOPS for Intel 2nd generation Intel Core i7-2600 51.2 GFLOPS and 80 GFLOPS for Intel Core i7-870 and Intel Core i7-970.

Theoretical performance does not completely reproduce the real life scenario. To evaluate how all the new technology enhancements are appropriate for HPC workload we have selected a couple of benchmarks. For the single core performance evaluation we started with a micro-benchmark matrix to matrix multiplication [1]. The size of the matrix used in our study is 2048 x 2048. Table 2 summarizes achieved results for matrix to matrix multiplication micro-benchmark.

Table 2: Matrix to matrix multiplication micro-benchmark.

Processor type	3rd gen. Intel Core i7-3770K	2nd gen. Intel Core i7-2600	Intel Core i7-970	Intel Core i7-870
Single core (GFLOPS)	18	16.3	9.0	9.8
Single core MKL (GFLOPS)	30.1	27.2	12.4	13.3
All cores OpenMP (GFLOPS)	63.1	57.9	36.7	31.7
All cores MKL (GFLOPS)	98.7	89.4	66.5	46.3

For the single core 3rd generation Intel Core i7-3770K processors with turbo mode enabled results are 18 GFLOPS and 16.3 GFLOPS for Intel Core i7-2600 and 9 GFLOPS and 9.8 GFLOPS for Intel Core i7-970 and Intel Core i7-870 respectively. The 3rd generation Intel Core i7-3770K single core performs is 10% better then single core Intel Core i7-2600 and 83% better versus Intel Core i7-870 and 100% better then Intel Core i7-970. When we compiled the same code with MKL the single core 2nd generation Intel Core i7-2600 achieves 11% weaker performance versus the 3rd generation Intel Core i7-3770K and 142%, 126% lower results for Intel Core i7-970, Intel Core i7-870. When we test all cores with OpenMP API we achieved results as follow 63.1 GFLOPS and 57.9 GFLOPS for the 3rd generation Intel Core i7-3770K and 2nd generation Intel Core i7-2600 and 36.7 GFLOPS and 31.7 GFLOPS for Intel Core i7-970 and Intel Core i7-870. Testing all cores with MKL does 98.7 GFLOPS and 89.4 GFLOPS for the 3rd generation Intel Core i7-3770K and 2nd generation Intel Core i7-2600 respectively and 66.5 GFLOPS and 46.3 GFLOPS for Intel Core i7-970, Intel Core i7-870. Achieved results represent 88%, 89%, 83% and 90% of theoretical peak performance, respectively for the 3rd generation Intel Core i7-3770K, 2nd generation Intel Core i7-2600, Intel Core i7-970 and Intel Core i7-870. This matrix to matrix multiplication micro-benchmark shows very significant results even without any hands-on optimizations.

The next benchmark suite we have tested is HPC Challenge benchmark. This is a set of tests that examines the performance of HPC architectures in a more challenging way than small matrix to matrix multiplication micro-benchmark. The HPC Challenge benchmark test suite stresses not only the processors, but also the memory system and interconnects. It is a better indicator of how HPC system will perform across a spectrum of real-world applications, unfortunately some of the test are ineffective in our testing scenario as HPC Challenge benchmark is optimized for complete installation

of supercomputer and clusters and not perfectly scaling down to single socket platform. However a few of the tests which are a good indicator for full system implementation are also suitable to estimate the single platform performance. The HPC Challenge benchmark consists of basically 7 tests: HPL, DGEMM, STREAM, PTRANS, FFT, Random Order Ring Bandwidth and Random Ordered Ring Latency [2]. In this section we will evaluate single platform based on the 3rd generation Intel Core i7-3770K, the 2nd generation Intel Core i7-2600 versus Intel Core i7-870 and Intel Core i7-970 across all the benchmark listed above.

The HPL benchmark is the portable version of LINPACK. This is a floating-point benchmark which solves a dense system of linear equations in parallel. The metric produced is Giga-FLOPS (GFLOPS) or billions of floating point operations per second. LINPACK performs operations called LU Factorization. These are highly parallel and store most of their working data set on the processors cache. It makes relatively few references to memory for the amount of computation it performs [3]. For floating-point performance of the platform we have selected LINPACK as it is most popular HPC benchmark. LINPACK is benchmark used to determine the performance of world's fastest computers published at the website http://ww.top500.org/. The fig. 1 shows HPL results for all tested systems.

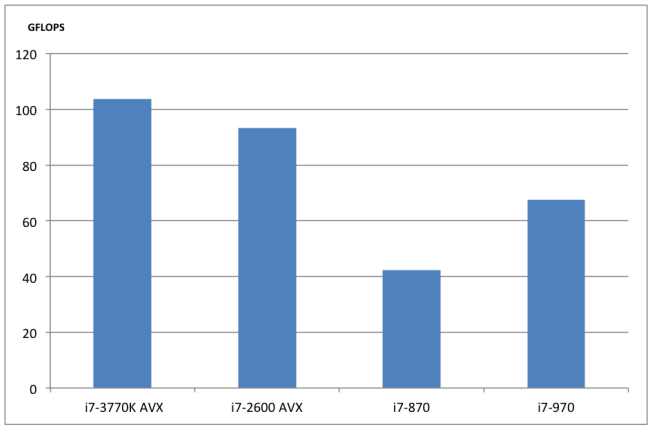

Fig. 1: LINPACK benchmark results.

Single system performance on LINPACK for Intel Core i7-870 is 42.35 GFLOPS, Intel Core i7-970 processor is 67.53 GFLOPS for 2nd generation Intel Core i7-2600 is 93.9 GFLOPS and for the 3rd generation Intel Core i7-3770K this is 103.7 TFLOPS. The achieved performance is 82%, 84%, 83% and 92% of the theoretical performance for Intel Core i7-870, Intel Core i7-970, 2nd generation Intel Core i7-2600 and 3rd generation Intel Core i7-3770K, processor. Intel Core i7-970 has 50% more cores than quad cores then other CPUs processor but AVX version of 3rd and 2nd generation of Intel Core processor have 38% and 54% better LINPACK result. Difference is 120% compeering Intel 2nd generation Intel Core i7-2600 processor to quad cores Intel Core i7-870 and 145% better results versus the 3rd generation Intel Core i7-3770K

The second aspect of platform performance we have evaluated is bandwidth. The benchmark we have used to measure the bandwidth is the STREAM benchmark. It estimates both memory reads and memory writes. This gives us an indication of how effective the memory subsystem is. It measures the performance of four long vector operations. These operations are representative of long vector operations and the array sizes are defined in that way so that each array is larger than the cache of the processors that are going to be tested The STREAM benchmark gives only results of memory system efficiency ignoring the cache efficiencies of the tested platforms. The 3rd generation Intel Core i7-3770K processor based platform has achieved 19.1 GB/s for STREAM using the fastest memory module of DDR3-1600 MHz. The results we have achieved for STREAM are very similar to Intel Core i7-970 18.9 GB/s only 1% difference. The Intel 2nd generation Intel Core i7-2600 processor achieved 17.8 GB/s so 7% weaker than the 3rd generation Intel Core i7-3770K processor. Difference between Intel Core i7-870 and Intel Core i7-970 are more noticeable 16.9 GB/s and 18.9 GB/s respectively. The achieved performance is 75% of theoretical memory bandwidth for 3rd generation Intel Core i7-3770K processor and 84% for Intel 2nd generation Intel Core i7-2600 processor based platforms, 80% Intel Core i7-870 and 73% for Intel Core i7-970. We achieve 73% of theoretical bandwidth result when using 3 channels and 6GB of DDR3-1066MHz on the Intel Core i7-970 based platform, this configuration offers only 1GB memory per core. For other platforms we have dual channel configuration with 8GB memory of DDR3-1333MHz or 1600 MHz and 2GB memory per core ratio.

DGEMM measures the floating point rate of execution of double precision real matrix-matrix multiplication. Fig. 2 shows performance of embarrassingly-parallel DGEMM for the four systems.

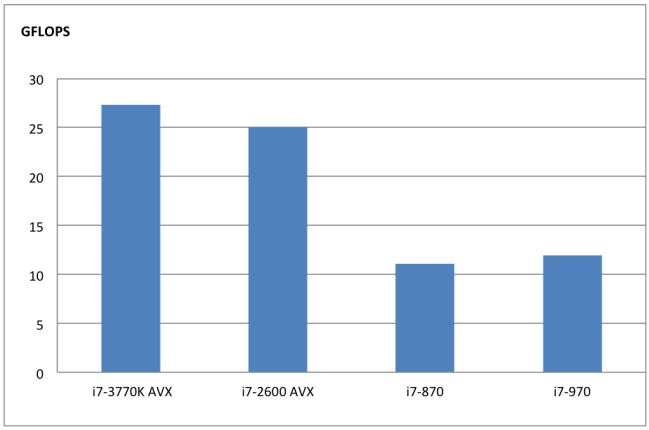

Fig. 2: DGEMM benchmark results.

The 3rd generation Intel Core i7-3770K processor based platform has the highest result 27.35 GFLOPS. The 2nd generation Intel Core i7-2600 processor based platform achieves 25.5 GFLOPS, Intel Core i7-970 processor based platform 11.95 GFLOPS and Intel Core i7-870 processor based platform 11.09 GFLOPS. The achieved performance by 3rd generation Intel Core i7-3770K processor based platform achieved 7%, 128%, and 146% better results than 2nd generation Intel Core i7-2600 processor, Intel Core i7-970 and Intel Core i7-870 processor based platforms respectively.

For FFT benchmark on all four systems we used Intel Compiler 12.0.0.084 as well as the Intel Math Kernel Library 10.3. The benchmark performs as mixture of flops, memory, and network bandwidth. The system based on 3rd generation Intel Core i7-3770K processor and 2nd generation Intel Core i7-2600 processor based platform have the same microarchitecture foundation but slightly different clock and memory subsystem DDR3-1333MHz versus DDR3-1600MHz. Thee difference is 15% but 91% better results versus Intel Core i7-970 and 76% Intel Core i7-870.

The PTRANS benchmark performance depends on the network and on memory bandwidth. The system based on 3rd generation Intel Core i7-3770K has more advance memory implementation and over performs 2nd generations Intel Core i7-2600 processor based system by 11%. Intel Core i7-870 achieved 19% and Intel Core i7-970 45% inferior results versus 3rd generation Intel Core i7-3770K processor based platforms.

The Random Access benchmark uses SANDIA_OPT2 algorithm as Giga Updates per second (GUP/s). All systems have similar memory bandwidth as it is no interconnecting element associated to this platform so results on all platforms are almost the same.

The random-ordered ring bandwidth (RORB) benchmark measures conflict in the network and reports bandwidth achieved per core in a ring communication model. The ROR bandwidth measures the accumulated bandwidth of the communication network of parallel computing systems. The algorithm uses an average, short and long messages transferred with different bandwidth values. Because 3rd generation Intel Core i7-3770K processor based platform has no interconnect element difference in the topology of communication network does not exist consequently the results are very comparable with results achieved by 2nd generations Intel Core i7-2600 processor based system and difference is very marginal. Intel Core i7-870 has achieved 67% lower results versus Intel Core i7-3770K processor based platform and Intel Core i7-970 even 172% below result of Intel Core i7-3770K processor based platform.

The random-ordered ring latency (RORL) measures the latency of the communication network of parallel and, or distributed HPC systems. Several message sizes, communication patterns and methods are used. The algorithm uses an average to take into account that short and long messages are transferred with different bandwidth values in real applications and this has consequences in latency as well [4]. As we have only single systems the relevance of this benchmark is minimal.

The last benchmark suite we have evaluated is the Numerical Aerodynamic Simulation (NAS) Parallel Benchmarks code. This benchmark has been developed by NASA Ames Research Center for the performance evaluation of supercomputers. The benchmark is based on code specifically developed in NASA computational fluid dynamics (CFD) applications department and represents real life applications codes used by NASA for simulating aerospace vehicle.

NAS Parallel Benchmarks consists of two major components five parallel kernel benchmarks and three simulated application CFD benchmarks. The simulated application benchmarks combine several computations defined by the problem size and memory requirements. New revisions of NPB have added three more benchmarks and new versions of problem size for small memory systems. In our study we have focused on the eight tests from the first implementation of NPB as the new added tests, Unstructured Adaptive, Data Cube operator and Data Traffic are not relevant for our testing scenario where we tested only one preproduction platform with single socket. Each benchmark runs two problem sizes Class A and Class B. Same benchmarks also run Class S of the problem size but NASA does not recommend using this problem size for benchmarking purposes [5].

Achieved problem size (Class A) results for 3rd generation Intel Core i7-3770K processor based platform show 8%-13% better results versus 2nd generation Intel Core i7-2600 processor based platform and 43%-113% better than Intel Core i7-870 and 56%-97% better then Intel Core i7-970 based systems. Fig. 3 shows the difference between the 3rd generation Intel Core i7-3770K processor based platform and the platform based on 2nd generation Intel Core i7-2600 processor and additionally compares the Intel Core i7-870 and Intel Core i7-970 based platforms.

Generally platform based on 3rd generation Intel Core i7-3770K processor performs very well and outperforms those based on Intel Core i7-870 and Intel Core i7-970.

For NPB Class B benchmarks we also observe impressive performance benefit of 3rd generation Intel Core i7-3770K processor based platform versus three other configurations. Fig. 4 shows the results from the 3rd generation Intel Core i7-3770K processor based platform versus platform based on 2nd generation Intel Core i7-2600, Intel Core i7-870 and Intel Core i7-970 based platforms for NPB Class B problem size.

For the Class B benchmarks we see that 3rd generation Intel Core i7-3700K processor based platform performs 2%-21% better then 2nd generation Intel Core i7-2600 processor and 43%-142% better than Intel Core i7-870 and 38%-91% superior versus Intel Core i7-970 based platform.

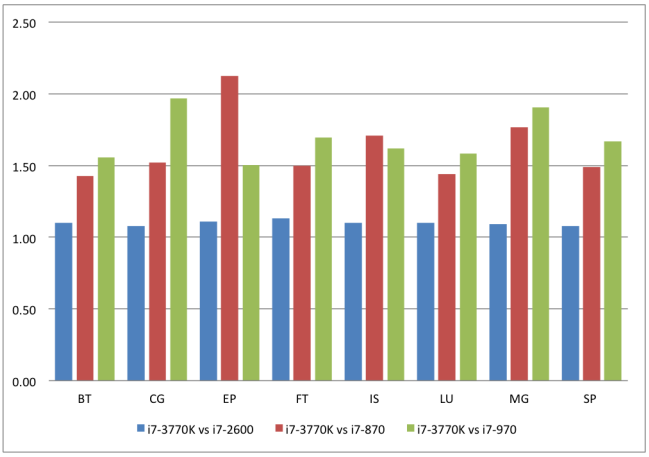

Fig. 3: NPB Class A relative benchmark results.

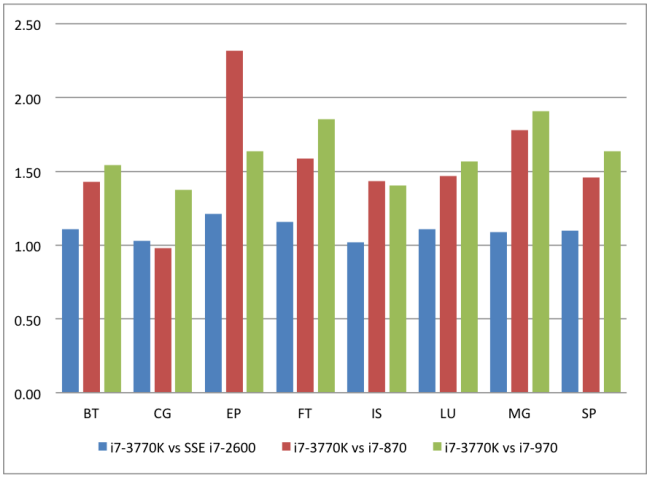

Fig. 4: NPB Class B relative benchmark results.

For IS benchmark 3rd generation Intel Core i7-3770K processor based platform has achieved better result then 2nd generation Intel Core i7-2600 but the difference is marginal only 2%. The Conjugate Gradient (CG) benchmark ran on Intel Core i7-870 got 5% better results than 2nd generation Intel Core i7-2600 processor based platform and even 2% better than 3rd generation Intel Core i7-3770K processor based platform. Overall 3rd generation Intel Core i7-3770K processor based platform confirms its performance superiority.

4. Conclusions

This paper examined the performance characteristics of the Intel 3rd generation Intel Core i7-3770K processor based platform versus its forerunners. In our evaluation study we have selected products which represent the highest CPU configuration in a particular segment and represent the same price point. Of course new generation products typically run on faster clocks and have more capability but our selection was based on the criteria of which product is going to replace its predecessor in a given price segment. So we have compared the same segment platforms from year: 2009, 2010, 2011 and 2012.

The achieved results clearly show that new 3rd generation 22 nm based CPU performs extremely well versus processors based on the Intel Core microarchitecture and results clearly illustrate that AVX instruction set provides major boost in the performance characteristic. The performance improvement we have been able to observe behaves as we have been expecting taking in to account theoretical performance of all CPUs. Intel AVX delivers significant performance improvements to compute-intensive codes and for the same test we have observed 146% difference between then 3rd generation Intel Core i7-3770K processor and its quad core predecessor. For well vectorized code like DGEMM or HPL where AVX can bring benefits the difference is more than 100%, if the code is more memory oriented the difference is smaller 5%-60%. Also six cores Intel Core i7-970 is not able to vie with new 3rd generation Intel Core i7-3770K processor and results show 18%-120% better results.

Performance advantages of 3rd generation Intel Core i7-3770K processor are not only limited to AVX instruction set extension but also the microarchitecture changes and new platform extensions like DDR3-1600MHz brought real performance improvement.

Intel Turbo Boost Technology was always active and delivers additional frequency improvement and consequently improvement in performance for all platforms.

In summary, we can state that 3rd generation Intel Core i7-3770K processor even utilizing a system configuration not optimized for HPC brings lot of performance improvement for compute intensive applications and will deliver a compelling platform for many of the new HPC installations.

Abstract—*Most researchers with little high performance computing (HPC) experience have difficulties productively using the supercomputing resources. To address this issue, we investigated usage behaviors of the world's fastest academic Kraken supercomputer, and built a knowledge-based recommendation system to improve user productivity. Six clustering techniques, along with three cluster validation measures, were implemented to investigate the underlying patterns of usage behaviors. Besides manually defining a category for very large job submissions, six behavior categories were identified, which cleanly separated the data intensive jobs and computational intensive jobs. Then, job statistics of each behavior category were used to develop a knowledge-based recommendation system that can provide users with instructions about choosing appropriate software packages, setting job parameter values, and estimating job queuing time and runtime. Experiments were conducted to evaluate the performance of the proposed recommendation system, which included 127 job submissions by users from different research fields. Great feedback indicated the usefulness of the provided information. The average runtime estimation accuracy of 64.2%, with 28.9% job termination rate, was achieved in the experiments, which almost doubled the average accuracy in the Kraken dataset.*

1. Introduction

High Performance Computing (HPC) is becoming increasingly important by addressing various applications related to science, engineering, service, commerce, security and defense [15]. To improve productivity, more laboratory researchers are starting to use supercomputers to solve large problems in their research fields. However, most researchers without a computer science background or help from HPC consultants have difficulties productively using the supercomputing resources. Programming for a large HPC system requires more experience than for a desktop computer. First, a user needs to know the system-specific information, such as what software packages are supported by the HPC system and how many compute cores are appropriate for a specific job on the system. Furthermore, to submit a job to an HPC system, a user is usually requested to estimate the runtime of a job for system scheduling. In general, the job runtime estimate is very inaccurate. According to the historical usage data of the world's fastest academic Kraken supercomputer, the average accuracy of the estimated runtime is less than 38% for each job category, and around 32.5% for the entire dataset, which is shown in Figure 1. An inaccurate estimate always causes negative effects. An underestimation increases the risk that a job is forcefully terminated by an HPC system before its completion. On the other hand, an overestimation of the job runtime usually results in a longer queuing time. In both cases, the productivity of an HPC user is damaged.

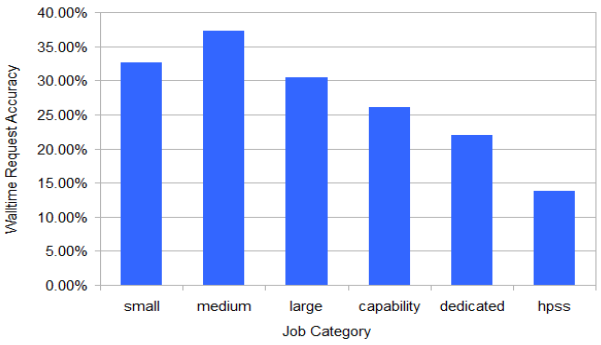

Fig. 1: Average accuracy of the requested walltime for each job category in Table 1.

In this work, we investigated the usage behavior patterns of the Kraken supercomputer, which is the world's fastest petascale academic supercomputer and the 11th on the latest Top500 list. We also developed a knowledge-based recommendation system to optimize user service and resource allocation with the purpose of improving user productivity at the application level. Historical usage logs of the Kraken supercomputer were used to analyze the underlying usage patterns, which were collected from January 2, 2011 to July 21, 2011. We implemented six unsupervised machine learning algorithms to identify usage behaviors, and applied three validation measures to compare the clustering algorithms and determine the appropriate number of behavior categories.

Table 1: Manual classification of jobs in the Kraken supercomputer, which is determined by the number of compute nodes requested by a user.

Categories	Compute Cores			$\text{Walltime}_{\text{max}}$
	Min	Max	Percentage	(hours)
Small	1	512	0-0.45	24.0
Medium	513	58,192	0.45-7.26	24.0
Large	8,193	49,536	7.26-43.88	24.0
Capability	49,537	98,352	43.88-87.12	48.0
Dedicated	98,353	112,896	87.12-100	48.0
HPSS	N/A	N/A	N/A	24.0

The correct jobs were grouped into seven categories, each of which represented a usage behavior of an HPC system. The clustering results can be used by an HPC center to better understand its user community and provide customized services to different groups of users with different types of job submissions. Moreover, considering the fact that HPC systems with different architectures perform differently on the same type of jobs, performance comparisons across different HPC systems provide the potential to identify which architecture is superior to execute which type of jobs. Then, based on the statistics in each behavior category, a knowledge-based recommendation system was developed to provide users with instructions about choosing software packages, setting job parameter values, and predicting job performance. The proposed system enables research communities to share usage experience of a supercomputer, and researchers may improve their productivity by looking at similar jobs successfully executed by other users in the same research area on the same HPC system.

The rest of the paper is organized as follows. Section 2 reviews existing work. Section 3 describes the historical usage data of the Kraken supercomputer, and discusses data preprocessing and feature extraction methods. The unsupervised machine learning algorithms and cluster validation measures are introduced in Section 4 for usage behavior analysis. The proposed recommendation system is also described in this section. Then, Section 5 presents the experimental results on Kraken. Finally, Section 6 concludes the paper.

2. Related Work

Although workload modeling was widely researched [19], only a few studies were reported to address the task of usage behavior analysis. A naive approach to solve this problem is to manually classify a job, based on the number of the requested compute nodes of the job, which is adopted by most HPC centers for job scheduling, such as the Kraken supercomputer [11] as shown in Table 1. Another statistical approach was introduced in [7] to characterize job behaviors and identify the most active users. Wolter [18] experientially classified supercomputer users into three groups. Song [14] proposed a mixed user group model to classify HPC users and analyze workload traces for job scheduling. However, the number of the usage categories was predefined, and the author did not explicitly validate the classification results.

Another related work is to predict the runtime of a job using historical data. The most widely used methods, such as in [10], [16], were directly based on the instances in the historical usage data, which estimated job runtime using the average runtime of a set of jobs with the highest similarity. However, a petascale supercomputer usually has millions of job submissions. It becomes inefficient or even infeasible for instance-based approaches to save all instances. Some model-based algorithms were also proposed for runtime prediction, including methods using artificial neural networks [8] and template-based approaches with greedy and genetic algorithms [13]. However, artificial neural network, as a black box model, failed to explicitly unveil the underlying structures of usage behaviors. In template-based approaches, the templates had to be defined manually, which are almost infeasible for a dataset with millions of samples.

3. Usage Data Processing

In this work, we looked at the historical usage data of the Kraken supercomputer [11], which is managed by the National Institute for Computational Sciences (NICS) at the Oak Ridge National Laboratory. Kraken provides a petascale computing environment fully integrated with the Extreme Science and Engineering Discovery Environment with access to the Cray XT5 system. The Kraken supercomputer consists of 18,816 compute sockets, 147 terabytes of memory, and 3.3 petabytes of storage. Access to computing resources is managed by the Portable Batch System, and job scheduling is handled by the Moab. The Lustre file system is used to support I/O operations.

Usage behavior patterns were analyzed mainly based on the historical data of jobs that were submitted to the Kraken supercomputer. Some instances of usage log entries are listed in Table 2. We also collected account information to determine to which research field each user belongs, and conducted surveys to gather specific information, such as whether a user was an HPC expert. Because most users are not HPC experts or with help from HPC consultants, it is unavoidable that their programs contain runtime errors and exit before completion. On the other hand, due to the lack of experience to run a job on a supercomputer, it is also very common that users underestimate job runtime, and a job is forcefully terminated by the HPC system. If a job neither completes correctly nor provides meaningful results, it is considered as an incorrect job. On the contrary, a job is defined *correct*, if it belongs to the set:

$$\mathcal{J}_c = \{j \mid (j.mem\_used \neq 0) \wedge (j.walltime > 30) \wedge (j.walltime < j.walltime\_req)\} \quad (1)$$

where "." represents attribute relationship, and the unit of the attribute *walltime* is second. Intuitively, a job is incorrect if

Table 2: A typical log file that records the usage activities of the Kraken supercomputer. This exemplary log file contains five instances. Each row represents a job submission, and each column denotes an attribute of a job.

1) it doesn't consume any memory, which indicates that the job fails to start executing, possibly due to some compiling problems, including the situation that the job is compiled on another HPC system with a different architecture; or 2) the job quits right after its execution, which is possibly caused by runtime errors, such as segmentation faults; or 3) the job is terminated by the HPC system, because it consumes the requested walltime. The second literal in (1) also contributes to remove the "Hello World" jobs and simple testing jobs, in which case a user is a learner or does not care about job runtime. Because incorrect jobs are always misleading, it is necessary to remove them to improve the performance of job classification and runtime estimation. On the other hand, it should be noted that the definition of a correct job does not remove all incorrect jobs, such as a job with runtime errors at the end of its execution. The rest of the incorrect jobs are considered as noise, or instances with errors.

A feature is a distinctive characteristic of an object, such as a job, which is often represented as a function of the object's attributes. In this work, four features are selected or extracted from job attribute space, which are defined as:

$$\begin{aligned} N_n(j) &= \log(\, j.nproc \,/\, C_n \,) \\ M_u(j) &= \log(\, j.mem\_used \,) \\ T_q(j) &= \log(\, j.start\_time - j.submit\_time \,) \\ T_r(j) &= \log(\, j.end\_time - j.start\_time \,) \end{aligned} \tag{2}$$

where N_n, M_u, T_q and T_r are the features encoding the information of number of allocated nodes, memory used, job queue time and job runtime, respectively; and C_n represents the number of cores on each node, which is 12 on the Kraken supercomputer. Because job attributes cover a large range of values, logarithmic scale is used to represent each feature to reduce a wide range to a manageable and comparable size.

4. Usage Pattern Modeling

We remove the jobs submitted by system administrators that typically perform system management tasks, such as system updating or reservation removing. Moreover, jobs in the HPSS queue and interactive jobs are also intentionally removed. HPSS jobs often start executing right after being submitted, without any compute nodes involved. Interactive jobs provide a user interactive access to compute resources, which are commonly used for debugging. At last, we manually classify the jobs requiring over 50,000 cores into the group of massive jobs. According to our survey, all users with very large job submissions are HPC experts or work with HPC consultants. Formally, the job dataset used in this work is defined as:

$$\begin{aligned} \mathcal{J} = \{\, j \mid (j \in \mathcal{J}_c) \wedge (\, j.nproc < 50000 \,) \\ \wedge (\, j.queue \neq \text{hpss} \,) \wedge (\, j.type \neq \text{interactive} \,) \,\} \end{aligned} \tag{3}$$

4.1 Cluster Analysis and Validation

To investigate the underlying structures of usage patterns, cluster analysis is applied on job set $\mathcal{J}$. Cluster analysis is an unsupervised learning technique, which groups objects with similar attributes into respective categories. In cluster analysis, we do not know either which job belongs to which category or the number of categories. Six clustering methods, in three categories, are applied to analyze usage behaviors:

- Partitioning clustering, including k-means [1] and Partitioning Around Medoids (PAM) [17];
- Hierarchical clustering, including DIvisive ANAlysis clustering (DIANA) [5] and Unweighted Pair Group Method with Arithmetic Mean (UPGMA) [9];
- Artificial Neural Network (ANN) based clustering, including Self-Organizing Feature Map (SOFM) [6] and Self-Organizing Tree Algorithm (SOTA) [4].

Cluster validation evaluates the performance of a clustering result by comparing it with other ones that are generated

by other clustering methods, or by the same method but with different parameters, such as different number of clusters. In this work, three internal validation measures, along with domain knowledge, are used to choose the best clustering methods and determine the number of clusters that is most appropriate for the dataset:

- Connectivity [2] measures cluster connectedness, with a value in the range $[0, \infty]$. A lower value indicates a better performance.
- Dunn index [3] is the ratio of the smallest distance between objects in different clusters to the largest intra-cluster distance. The value of Dunn index lies in $[0, \infty]$, and a greater value indicates a better performance.
- Silhouette width [12] measures the degree of confidence in the clustering assignment of an object. Its value lies in $[-1, 1]$ with a greater value indicating a better clustering performance.

4.2 Information Recommendation

It is clear that jobs have a wide range of system demands and might perform differently on the same HPC system. For example, computation-intensive and data-intensive jobs might have significantly different runtime, even if they request the same number of compute nodes. The proposed knowledge-based recommendation system is based on the plausible assumption that job submissions in the same research field tend to perform more similarly, since jobs submitted by researchers in the same field are more possible to address similar problems with similar algorithms using similar software and packages. Moreover, jobs in the same clustered categories also tend to behave more similarly due to the similarity of their attributes. In consideration of both assumptions, we predict the parameters of a target job based on the information of the jobs that are in the same category and same research field as the target job.

In the first step, customized information is provided to a user by the recommendation system, including the distribution of the jobs, the statistical information of several job features, and a list of the most frequently used software and packages in the given research field. Jobs in a research field conforms to the multinomial distribution given job categories. A bar graph is used to intuitively represent this distribution. Then, the statistical summaries of several features are graphical displayed using box plots. Each box plot represents the distribution of a feature, its central value, and variability. The displayed features include N_n and M_u, i.e., the number of requested compute nodes and consumed memory. At last, a list of software and packages is provided, which is obtained by ranking the most frequently used software and packages used by previous users in the same research field. In this step, a user is required to determine the number of requested cores and memory, under the guidance of the recommendation system.

In the second step, after the number of requested cores and memory are decided, the features N_n and M_u are computed according to (2). Then, the queuing time and runtime of the target job are predicted based on the job distributions and the job statistics in each behavior category. More precisely, our goal is to predict the feature vector $\boldsymbol{z}_j = \{T_q, T_r\}$. Let $\boldsymbol{y}_j = \{M_u, Nn\}$ be the feature vector that is determined in the first step by a user in field r_j. Then, the distance between $\boldsymbol{y}_j$ and the center of the behavior category k can be computed using Euclidean distance: $d_{jk} = \|\boldsymbol{y}_j - \mathrm{E}[\boldsymbol{y}_{jk}]\|$, where $\mathrm{E}[\boldsymbol{y}_{jk}]$ is the feature vector expectation of the jobs in the behavior category k and the research field r_j. Then, the target feature vector $\boldsymbol{z}_j$ can be computed by:

$$\boldsymbol{z}_j = \frac{1}{Z_j(\boldsymbol{y}_j, \boldsymbol{\theta}_j)} \sum_{k=1}^{K} \frac{\theta_{jk}}{d_{jk} + \sigma} \mathrm{E}[\boldsymbol{z}_{jk}] \tag{4}$$

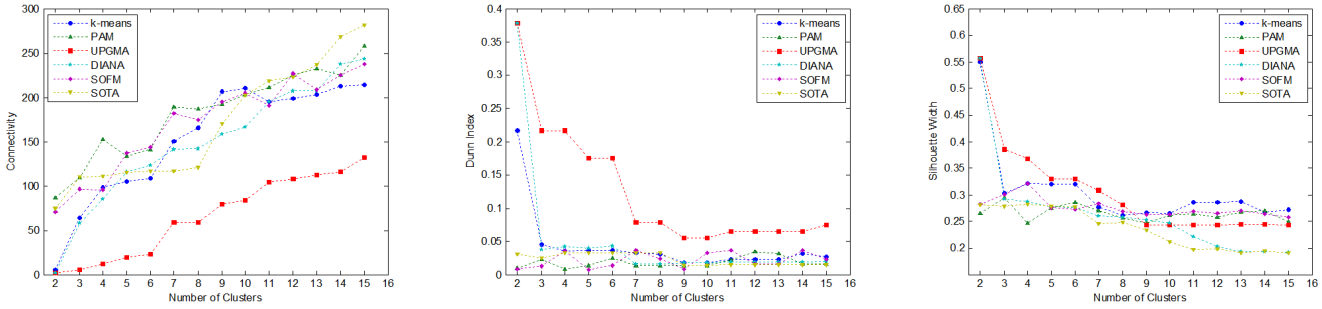
where θ_{jk} is the probability that job j belongs to category k; σ is a small positive number to avoid a zero denominator; and $Z_j(\boldsymbol{y}_j, \boldsymbol{\theta}_j)$ is a normalizing factor. The feature vector $\boldsymbol{z}_j$ is computed using a mixture of corresponding cluster means. The mixture coefficient considers both the clustering result of the target job, which is represented by the distance to each cluster center, and the prior knowledge $\boldsymbol{\theta}_j$ that is the distribution of the jobs in the target job's research field. Both elements are important for job classification. While the distance of a job to a cluster center determines the probability that the job belongs to the cluster, the job distribution in a research field, as a prior, prefers the cluster containing a larger number of jobs that are previously observed. After the feature vector $\boldsymbol{z}_j$ is calculated, the queuing time can be computed by: $\hat{j.queuing} = 10^{T_q}$. In most cases, users care more about job runtime, which is a required parameter by most supercomputers to submit a job. According to our experiments, the job runtime can be better estimated by:

$$\hat{j.runtime} = 10^{(1+\alpha)T_r + \beta} \tag{5}$$

where $\alpha, \beta \in [0, 1]$. A good job runtime estimation can be computed with $\{\alpha, \beta\} = \{0.05, 0\}$, and a safer estimation can be obtained with $\{\alpha, \beta\} = \{0.05, 0.3\}$, which can be applied to request system walltime. The coefficient $(1 + \alpha)$ of T_r considers the fact that, for a larger job with more compute resources and longer runtime, users often tries to make the job safer (i.e., with a higher probability to successfully complete the job), by intentionally requesting a longer system walltime. If a large job is forcefully terminated by the system before its completion, it often costs much more than a small job.

5. Experimental Results

We used the historical usage data that were collected from January 2 to July 21, 2011, after Kraken was upgraded to the Cray XT5 system. During the time of data collection, 321,290 jobs in 24 different research fields were submitted to



(a) Connectivity measure (b) Dunn index measure (c) Silhouette width measure

Fig. 2: Internal cluster validation of the clustering methods with different number of clusters.

Kraken by 843 researchers from 367 accounts. The Kraken dataset was first preprocessed to get job set $\mathcal{J}$. In this step, 112265 jobs were removed from the original Kraken dataset, including 102206 incorrect jobs (termination-rate = 31.8%). Then, feature vectors were computed for the rest of the jobs according to (2), and related information, including research field and software name, was documented.

5.1 Cluster Analysis and Validation

Before clustering the Kraken dataset, a cluster was manually defined as the massive job category that contains jobs requiring more than 50,000 compute cores, which contains 168 job submissions in the entire preprocessed dataset.

Six clustering approaches were applied to cluster usage behaviors, and three internal validation measures were employed to compare the clustering performance and to find the appropriate number of clusters. The performance evaluation results are depicted in Figure 2a, 2b and 2c, respectively. A most important conclusion is that the UPGMA algorithm performs consistently better than other clustering methods when using less than nine clusters, which is indicated by all internal validation measures. We can also observe that other clustering techniques, if the number of clusters is greater than three, have similar performance but are generally worse than the UPGMA algorithm. Thus, the UPGMA algorithm, an agglomerative hierarchical clustering algorithm, was selected to cluster usage behaviors.

The validation measures were also applied to determine the appropriate number of clusters. For all clustering algorithms, the connectivity measure in Figure 2a indicates that, with the increase of the number of clusters, the clustering performance tends to decrease. Similarly, both the Dunn index in Figure 2b and the silhouette width in Figure 2c indicate that clustering performance cannot be improved by simply increasing the number of clusters. We can also observe that, for the k-means, PAM and UPGMA algorithms, two is the best choice for the number of clusters, which is supported by the connectivity measure and the Dunn index measure, and partially by the silhouette width measure. On the other hand, in order to increase the resolution of the job clustering results, we prefer a larger number of clusters. For the chosen UPGMA algorithm, the clustering performance almost consistently declines with the increase of the number of clusters. But the performance of the algorithm does not change greatly with the number of clusters lying between three and six. To balance clustering performance and clustering resolution, six clusters were selected, in which case, we increased the clustering resolution by sacrificing some clustering performance. The resulted dendrogram with six clusters is depicted in Figure 4.

Table 3: Algorithmic mean of each job feature in different categories in the Kraken dataset.

Feature	c1	c2	c3	c4	c5	c6	c7
E(T_q)	4.24	2.62	2.87	1.89	4.65	3.74	4.27
E(T_r)	4.19	3.63	3.22	2.38	4.15	2.64	3.22
E(M_u)	4.05	4.03	5.11	4.09	4.17	4.12	5.07
E(N_n)	0.19	0.26	1.01	0.98	1.51	1.51	3.90

The algorithmic means of job features in each category are listed in Table 3. Several interesting phenomena should be noted. First, the behavior category c3 can be considered as the set of data-intensive jobs. Jobs in this category use significant memory but relatively less number of compute nodes. Second, the jobs in the manually defined category c7 are greatly different from the jobs in other categories, which are both computational and memory-intensive. However, jobs in this category do not have the longest queuing time, because the massive jobs have a high priority on the Kraken supercomputer, and researchers running such jobs usually reserve the compute resources in advance. These massive jobs do not have the longest job runtime either. Besides the fact that the massive jobs use considerable amount of resources that can speed up job execution, this phenomenon can be partially explained by the fact that most users running such jobs have rich HPC knowledge. In most cases, the massive jobs are optimized. Third, if we only consider the

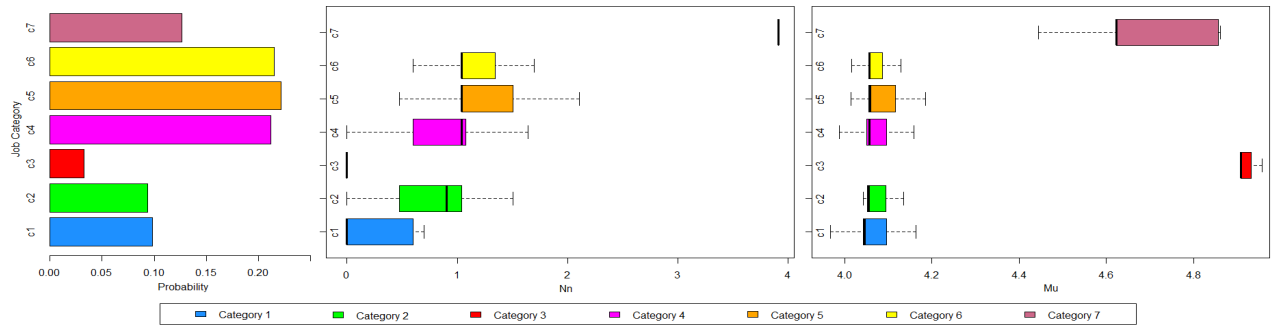


Fig. 3: Customized information of the jobs in the research field of Astronomical Sciences, which is generated in the first-round recommendation. The bar graph (left) represents the distribution of the previously submitted jobs on Kraken. The box plot (center) summaries the statistics of the number of compute nodes requested by the jobs in each category in log scale. The box plot (right) represents the statistical summary of the consumed memory of the jobs in each category in log scale.

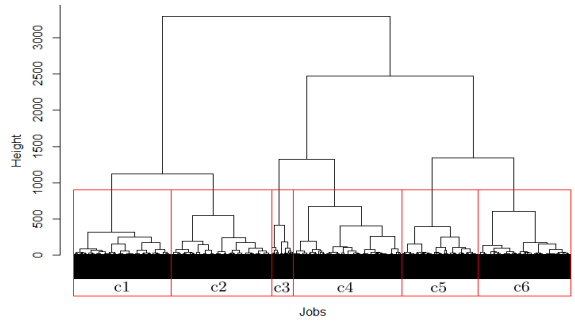

Fig. 4: Dendrogram generated by the UPGMA algorithm with six categories on the Kraken dataset.

requested compute nodes and the consumed memory to classify jobs, we can combine the category pair: c1 and c2, c3 and c4, c5 and c6 in to larger clusters, due to the similarity of the features in each category pair. This phenomenon is well supported by the dendrogram. If the UPGMA algorithm is set to stop with three clusters, the dendrogram will be cut at the height of 2000, as shown in Figure 4. Fourth, jobs in the categories c1 and c2 have the longest runtime. Besides the fact that these jobs use less compute resources, another possible explanation is that users executing such jobs usually have less HPC experience and their jobs are not well-tuned.

5.2 Information Recommendation

To demonstrate how the proposed recommendation system instructs a user to select appropriate job parameters and predict job performance, a real case is used as an example, in which case, a researcher planned to solve a problem in the field of Astronomical Sciences. In the first-round recommendation, the system first provided a list of packages that were most frequently used on Kraken to solve problems in Astronomical Sciences, such as GADGET, YT, SSES, and CHIMERA. After comparing the packages, the researcher decided to use Gadget, which is a cosmological smoothed particle hydrodynamics (SPH) simulator. The proposed system also provided the researcher with customized information about the job statistics in Astronomical Sciences, as shown in Figure 3. Some important phenomena were observed by the researcher. First, more large jobs in c4, c5, c6 and c7 were executed in this field. Second, almost all massive jobs in c7 used considerable resources with similar number of compute nodes but widespread memory. Third, only a few jobs were data-intensive which generally consumed a very small number of compute nodes but significant amount of memory. Fourth, the non-massive non-data-intensive jobs, in c1, c2, c4, c5 and c6, consumed similar amount of memory, as shown by the right box plot. The medians of the number of requested compute nodes of jobs in c4, c5 and c6 were very close, as indicated by the center box plot in Figure 3. Based on these observations, the researcher decided to request 12 GB memory ($\hat{M}_u \approx 4.1$) and 12 compute nodes ($\hat{N}_n \approx 1.1$) for the job.

In the second-round recommendation, the values of T_q and T_r were computed according to (4), given $\hat{M}_u$ and $\hat{N}_n$. The architecture of the recommendation system and the estimating process were transparent to users. All feedback the researcher received from the system was the estimated queuing time, runtime, and a safe runtime, which can be used to request system walltime on the Kraken supercomputer. In this case, the estimated queuing time was 7079 seconds ($z_{Tq} = 3.85$); the estimated runtime was 5624 seconds ($z_{Tr} = 3.57$); and the estimated safe runtime was 11221 seconds. After successfully compiling the program on Kraken, the researcher used the estimated runtime as the requested system walltime to execute the job. After waiting in the queue of type *small* for 11175 seconds on Kraken, the job started executing, and the actual runtime was 5049 seconds, which was smaller than but quite close to the job estimated runtime provided by the proposed recommendation system.

In order to quantitatively measure the accuracy of the runtime estimation, we applied the Walltime Request Accuracy (WRA) for a correct job j in $\mathcal{J}_c$, which is defined as:

$$WRA(j) = \frac{j.walltime}{j.walltime\_req} \times 100\% \quad (6)$$

In the evaluation, 127 jobs submitted by seventeen researchers from different research fields were used to test the proposed system. The researchers were not HPC experts or worked with HPC consultants, and the jobs were moderately optimized. According to their feedback, all researchers considered that the information provided by the recommendation system was helpful, especially the job statistics in a research field. For job runtime estimation, when the researchers were asked to use the estimated runtime provided by the recommendation system as the requested walltime, 28.9% jobs were terminated in force by the Kraken supercomputer, due to running out of requested walltime. For the correct jobs, an average WRA of 64.2% was achieved. Comparing to the average WRA of 32.5% with the termination rate of 31.8% in the Kraken dataset, the estimation performance was greatly improved. If the users were asked to use the safe runtime estimate to request system walltime, only 12.2% jobs exceeded their requested walltime. But the average WRA decreased to 33.3%. In this case, although the resulted average WRA was similar to the average WRA in the Kraken dataset, the termination rate was greatly decreased. In order to quantitatively measure the error of the estimated queuing time, the mean absolute percentage error (MAPE) was applied, which is defined as:

$$MAPE = \frac{1}{T}\sum_{t=1}^{T}\left|\frac{j.\hat{queuing} - j.queuing}{j.queuing}\right| \quad (7)$$

where T is the number of testing instances, and $j.\hat{queuing}$ and $j.queuing$ are the estimated and actual queuing time, respectively. The resulted MAPEs were 67.2% and 105.8% using the estimated runtime and the safe runtime to request system walltime, respectively. This result indicated that the queuing time is harder to estimate, which is heavily dependent on the job queue status. Fortunately, the researchers, like most HPC users, did not much care about the queuing performance according to their feedback.

6. Conclusion

Usage behaviors of the Kraken supercomputer were systematically investigated and a knowledge-based recommendation system was developed to improve job performance and user productivity at the application level. Besides manually defining a category for massive job submissions, six behavior categories were identified with the UPGMA algorithm, which presented the most promising performance on the Kraken dataset. Then, a knowledge-based recommendation system was developed based on the identified behavior categories and job statistics. The proposed recommendation system is able to: 1) provide customized information to help a user determine the software packages, and the number of compute nodes and amount of memory to request for a job, 2) predict job queuing time and runtime, and estimate a safe job runtime to request system walltime. Great feedback from users demonstrated the usefulness of the recommendation system. The average runtime estimation accuracy of 64.2%, along with the job termination-rate of 28.9%, was achieved, which almost doubled the previous average accuracy in the Kraken dataset.

Parallel Implementation of Moving Averages and Stock Market Prediction

John Jenq
Computer Science Department, Montclair State University, Montclair, New Jersey, USA

Abstract - *In recent years, graphics processing units have made parallel processing affordable with the price of personal desktop computers. This report investigates the computational aspects of calculating simple moving average and exponential moving average operations, two of the most popular financial indicators. In this report, we also investigate the usage of GPU to run artificial neural network as a mean of predicting stock market pricing. Feedforward and Backpropagation artificial neural network was used for this study. Financial data including major stock indices, volumes, pricing, and moving average of stocks were used as input. The future stock prices can be predicted as the output. The speedup factor by adopting GPU and CPU together over traditional CPU alone implementation was not significant. The computation of compute moving averages on GPU was also discussed.*

Keywords: artificial neural network, stock prediction, GPU computing, parallel processing, high performance computing.

1 Introduction

Graphic processing unit (GPU) has transformed a regular PC into a personal supercomputer. For example, in [5], the GeForce GTX 580 can perform single precision operation that reaches more than 1500 GFlops. These computing powers significantly speed up the computational intensive applications with a price of a PC. Many tools have been developed to make the GPU computing much easier than ever before. Personal supercomputing is now a reality to us.

Artificial neural networks are used for pattern recognition, clustering, and optimization. Neural networks can also be used to solve problems which are not easily solved by traditional calculation methods, particularly if there is no strong underlying theory to explain the data. Neural networks have been developed as generalizations of mathematical methods of neural biology, based on the assumption that the information processing occurs at many simple elements called neurons. Signals are passed between neurons over connection links. Each connection link has an associated weight which multiplies the signal transmitted. Each neuron applies an activation function to its net input to determine its output signal.

There are researchers using neural network in financial and economic computations. For example, in [3], Li and Liu used LM BP algorithm to predict the Shanghai stock market. In [9], Wang developed a HLP method that gets stock high low points with different frequencies and amplitudes. The extracted data is then fed into a neural network to forecast the stock direction and price. In [8] Tirados and Jenq used neural networks to predict GDP with ten leading economic indicators as the input. In [4] Lin and Feng combined neural network and pattern matching techniques to analyze and forecast oil stock prices. In [10], Zhou and Zhang used financial indicators such as moving averages, volumes, relative strength index, etc. on neural network to predict future stock prices.

In the past, CPU clusters have been used to achieve high performance computation. GPU computing uses GPU as a co-processor to accelerate CPUs for general purpose scientific and engineering computing. It shifts computation intensive program segments into GPU while keeping the rest of the program segments, which are serial in nature, on the CPU. This kind of hybrid computing improves the performance of many computer applications.

The GPU computation can be used on financial computations as well. Researchers in the financial world find the benefits of using GPU in financial computation. In [6], Peng, et. al., compute option pricing on GPU with backward stochastic differential equation. in [1], Lee, et. al., did financial derivative modeling using GPUs. In [7] Solomon et. al., used trinomial lattice strategy to implement the pricing of European option and American lookback option pricing using GPU. In [2], Lee, et. al., investigated random number generation and the Monte-Carlo simulation to predict future stock prices. They also discussed the out of core case when graphics DRAM is not big enough to hold all the application data.

The rest of the paper is organized as the following. Section 2 discusses methodologies and implementation of an artificial neural network. Parallel implementation of simple moving average and exponential moving average will be discussed as well. Section 3 discusses and analyzes the experimental results. Section 4 gives conclusion remarks.

2 Methodologies and implementations

Three-layer neural network was chosen to implement our prediction system. The inputs are major industrial stock indices and stock indicators. The goal is to forecast future stock prices. Feedforward and backpropagation neural network was used. Backpropagation is a gradient descent neural network method used to minimize the total squared error of the output calculated by the network. The network is developed to achieve a balance between the ability to respond to the input patterns that are used for training and the ability to give good responses to input that is similar, but not identical, to that used in training. Like with multiple regression, backpropagation was used to develop a correlation between the input of stock market data in order to determine the future stock price.

The training of a network by backpropagation involves three stages: the feedforward of the input training pattern, the calculation and backpropagation of the associated error, and the adjustment of the weights. After training, application of the network involves the computations of the feedforward phase only.

To prevent the larger data from dominating the outcome, the raw data will be processed before being fed into the neural network. The raw data has been modified. In the following discussion, *B* represents the raw form of the original data, and C is the normalized version of *B*.

$$C_t = 2\left(\frac{B_t - B_{\min}}{B_{\max} - B_{\min}}\right) - 1 \qquad (1)$$

This transformation map our data to between -1 and 1. The activation function selected is the bipolar sigmoid function, which has a range of (-1, 1), and is defined as

$$f(a) = \frac{2}{1 + exp(-a)} - 1 \qquad (2)$$

$$\frac{df(a)}{da} = \frac{1}{2}[1 + f(a)][1 - f(a)] \qquad (3)$$

2.1 Feedforward Backpropagation Neural Network

The traditional Neural Network algorithm can be simplified as below

```
while (cycle < maxCycle  && averageError > toleranceEerr)
{
    for (int i= 0; i < totalRecords;  i++)
    {
        forwardPropagation();
        backwardPropagation();
        accumulateError();
        updateWeights(learningRate);
    }
    compute averageError;
}
```

To simplify the discussion, let's denote the connection weights between the input layer and hidden layer to be *w*. Also let's denote the connection weights between the hidden layer and output layer as *v*. Note that both *w* and *v* are vectors. To parallelize the code in order to fit into GPU computing, some modifications will be made. Instead of performing backpropagate operation for each pattern to update weights, we will compute the *dw* (the update of weight *w*), *dv*(update of weights *v*) and then do the update of the weights at the end of each cycle. It means that we move the updateWeights(learningRate) function out of the traditional algorithm above. Instead of performing these operations for each record for each cycle, we reduce them to once per cycle. Therefore the total weights to be updated would be the summation of *dw* and *dv*, which are calculated by an individual pattern during the process. Note that the *dw*s are the weights to be added to the *w*, the weights between input layer and hidden layer. And *dv*s are the weights to be added to *v*, the weights between hidden layer and output layer. Here we assume there is one output neuron although more output neurons are possible. The updateWeights function can be done by binary reduction which can be performed in *logN* steps using *N* threads. Although the backwardPropagation and updateWeights functions may be parallelized, the gain of speedup may be limited. This setup allows us to assign one pattern to each thread in order to speed up the process.

Because the binary reduction operation may slow down the whole system performance, it is interesting to find out if assigning more than one pattern to a thread for processing will improve the performance. Once again, it depends on how many clock cycles will be used to synchronize the threads. If more threads are to be synchronized, then we would expect more time for the reduction operation. An interesting aspect is to find out how to organize operations so that we can get the best possible performance.

2.2 Moving Average

Moving averages can be used as financial indicators. There are various types of moving averages, of which two of the most popular are simple moving average and exponential moving average.

2.2.1 Simple Moving Average

Assume the daily closing price for day *t* is C_t. The *n*-day simple moving average can be defined as $SMA(t) = \frac{\sum_{i=t-1}^{i=t-n} C_i}{n}$, where C_i is the closing price at day *i*. So simple moving average can be computed by taking the average closing price of a stock, over the last *N* periods. Popular simple moving

averages are 5, 10, 20, 40, and 200. Let's assume that the last five periods for a stock are 1,3,5,7, and 9. Then, the 5 day simple moving average can be computed as (1+3+5+7+9)/5 = 5. While simple moving average giving all past *n*-day closing prices are weighted equally, the *n*-day exponential moving average assigns more weight to the most recent price, which will be discussed in the next subsection.

Simple moving average on a parallel computer can be done by using Prefix Sum operation. It also known as Scan operation. A Prefix Sum can be defined as the following. Given a set of *N* values $a_1, a_2, a_3, \ldots, a_n$, and an associative operation @, the Prefix Sums operation will compute the *N* quantities (a_1, $a_1@a_2$, $a_1@a_2@a_3$,..., $a_1@a_2@a_3@\ldots@a_n$). By using the Prefix Sum operation, the *N*-day Simple moving average of day *"i"* can be calculate as

$$SMA[i] = (prefixSum[i] - prefixSum[i-N])/N \quad (4)$$

where *SMA[i]* is the *N* day moving average at day *i*. Table 1 gives an example that uses Prefix Sum to compute 3-day moving averages. Assume the missing period (period -1, and -2 in our example) values are 0.

Period	1	2	3	4	5	6	7
Value	1	3	5	7	9	10	12
prefixSum	1	4	9	16	25	35	47
Total of subsequence	1	4	9	15(= 16-1)	21(= 25-4)	26(= 35-9)	31(= 47-16)
Simple Moving Average	1	2.5	3	5	7	8.67	10.33

Table 1 Example of calculation of *SMA* using prefixsum

2.2.2 Exponential Moving Average

Exponential moving average can be defined as $EMA(t) = (P_t - EMA(t-1)) * \alpha + EMA(t-1)$, where P_t is the closing price at day *t*. The α is weighting factor and can be defined as $\alpha = 2/(n+1)$, where *n* is the number time periods involved in the computation. For example, for 10-day period EMA, $\alpha = 2/(10+1) = 0.181818$, while 20-day EMA, $\alpha = 2/(20+1) = 0.095238$. One can rewrite the above EMA definition using past *n*-day closing prices and α as follows. Note that weights are decayed exponentially and the most recent prices carry more weights in the computation.

$$EMA(t) = \alpha P_t + \alpha(1-\alpha)P_{t-1} + \alpha(1-\alpha)^2 P_{t-2} \ldots + \alpha(1-\alpha)^{n-1} P_{t-n+1}$$

Even though *EMA* can be easily computed by using the method as mentioned in the previous paragraph, however it has serial nature in the computation. In order to deliver a parallel algorithm, let's define $\beta = (1-\alpha)$ where α is the multiplier that we define from the previous discussion. The formula to compute exponential moving average then becomes the following

$$EMA(t) = \alpha P_t + \alpha\beta P_{t-1} + \alpha\beta^2 P_{t-2} \ldots + \alpha\beta^{n-1} P_{t-n+1}$$

We will partition the whole data array into segments with lengths of powers of 2. Assume the leftmost data is the most recent data(the lowest index) and rightmost one (the highest index) is the oldest timing data. By using $O(N)$ memory to store the comupted information, we can therefore compute exponential moving average of P period in $O(log_2 P)$ time. Here, N is the number of records. Actually one can reduce the total memory to $2N$ as we will discuss shortly.

The computation of *EMA* involves two phases. In the first phase, we will generate the required data through iterations. In the first iteration, two pieces of data that are adjacent to each other will be processed to create a combined length-2 information. In the second iteration, combined length-4 segment information can be generated from the combined length-2 information. To simplify, let's assume p is power of two. In $log_2 P$ iterations, one can create $\frac{P}{2} + \frac{P}{4} + .. + 1$ which is a total of $P - 1$ pieces of data information for each segment of length *P*. This information will be used in the second phase of our *EMA* computation. Table 2 gives an illustration of the first phase *EMA* computation. Note that $\beta = (1-\alpha)$.

0	1	2	3	4	5	6	7
	(01)		(23)		(45)		(67)
		(0123)				(4567)	
				(1->7)			
	$c_0 + \beta c_1$	$c_0 + \beta c_1 + \beta^2(c_2 + \beta c_3)$	$c_2 + \beta c_3$	$c_0 + \beta c_1 + \beta^2(c_2 + \beta c_3) + \beta^4(c_4 + \beta c_5 + \beta^2(c_6 + \beta c_7))$	$c_4 + \beta c_5$	$c_4 + \beta c_5 + \beta^2(c_6 + \beta c_7)$	$c_6 + \beta c_7$

Table 2 Phase one of EMA Computation: data store scheme

For a segment of *P* periods of data on a *N* data array, where *P* < *N*, our job is to find the *EMA* for all the data on the data array with *N* data. Our approach is to partition any segment from index *a* to index *b*, where (*b-a+1*) is the period *P*, into at most two segments. It is possible that there is only one segment if the segment starts with index of power of 2 and ends with a power of 2 minus 1. In that case, we can compute the *EMA* value. It is just the value in the array of index $\lceil (a+b)/2.0 \rceil$. For example, if *a* is 56, *b* is 63, and *P* is 8, then index 60 holds the *EMA* value. Refer to Table 2 above to see how the combined values are stored. Note that this is the

best case since there is only one segment. For other *P-1* cases, out of every segment of length *P*, there are two segments. Let's assume these two segments are P_1 and P_2. First of all, we have to find out the cutline index. The first segment P_1 starts with index *a* and ends with an index which is to the power of 2 minus 1. Let's call this index *cutindex*. It can be computed as $b/p \times p$. Consider a segment from index 53 to 60: the resulting cutline index is 56. Note $60/8 \times 8 = 56$. The second segment P_2 starts with an index 56, which is to the power of 2, and ends with *b*, which is 60 in this case. Note that segment P_1 and P_2 can be formed by elements with lengths of power of two. For example, if segment $P_1$is of length 11, then it can be formed as a sum of segments of lengths 1, 2, and 8. Note here that the lengths of the segments from left to right are in increasing order. P_2 can be processed similarly, however the size of the component segments are decreasing. Distinguishing the order of increasing and descreasing of these components is important. For example, if P_2 is a segment of length 14, then the component sub-segments will have lengths of 8, 4, and 2. This is the order to retrieve the information. Note also that these component segments never carry the same length as other component segments in its combination. We can use a loop to mark the partioned segments if they are not zero and then add them up to get the resultant *EMA*. Note that during the loop computation, different power of β need to be applied to the retrieved value so the power of β shall be correctly applied to faithfully reflect the weights assigned to these segments. For the above example, a segment from 53 to 60 is considered. After computing the value of P_1, the resultant computing value from P_2 needs to be multiplied by β^3 before we add the resultant value from the computation of P_2. It is cubed because the segment 53 to 55 has length of 3. The multiplication by the power of β applies to the process of computing the values of P_1 and P_2 with the same reason. Details are omitted.

3 Conclusions

The experiments were conducted on a Intel i7 with Nvidia GeForce 550M. The parallelized moving average and neural network version was constructed using CUDA C. Due to the small size of records and the nature of the neural network, the speedup wasn't observed. The main reason is due to the requirement of synchronization of these threads. It is apparent that the expensive cost of synchronization makes the CPU implement more appealing. We expect that when the number of neurons and number of data increases, we shall get better results. We trust Nvidia will come up with a better solution to deal with the synchronization of threads.

For moving average computation, GPU computing does not provide advantages over CPU computing when there is a small amount of data. If the amount of data by simulation is increased, some improvement can be achieved. We understand that different machines with different models of CPU and GPU can create different results.

4 Conclusions

The parallel versions of moving average computation used in the financial industry and back propagation neural network computation were developed to run on Nvidia GPU using CUDA C. The GPU version of moving average does not give significant speedup over traditional CPU version using prefix sum operation. For neural network training process, GPU computation does not provide significant performance over traditional CPU implementation due to the requirement of thread synchronization. Even if we tried to minimize the number of synchronization by using device kernel calls, then speed up over the traditional CPU approach wouldn't be significant. Actually, in some situations when the number of records are small, the CPU implementation is superior. The implementation of real time predicting system over a huge data set in the financial industry is an interesting and challenging problem for future investigation.

Abstract *- This paper presents a comparison of parallelization frameworks for efficient execution of computational finance workloads. We use a Value-at-Risk (VaR) workload to evaluate OpenCL and OpenMP parallelization frameworks on multi-core CPUs as opposed to GPUs. In addition, we study the impact of SMT on performance using GCC (4.4) and IBM XLC (11.01) compilers for both single-precision and double-precision codes. We use an 8-core, 4-way SMT IBM Power7 with Linux (RHEL 6.0, 2.6.32 kernel) to evaluate OpenCL and OpenMP. Using the IBM XLC compiler, 2-way SMT is able to provide over 30% average improvement as compared to 1 SMT thread per core, whereas, 4-way SMT is able to provide over 50% average improvement as compared to 1 SMT thread per core.*

1 Introduction

The global financial crisis of 2008 has pointed to the lack of efficacy of financial models and systems to run those models efficiently. Smarter systems can help bridge that gap by providing programming frameworks that are easy to learn, use and deploy. Also these frameworks must support languages that are functionally portable and provide the maximum degree of performance portability. As systems are confronted with the diminishing returns of clock-speed improvements, they must turn to uncovering task and data parallelism in workloads to maintain performance growth. This is needed to efficiently use the increasing multitude of cores that are being provided on modern CPUs today. Unfortunately, parallel programming is hard and significant research in academia and industry is attempting to bridge the gap between programmability, portability and performance [12].

OpenMP [2] has emerged as the de-facto standard for programming SMP (Shared-Memory) machines using user-provided compiler directives. The standard has also been extended recently to support accelerators and thread affinity [2]. OpenCL [1] (Open Compute Language) is vying to become the de-facto standard for programming accelerators. Originally designed for targeting graphics chips and accelerators, it is also emerging as a programming framework for parallelizing workloads on multi-core CPUs. In this paper, we investigate how OpenCL may be used for programming multi-core CPUs as *opposed* to GPUs (Graphics Processing Units). We compare the productivity and performance of OpenCL with OpenMP for multi-core CPUs. We also investigate how SMT (Simultaneous Multithreading) i.e. sharing of a CPU's physical resources by use of multiple hardware contexts can improve performance. This paper investigates the use of SMT for computational finance workloads that tend to be compute bound. In this paper, we use the term SMT "degree" to indicate the number of SMT threads per core.

Computational finance workloads are diverse in their computational characteristics. They tend to be sensitive to square root, exponential, logarithmic and reciprocal functions. They are run in single precision (SP) or double precision (DP) modes. A common practice is to replicate sequential implementations of these workloads across a large CPU cluster. In this paper we investigate how parallelism may benefit computational finance workloads. We built a VaR (Value-at-Risk) workload based on [3] and interaction with users at various conferences [13, 14, 18]. The VaR workload is rich with elementary math and transcendental math functions. It also displays significant amount of task and data parallelism.

We begin by exploring the characteristics of computational finance system stacks for computational finance in Section 2. Section 3 describes the parallelization frameworks that we evaluate in this paper. Section 4 presents the system architectures on which the aforementioned parallelization frameworks will be run. Section 5 describes the workload and avenues for parallelization in this workload. Section 6 describes implementation issues and Section 7 provides performance results with detailed analysis. Section 8 details the impact of performance evaluation. Section 9 discusses related work. Section 10 concludes the paper with future work.

2 Computational Finance Systems

We participated in several conferences over the past few years and learnt that customers in the HPC finance community use Linux for their computational needs [13, 14, 18]. The use of x86 CPUs (which support 2-way SMT) is highly widespread in this community. We decided not to take this practice for granted and investigate higher degrees of SMT cardinality or "degree". Users usually run models on R,

Matlab [15] or Mathematica [16]. They then convert this to C/C++ when the logic and mathematics become stable. The conversion to C/C++ allows programmers to check for numerical stability and convergence. There is a tendency to run these single threaded C/C++ programs by brute-force replication across large number of cores. The C/C++ code tends to be sensitive to sqrt(), log(), inv() and exp() performance.

We decided to explore parallelization so that users could get speedups on their codes, execute models in a reduced amount of time and be able to trigger changes to their business process because of this newly attained efficiency. We decided to investigate OpenCL [1] and OpenMP [2]. OpenMP has been widespread in the HPC community where automatic thread parallelization is sought by using compiler directives. OpenCL has become popular in the HPC community as the medium for programming GPUs. In this paper, we investigate how OpenCL can be used for parallelizing codes across *CPUs* especially when they are enabled for SMT.

Based on our user investigations and findings, we came up with the following requirements for systems that are suited for computational finance –

1) Run Linux on HPC building blocks

2) Support throughput computing using large number of threads or cores

3) CPU should also be capable of high single threaded performance

4) CPU, compilers and runtimes are optimized for sqrt(), log(), inv() and exp() performance. Additionally, they must support elementary math functions (e.g. IBM MASS [4] and linear algebra libraries (e.g. ESSL [4] and ATLAS)) with high performance

5) Provide parallelization that is user-directed and performance portable across a given set of platforms by investigating OpenCL and OpenMP

6) Provide the capability to port codes across new generations of hardware

The workload-optimized stack structure for computational finance is shown in Figure 1.

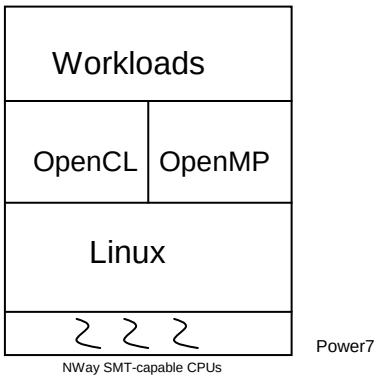

Figure 1. Initial Selection of Stack Components

3 Parallelization Frameworks

OpenCL (Open Compute Language) [1] is an open standard and is backed by a consortium of companies that has developed a framework for standardizing a high-performance computational language which is portable across a variety of platforms. Compute-intensive codes are packaged into a so-called OpenCL "kernel" that can be task- and data-parallelized. The OpenCL model is inspired from GPU programming (CUDA/OpenGL) and draws from the strengths of other parallel programming frameworks. The most fundamental action of an OpenCL kernel is to a "work item" and "work-items" are grouped into "workgroups". "Workgroups" are scheduled to hardware resources e.g. cores. The IBM OpenCL compiler is available on IBM developerWorks for POWER and x86 and this paper uses v0.3 [7]. The host CPU schedules kernels on the attached accelerator or CPU cores and must also ship data required by the kernels.

OpenMP [2] is a standard for parallel programming for shared memory machines and is backed by a consortium of companies. The user supplies OpenMP compiler directives to parallelize loops across resources. Operations like reduction are directly supported in the pragma. The standard is now being extended to support accelerators, thread affinity and embedded systems. IBM supports OpenMP pragmas in addition to its own pragmas for user-directed parallelization. We use OpenMP shipped with 2.6 Linux kernels for IBM Power7 for this paper. The OpenMP compiler generates pThread calls and pThreads are scheduled by the Operating System. We do not use any of the new OpenMP extensions for accelerators or thread affinity.

4 System Architecture

The system architecture used in this paper is a compute blade. This is essentially a multi-core system which is capable of large N-way SMT threads. We use the Power7 CPU [8] which has 8 cores and is capable of 4-way SMT for a total of 32 SMT threads. The CPU runs Linux (RHEL 6.0 with a 2.6.32 kernel). Both OpenCL and OpenMP may be parallelized across multiple CPUs. SMT threads are exposed

by the Operating System as additional "logical" CPUs. OpenCL kernels and OpenMP threads are scheduled across multiple SMT threads. We use GCC 4.4 and IBM XLC 11.01 for C/C++ code compilation. IBM XLCL v0.3 is used for OpenCL kernel compilation. We use the MASS [4] library (Mathematical Acceleration Subsystem) for optimized elementary and transcendental math functions with our C/C++ code. This is used as a high-performance alternative to the standard math library. In the next section, we describe the computational finance workload used to evaluate our system architecture.

5 Risk Analysis Workload

This section describes the risk analysis workload and its computational composition. We also highlight workload components where parallelism may be uncovered. The risk analysis workload uses the "value-at-risk" financial framework which will be described next. The workload has been built with user input and is based on the mathematics described in [3].

5.1 VaR – Value-at-Risk

Value-at-Risk is the potential loss in value of a risky asset over a defined period of time for a given confidence interval. VaR is widely used in commercial and investment banks to capture the potential loss in a traded portfolio from adverse market movements for a given period, e.g. If the VaR of an asset is $ 100 million at one-week, 95% confidence interval, it means that there is a 5% chance that the value of the asset will drop more than $100 million over any given period of one week. There are several popular computational methods used to calculate VaR – (i) historical simulation, (ii) variance-covariance, (iii) Monte-carlo and (iv) Delta-gamma. This paper uses the Monte-Carlo method and will be described next.

5.2 Monte-Carlo VaR

A Monte-Carlo method is used to approximate the probability of outcomes by performing so-called "random walks". "Random walks" simulate multiple trials of a random variable. In the case of VaR, portfolio returns over a given period of days is computed and then sorted. The largest loss corresponding to the VaR period is reported as shown in Figure 2. There are number of ways of computing portfolio returns over a given period but we use the Black-Scholes model to price financial instruments. In this model, the price of a financial instrument consists of log(), inv(), sqrt() and exp() functions in its closed-form representation.

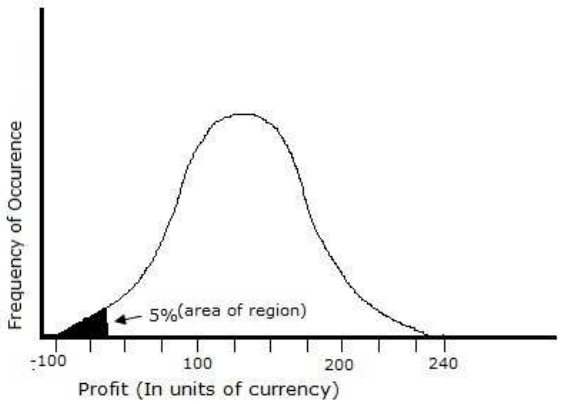

Figure 2. Value-At-Risk Distribution

5.3 Monte-Carlo VaR Parallelization

The Monte-Carlo VaR implementation pseudo code is below. As a first step, we provide the co-variance matrix which captures the portfolio details, the number of portfolios, number of Monte-Carlo simulations and the confidence interval. A number of parallelization strategies are possible. We could equally divide the portfolios across multiple cores and each of the portfolio groups could be computed concurrently. Alternatively, a single portfolio could be computed at a time and the simulations could be parallelized across multiple cores. We use the latter strategy. The values needed for random walks are computed using random number generation which can be computationally intensive. Each simulation prices a financial instrument using a closed form representation composed of log(), inv(), sqrt() and exp() functions. These returns (in currency units) are sorted and the partial distribution is sent to the root CPU for aggregation and merge-sorting. After all CPUs complete their computation, the root CPU forms a distribution similar to Figure 4. The VaR calculation picks the loss corresponding to the confidence interval from the sorted distribution, which is aggregated from all participating CPUs.

1. Supply covariance matrix, number of portfolios, number of simulations and confidence interval
2. For portfolio = 1…N
3. **do**
    1. Compute random numbers 1..M
    2. For simulations = 1 … M
    3. **do**

        Compute portfolio return by pricing financial instruments in the Black-Scholes Model

    End Loop

4. Sort and form partial distribution of returns vs frequency

5. Send partial distribution to root CPU

6. Root CPU Merge-Sorts partial distributions

7. Root CPU forms aggregate distribution

8. Root CPU extracts VaR value from aggregate distribution

End Loop

6 Implementation Issues

This section describes the implementation issues for OpenCL and OpenMP code. We used the Armadillo [17] library for implementing the VaR code, since it gave us function wrappers for BLAS and LAPACK libraries. In addition, it gave us matrix template classes. We used the cholesky decomposition and convolution operations as the principal linear algebra functions. Our elementary math functions included the erlang function, log(), inv(), sqrt(), rnd() and exp().

6.1 OpenCL

We encoded the entire Monte-Carlo simulation into an OpenCL kernel. We support both single precision and double precision calculations inside the kernel as a compile-time option. We did not pre-calculate random numbers but supply them to the kernel during execution. The IBM OpenCL runtime v0.3 reported upto 32 workgroups for the Power7 blade with 32 SMT threads across 8 cores with 4-way SMT. It also reported a global workgroup size of 1024. We inferred that a single workgroup is being scheduled to each SMT thread and used a local workgroup size of 32. The OpenCL program evaluates a single portfolio at a time and the simulations for a particular portfolio are mapped across the local workgroup size of 32 work-items in a given workgroup.

6.2 OpenMP

For the OpenMP implementation, we compute a single portfolio at a time and parallelize the simulations across multiple SMT threads of the 8-way Power7 system. A single OpenMP pragma was needed to parallelize the simulations.

7 Performance Evaluation

We now describe the performance evaluation of the risk analysis workload for OpenCL and OpenMP implementations. We measure speedup and execution time against the number of SMT threads available on the system. We have an 8-way Power7 blade which is capable of supporting 32 SMT threads. The Risk Analysis Workload (VaR) is evaluated with a portfolio size of 10,000 and with 112,640 simlulations. We measured each data-point three times and used the average in the plots below to eliminate any OS-jitter effects. We configured the Linux OS scheduler to schedule user-level threads on SMT hardware contexts in an even fashion so load is evenly balanced, e.g 11 threads across 8 cores means that 1 SMT thread is scheduled on each core, while 3 cores have an additional SMT thread running. Each user-level software thread is mapped to a single SMT thread.

7.1 Single Precision Floating Point (SP)

Figure 3 shows the execution-time performance of OpenMP (with standard math library, also called OpenMP-std-math), OpenCL and OpenMP-with-MASS implementations using the GCC compiler with –O3. MASS is the IBM Mathematical Acceleration Subsystem [4] library which is optimized for transcendental and elementary math operations. The OpenCL compiler (v0.3, XLCL) was used to compile the OpenCL kernel and then GCC was used to link and bind all object modules. The performance of the code with the standard math library performs worse than the OpenCL and OpenMP-with-MASS implementations.

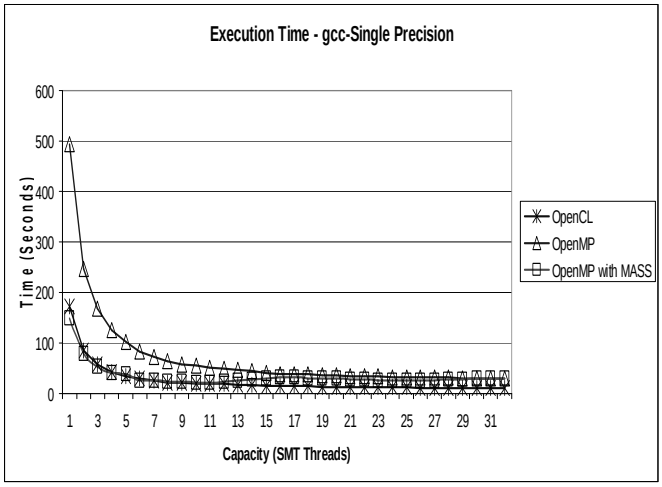

Figure 3. Execution Time vs SMT Threads (GCC, SP)

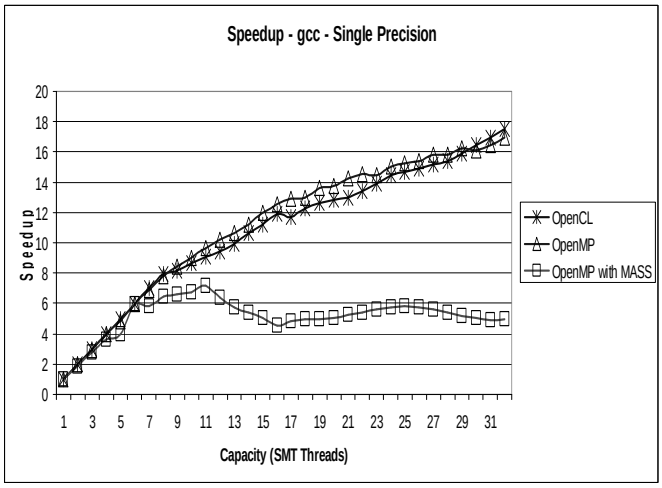

Figure 4. Speedup vs SMT Threads (GCC, SP)

The OpenMP-with-MASS implementation tracks the OpenCL compiler performance until 11 SMT threads and then starts diverging. The OS scheduler schedules 8 SMT threads across 8 cores and 3 threads across 3 cores, so 3 cores have 2 SMT

threads running. We ran the "perf stat" profiler and found that IPC decreases and cache misses of the GCC-generated code increases beyond 11 SMT threads. We attribute this to resource conflicts due to OpenMP thread data sharing using the highly-optimized MASS library. Enhanced MASS optimizations leads to reduced number of pipeline stalls and cache misses. Thus, they do not benefit from SMT. Note that OpenMP with the standard math library does not display this behavior as it does not provide efficient optimizations. OpenCL code compilation follows a two-step process and the IBM Power OpenCL compiler is able to do a better job of compacting thread and data state to avoid resource conflicts. 4-way SMT on Power7 for this workload is able to provide a 50% reduction in elapsed time at 32 SMT threads (four per core) over 8 SMT threads (1 per core) for the OpenCL and OpenMP-std-math codes.

The speedup curves in Figure 4 show OpenMP-with-std-math and OpenCL codes providing near-linear speedups but the OpenMP-with-MASS codes flattening after 11 SMT threads. This is easily attributed to enhanced optimization with MASS leading to higher floating point pipeline utilization that does not benefit by SMT. Additionally, the single thread performance of OpenMP-with-MASS is higher than OpenMP-with-std-math and slightly higher than OpenCL.

We used the IBM XLC compiler to compile our codes and found that the OpenMP-with-MASS implementation does much better than the corresponding GCC-generated code of Figure 3. In fact, the OpenMP-with-MASS implementation equals or betters the OpenCL implementation using the IBM XLC compiler. The execution times are shown in Figure 5 and the speedups are shown in Figure 6. The speedup curves of OpenCL are close to linear than OpenMP-with-MASS because the OpenMP implementation does better at execution time of 1 SMT thread but not at higher thread counts, as the enhanced optimization leads to optimal resource utilization of the floating-point pipeline and cache.

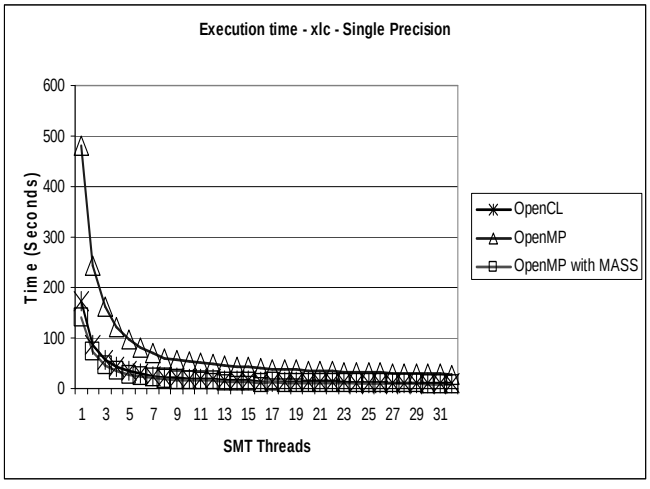

Figure 5. Execution Time vs SMT Threads (XLC, SP)

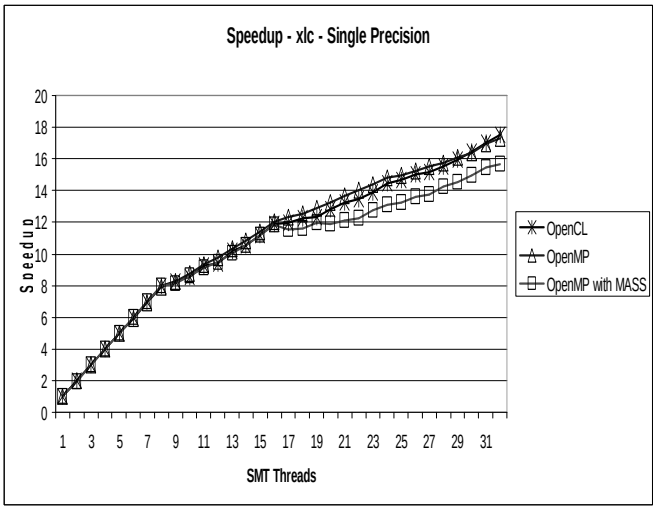

Figure 6. Speedup vs SMT Threads (XLC, SP)

7.2 Double Precision (DP)

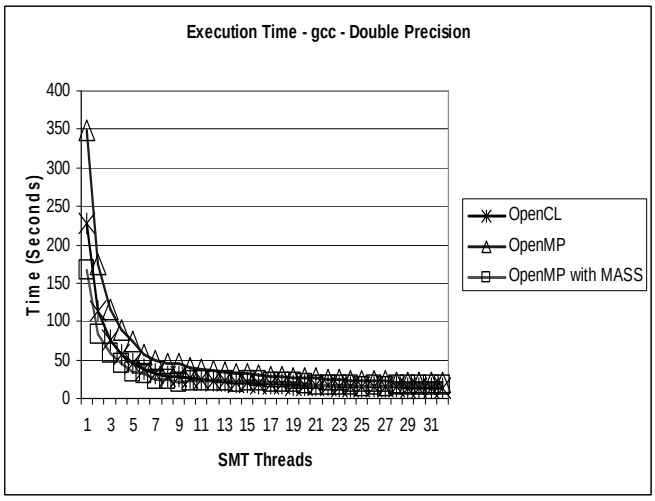

Figure 7. Execution Time vs SMT Threads (GCC, DP)

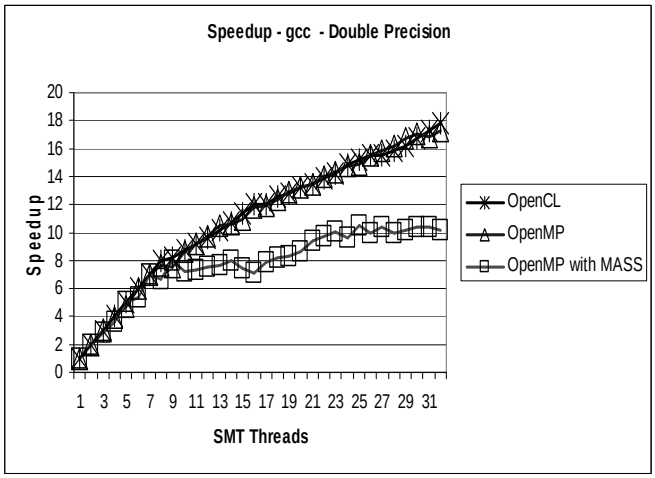

Figure 8. Speedup vs SMT Threads (GCC, DP)

Most codes in computational finance are run with double precision floating point and we discuss the results with GCC- and XLC-generated code. Figure 7 and Figure 8 show GCC-generated code performance for OpenCL, OpenMP-std-math and OpenMP-with-MASS. The OpenMP-with-MASS code shows similar behavior as seen for the single precision case where the execution time elongates slightly at 12 SMT threads due to resource conflicts. In Figure 8, OpenCL and OpenMP-with-std-math show close to linear performance but OpenMP-with-MASS flattens after 8-10 SMT threads. This is attributed to the higher performance of OpenMP-with-MASS at 1 SMT thread. Additionally, the use of MASS leads to efficient code that utilizes floating point and cache resources efficiently, leading to poor speedups when physical cores are shared with SMT.

Figures 9 and 10 show the performance of XLC-generated code. Both OpenMP-std-math and OpenMP-with-MASS performance exceeds the performance of the OpenCL code using the IBM XL compiler. This is attributed to better scheduling of code and resources in double precision mode by the XLC compiler leading to better utilization of the floating-point pipeline. If Figure 9 is compared with Figure 5, where Figure 5 is XLC-generated code in single precision mode, OpenMP-with-std-math in double precision does better than corresponding single precision code. In comparison, XLC-generated OpenCL code in double precision does worse than single precision code. We attribute the better performance of OpenMP-with-std-math code in double precision to better utilization of the floating point pipeline and instruction scheduling by the XLC compiler. In the case of OpenCL and OpenMP-with-MASS, both see reduced performance for DP code as the CPU can usually sustain more SP operation throughput than DP operation throughput. For DP code, OpenMP-with-MASS does much better than OpenCL as the XL compiler for C/C++ is able to do a better job of instruction scheduling and floating-point utilization than the XL compiler for OpenCL.

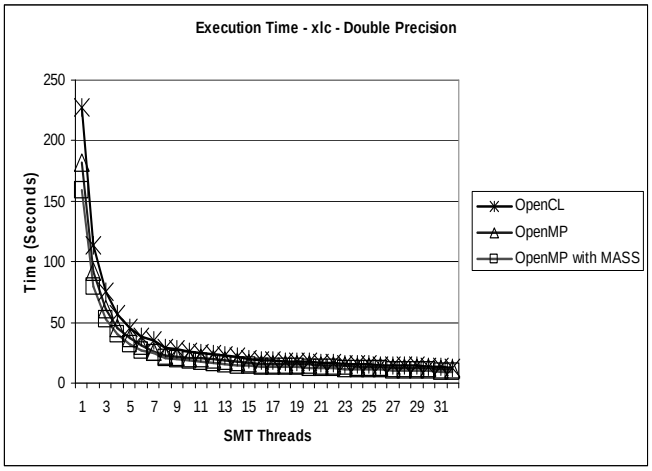

Figure 9. Execution Time vs SMT Threads (XLC, DP)

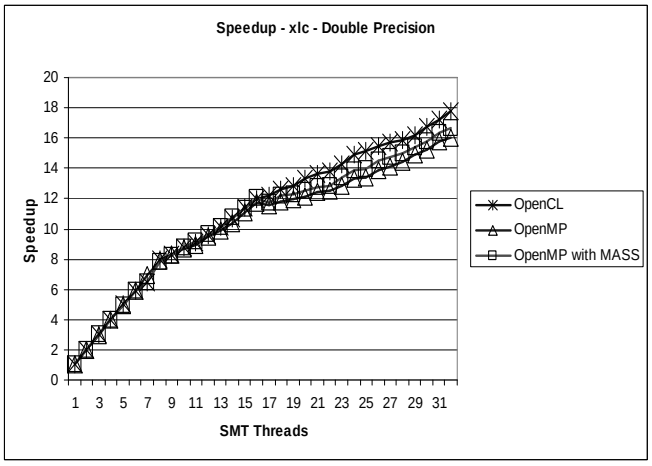

Figure 10. Speedup vs SMT Threads (XLC, DP)

The speedup curves of Figure 10 show OpenCL code showing close to linear performance while the OpenMP code flattening around the 16 SMT thread region. This region involves two SMT threads sharing a physical core. The sublinear performance in this region is easily attributed to resource and cache conflicts.

7.3 Impact of SMT

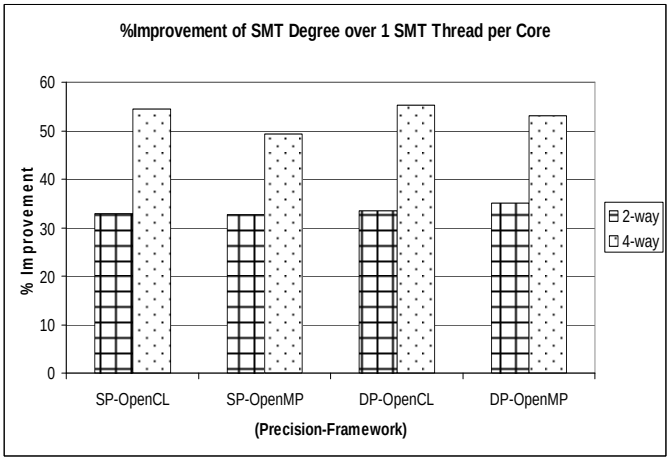

Figure 11. Impact of SMT Degree (XLC)

Figure 11 shows the impact of SMT degree for the VaR workload using the XLC compiler. 2-way SMT gives an average of 33.4% improvement across OpenCL and OpenMP while 4-way SMT gives an improvement of 53% across OpenCL and OpenMP. For the 2-way improvement calculation, 16 SMT threads on the 8-core system (2 threads/core) are compared to 8 SMT threads (1 thread/core). For the 4-way improvement calculation, 32 SMT threads on the 8-core system (4 threads per core) are compared to 8 SMT threads (1 thread/core). All comparisons are based on execution times of the VaR (Value-at-Risk) workload for different SMT thread counts using the XLC compiler.

8 Post-Evaluation Analysis

For the homogeneous multi-core architecture, the learning curve for OpenCL can be steep. For OpenMP, we simply had to use a single-line OpenMP pragma to parallelize the entire program, although, we could only match OpenCL performance using the right choice of IBM compiler toolchains and libraries. With OpenCL, we can run the OpenCL kernel unchanged from a CPU to an accelerator like a GPU. OpenCL allows portable interface with accelerators but OpenMP provides ease of use with high-level OpenMP directives. We were able to match OpenMP and OpenCL performance using the right set of compiler tool chains and libraries. The stack of Figure 1 should be updated to reflect the use of IBM XL C/C++ compilers and MASS libraries. For programming homogeneous multicores, OpenMP with XLC and MASS seems to emerge as a formidable framework. It provides better productivity and can match OpenCL performance.

OpenCL provides a portable way to program multicores and accelerators. For example, one may prototype programs on a multicore and then launch these on CPU-GPU clusters. OpenCL is a low-level mechanism to exact parallelism and performance. OpenMP relies on the compiler and so the right compiler tool chain and libraries is needed to match OpenCL performance. OpenACC [5] is a newly emerging standard that stipulates compiler directives for use with accelerators and provides best of both worlds – OpenMP and OpenCL. The results of this paper reveal that 4-way SMT provided by the POWER architecture can lead to additional benefits by reducing execution time. In other words, if application code optimizations and compiler action are sub-optimal, SMT degree can be used to get better processor pipeline utilization and enhanced execution time. SMT is beneficial for the VaR workload because SMT threads are able to share instructions and data.

9 Related Work

[9, 10] focus on random number generation and their implementation complexity on the IBM Cell BE accelerator for value-at-risk calculations. They do not focus on understanding scaling issues and implications of programming models and frameworks. Similarly, [11] focuses on market risk calculations on GPUs (Graphics Processing Units). They also do not focus on scaling or use of parallelization frameworks. This paper uses CPUs for market risk calculations and investigates the use of SMT to increase processor utilization, while analyzing scaling.

10 Conclusion and Future Work

We evaluate OpenCL and OpenMP for both single precision and double precision VaR codes. We find that although OpenCL has a steeper learning curve, it provides good performance without use of additional libraries. OpenMP is based on user-directed parallelism but requires the right compiler toolchain (XLC) and library combination (MASS) to match OpenCL performance. The use of OpenCL and OpenMP parallelization frameworks can lead to better utilization of POWER cores using SMT. We find that SMT degree does help execution. We are currently evaluating a library that will allow OpenCL kernels to be dispatched onto attached blades from a large SMP system. This will allow computation to be scheduled close to data than moving data to the computation. We are also addressing how OpenCL kernels can be accelerated by explicit use of data parallelism. OpenCL allows portability of kernels across CPUs and accelerators. The new OpenMP directives [2] are also attempting to make OpenMP easy to program accelerators. OpenACC [5] is also headed in the direction of using compiler directives to program accelerators. As the race to find "Utopia" for parallelization frameworks continues, the systems community must constantly evaluate workloads against new system architectures. This will help determine which workload classes benefit from new and emerging parallelization frameworks.

Computational Finance with Map-Reduce in Scala

Ron Coleman, Udaya Ghattamaneni, Mark Logan, and Alan Labouseur
Computer Science Department
Marist College
Poughkeepsie, NY, 12601

Abstract – This paper presets results of computational finance experiments using map-reduce in Scala. We observe superlinear speedup, super-efficiency, and evidence for a high degree of compute and I/O overlap in the median runtimes using "naïve," memory-bound, fine-grain, and course-grain parallel algorithms on three different hardware platforms.

Keywords - Computational finance, map-reduce, Scala, actors, parallel programming, bond pricing, securities pricing

1 Introduction

Computational finance is a multidisciplinary field at the crossroads of mathematical finance and computer science. [29] The emphasis is on development and utilization of numerically intensive methods for pricing, risk analysis, forecasting, automated trading, and other applications. Map-reduce [3] is a framework generally to speed-up data analysis using distributed computing. While map-reduce has been applied to different problem domains, many of a data-intensive nature, almost no attention has been given to opportunities for computational finance as a mixture of floating point and data-intensive operations.

Scala [23] is a modern, high-level Java Virtual Machine (JVM) language that blends object-oriented and functional programming styles with actors, a shared-nothing model of concurrent computation inspired by physics theories. [13] Proponents have argued that Scala language features are suited to solving large-scale computing tasks on inexpensive, commodity multicore and multiprocessor platforms [11] in an expressive manner that avoids the concurrency hazards and run-time inefficiencies of shared, mutable state programs. Indeed, the function-oriented style of Scala would seem to lend itself precisely to coding mathematical expressions which characterize quantitative operations.

We endeavored to put Scala's scalability claims to the test on a large quantitative problem, namely, finding the fair value of bond portfolios. We chose bonds because fixed income pricing theory is fairly transparent. [6, 14, 29] Furthermore, the price of a bond informs or is closely related to a number of different financial instruments, including annuities, bond derivatives, and interest rate swaps, the most heavily traded financial derivative in the world. [14] Thus, we posit that the practical performance implications of bond portfolio analysis extend to scientific and technical computing.

In this paper, we study several parallel algorithms in relation to two serial algorithms to price bond portfolios using map-reduce in Scala. For three different multicore platforms, the data generally show superlinear speedup and super-efficiency [9] in the median runtime that is in line with the maximum performance expectations published by the original equipment manufacturer (OEM) [15]. The data show that the parallel "naïve" algorithm, which assigns one portfolio per map function object, has median performance little different from, if not better than, memory-bound, fine-grain, and coarse-grain parallel algorithms. In other words, the Scala actor model, which underlies map-reduce, appears to exploit hardware threads (i.e., "hyper-threads") very efficiently. To our knowledge these findings have not be reported elsewhere.

The Scala source code we used in this study and detailed experimental results are available online [1,7].

2 Related work

The literature shows enduring interest in speeding up computational finance algorithms [2,22,26], most notably using specialized hardware and ad hoc low-level programming techniques [19,22], which do not, in our experience and opinion as programmers, promote software reusability or programmer productivity. The literature furthermore indicates map-reduce is a widely accepted approach to speeding up computation for various problem classes, although many of these efforts appear to be of a data-intensive nature. [3,8,16,27] Few, to our knowledge, have investigated computational finance applications. Zhang, et al [32] investigates map-reduce for option pricing using the backward stochastic differential equation (BSDE) method. However, the focus there is on the computational aspect of solving BSDE; we consider the end-to-end process, namely,

compute and I/O phases that characterize more practical settings. Woo and Xu [31] use map-reduce to perform market basket analysis with Amazon's EC2 service. This effort is geared toward data analysis, not computational finance; and cloud computing rather than parallel processing (i.e., speedup and efficiency) which is our primary focus. There is at least one cloud map-reduce framework for JVM languages [10], although this framework has have not been specifically designed for Scala. We instead use a pure-Scala map-reduce API from Haller and Sommers (H-S) [12]. Scala also has a library which is not actor-based in which it is also possible to employ map and reduce parallel functions directly on parallel-enabled collections (e.g., lists, arrays, etc.). [25] We do not investigate parallel collections here.

3 Methods

In this section we develop the methods of the paper. We discuss of bond pricing theory, portfolio valuation, the serial processing of portfolios in Scala, and the parallel processing of portfolios using map-reduce in Scala.

3.1 Bond pricing theory

A bond is a fixed income security. [6, 14, 29] For our purposes in this paper, we are considering only simple bonds, b_i, defined by the 5-tuple:

$$b_i = [i, C, n, T, M] \tag{1}$$

i is an integer type which plays no part in bond pricing except to uniquely identify the bond in an inventory which we describe below; C is the coupon payment amount; n is payment frequency per annum; T is the time to maturity in years; and M is the face value due at maturity. The sum of the net present value of these cash flows, C and M, is the price of the bond. Thus, the fair value, $P(b_{i,}r)$, of a bond, b_i, is functionally defined follows:

$$P(b_i, r) = \sum_{t=1}^{n \times T} \frac{C}{(1+r_t)^{t/n}} + \frac{M}{(1+r_T)^T} \tag{2}$$

The parameter, r, is the time-dependent yield or yield curve, the general discussion of which is beyond the scope of this paper. For simplicity sake without loss of generality, we use the United States Treasury on-the-run bond yield curve and interpolate between the tenors (i.e., bond maturity dates) using polynomial curve fitting.

It is worth noting that Equation 2 informs a number of different quantitative finance calculations which is one of the reasons we have chosen to model bonds. The first term of the right hand side of Equation 2 is an annuity embedded in the bond's price. The bond price also is used to calculate the conversion factor for bond futures and the fair value of bond forwards and bond options. Swap contracts, the most heavily traded financial derivative in the world [14], involve discounted cash flows similar to Equation 2. Indeed, the bond price itself may also be used in swap valuation. The point is that Equation 2 underlies and plays a part in a number of other quantitative finance problems and for this reason bond pricing is important as a kind benchmark computation.

A portfolio is a collection instruments, in our case, bonds. The fair value, $P(\phi_j)$, of a portfolio, ϕ_j, with a basket of Q bonds is functionally defined as follows:

$$P(\phi_j) = \sum_{q=1}^{Q} P(b_{\phi(j,q)}, r) \tag{3}$$

In other words, the portfolio's value is the sum over the value of all its constituent bonds.

3.2 Bond generation algorithm

We generate simple bonds that model a wide range of computational scenarios. The goals are to 1) produce a sufficient number of bonds to mimic realistic fixed income portfolios and 2) avoid biases in commercial-grade bonds that depend on prevailing market conditions. Specifically, we have the collections, $\vec{n}$={1, 4, 12, 52, 365), $\vec{T}$={1, 2, 3, 4, 5, 7, 10, 30}, and $\vec{\delta}$={0.005, 0.01, 0.02, 0.03, 0.04, 0.05}. We derive the parameters for a bond object from the bond generator equations below:

$$M=1000 \tag{4a}$$

$$n = \vec{n}[\bullet] \tag{4b}$$

$$T = \vec{T}[\bullet] \tag{4c}$$

$$C = \mathrm{M} / \mathrm{T} \times \delta[\bullet] \tag{4d}$$

where $\bullet$ is an integer uniform random deviate in the range of [0, s); and s is the size of the respective collection. We invoke Equations 4a - 4d a total of 5,000 times to produce the bond inventory, V, which we store in an indexed document-oriented database that we describe later.

We generate a portfolio by first selecting its size, that this, the number of bonds, Q, as per the equation below.

$$Q = v + \sigma \times \eta \tag{5}$$

η is a Gaussian deviate with mean of zero and one standard deviation. σ and v are configurable parameters set to 60 and 20, respectively. Finally, we construct a

basket of size, Q, bonds for a portfolio, ϕ_j , per the equation below.

$$i = \bullet \quad (6)$$

where $\bullet$ is an integer uniform random deviate in the range of $[1,|V|]$ and $|V|$ is the size of the bond inventory. The universe, U, of bond portfolios are also stored in a persistent repository.

3.3 IO design

We store the inputs, the bond and portfolio objects, b_i and ϕ_j in MongoDB, a document-oriented database. [20] We also store the outputs, the portfolio prices, in the database. A portfolio document, ϕ_j, does not contain the bond, b_i, directly but a reference to the bond, namely, the bond's primary key, i. In other words, the database is in third object normal form [17,19]. This means that to evaluate Equation 3 end-to-end, 2+Q accesses are required: one to fetch ϕ_j, Q to retrieve each b_i, and finally one to update the portfolio with the price.

3.4 Pricing algorithms

All the pricing algorithms, serial and parallel, work with the database in the same way. They retrieve from the database the same subset, $U' \subseteq U$, of random portfolios and then retrieve the bonds that have been randomly assigned to a portfolio. The algorithms evaluate Equation 2 and Equation 3, and then update the database with the result of Equation 3.

3.5 Serial algorithms

There are two serial algorithms. Both algorithms price portfolios serially using a triple-nested `foldLeft` function, the inner `foldLeft` for Equation 2, the middle `foldLeft` for Equationn 3, and the outer `foldLeft` passes over all portfolios in *U'*. One serial algorithm fetches a bond from the database only when the bond is needed by the pricing function literal. The other serial algorithm, the "memory-bound" algorithm, works the same way except it pre-fetches into memory all the bonds that are needed by the portfolios.

3.6 Parallel naïve algorithm

The naïve parallel algorithm is so-called because it "naively" assigns one portfolio to a mapping function whose inner `foldLeft` evaluates Equation 2 and whose outer `foldLeft` evaluates Equation 3. The H-S function, *mapreduceBasic* method, relates portfolios in *U'* to two functions: a mapping function and a reducing function. The prototype for our mapping function is below.

```
def mapping(portfId: Int,
                    r: List[Double]):
  List[(Int,Result)]
```

The parameter, *portfId*, is the portfolio id and the parameter, *r*, is the time-dependent yield curve. The return result is a list with one element, a two-tuple that has the portfolio id and the pricing result. The prototype for the reducing function is below

```
def reducing(portfId: Int,
                 vals: List[Result]):
  List[Result]
```

Note that this function is trivial: it just needs to return the only element in the parameter, *vals*, list.

3.7 Parallel memory-bound algorithm

The parallel memory-bound algorithm is nearly identical to the naïve algorithm. The difference is that the bonds are first pre-loaded into memory from the database, just like the serial memory-bound algorithm except the transfer of bonds to memory is done in parallel with actors and task-level parallelism. However, the parallel memory-bound algorithm uses task-level parallelism using actors to load the bonds in parallel. The parallel memory-bound reducing function which H-S *mapreduceBasic* requires is the same as the naïve reducing function. The parallel memory-bound mapping function prototype is below.

```
def mapping(portfId: Int,
              bonds: List[SimpleBond]):
  List[(Int, Result)]
```

3.8 Parallel coarse-grain algorithm

The parallel coarse-grain algorithm uses the same mapping and reducing functions as the naïve algorithm. The difference is the coarse-grain algorithm uses the H-S *coarseMapReduce* method which takes two extra parameters: the maximum number of mappers and the maximum number of reducers. We set the number of mappers and the number of reducers both to the number of processors which we get from the Java class, *Runtime*. The *getRuntime().availableProcessors()* method of this class returns the number of hyper-threads, not the number of cores or execution units. [4] As far as we know, it is not possible to get the number of actual hardware execution units except from the OEM data sheets.

3.9 Parallel fine-grain algorithm

The parallel fine-grain algorithm is similar to the naïve algorithm. The difference in this case is its map function uses a single (non-nested) `foldLeft` to evaluate

Equation 2. The reduce function evaluates Equation 3. Thus, the prototype for the map function we pass to the H-S *mapreduceBasic* method is below.

```
def mapping(portfId: Int,
            bondId: Int):
  List[(Int,Result)]
```

The *bondId* parameter is the bond id which the mapping function uses to retrieve the bond object. However, since bond id cannot be known in advance, it corresponding portfolio was pre-loaded prior to invoking the mapping function. This pre-load time is taken into account in the runtime measurement. The portfId parameter is only used to link the bond price result with its portfolio which allows the reducer to reduce the bond prices properly.

The reducing function sums all the bond prices by their portfolio id. The reducing function prototype is the same as the naïve algorithm.

4 Experimental design

In this section we describe the experimental design, including the hardware environment, trials, and speedup calculations.

4.1 Environment

The environment consisted of three hardware platforms of different Intel multicore processors. The table below gives the system configurations and year of introduction in each case.

Table 1. Platforms

CPU	Clock	Cores	Threads	RAM	Year
W3540	2.93	4	8	4 GB	2009
i5-650	3.20	2	4	4 GB	2010
T3300	2.50	2	2	3 GB	2008

The clock is in giga-hertz and the year is the year the processor was introduced by Intel. The W3540 and i5 systems run Microsoft Windows 7 Professional, Service Pack 1. The T3800 runs Microsoft Windows XP, Service Pack 3. The code is compiled by Eclipse 3.7 [5] using the Scala IDE plugin [28] version 2.0.0 with the 64-bit JVM on the W3540 and i5 and the 32-bit JVM on the T8300.

4.2 Trials

To obtain statistically conservative results [8], we use the median result of 11 to 22 trials in which we observe the runtime performance for an ensemble of workloads of *U'* portfolios randomly selected portfolios from a total of *U*=100,000 portfolios. Any given workload in the ensemble contains $u=2^x$ portfolios where $x=\{0,1,2,3\ldots10\}$ for each trial. Since the mean number of bonds in each portfolio is 60 with a standard deviation of 20. The largest workload analyzes *u*=1024 portfolios with an average of about 60,000 bonds total.

We measured the serial algorithm time, T_1, for processing an ensemble using each of the platforms listed in Table 1 above. We also measured the map-reduce parallel algorithm time, T_N, for naive, coarse-grain, and fine-grain map-reduce algorithms. In the case of the memory-bound algorithms, we have given the compute and the I/O runtimes separately. The memory-bound compute measurement is the median runtime to value the portfolios. The memory-bound I/O measurement is the median runtime to load the bonds into memory.

To get a better understanding of how IO might be impacting the process, we furthermore separated out compute and IO phases by first loading all the bonds into memory before processing them in both serial and map-reduce cases.

4.3 Speed-up calculations

Given T_1 and T_N , we have the speed-up, *R*.

$$R = T_1 / T_N \tag{7}$$

N is going to be the number of cores or execution units, not the number of hyper-threads.

With *R* we have, *e*, the efficiency.

$$e = R / N \tag{8}$$

5 Results

We run trials from *u*=1..1,024 bond portfolios.

5.1 Parallel naïve results

The results for the naïve (∗), memory-bound compute (+), and memory-bound I/O-only (△) measurements for the W3540 are summarized in the graph below.

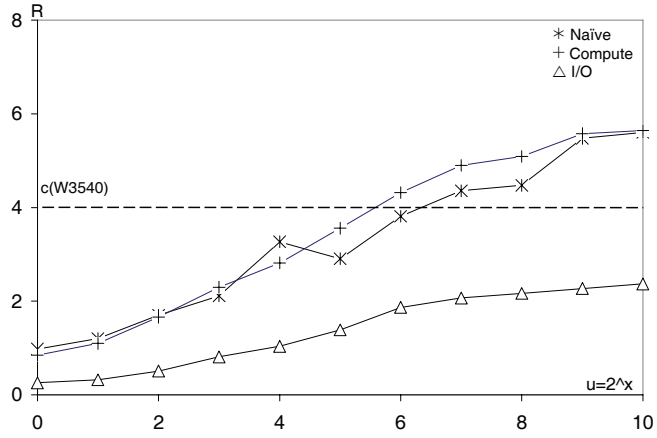

Figure 1. W3540 results

Note that speedup, R, above the dashed line is superlinear and super-efficient performance. The corresponding numerical data for the W3540 for

u=1,024 bond portfolios for the naive algorithm is in the table below.

Table 1. W3540 with u=1,024 bond portfolios

	T_N	R	e
Naive	8.58	5.64	141%
Memory-bound compute	7.13	5.60	140%
Memory-bound I/O	2.50	2.37	59%

The naive algorithm results for the i5 are summarized in the graph below.

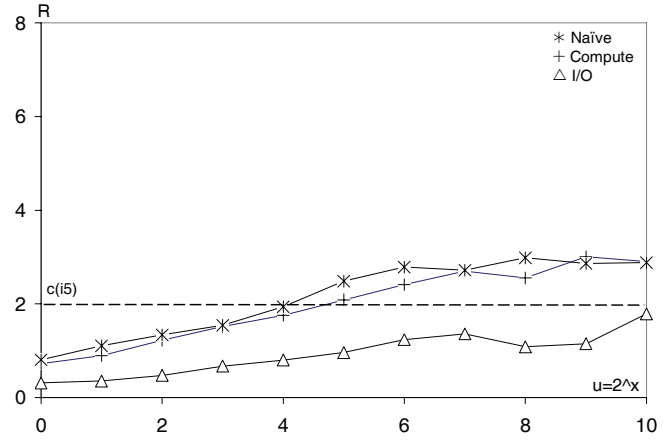

Figure 2. i5 results

The corresponding numerical data for the i5 for u=1,024 bond portfolios for the naive algorithm is in the table below.

Table 2. i5 with u=1,024 bond portfolios

	T_N	R	e
Naive	16.87	2.90	145%
Memory-bound compute	13.42	2.88	144%
Memory-bound I/O	3.54	1.79	89%

The naive algorithm results for the T8300 are summarized in the graph below.

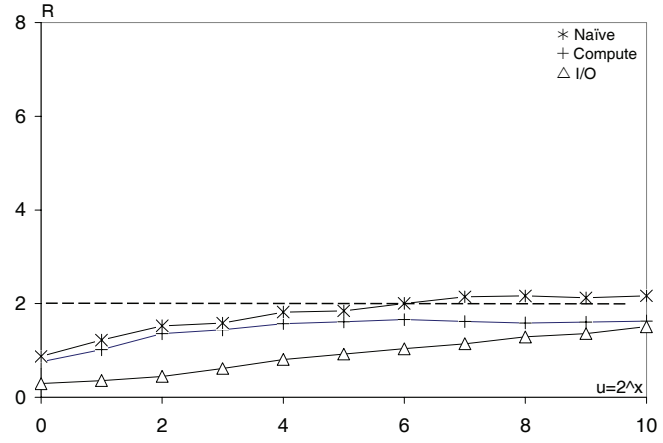

Figure 3. T8300 results

The corresponding numerical data for the T8300 for u=1,024 bond portfolios for the naïve algorithm is in the table below.

Table 3. T8300 with u=1,024 bond portfolios

	T_N	R	e
Naive	73.77	1.63	81%
Memory-bound compute	67.34	2.16	108%
Memory-bound I/O	8.07	1.51	75%

5.2 Parallel fine-grain results

The composite fine-grain results for the W3540 (×), i5-650 (□) , and 8300 (◇) are summarized in the graph below.

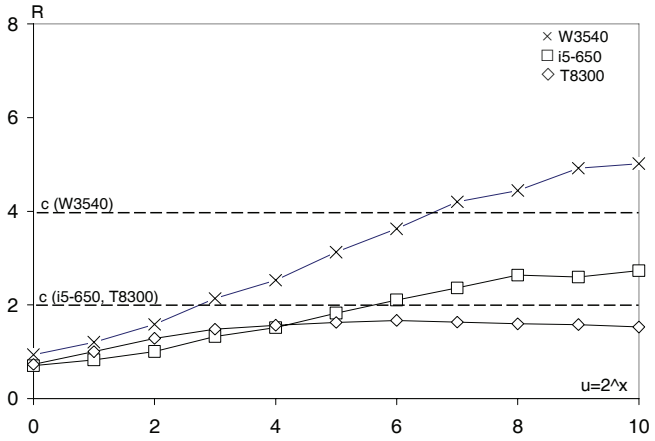

Figure 4. Fine-grain results

The corresponding numerical data for the W3540, i5-650, and T8300 for 1,024 bond portfolios for the naive algorithm is in the table below.

Table 4. Fine-grain with u=1,024 bond portfolios

	T_N	R	e
W3540	9.65	5.02	125%
i5-650	17.93	2.73	137%
T8300	78.52	1.53	76%

5.3 Parallel coarse-grain results

The coarse-grain results for the W3540, i5, and T9300 are summarized in the graph below.

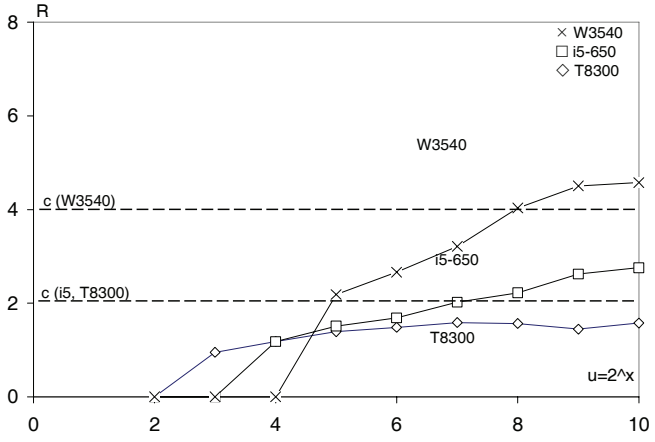

Figure 5. Coarse-grain results

The corresponding numerical data for the W3540, i5-650, and T9300 for 1,024 bond portfolios for the naive algorithm is in the table below.

Table 5.

	T_N	R	e
W3540	9.16	5.29	132%
i5-650	19.55	2.50	125%
T8300	79.20	1.51	76%

6 Discussion

The naïve algorithm appears to be the best performing overall end-to-end, achieving super-linearity and super-efficiency for levels of u, depending on the processor type. For instance, the more modern processors, the W3540 and i5, realize super-linearity and super-efficiency for u as small as 64.

Most interestingly, I/O is broadly sub-linear which, by itself, is not surprising. However, I/O does not appear to be a processing bottleneck since the difference between compute and memory-bound compute plus memory-bound I/O over the range of u appears to be insignificant.

7 Conclusion

This investigation of map-reduce for computational finance lead us to consider other avenues for future work. First, we would like to explore changes to H-S to support multiprocessor parallelism. Second, there are open questions on how to "shard" or parallelize the data. Finally, we had briefly mentioned Scala's parallel collections. A very worthwhile study might examine parallel collections and compare the coding style and performance to H-S map-reduce.

Multicore Clusters for CFD Simulations Comparative Study of Three CFD-Softwares

A. de Blanche, N. Namaki, S. Mankefors-Christiernin
Division of Automation and Computer Engineering
University West, Trollhättan, Sweden

Abstract

Multicore processors have come to stay, fulfill Moore's law and might very well revolutionize the computer industry. However, we are now in a transitional period before the new programming models, numerical algorithms and general computer architecture have been developed and the software has been rewritten. This paper focuses on the effects multicore based systems have on industrial computational fluid dynamics (CFD) simulations. The most significant finding was that five of the models ran faster when only one process was executed on each multicore node instead of two. In these cases the execution time was increased by between 6.5% and 64% with a median increase of 10% when utilizing both cores.

Keywords: multicore, cluster, non-uniform inter-process communication

1 Introduction

Getting the most out of any computer system, and especially a new architecture, has always been a challenging task. When new hardware technologies are introduced and put to use it is not obvious that the application performance will increase – even if the technology is immensely superior. The existing applications have been optimized to run on the current systems and they might not at all be suitable for the next-generation high-performance computers. The latest major addition is the introduction of multicore systems.

As suggested by James Peery et. al. [1], at Sandia national laboratory, the execution time might increase if more cores are utilized. Using Sandia key algorithms they showed that when using sixteen cores the performance was barely on par with two cores. According to Arun Rodrigues this is an issue to which the industry has no known solution and that often is ignored [1]. The addition of a second core could theoretically double the computing capacity of a computer node [2], however in many cases the bottleneck moved to another component. As pointed out by [3] [4] [5] the most notable is the processor versus memory size and bus ratio, both when it comes to latency as well as bandwidth.

Traditionally high performance computer designs have tried to balance three factors [6]: Compute power, memory and I/O-capacity. According to Vaughan et. al. [7] the new generation of COTS distributed parallel computers (clusters) [8] [9] has added inter-node communication capacity as a crucial factor. For Multicore processors Vaughan's addition should be split into two, namely intra-node and inter-node communication capacity due to the non-uniform inter-process communication architecture.

In this paper we present a, first study on the effects multicore based systems have on industrial computational fluid dynamics (CFD) simulations. Do multicore processors facilitate a decrease in execution time within the CFD area or will the already long execution times increase? During our investigation we found that for five of our nine models there were configurations in which the execution times increased by 6.5% to 63% when utilizing two cores in each processor instead of one. Six configurations paged to the hard drive due to lack of memory and were excluded.

2 Multicore Architecture and Issues

Typical modern computer architecture is based on a microprocessor, system memory, busses and various other components. Very much like the schematic overview in figure 1. All information that goes from the main memory to the processor has to pass through the system bus (Front Side Bus/FSB), the memory controller and the memory bus.

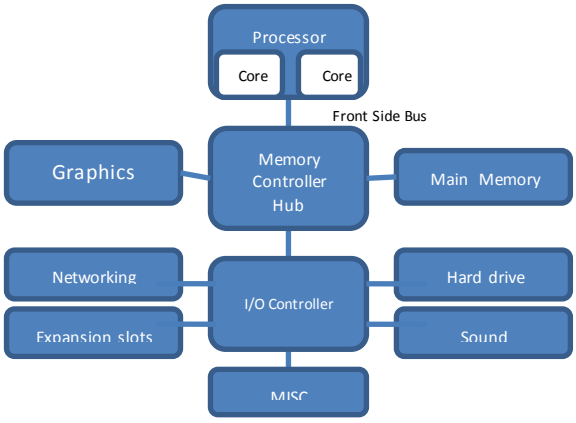

Figure 1: Architectural overview of a modern computer

In this section we go through the four most important systems in a computer; processor, memory, I/O-capacity and inter-process capacity. The three first are proposed by [6] with the addition of *inter-node communication* suggested by [7], although we find inter-process capacity to be a better description. Over the last 30 years the execution speed of a microprocessor has increased from 5 MHz to approximately 4 GHz. During this time many new techniques that improves the processors were introduced, such as pipelining and speculative execution as well as advanced instruction level parallelism. The old recipe of creating a faster processor by raising the clock frequency relied on the possibility to

manufacture smaller components inside the processors. Advances in this field are no longer possible due to the laws of physics.

The solution to higher speeds taken by almost all manufacturers is multiple processor cores on the same chip.

2.1.Memory Challenge

So far the memory architecture shown in figure 1 has not changed notably between the single and multicore processors. One of the major challenges of the multicore systems will be to design a system that can keep up with the tremendous computing power in a single multicore chip. This puts enormous pressure on, among other things, the FSB and the memory subsystem. At the moment the memory subsystem, on its own, is not fast enough to keep up with a single core processor; as a result it utilizes a two to four level memory hierarchy of increasingly faster memories closer to the processor. When extra cores are added some memory problems might be fixed by adding additional memory levels [3].

By comparing the historical capacity of processors using the SPEC-benchmark [10] with the FSB and memory bus [10] [11] we find that the difference has increased quite drastically over the years. Consider an application that was written for a system in 1993 and perfectly optimized for that "balance", would on a modern computer wait for memory approximately 50% of the time. It is a crude comparison and it is based on using one core in the modern multi core chip.

The problem of sustaining a high memory throughput to several processors is not a new problem for multiprocessor systems [12]. However, there is a difference between using multiple processors and multiple cores.

2.2.Inter Process Communication Challenge

All but the simplest parallel and distributed applications implement some level of inter-process communication. One problem that arises with the introduction of multicore clusters is that they have a non-uniform inter-process communication architecture. There are at least two different levels of communication costs involved when passing messages in a multicore cluster, either over the loopback interface or over the network.

Consider an application with four processes that implements message passing. If designed in 2003 it would be written to work well on Pentium 4 processors and gigabit Ethernet.

When executing a 16 process job on 4 computers each equipped with 2 dual core processors. The inter-process communication will be even more non-uniform with the additional two different levels of intra-node communications. Especially when compared to the 16 single core computers that the application was designed to be executed over. In that case the link capacity would still be $1/16^{th}$ of gigabit Ethernet, since it scales linearly.

2.3. I/O Utilization

The fourth important subsystem in regards to system balance is the I/O-subsystem. However the CFD applications that we focus in this investigation are very light on the I/O side. They only read the input files in the beginning of the execution and write the output at the end. Therefore we do not have any focus on the I/O utilization.

3 Computing Platform and Benchmark Applications

The aim of this experiment is to investigate the effect multicore processors have on applications in the Computational Fluid Dynamics (CFD) domain. Or more precisely, to determine if the efficiency of a simulation increases when two simulation processes are executed on each dual core node compared to one process per node.

3.1. High Performance Computing Platform

The Intel Core 2 is a common processor in many high performance environments. The cluster used in this investigation consists of 180 identical computers based on the Core 2 E6550 processor. The E6550 is manufactured using 65nm technology and has 291 million transistors.

The Intel Core 2 processor has two processor cores, each core has 2*32KB of private L1 cache (data and instructions), at the next level the cores share a 4MB L2 cache. Having a shared L2 cache has its benefits as well as drawbacks. While it allow cache sharing between cores and allowing the entire cache to be used by one of the cores as well as decreasing the cache impact of moving processes between cores it make the cores compete for the cache resources the hit latency is longer than for separate caches [12].

The memory controller and front side bus (FSB) of the Core 2 system are located off-chip, i.e. the architecture mimics that in figure 1. The transfer rate of the FSB has a maximum capacity of 10.6 gigabyte/s while the memory sustains 5.33 gigabyte/s per channel. The upper limit for fetching data from memory is limited to 10.6 gigabyte/s. However, for this to be achieved there has to be no other transfers affecting the busses. If the data is saved on the circuits in the same memory bank, the maximum theoretical transfer speed is 5.33 gigabyte/s.

The STREAM benchmark [13] [14] was used to measure the sustainable bandwidth of the memory system for reference purposes. During several executions with different sized matrixes of a size between 48 and 1800 megabyte, the sustained bandwidth never exceeded 4080 megabyte/s. When the matrix size was increased to span both memory channels the total sustained bandwidth was even decreased to 3900 megabyte/s.

The cluster is connected by a hierarchy of gigabit switches. During the experiments the computers were connected by a single gigabit Ethernet switch. A more detailed description of the hardware can be found in table 1.

Table 1: Cluster computer and network equipment specifications.

Processor	Intel Core 2, E6550
Clock Frequency	2.33GHz
# of cores	2
Hyper threading	No
Technology	65nm
Transistors	291 Millions
L1 Cache	32 KB code and 32KB data
L2 Cache	4MB cache shared between cores, non-

	inclusive with L1 cache
Front side bus	Q35
Frequency	1333MT/s
Bandwidth	10.6 gigabyte/s
Memory	DDR2
Size	2GB
Specification	PC2-5300
# of channels	2, dual channel
Frequency	667Mhz
Bandwidth	2 * 5.33 gigabyte/s
Measured Bandwidth	4.08 gigabyte/s (STREAM [13])

3.2.Applications and Models Used

Three applications were used in this investigation. Two commercial CFD applications; CFX [15] and Fluent [16] and the open source package Openfoam [17]. Nine CFD models, three per application, were used in the experiments. Since the behavior of these applications are dependent of the type of flow simulated so are the solution times. Three representative "real world" models were selected from two multinational high-tech companies for each of the two commercial applications. The CFX models ith Openfoam one real world and two research models from scientists were used together with Openfoam. Table 2 gives an overview of the models which have bearing on the aerospace domain.

Table 2: Sizes and names of the nine models used in the evaluation. The Number of elements gives a first order approximation of the size of the model.

Name	CFX	Fluent	Openfoam
M1	817 460	817 460	702 000
M2	1 811 036	743 223	1 980 900
M3	2 935 295	5 529 223	5 379 520

The sizes of the models as well as the run-time differ between models. As an example the Fluent M1 require approximately 4 hours to execute all the way through over eight nodes while Fluent model 2 require somewhere around 12 hours to complete and the M3 models need several days.

Those knowledgeable in the area of computational fluid dynamics know that there are two basic ways to determine when a simulation should end, either by specifying the number of calculations (iterations) to run or by specifying some convergence criteria (transient) [18].

When dealing with real world industrial applications and models one problem is that they are not well defined small units that execute in a minute. Real world CFD calculations are huge problems that often require tens of gigabytes of memory and take weeks to execute on a single computer. If all models in this investigation were to be executed all the way though it would require several years of runtime. In [19], Yang, et. al. however showed that a partly executed simulation fairly well matches a full execution of the code. Their empirical performance prediction results are constrained to cases where the problem and input sizes do not vary.

To be able to perform this investigation we decided to limit the execution time of the experiments. It was decided that we would use the iteration method (mentioned above) to limit the execution time. Each model was executed, in parallel, over eight computer nodes, with one process per node. After 1000 seconds of execution, the executing iteration was extracted from the application log file. This iteration was then used as the stop criteria for all experiments with that particular model, ensuring the exact same number of iterations and execution behavior in all comparable runs for that model-application combination. In this way only the changes in the number of processes and hardware could be responsible for the changes in run-time.

4 Experiment Setup

To determine the usefulness of multicore processors within the engineering simulation domain, the nine (9) fluid simulations in table 2 and their corresponding applications were executed in two different setups, Single and Dual.

Although utilizing the same hardware the difference between the two setups was that in the single setup each process is executed on one dual core node, as if it were a single core system, although the second core will execute various other system tasks. The dual setup on the other hand refers to when two processes are placed on each dual core computer node.

This means that when executing a eight processes job the Single setup will use eight dual core nodes and place one process on each node, effectively only utilizing one of the cores for simulation purposes. The dual setup, however, would employ four computers and utilize both cores in all machines: using a total of eight cores.

The models (table 2) were pre-partitioned into [2 4 6 8 16 32] partitions to be run in parallel by the same number of processes. This partitioning was done using the applications' default mechanisms.

For the simulations where the amount of memory needed for the execution was greater than the available system memory (figure 3 and table 6), thus forcing the systems to page to disk, was removed from the study. The reason behind this was that their execution times increase by several orders of magnitude. This threshold was reached earlier with the Dual setup since the node memory is shared between two processes. When adding more computer nodes and processes the amount of global memory effectively increases which in turn allow the applications to run entirely in memory.

During the execution of the applications the run time was measured and the processor, memory and network loads were monitored. To calculate the runtime a timestamp were made before and after the execution of the pre-partitioned simulations. The timestamps were taken with the gettimeofday() system call which has a relatively high resolution (ms). Although compared with a runtime between 253 and 6388 seconds the error is negligible.

The processor, memory and network loads were calculated as averages over 180 second intervals. These measurements were all made through the /proc kernel interface. One measurement set consumed ~8 ms of processor time, according to measurements done by strace [20].

5 Results

In order to investigate the effect multicore processors have on our three applications and the nine models that were executed in a

Single and Dual core setups, see section 4. Figure 3 a-i) contain graphs depicting the results from the experiments. The black lines show the execution time of the Single setup, i.e. where one process is placed on each node, and the dashed line represents the Dual setup where two processes are placed on each dual core node.

At a first glance the results look as one would expect them too, the Single setup for the same number of processes out performs the Dual setup, see figure 4. This was expected since the Single setup use two times the number of computers and effectively has twice the amount of memory, twice the level 2 cache (not applicable to all multicore processors) and an extra core to use for running operating system and other tasks, etc.

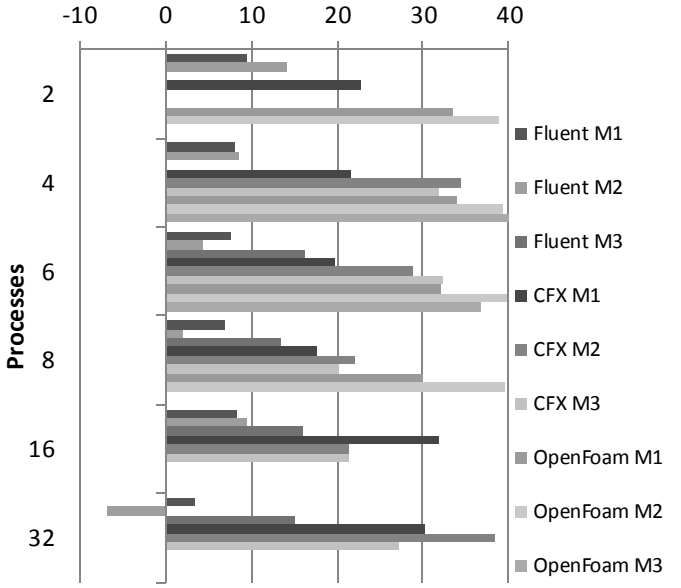

Figure 4: The number of percent by which the Single setup outperforms the Dual setup for the same number of processes.

This was the case for all models, apart from Fluent model 2, when divided into 32 processes as can be seen in figure 3 b). The dual setup outperformed the single with 22 seconds out of 341, so by ~6.5%. Fluent model 1 is not much larger and shows the same behavior, although the single setup still outperforms the dual with 3.5%, at 32 processes.

In table 4 the speedups (scalability) of the different applications and models are listed. To compare both single and dual setups with each other the speedup of the dual setup uses the same baseline as the single. Thus all values for each model are normalized after the single setup with the least amount of processes.

The speedup obtained when adding processes to the computation does not follow the theoretically best possible of $\mathbf{T_s/P}$ (time to execute simulation/number of processes) but for software in the CFD area scalability in this range is considered comparatively well [18] [21].

In table 3 we can see that when going from two Single to two Dual processes, i.e. from two cores on different computers to two on the same, Openfoam does not perform as good as the other two applications. Openfoam M2 models also shows a strange plateau, at 4 to 6 nodes as well as 8 to 16, where there is little to none scalability. Although for eight nodes it shows a decent scalability. Fluent M3 shows a similar, but not at all as bad, pattern between eight and sixteen nodes.

Quoting the execution times and speedups based on the amount of processes the problem is divided into is a straightforward approach. However, when dealing with computer clusters and multicore processors the speedups and execution times depending on the amount of computers is of interest.

Table 3: The execution time (T) of the different setups normalized to the equivalent lowest number single setup execution, T_N. The norm was given the value 100.

Model	Setup	Processes					
		2	4	6	8	16	32
Fluent M1	Single	100	53	39	32	17	13
	Dual	110	58	42	34	19	13
Fluent M2	Single	100	57	48	34	22	18
	Dual	116	62	50	35	24	17
Fluent M3	Single	-	100	72	63	57	24
	Dual	-	-	86	73	68	28
CFX M1	Single	100	54	39	34	22	17
	Dual	130	69	49	41	32	24
CFX M2	Single	100	56	40	34	21	15
	Dual	-	85	57	44	27	24
CFX M3	Single	100	55	41	35	23	18
	Dual	-	80	60	44	29	24
OFoam M1	Single	100	47	31	24	-	-
	Dual	150	72	46	34	18	-
OFoam M2	Single	100	52	53	26	-	-
	Dual	163	85	88	44	43	-
OFoam M3	Single	-	100	93	59	-	-
	Dual	-	269	147	59	41	-

5.1.Dual core Processor Efficiency

Turning to the less obvious result, for some models/setups the problem is actually solved faster when only one process instead of two is executed on each dual core computer node. This occurred at the higher number of computers and the speedup was between 6.5% and 64%, see table 4 for details. For the lower number of computer nodes the Dual setup always outperform the Single – given that there is enough resources to execute at all. E.g. the Fluent M2 model required more than 4 gigabyte of ram and would there for not execute on 2 machines or less. Then as more nodes are added the time gap between the Single and Dual setups close and for 5 of the 9 models the curves actually switch place, leaving the Single setup to outperform the Dual for the higher number of nodes.

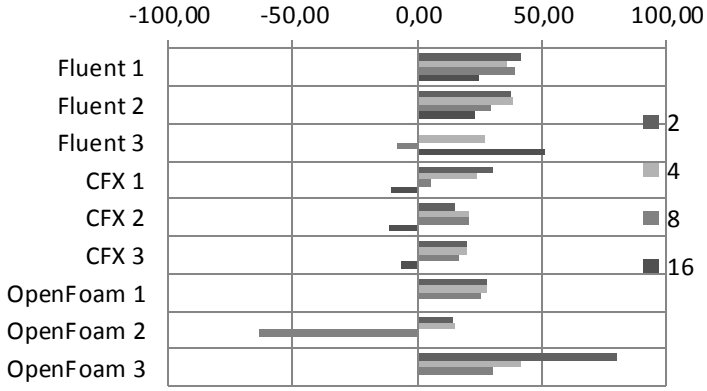

Figure 5: The number of percent by which the dual setup outperformed the single setup for the same number of computers [2,4,8,16].

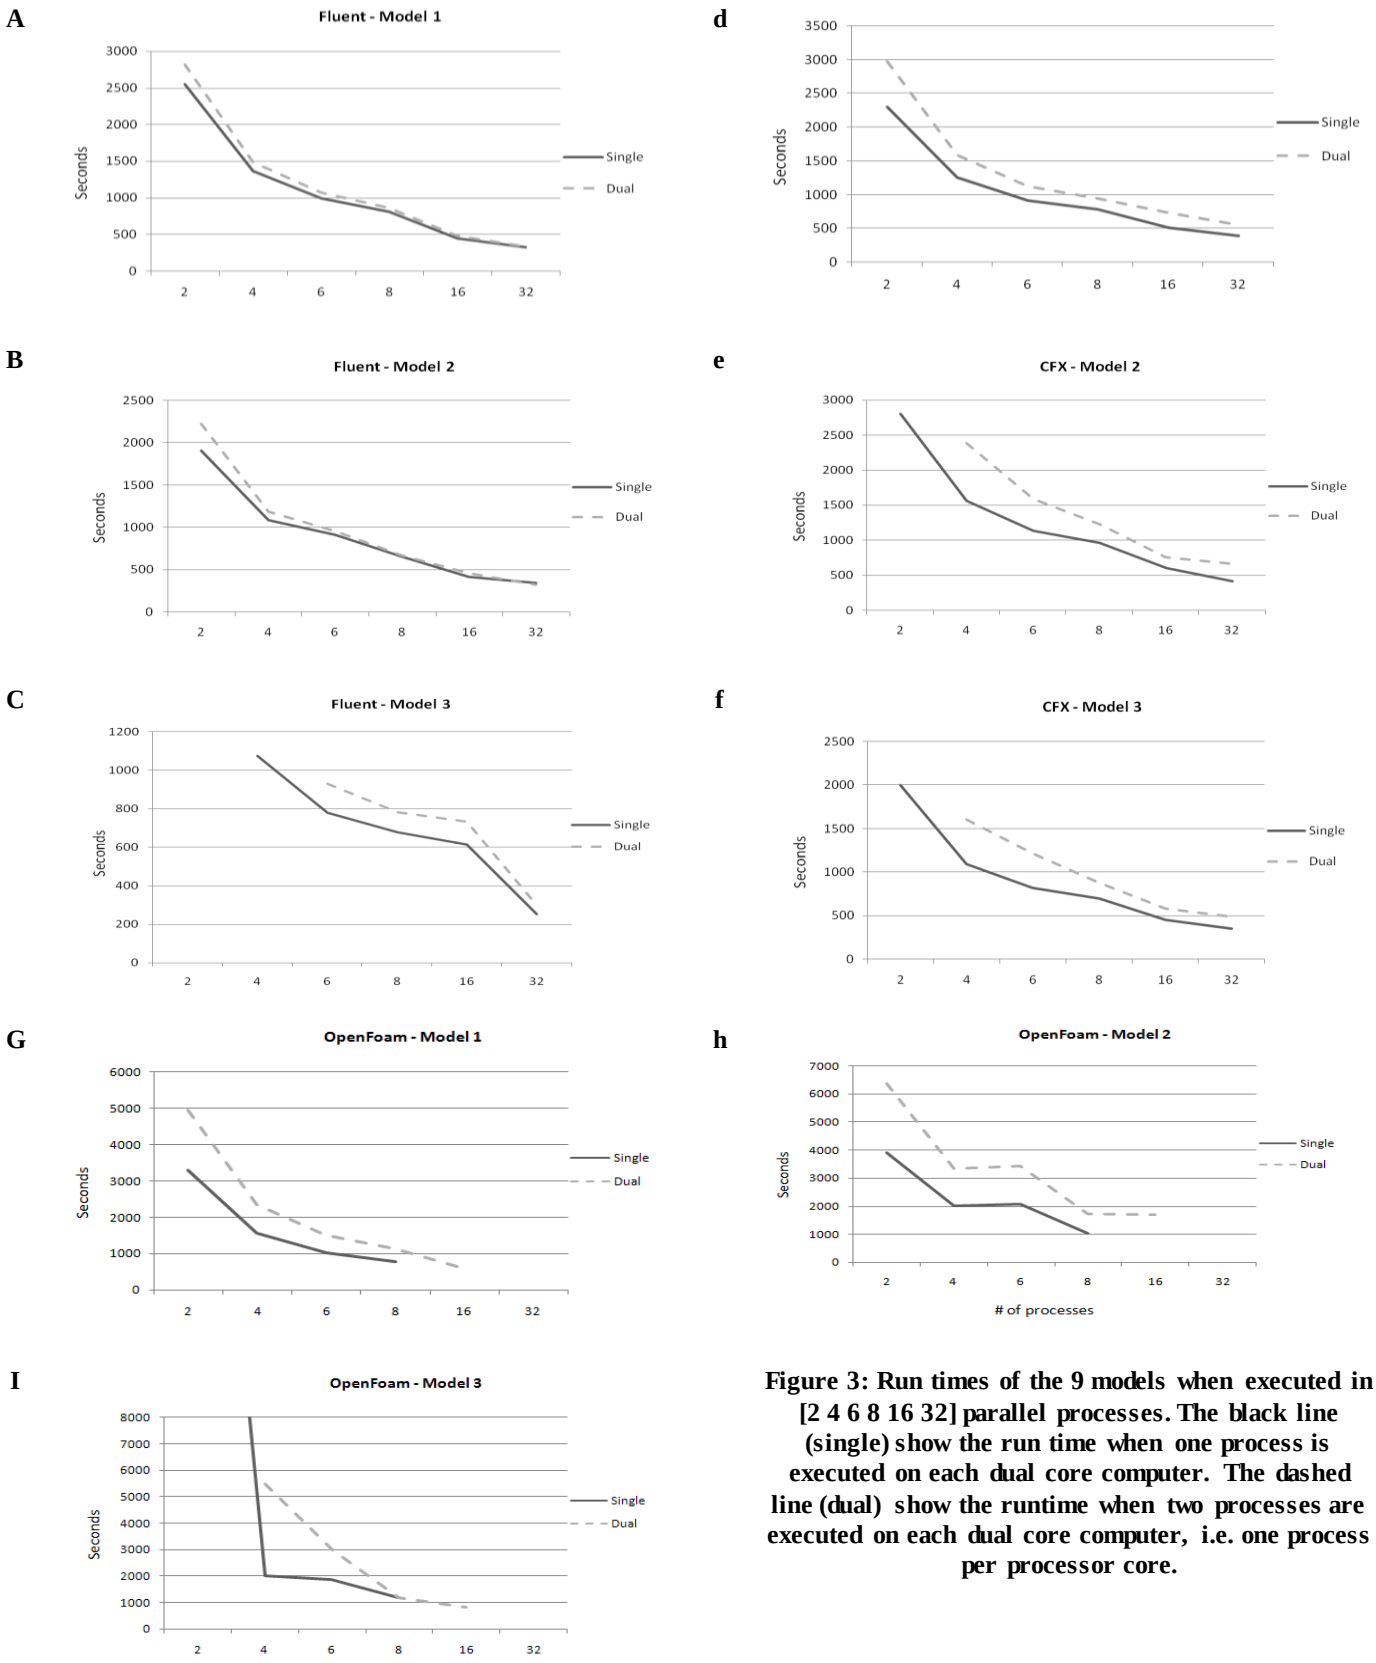

Figure 3: Run times of the 9 models when executed in [2 4 6 8 16 32] parallel processes. The black line (single) show the run time when one process is executed on each dual core computer. The dashed line (dual) show the runtime when two processes are executed on each dual core computer, i.e. one process per processor core.

The Single node executions that outperformed their Dual counterparts are listed in table 4 together with the speedup gained. Using Fluent model 3 as an example, the application actually solves the problem faster if you divide it into 8 parts and run it on 8 dual core processors compared to dividing it into 16 parts and running one process on each core on 8 dual core nodes. Hence, if there are 8 dual core nodes it will take 8% longer time to execute the problem if you utilize both cores instead of just one. The same applies to all CFX models when executed on 16 computers as well as for Openfoam model M2 when executed on 8 computer nodes. For the Openfoam model M2 the speedup gained, when executing one process per computer instead of two was as high as 63%.

Table 4: The following models execute faster when executed with one process on each dual core computer than when executed with two processes on each computer.

Model	# of computers	Speedup for single
Fluent M3	8	8%
CFX M1	16	10%
CFX M2	16	11%
CFX M3	16	6,5%
OF M2	8	64%

Based on the results presented one can draw the conclusion that the generally most time efficient solution is to execute the CFD simulations according to the Single scheme. E.g. executing only one process on each computer; leaving the second core virtually unused. For the lower amount of processes the Single setup require two times the computers that the Dual setup. This effectively doubles the hardware investments, but using two times the processes also doubles the software license costs. This issue was investigated in [22] [23] where the conclusion was that the cost of adding hardware is preferred to the cost of the added software licenses.

For Fluent and CFX the advantage seems to decrease as the number of processes increase but then raise again at 16+ processes, this statement is true for all but Fluent M2. As Openfoam goes the difference is even larger, here the Single setup outperformed the Dual for all number of processes with between 29% and 40% (on average 32%), although this does not include the Openfoam M3 Single 2 and Dual 4 simulations since they did not fit completely into memory.

6 Analysis and Discussion

The most notable results from the investigation are those presented in figure 5 and table 4 – In these cases the application and model combinations execute faster with one core inactive on each compute node, i.e. when one process (P) is executed on each one of the dual core computer nodes (N) compared to when two processes are executed on the same number of nodes.

The main issue is to determine if this behavior is dominated by hardware bottlenecks or the software scalability. If an underlying mathematical or programming intricacy causes behavior, the application should behave *the same as long as the number of processes are constant*. If all resource demands are satisfied the Dual(P) and Single(P) runs would execute in the same amount of time. Since this is not the case to try to identify the resource(s) that Dual(P) uses more of than Single (P). We now continue with a more detailed analysis looking the three candidate resources suggested in section 2 above.

6.1. Network Usage

The investigated applications at hand communicate on a process to process basis. All processes can communicate with all other processes as well as carry out collective MPI operations, such as broadcasts and scatter-collect operations. A process in a Single setup that sends a message to another process will always send it thru the switch (1). Where Switch represents the amount of traffic traversing the switch, N is the number of nodes, P is the number of processes and M is the average number of Megabytes transmitted by each process to each other process.

$$Switch_{Single} = (N^2-P) * M \quad \text{(eq. 1)}$$

A process in a Dual setup, however, will carry out a portion of its communication over the loopback interface but the larger part still goes through the switch.

$$Switch_{Dual} = (N^2-2P) * M \quad \text{(eq. 2)}$$

When comparing Eq. 1 and 2 it is obvious that the switch is subject to a higher utilization in the Single setup then in the Dual. However, in the Dual setup both processes on a computer node share the same network connection as well as the internal busses. The average load on each computer node is calculated as (switch/N)*(P/N). Nevertheless, consumed bandwidth is quite low. The Fluent M2 in 16 process Single configuration had the highest measured computer node communication 7.77 megabyte/s. It is one out of ten configurations that had a node communication of more than 5 megabyte/s i.e. 40 megabit/s. All CFX and Openfoam models had a per node communication less than 2.5 Megabyte/s.

Based on these numbers it is highly unlikely that the single process per machine performs faster than two processes per machine depends on the network resources. The increase in network utilization might impact the execution time in a negative way but not at all on the scale observed.

6.2. Memory Footprint

The investigated applications use a technique called bulk synchronous parallel [24], as do the majority of the industrial simulation codes in the CFD and FEM areas. This means that these applications at the global level hold a large matrix in memory of #E number of elements, where each element has a size of E_{size} in memory. The total memory size of the matrix is then $\#E * E_{size}$. Considering the inherent memory footprint M of the application, one could naively expect the memory usage per process to scale according to eq. 3 below, where P is the total number of processes.

$$M + (\#E * E_{size}/P) \quad \text{(eq. 3)}$$

However, all three applications use some optimization schemes to obtain higher performance. To avoid using the network too much some boundary data is stored with several processes. Instead of communicating, which in best case results in the introduction of network latencies and in the worst case bandwidth depletion, some elements are calculated and stored locally by several processes. The memory demands can thus more correctly be described by eq. 4, where Δ represents the amount of redundant information stored for optimization reasons.

$$M + (\#E * E_{size}/P+\Delta)$$

(eq. 4)

As can be seen in figure 9 the amount of memory does not decrease linearly with the number of processes. For many of the cases the per computer memory usage actually increases with the number of nodes. Evidently RAM-memory shortage cannot explain why the applications execute faster when only one process is placed on each dual core computer instead of two.

6.3.Memory Bandwidth

Despite that each process is identical in both execution and memory demands regardless of it being executed by itself on a compute node or together with an additional process, there is an important difference in technical context. Even if the memory allocated for two processes still easily can be fitted into the main memory (see above), the number of memory accesses will be (more than) doubled.

At the same time there is a major difference between the single and dual setup due to the shared L2 cache of the Intel Core2duo architecture. In the Single setup each process has a 4 megabyte L2 cache while in the Dual setup it has to be shared between the two processes, and the processes works on two different datasets. Thus, while the number of memory accesses *increases* by a factor of two or more (inter process communication among other things will create some extra load), the available L2 cache will in practice *decrease* by a factor of two. It is consequently reasonable to suspect that this change will give raise to additional delays not present in the single execution setup. When the STREAM benchmark was used to measure the sustained bandwidth it never exceeded 4080 megabyte/s, see section 3.1 for more details.

7 Conclusion

In this paper we investigated the impact multicore processor based clusters has on the execution of industrial simulations, namely computational fluent dynamics (CFD). Almost all new cluster installations are equipped with multicore processors, but according to our results it is far from trivial to determine if this is in fact a blessing or a curse.

The most significant finding was that five of the models, ran faster when only one process (P) were executed on each multicore node (N). When two processes were executed on each node the execution time was increased by between 6.5 and 64% with a median increase of 10% in these cases. In general the trend is that at a low number of nodes two processes per computer, i.e. one process per core, outperforms once process per node, but as the number of nodes and processes increase the gap closes and eventually the single placement strategy wins.

We evaluated four different possibilities, application scalability as well as processor, memory and inter process communication capacity as suggested by [6] as well as [7]. Application scalability was ruled out early since there were no scalability issues with the number of processes that were executed with one per computer node instead of two. The inter process communication capacity were also ruled out as a major contributor. Turning to the memory and memory bandwidth utilization it is obvious that the shared FSB and L2 cache of the Intel Core2duo architecture affects the performance. In the Single setup each process has a 4 megabyte L2 cache which in the Dual setup is shared and they work on two different datasets.

Ultimately we draw the conclusion that it is not obvious that utilizing more than one core of a dual core processor is beneficial. Furthermore we know that there are several cases where it is a great deal better to only use one core, especially when factoring in the per process license costs. The reason behind this (technical) behavior is still unknown although it is likely that it is linked to the memory hierarchy, and it is highly unlikely that it depends on the inter-process communication or the processor utilization.

Combining Cache Aware Scheduling with Lazy Threads

Yosi Ben-Asher[1] **and Gil Kulish**[1]
[1]CS Department, University of Haifa, Haifa, Israel

Abstract— *We consider two factors that can dominate performances of fine grain parallel programming on multicore machines:*

- *Cache coherency protocols, which preserve cache coherency and by this, add large overhead.*
- *The number of real kernel threads that are used to execute the possibly large number of program threads explicitly generated by the parallel constructs of the program.*

As for the first factor we designed a cache aware scheduling scheme which, based on memory profile, schedules threads such that cache misses are minimized. As for the second factor, we implemented a lazy thread system, which replaces threads with loop iterations and function calls- minimizing the number of real threads spawned throughout the execution. These two techniques may be conflicting each other since by reducing the number of real threads that are generated we reduce the freedom degree of the cache aware scheduler to minimize cache misses. We consider ParC a programming language that is similar to OpenMP but supports a more generalized scoping rules than OpenMP, and designed a lazy thread system for it, enhanced with cache aware scheduling. Our results prove that cache aware scheduling can be effective even with very aggressive lazy thread optimizations. The implementation of the scheduling system is optimized for the MESI cache coherency protocol.

Keywords: Multicore, Cache, Lazy threads

1. Introduction

We consider parallel programming over a multicore machine wherein shared memory is simulated by maintaining a cache coherency protocol, such as MESI [14]. For parallel programming, we consider two parallel constructs that can be freely nested: $parfor(i = 0; i < N; i++)\{body\}$- A parallel version of C for-statement generating a separate thread for each iteration i. $parblock\{body_1\} : \ldots : \{body_k\}$- A parallel version of C block-statement generating a separate thread for each $body_i$ The threads generated by the execution of such programs should be executed in parallel by different cores of the machine so that parallelism is obtained. Accessing variables by such a code might imply use of shared memory since the same variable can be accessed by different threads executed on different cores.

One factor that can easily reduce the speedups of parallel programs executed on a multicore machine is the overhead involved with simulating the shared memory. Typically, shared memory over a set of cores is simulated via a cache coherency protocol, e.g., MESI [14]. MESI is a distributed protocol that ensures values of shared variables in the different cores' caches and in the main memory are consistent. In particular, MESI ensures that all the different copies of a shared variable stored in the different caches and the main memory have the same value when accessed. This is done by invalidating copies at remote caches every time a core updates a shared variable in its cache and updating the memory. Consequently, a cache miss (accessing an invalid copy of a shared variable) results in a bus transaction needed to fetch a value from the main memory. A cache line is always in one of the following states: Invalid, Shared (other caches contain a copy), Exclusive (only this core contains a copy), and Modified (local copy differs from the copy in the main memory). Consequently read/write operations on shared variables can lead to a bus-transaction that may slow down the computation significantly (we measured a factor of 40 times slower for accesses that are not cache-hit). Thus it is important to reduce the number of shared memory references that are cache misses and incur bus transactions to the main memory. Note that accessing two shared variables separately by two threads that are executed in different cores typically results in cache misses and bus transactions

In this respect it is natural to consider the possibility of scheduling the threads that are generated during the execution of a parallel program, such that the overhead of accessing shared variables is minimized. Consider for example the following parfor executed on a multicore machine with $p = 2$ cores:

```
parfor(int i=0;i<=n;i++)
  if(i < n/2)
     for(int j=0;j<i;j++) A[j]+=f(j);
  else for(int j=0;j<i;j++) B[j]+=g(j);
```

Let T_i be the thread generated by the i'th iteration of the above parfor and consider two possible schedules (where $T_i \mid\mid T_j$ indicates that T_i executed by the first core and T_j by the second core:

$$\begin{array}{lcl} T_0||T_1; & & T_0||T_{n/2}; \\ T_2||T_3; & & T_1||T_{n/2+1}; \\ T_4||T_5; & and & T_2||T_{n/2+2}; \\ \ldots\ldots & & \ldots\ldots \\ T_{n-1}||T_n; & & T_{n/2-1}||T_n; \end{array}$$

Clearly, the leftmost scheduling will result in many cache

misses and MESI bus transactions as the first half of threads are executed in parallel repeatedly updating the shared array $A[]$ and similarly for the second half of the threads all accessing $B[]$. The rightmost scheduling is significantly better since when two threads are executed in parallel then most of their shared memory references point to different arrays. In this work, we consider ways to compute this $cache\ aware\ scheduling$ and execute it for a parallel program. We propose a specific technique that is based on memory profile analysis combined with simulation of the MESI protocol.

Our cache aware scheduling is part of the thread system that executes the parfor iterations and the parblock bodies of the parallel program since it affects the scheduling decisions made by the underlying thread system. Thus, cache aware scheduling should be evaluated in the context of the underlying thread system and not as a separate optimization. For example, scheduling strategies in thread systems are used to balance the execution time of the threads between the different cores. Thus, cache aware scheduling may potentially affect the ability of the underlying thread system to obtain good load balancing between the core. In this work we consider another aspect of thread systems called "Lazy Threading", which can potentially conflict with the ability to effectively execute cache aware scheduling. Basically, lazy threading maximizes the number of program threads (parfor iterations and parblock bodies) that are executed sequentially as loop iterations (for parfor iterations) or as local function calls (for parblock bodies), as opposed to kernel threads. This is an important feature of thread systems proposed by Goldstein et al. [10] implying that the possibly large set of program threads can be statically packed into a smaller set of threads which are actually executed by the underlying thread system. A common simple case of lazy threading is known as "chucking" where the n iterations of a $parfor(i = 0; i < n; i++)\{\ldots\}$ are executed in parallel using p real threads each executing a chunk of $\frac{n}{p}$ iterations sequentially. For example, the thread system of OpenMP automatically chunks all the iterations of every parfor ignoring possible dependencies that might exists between the different iterations of this parfor (though OpenMP allows the user to specify the number of threads a given parfor should use). In this way the large overhead involved with thread creation, termination and preemption is reduced. However, lazy threading can potentially reduce the effectiveness of cache aware scheduling since it eliminates most of the program threads reducing the number of possible scheduling available for the cache aware scheduling. Figure 1 illustrates this problem showing a program that spawns eight threads $T3 \ldots T10$ via two parfor statements to be executed on a multicore with $p = 2$ cores. Applying lazy threading to the program of figure 1 will result in clustering the threads $T3 \ldots T6$ and $T7 \ldots T10$ as two real threads, which, as depicted in figure 1, will prevent efficient cache aware scheduling. As depicted in figure 1 right bottom side, the scheduler can potentially schedule $T3 \ldots T10$ such that no cache misses occurs if it avoides lazy threading. Thus, in this work we would like to see if the reduced set of threads that remains after lazy threading and even a highly aggressive form of lazy threading still allow efficient cache aware scheduling.

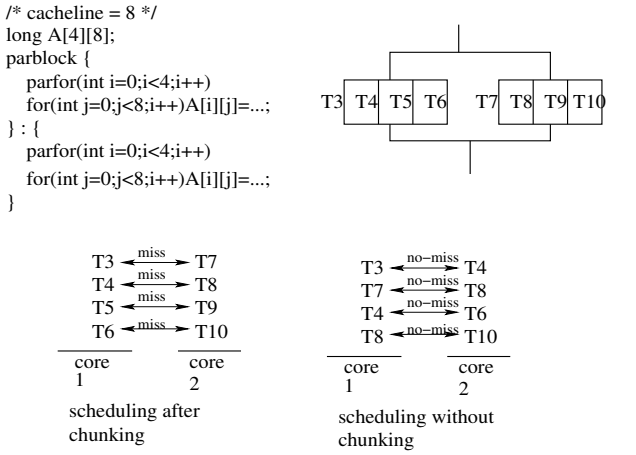

Fig. 1: Lazy threads prevent cache aware scheduling

We have implemented the cache aware scheduling and the aggressive lazy threading for ParC [3]- a parallel programming variant of C/C++ which is similar to OpenMP commonly used for programming multicore machines. Thus, the technique proposed here is general and can be used for OpenMP and other thread-systems running parallel programs over multicore machines.

The contributions of this work are as follows:

1) Developing a cache aware scheduling scheme for MESI protocol, which to the best of our knowledge, has not been proposed elsewhere.
2) Creating an aggressive lazy threading scheme that maximizes the number of program threads that are executed sequentially as function calls and loop iterations. Previously suggested schemes for lazy threading did not handle parfor constructs and while-loops whose termination depends on shared variables modified by other threads.
3) Showing that the combination of lazy threads and cache aware scheduling is beneficial.

2. Thread systems and lazy execution of threads

In order to execute a parallel program by a multicore machine it is necessary to use a thread system that can execute the multiple program threads generated by the parallel program on the small fixed number of available cores (typically 4-8). Basically such a thread system consists of two

queues of threads: ready-queue containing thread's control blocks that can be executed and a suspend-queue containing control blocks of threads that are suspended waiting for some event to occur. Threads are pulled from the ready-queue, executed for a while, stopped, and then their execution state is stored in the ready-queue again. Threads that spawn new threads due to nesting of parallel constructs are placed in the suspend-queue until all its descendants threads terminate. This general notion of ready-queues is basically valid for any thread system. We use the term $scheduler$ to describe the module that is responsible for selecting the next set of threads from the ready queue and assigns the thread to an available core. Clearly, for a given state of the ready-queue there can be many possible scheduling strategies: Round-robin- selecting the oldest thread in the ready queue and assigning it to the next available core. Random- selecting k threads at random where k is the current number of free cores. Random selection can improve load balancing between the cores as described in [2]. Multiple-queues-maintaining p (number of cores) ready/suspend-queues one for each core and exporting newly spawned threads between the different queues. In this case the scheduling strategy includes rules for selecting the next thread for each core from its ready-queue. It also includes rules for exporting newly spawned threads between the different cores. For example, we may decide to partition new threads spawned by a $parfor$ evenly between the cores' ready-queues or send them to a core whose ready-queue contains the least number of threads out of all cores. There are several alternatives to switching between a running thread and a suspended thread waiting inside the ready-queue. One option is to use time interrupts and switch threads after some fixed time quantum, another alternative is that the compiler will insert explicit instructions in the code of the threads causing it to explicitly switch to another thread. Thus, a thread system (TS) is a software module that consists of: ready-queue, suspend-queue, scheduler, context_switch_mechanism and a source of new threads which is the execution of the parallel program. A multiple queue thread system is a fixed set of TS_i and rules for exporting new threads to the different ST_is.

In this work we, use a three level TS model containing the following levels: Kernel threads generated using Pthreads [12] with one thread per core, User threads- generated by Pth [8] forming a lighter thread levels driven by explicit Pth context-switch instructions. A User-Level TS is generated once per each Kernel Thread. Program threads- that are even lighter threads that run to completion in lazy thread mode that is explained next. A single thread at each user level TS will execute the lazy TS. Lazy execution of threads and Parallel loops load balancing are known concepts and basically imply that a maximal number of parfor iterations will be executed sequentially without generating any thread.

Feitelson and Rudolph addressed the issue of how a multiprocessor should divide its processing resources among competing jobs. [9]. Since then many researches were done in the field of clustering threads into gangs and scheduling them to run over multiprocessors. Recent work of Nikolopoulos and Polychronopoulos [13] addressed the issue of of data locality. Calandrino and Anderson [6] [5] attempted to prevent a case in which two threads that use different areas of the memory and use the cache intensively run concurrently. Thibault, Namyst and Wacrenier [15] [16] address the problem of poor scheduling APIs. Chu, Ravindran and Mahlke [7] proposed a profile-guided method for partitioning memory accesses across distributed data caches. "Lazy threads" were proposed in [10] but in a limitted form using fork operations only. OpenMP suggests several keywords that allow the programmer to predefine the scheduling scheme [4]. several works done in the field such as [1] suggest to preserve spatial locality, by assigning contiguous chunks of iterations to the same thread whenever possible.

3. Proposed lazy thread mechanism

The simplest form of lazy threads it to partition the n iterations of a $parfor(i=0;i<n;i++)S_i$ to p chunks of n/p iterations that are executed sequentially:

$$parfor(k=0;k<n;k+=n/p)$$
$$\quad for(i=k;i<k+n/p;i++)\ S_i;$$

We use a function $selector(f,t,S_i)\{\ for(i=f;i<t;i++)\ S_i;\}$ to execute a chunk of parfor iterations $i=f\ldots t-1$. There are two cases in which a chunk cannot be executed sequentially using loop iterations. In the first, one of the $parfor$ threads (say i) of a chunk (from f to t) executes a context switch instruction. Note that the ParC compiler should insert a context switch instruction only inside those while-loops whose condition may depend on the value of shared variables. In this case, it might happen that such a while-loop (of ParC thread i) depends on a "releasing" assignment that will be executed by one of the remaining iterations (threads) of this chunk $i+1\ldots t-1$. Thus, in case of a context switch, the selector function might be forced to send the remaining $t-i-1$ iterations to be executed concurrently on a new user thread, in order to allow the execution of the aforementioned "releasing" assignment. The second case occurs when the i'th iteration spawns a new parallel construct. Here, a new selector function should be called by the current selector. The problem in this case is that a local descendant of this new parallel construct might be dependent on one of the remaining $i+1\ldots t-1$ siblings of the spawning thread i. However, the remaining $i+1\ldots t-1$ siblings will not be executed until the new call returns.

In order to reduce the number of user threads that are used during the execution, we must take care not to create a new kernel thread whenever a spawn occurs. A spawn request in thread i can be executed in one of two ways:

either by sending the remaining $i+1 \ldots t-1$ threads to be executed by another user thread, or by first executing the new spawn locally (sequentially). Then, when all its descendants terminate, local execution of the remaining $i+1 \ldots t-1$ threads can be carried out sequentially. In our scheme, we propose to delay the decision about how the spawn should be executed, first we try to perform the remaining threads sequentially, without spawning new threads, until we discover that a descendant of the current thread i has performed a context switch. If all the spawned descendants of i have terminated without executing a context switch, then the execution of the remaining threads $i+1 \ldots t-1$ can continue as if the spawn in i did not occurred. Otherwise, a new thread will execute the remaining threads must be created. This is because of possible dependency (through shared variables in a while-loop) of this thread on one of the remaining threads that can only be resolved by executing a context switch.

The usefulness of this scheme for lazy threads is demonstrated in the following example. Consider the execution of the following program using the proposed scheme. There is a spawn in the first thread $i == 0$. Thus, the range $1 \ldots \frac{n}{p} - 1$ is stored in the remaining stack. The chunks of the inner $parfor$ contain a while-loop $while(x)$, causing a context switch to occur. Thus, the remaining iterations $1 \ldots \frac{n}{p} - 1$ will be executed concurrently by another thread. As a result, thread $i == 1$ will set $x = 0$ and free the threads of the inner $parfor$ that are waiting in $while(x)$. Thread $i == 0$ will execute $y = 0$, allowing the termination of all the $while(y)$ in threads $i = 2 \ldots n$. This is close to the optimal scheduling, as most of the while-loops' flags will be reset as soon as thread $i == 1$ executes $x = 0$.

```
int x=1,y=1;
parfor(int i=0;i<n;i++) {
  if(i == 0){
    parfor(int j=0;j<n;j++){ while(x);}
    y = 0;
  }
  else if(i== 1) x = 0;
  else while(y);
}
```

4. The cache aware scheduling algorithm

In here we outline the main stages and detailes involved with the cache aware scheduling. The cache aware scheduling is executed using the following steps: Program execution step- the program is compiled using the ParC compiler that generate C++ program with suitable function calls to spawn threads. The compiler implements the aggressive lazy thread technique described earlier. The resulting code is linked with the thread system and is executed in parallel on every core. Figure 2 illustrates a snapshot in the execution of a program where the lazy threading generated four user-threads $T_1, T2, T3, T4$ such that T_1, T_3 reside in core-0's ready queue and T_2, T_4 reside in core-1's ready-queue. Note that this implies that any profile information collected is relevant only to the specific scheduling that occurs during the program's execution.

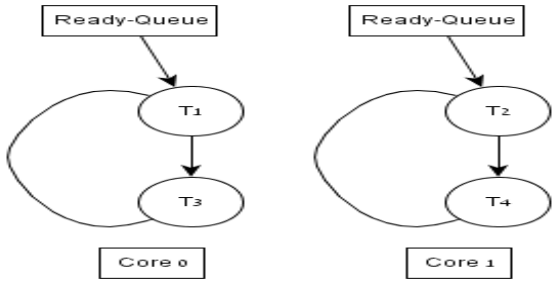

Fig. 2: Executing a program

Cache profile step- where each memory reference is instrumented such that upon execution, a logfile containing cache access statistics is generated. For every cache line L_j and user thread T_i, we record the number of times T_i updated a variable in L_j.(as depicted in figure 3). This number is called $T_{i,j}$. In order to capture potential cost for threads that run from different cores, we assume that each thread is executed from a different core. The cache simulation used here does not include cache associativity. Time intervals of cache references are used to determine when two threads have a possible cache conflict. Threads that originate from the same parallel constract, e.g. , chunks originating from the same parfor, are also considered conflicting. The potential conflict cost generated from two conflicting threads T_{i1} and T_{i2} is the sum of all minimums between($T_{i1,j}$ and $T_{i2,j}$) where j represent conflicting cache lines for threads T_{i1} and T_{i2}.

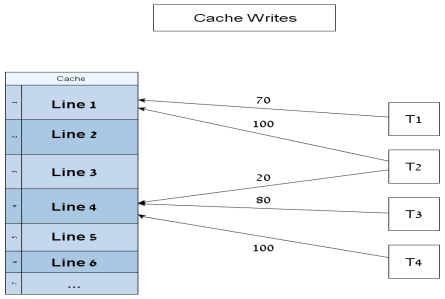

Fig. 3: Cache statistics obtained for the execution of figure 2.

MESI profile step- where each memory reference is instrumented such that upon execution, a logfile recording MESI's bus transactions will be generated. The simulation refers

to different threads as different cores. During execution the MESI operation in each thread is fully simulated and bus transactions resulting by accessing shared variables are recorded. The information is collected such that for every two threads $< T_i, T_j >$ we record the number of bus-transactions resulting from a consecutive accesses of T_i and T_j to the same cache line. For example assume that T_i updates a shared variable x residing in cache line L_8 invalidating L_8 in the remote core where T_j is executed. Next T_j attempts to read y which is also mapped to L_8. Thus, T_j will cause a MESI bus-transaction which will increment the counter of bus-transactions between T_i and T_j. These type of threads will be defined as conflicting threads. The cache simulation used here does include cache associativity.

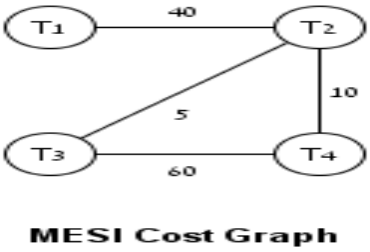

Fig. 4: MESI statistics obtained for the execution of figure 2.

Unified profile step- where the Cache profile information and the MESI profile information are unified. This is done by first summing the common cache accesses between every two conflicting threads $< T_i, T_j >$ based on the information in figure 3. Next we factor in conflicting threads information collected during the MESI profile, for every two conflicting threads $< T_i, T_j >$ we add the half of the MESI statistics as depicted in figure 5. Note that both profiles are needed

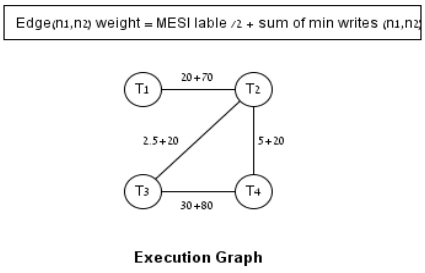

Fig. 5: Unifying MESI profile and the cache profile for the execution example of figure 2. $edge(T_{in}, T_{im}) = 0.5 * MESI(T_{in}, T_{im}) + \sum_{j=1}^{cache\ lines} minimum\ cache - profile(T_{in,j}, T_{im,j})$

since:

- The MESI profile is more accurate than the cache profile since it counts real bus-transactions skipping cache references that do not lead to bus transactions. For example, consecutive updates to a variable that is in state Exclusive should not be counted.
- The MESI profile can be misleading as well since it can only count bus transactions that occur between threads that run concurrently. However, since the actual cache aware schedule that will occur during the final run of the program might be different than the original one used for collecting the MESI profile, we might ignore cache misses between threads that were not executed is parallel in the original schedule.
- The reason for dividing the MESI profile values by two when factoring it with the weights of the cache profile is due to the fact that the Cache profile represents a set of possibly bad events that can occur under any schedule while the MESI profile is relevant only for a specific schedule.

The unified profile also includes the number of memory references executed by each thread (associated with every node) Graph partition step- where we use a graph partition package [11] to partition the nodes of the unified profile graph into p clusters of threads such that:

- The total weight of edges connecting threads between different clusters is minimized.
- The total weight of nodes in each cluster is about the same.

In the cache aware schedule all the threads that were allocated to the same cluster will be schedule to the same core. The graph partition thus obtains good load balancing while minimizing the number of bus transactions that are likely to occur between threads that are executed on different cores. Figure 6 depicts the resulting graph partition of the unified profile graph.

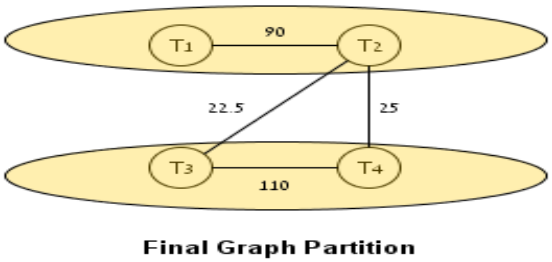

Fig. 6: Graph partition of the unified profile graph of figure 5.

Final execution step- where the resulting graph partition is recoreded into a configuration file that is used by a future run of the program with possibly a different input. The program must be recompiled with a suitable flag to avoid the

overhead of the instrumented code used to collect the profile information. Figure 7 depicts the resulting scheduling that will occur when the program will be executed with specific directions for the scheduler reflecting the graph partition obtained by the profile gathering stage. It follows that the resulting cache aware schedule reduces the expected number of bus-transactions from $90 + 110 + 22.5$ to $22.5 + 25$. Obviously, this is only an estimation and does not reflect real numbers of bus transactions that will occur in an actual execution.

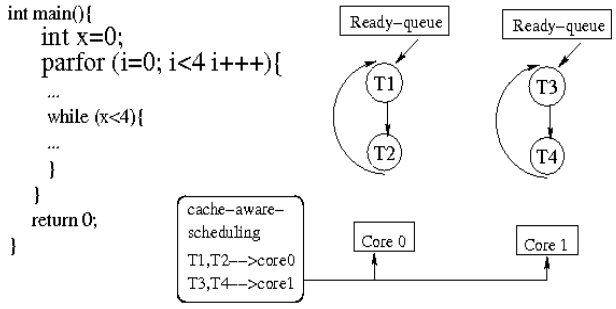

Fig. 7: New execution guided by the graph partition of figure 6.

A final aspect related to the proposed technique is how threads are labeled during the profile gathering stage and in during actual execution of the program that is using the resulting cache aware scheduling. Technically the labels of threads should allow us to:

- Uniquely identify threads resulting from the different parfors and parblocks of the program.
- Match between the set of threads generated during the profile-state and the set of threads generated by a "final-run". Note that since the final-run will use a different input than the one used for the profile run then the set of threads that it generated can be different than the one for which the cache aware scheduling was computed with,

We thus use thread-labels that are based on the static nesting structure of the program which is the same for both runs as follows:

- Each parfor/parblock in the source code is assigned a unique label, e.g., PF1,PB2, and so forth.
- Upon execution when a thread is generated its label is concatenated to the label of the thread that spawned it, e.g., for a three level nested parfor the innermost thread labels will be of the form PF5.PF10.PF17.
- Iterations numbers are also dynamically concatenated to the labels according to the range of iterations of the $selector()$ functions, e.g., $PF1_10 : 20.PF5_77 : 198$.
- Sequential executions of a parallel construct, such as parfor will result in a rising sequential iteration number.

If a configuration file with a cache aware scheduling is available, the scheduler at the current run will use the labels to match threads to cores and implement the scheduling in the order specified in configuration file. Threads whose labels do not match the labels in the configuration file are scheduled in the core that scheduled one of their ancestors according to their label.

5. Experiments

We describe and analyze the results of running 7 known benchmarks to compare OpenMP with ParC. The benchmarks were downloaded for OpenMP and implemented for ParC. We were extra careful to ensure that the ParC code will be true to the original OpenMP source code, meaning, no changes were made to the structure of the code in order to give synthetic advantage to ParC. We used 8 kernel threads for both OpenMP and ParC assuming two hardware threads per core. The experiments in this section were conducted on Core. i7 64 bit machine with Core. i7 920 processor, 48 Giga bytes of memory and four cores. In the following experiment, we measure the performance improvement gained from using the cache aware scheduling (lazy scheduling was turned off by using eparfor). Not optimized, the code bellow will spawn multiple threads, which most probably access the same cache line in the same time from different cores. After running the profiler, the threads will be grouped in such a way that threads which share a cache line will be executed from the same core.

The following experiments are public benchmarks used to compare OpenMP vs ParC performance. ParC showed a consistent advantage of X 1.2 shorter execution time on various matrices sizes. For example the following table contains the results for matrix multiplication:

Matrixes sizes	2000	2500	3000
OpenMP	24	49.5	90
ParC	20	41.5	75
Improvement Ratio	1.2	1.19	1.2

Table 1: OpenMP VS ParC Matrix multiplication comparison.

Other benchmarks include: NASA's NPB2.3, Molecular Dynamics (MD), a Clustering Algorithm, Game Of Life (GOL), Hopfield Neural Network (HNN), and Discrete Cosine Transform (DCT), Table 2 shows the improvement obtained due to the use of our cache aware scheduling summery of all of the above benchmarks:

Abstract— *The process of weather forecasting produced by numerical weather prediction (NWP) models is complex and not always accurate. Moreover, it is generally defined by its very nature as a process that has to deal with uncertainties. In previous works, a new weather prediction scheme, Genetic Ensemble (G-Ensemble), was presented, which uses evolutionary computing methods. Particularly, it uses Genetic Algorithms (GA) in order to find the most timely 'optimal' values of model closure parameters that appear in physical parametrization schemes, which are coupled with NWP models. The presented scheme showed significant improvement of weather prediction quality and, moreover, the waiting time for an enhanced weather prediction result was reduced by executing a parallel G-Ensemble scheme over HPC platforms. In this work, however, we test the same scheme with different GA configurations regarding its Crossover type and ratio, and by variating its initial population size in order to get better predictions. The main concern behind this work is to provide a more detailed study on how the GA used in G-Ensemble scheme could be tuned depending on the available computational resources in operational scenarios. Finally, experimental results are discussed of a weather prediction case using historical data of a well known weather catastrophe: Hurricane Katrina that occurred in 2005 in the Gulf of Mexico. Obtained results provide significant enhancement in weather prediction.*

Keywords: numerical weather prediction; HPC; genetic algorithm; ensemble prediction; parameter estimation.

1. Introduction

It is generally agreed that weather has a widespread impact on people's personal and social lives, including their jobs, their recreation, their safety, and their property. When the weather is bad, many activities become more difficult to perform. Commercial transportation slows down on the roads, on the waterways, and in the air. Businesses of all kinds are interrupted by bad weather. Power plants and energy traders rely on knowledge of the weather to operate their equipment and to deliver power to consumers, government and business. Furthermore, accurate predicted weather variables are critically needed for other environmental modeling systems. For instance, wind direction and velocity variables are needed as precise as possible to predict the expansion direction and velocity of a fire propagation disaster predicted by wildfire models.

Weather forecasting that predicts future weather state evolution is realized mainly by Numerical Weather Prediction (NWP) models that are commonly solved by means of computing facilities. That is, a numerical weather prediction is the process of guessing the future state of the atmosphere based on current weather conditions. Mathematical models are used to do the job, which treat the atmosphere as a fluid. As such, the idea of numerical weather prediction is to sample the state of the fluid at a given time and use the equations of fluid dynamics to estimate the state of the fluid at some time in the future.

On the other hand, from a computational point of view, NWP models are considered as soft-real time large scale applications. The importance of having a certain degree of accuracy in the prediction in a certain time is a real challenge. Many factors may determine the accuracy of the predicted weather variables: the available computing power for model execution, the model itself, and the input data. Thus, ongoing research concentrates on methods to enhance the process of prediction and get results of this process faster.

However, and as most simulation software works with well-founded and widely accepted models, the need for input parameter optimization to improve model output is a well-known and often-tackled problem. Particularly, in environments where correct and timely input parameters cannot be provided, efficient computational parameter estimation and optimization strategies are required to minimize the deviation between the predicted scenario and the real phenomenon behaviour.

With the continuously increasing availability of computing power, evolutionary and parallel optimization methods, especially Genetic Algorithms (GA), have become more popular and practicable to solve the parameter problem of environmental models.

In [1], a study discussing the sensitivity of forecast skill to a set of NWP model closure parameters (input parameters)

This research has been supported by the MEC-MICINN Spain under contract TIN2007-64974.

is provided. Furthermore, *G-Ensemble* prediction scheme is presented, which uses a GA to estimate 'optimal' values for these parameters for a certain forecast, in order to enhance forecast skill. The proposed scheme showed significant enhancement in prediction quality. In this work, more prediction results are presented and discussed regarding different configurations and scenarios of the used GA in the *G-Ensemble* prediction scheme. The aim of the presented work is to show how better predictions could be achieved by tuning the implemented GA in the *G-Ensemble* approach.

The rest of the paper is organized as follows: Section 2 gives an overview of NWP models, a NWP general scheme, and a brief description of the Weather Research and Forecasting Model (WRF), which constitutes the most commonly used model for weather and meteorological predictions. Section 3 discusses the predictability sources of error in NWP models and also describes the most widely used methods for NWP enhancement in practice. In section 4, *G-Ensemble*) is described briefly. Section 5 discusses experimental results obtained with a test case, where we compare our proposal with other enhancement methods. Finally, conclusions and future work are described in section 6.

2. Numerical Weather Prediction Models

Weather stems from the constant evolution of the atmosphere governed by physical laws. Using high-speed computers to solve a complex set of mathematical equations that represents the governing laws, NWP is a technique for simulating the atmospheric evolution in order to delineate the resultant weather changes. The variables involved in the equations include wind, temperature, pressure and moisture content. In principle, given the initial and boundary conditions, the atmospheric variables can be numerically solved as functions of time and form the basis of weather forecast. That is, NWP is described generally as "an initial-boundary value problem": given an estimate of the present state of the atmosphere (initial conditions), and appropriate surface and lateral boundary conditions, the model simulates (forecasts) the atmospheric evolution. The more accurate the estimate of the initial conditions, the better the quality of the forecasts.

Certain areas where atmospherical future conditions are to be predicted are represented by three-dimensional uniform-gridded-rectangles referred as domains or grids. The input data, which describe an estimation of the actual state of the atmosphere, are called initial conditions. Those initial conditions are assigned to all points of the grid. The horizontal distance between grid points is referred as the spatial resolution of both the initial conditions and prediction results. Regional models (also known as limited-area models, or LAMs) allow for the use of finer grid spacing (higher resolution) than global models because the available computational resources are focused on a specific area instead of being spread over the globe. This allows regional models to resolve explicitly smaller-scale meteorological phenomena that can not be represented on the coarser grid of a global model. Hence, a NWP model will predict the new values of the initial conditions over future time scale.

The first step of a NWP process is to extract initial conditions that are usually obtained from a global forecasting. These initial conditions are assigned to the domain grid points and, by means of the NWP model applied over a time line, at each pre-defined time period, a new 3-dimensional domain is produced having new (predicted) values of meteorological variables at all grid points.

The Weather Research and Forecasting model (WRF) [2] is a widely-used numerical weather prediction system, which is considered as a next-generation mesoscale numerical weather prediction model designed to serve both operational forecasting and atmospheric research needs.

WRF is composed of a variety of programs to facilitate the prediction process. It includes modules for global terrain data extraction, modules for real observation injection while model integration, and modules for output post-processing. It should be mentioned that although we have applied our methodology to WRF, the proposed strategy is a model-independent design, which could also be used with other existing NWP models such as the PSU/NCAR Mesoscale Model [3] known as (MM5).

3. Related Work

NWP models as well as the atmosphere itself can be viewed as nonlinear dynamical systems in which the evolution depends sensitively on the initial conditions. Moreover, weather prediction is, by its very nature, a process that has to deal with uncertainties. The initial conditions of a NWP model can be estimated only within a certain accuracy. During a forecast, some of these initial errors can amplify and result in significant forecast errors. Besides initial-condition error, weather and climate prediction models are also sensitive to errors associated with the model itself. In particular, the uncertainty due to the parameterizations of sub-grid-scale physical processes is known to play a crucial role in prediction quality (e.g., [4]). Prediction errors caused by the uncertainty in physical parameterizations is commonly referred to as model errors. Weather predictability errors are normally subject to two kinds of errors: initial condition errors and model errors.

As it has been stated before, in the case of initial conditions, input data is extracted from global forecasts. Normally, global forecasts are conducted using domains of lower grid resolutions (the distance between grid points is large). This is due to the computational power needed if the whole globe is to be predicted using finer grid spacing. As a result, interpolations are needed to extract initial conditions from lower resolution domains to assign them to local domains of

higher resolution. Unfortunately, this process is not perfect and the assigned values do not reflect the actual real state of the atmosphere. This problem is generally referred as the uncertainty of weather initial state.

On the other hand, physical parametrization is the representation of sub-grid scale physical processes, that is, some meteorological processes are too small-scale to be explicitly included in NWP models. Hence, parametrization enables the representation of these processes by relating them to variables on the scales (the points of the gridded domain) that the model resolves. For example, an important meteorological process is the surface flux of energy transmitted by the terrain which helps in enhancing the prediction of other important variables like near-surface temperature, sea surface temperature and even near-surface wind velocity variables. This process normally occurs in scales smaller than 1 kilometer, while NWP models predicts normally on domains of grid-scales higher than 1 kilometer. Parametrization is needed in such cases to represent this process on a certain domain scale.

By figuring out the main sources of error in predictability of NWP models, and over the past 20 years or so, stochastic or "ensemble" forecasting [5] became as a practical and successful way of addressing the predictability problem associated with the uncertainty in initial conditions. Moreover, several weather prediction centers have addressed this problem by developing operational ensemble prediction systems (EPS) (e.g., [6]). The main idea behind an EPS comes from the fact that the initial state of a certain variable should be seen as a probability distribution and not as a unique value, and thus, the ultimate goal of ensemble forecasting is to predict quantitatively the probability density of the state of the atmosphere at a future time. This is done by running multiple forecasts, each of which is initiated with small perturbations in the estimated initial conditions. Then, an ensemble forecast is usually evaluated in terms of an average of the individual forecasts (ensemble members) concerning one forecast variable, as well as the degree of agreement between various forecasts within the ensemble system, as represented by their overall spread [7].

However, and although it has been realized that there is a stochastic nature of physical parameterizations in ensemble prediction (predictability is sensitive to variations in physical parameters), it has not been straightforward to develop theoretically sound, and also practical, formulations for how to insert parameterization uncertainty into ensemble development [8], [9].

4. G-Ensemble

In this section, Genetic Ensemble (*G-Ensemble*) approach [1] for prediction enhancement is briefly described, as well as the set of the model closure parameters targeted for better estimation. The main objective of the presented scheme is to enhance prediction quality by improving the estimation of a set of NWP model closure parameters. The study is focussed on finding 'optimal' values of *Landuse* and *Soil* closure parameter (the land surface parameters and the impact they have are described in [10]). The optimization of these parameters will serve as a prove of concept of our method, which could be applied to other parameters. These parameters are found in land surface physical schemes (LSM) (e.g., [11], [12]) that are coupled to most NWP models. The proposed scheme consists of two phases: Calibration Phase and Prediction Phase (depicted in Fig.(1)).

Considering that t_i is the instant time from which the meteorological variables are going to be predicted, i.e. prediction is done within the period (t_i-t_{i+n}), Calibration Phase starts at a time prior to prediction time and ends at time 00:00 (t_i) of prediction period, i.e. calibration is done within the period (t_0-t_i). The process of closure parameter estimation in Calibration Phase proceeds as follows:

1) at the beginning of Calibration Phase (time t_0 in Fig. (1): a sample of the targeted parameter values from ensemble proposal distribution is generated (perturbations in closure parameter values);
2) the generated parameter values are inserted to the ensemble prediction model;
3) an ensemble of forecasts (the prediction model is different for each ensemble member regarding the targeted parameter values) is conducted to predict meteorological variables at time t_i, where real observations are available;
4) evaluation of a fitness function for each ensemble member is done at time t_i;
5) genetic algorithm functions (selection, crossover and mutation) are used to generate a new ensemble distribution from the set of combinations of closure parameters which score better predicting at time t_i;
6) the process is repeated iteratively until a predefined number of iterations, or an acceptable error value is achieved.

The used fitness function depends on the number of meteorological variables to be better predicted.That is, if the *G-Ensemble* is used to enhance prediction for one single meteorological variable, the root mean square error ($RMSE$) as shown as shown in equation (1), is used to be the fitness function for the GA. We refer to this approach as *Single-Variable G-Ensemble*. Referring to equation (1), x_{obs} is an observed value of a variable x and x_{pre} is the predicted one for the same variable.

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n}(x_{obs,i} - x_{pre,i})^2}{n}} \qquad (1)$$

In contrast, as it is necessary to enhance prediction for a set of meteorological variables, the normalized root mean square error ($NRMSE$), is implemented as the fitness function to be minimized during Calibration Phase (equation (2)).

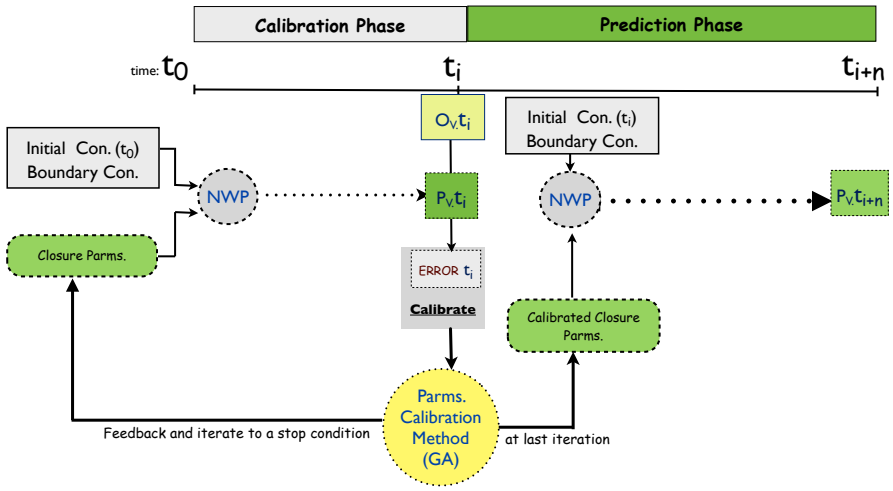

Fig. 1: Two-phase prediction scheme; NWP is the a numerical weather prediction model. t_i is time 00:00 of prediction process, t_0 is a time instant previous to Prediction Phase (initial time of Calibration Phase), t_{i+n} is the future time to be predicted. "O_V" is an observed meteorological variable at time t_i, "P_V" is the predicted variable at the same time using a NWP model.

$$NRMSE = \frac{\sqrt{\frac{\sum_{i=1}^{n}(x_{obs,i}-x_{pre,i})^2}{n}}}{x_{obs(max)} - x_{obs(min)}} \quad (2)$$

This approach is called *Multi-Variable G-Ensemble*. In $NRMSE$ equation, x_{obs} is an observed value of a variable x and x_{pre} is the predicted value for the same variable. The Normalized $RMSE$ ($NRMSE$) is the value of $RMSE$ divided by the range of the observed values of a certain variable. $NRMSE$ indicates the error percentage of the predicted value of a certain variable, compared to the range of its observed values. In order to consider more than one variable at a time, we evaluate $NRMSE$ for all variables, and then, we consider the addition of all of them as the Multi-Variable fitness function.

Despite the fact that the objective in the presented approach is to minimize the $RMSE$ or $NRMSE$ in Calibration Phase, as the fitness function used for the evaluation of ensemble members, other fitness functions can be applied in the presented scheme. The GA could be oriented to minimize any other targeted fitness functions.

At the last iteration in the Calibration Phase, the values of closure parameters, which produced the least value of $RMSE$ or $NRMSE$, i.e. the ensemble member with the best forecast skill score at time t_i, is selected to be used in Prediction Phase. This ensemble member is called: Best Genetic Ensemble Member ($BeGEM$). Our hypothesis is that, for short-range weather forecasts, if the forecast skill is improved in the Calibration Phase by a set of a calibrated closure parameters then the same closure parameter values will also improve forecast skill during Prediction Phase.

By now, in Prediction Phase, a deterministic forecast is used in our experiments. In other words, the $BeGEM$, which is the ensemble member having the calibrated closure parameter values is the single forecast to be conducted in Prediction Phase. However, the produced $BeGEM$ could be integrated in any type of EPS considering perturbations in initial conditions during Prediction Phase.

G-Ensemble scheme was extended in [13] to evaluate ensemble members according to a window of observations rather than 'one-point' observation. Time windowing to the optimization procedure was introduced and the performance (prediction quality) of *G-Ensemble* was enhanced as the used GA was better guided when more observation intervals were considered in the evaluation of ensemble members. Moreover, *Parallel Multi-Level G-Ensemble* was presented in [14], where a multi-chromosome GA was implemented in *G-Ensemble* scheme to optimize various sets of input parameters and the whole scheme was paralleled using Master/Worker paradigm and was tested on a HPC platform.

The obtained results showed significant improvements in prediction quality and less execution times over classical prediction scenarios. It should be mentioned, however, that the implemented GA in *G-Ensemble* scheme was tested in [1], [13], [14] using the same type of GA Crossover and fixed Crossover and Mutation probability ratios. In the next section, more experiments are conducted and discussed regarding different execution scenarios, were different GA configurations are introduced to *G-Ensemble*, in order to evaluate the gained prediction quality in accordance to each different configuration.

5. Experimental Evaluation

To test our approach, we used historical data of hurricane Katrina [15], which occurred on August 28, 2005 in the Gulf of Mexico and unfortunately caused the death of more than 1,800 persons along with a total property damage that was

estimated at $81 billion (2005 USD). The objective of the experiments is to predict the evolution of a meteorological variable from time: 12:00 h. of the day 28/08/2005 to time 00:00 h. of 30/8/2005 (a period of 36 hours in which the major effects of the hurricane were produced). The model is configured to predict the evolution of meteorological variables every three hours; and the spatial resolution of the domain was 12km. The used NWP model in our experiments was WRF and all Physics schemes were the same for all experiments.

To get the evolution of meteorological variables at 12:00 h. of 28/08/2005, we used initial conditions of the atmospheric state in the zone three hours before, i.e. model started prediction from time 09:00 of 28/08/2005. For our approach (*G-Ensemble*), the Calibration Phase started from time 00:00 of 28/08/2005 to time 09:00 of the same day.

The predicted variable in the following experiments is the *Latent Heat Flux (LHF W/m2)* using the *Single-Variable G-Ensemble* approach. However, it must be pointed out that any other meteorological variable could have been used and similar conclusions would be obtained. Examples of such variables can be find in [1], [13], [14], where both approaches of the *G-Ensemble* (*Single-Variable G-Ensemble* and *Multi-Variable G-Ensemble*) are tested to enhance prediction for a set of meteorological variables. The presented results explore the sensitivity of *G-Ensemble* forecast skill to some variations in its GA operations. In particular, we study the sensitivity to the GA Crossover type (one-point and two-points), to the probability to the initial GA population size (initial ensemble members size) and, finally, to the number of GA generation iterations in the Calibration phase.

The goal behind these tests is to provide a more completed insight of the scenarios and possibilities of how to configure an operational *G-Ensemble* according to the time allowed for prediction process and to the number of computing resources available. In the subsequent experiments, prediction errors $RMSE$ produced during Prediction Phase of two ways of prediction are compared:

1) *Single Variable G-Ensemble* approach, with different initial ensemble sizes, Crossover type and ratio, and different number of iterations in Calibration Phase.
2) The EPS approach, which is used to refer to the average error of an ensemble forecast conducted by the initial ensemble members used in the first iteration of Calibration Phase (an ensemble forecast such that the prediction model is different for each ensemble member regarding the targeted parameter values, these variables are not calibrated).

Firstly, Fig. (2) shows an experimental result for a classical EPS prediction of 40 ensemble members (each of which has a different combination of the targeted closure parameters) to predict (every 3 hours) the evolution of *Latent Heat Flux LHF*. The evolution of the values of LHF variable was notably under-estimated in this case. Thus, it could be easily concluded that there is a significant margin of enhancement in prediction which could be achieved.

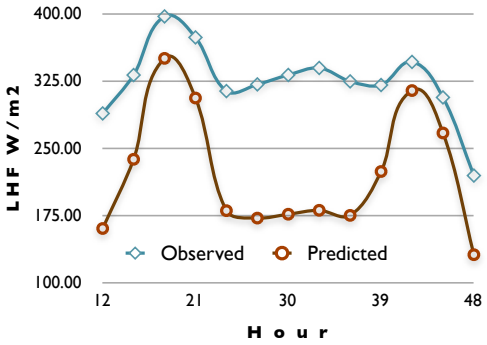

Fig. 2: Classical EPS prediction results compared to observed values.

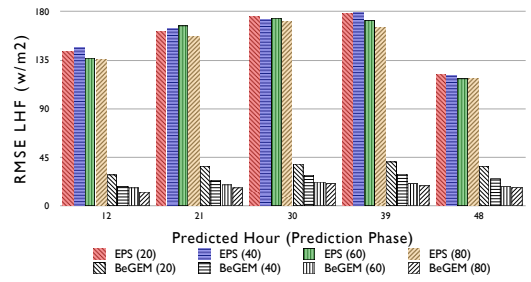
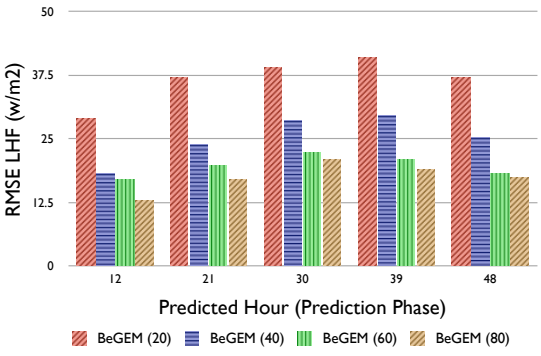
In Fig.(3(a)), prediction error is shown by using the *G-Ensemble* approach with different initial ensemble sizes to predict LHF variable compared to the classical EPS of the same ensemble sizes. The prediction error of the *G-Ensemble* approach is also depicted alone for the sake of clarity in Fig.(3(b)).



(a)



(b)

Fig. 3: RMSE of LHF pediction. (a): Single-Variable G-Ensemble prediction error Vs. Classical EPS prediction error. Results are of classical EPS(x) and the BeGEM(x), where x refers to the initial ensemble size. (b): A snapshot of (a) to demonstrate RMSE of the different BeGEM(x).

The Genetic Algorithm was configured to iterate 20 times over an initial population size of 40 individuals. Its

three main operators were configured as follows: *Selection*: (elitism: best one of two), *Crossover*: (probability=0.7, type: two points Crossover), and *Mutation*: (probability= 0.2). As shown in Fig.(3), in all cases with different initial ensemble sizes, *G-Ensemble* provides less error values in prediction compared to EPS predictions with the same initial ensemble members. A significant improvement in prediction quality is always gained.

Additionally, it can be observed that increasing the size of an EPS does not produce better results. Actually this happens because EPS results represent an average of the predictions of all ensemble members and, knowing that these members are variated regarding their closure parameters in a random way, using more members does not assure less average error. In contrast, increasing initial ensemble size, which will be calibrated iteratively by the *G-Ensemble* provides better prediction results as observed in the same figure. That is, by increasing the initial ensemble size in *G-Ensemble*, the probability for finding better solutions through GA iterations, also increases.

On the other hand, Fig.(4) shows the GA convergence in the Calibration phase of *G-Ensemble* approach. As such, the error of the best ensemble member through GA iterations is depicted in the figure, using different initial ensemble sizes. As it could be observed, the *BeGEM* produced after 10 iterations when *G-Ensemble* was conducted using an initial ensemble size of 80 members, was equal or slightly better than the same *BeGEM*, produced after 20 iterations when *G-Ensemble* was conducted by 20 initial ensemble members.

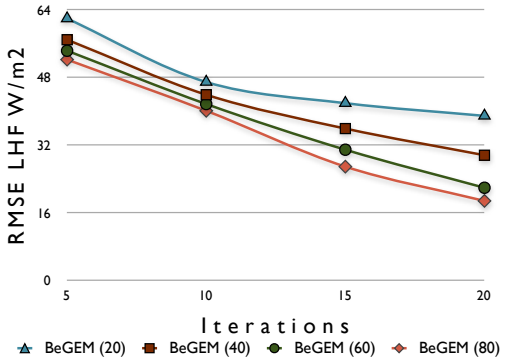


Fig. 4: Calibration phase: BeGEM performance through the Calibration phase iterations for different initial ensemble sizes.

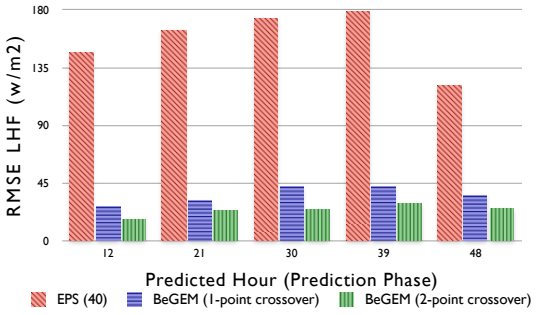
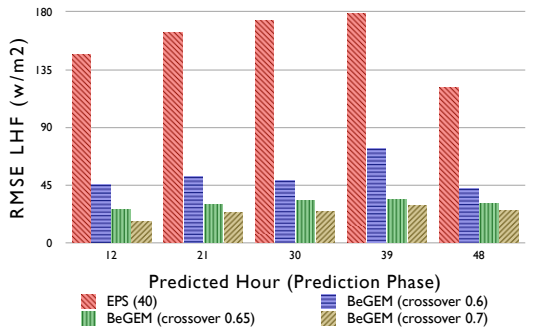
Then, according to the availability of computing resources, their number and the interval of availability, a certain scenario of the combinations between initial ensemble size and number of iterations, could be selected. Execution times and *G-Ensemble* scalability on HPC systems for different combinations regarding the number of iterations during Calibration Phase could be found in [14].

We also tested the *G-Ensemble* approach to predict the same meteorological variable (LHF) by changing the type of the GA Crossover during Calibration phase (Fig. 5(a)), and by changing the GA Crossover probability (Fig. 5(b)).



(a)



(b)

Fig. 5: BeGEM $RMSE$ in prediction of LHF produced in (a): using 1-point and 2-point GA Crossover in the Calibration phase, and (b): using 2-point GA Crossover but with different Crossover probability ratios.

The obtained results show that when *G-Ensemble* used 2-points Crossover in its GA during Calibration phase, prediction results were slightly better, and the same happened when Crossover probability was higher.

That is, when configuring the GA implemented in the *G-Ensemble* scheme on a relatively small size of initial ensemble members, better prediction quality could be obtained by 2-points Crossover and higher Crossover probability. Actually, this is due to the size of the initial ensemble size (initial population size): by using 2-point Crossover and a higher probability of Crossover operations, more variations in ensemble members could be obtained during each iteration of the Calibration Phase. This enhances the ability of the GA to look for better solutions over small initial populations, which is normally the case of NWP executions, where ensemble sizes are normally up to 50 ensemble members.

The results obtained in our experiments confirm our hypophysis that, on one hand, better estimation of model closure parameter values enhances weather prediction quality and, on the other hand, the proposed Calibration Phase leads to better estimation of closure parameter values by tuning the used GA. Additionally, different scenarios could

be applied in an operational *G-Ensemble* according to the available computing resources by variating initial ensemble sizes and the number of GA generation iterations.

We can conclude that *G-Ensemble* is a better choice compared to classical EPS. As shown here, *G-Ensemble* outperforms EPS in terms of parameter estimation but it has been also shown in [1], [13], [14] that the proposed *G-Ensemble* approach is cost effective computationally compared to the classical EPS over a parallel computing environment. In those works many execution scenarios were tested over a HPC environment, and the prediction quality was significantly enhanced, whereas, execution times were reduced in comparison with executions of classical EPS in Prediction Phase.

6. Conclusions and future work

This work describes our ongoing research focused on enhancing short-range weather forecasting by estimating 'optimal' NWP model closure parameter values, using an evolutionary computing method.

In [1], it was shown how forecast skill is sensitive to model closure parameter values. Moreover, *G-Ensemble* prediction scheme was presented, which aggregated a Calibration Phase to the prediction process, where these parameter values were optimized to improve forecast skill. The *G-Ensemble* prediction scheme showed a significant improvement in prediction quality. *Parallel Multi-Level G-Ensemble* was presented in [14], where a multi-chromosome GA was implemented in *G-Ensemble* scheme to optimize various sets of input parameters. Additionally, the whole scheme was paralleled using Master/Worker paradigm and was tested executing it over a HPC platforms. The obtained results showed significant improvements in prediction quality and less execution times over classical prediction scenarios.

In this paper, a complementary work is introduced by conducting and discussing more experiments regarding different *G-Ensemble* execution scenarios, where different GA configurations are introduced to *G-Ensemble* in order to evaluate the gained prediction quality in accordance to each configuration. As a result, it could be concluded that in scenarios of limited number of the available computing resources, where only small ensemble sizes could be applicable, *G-Ensemble* scheme provides better weather predictions by using 2-point Crossover in its GA, and also by using higher Crossover probability ratio. On the other hand, in scenarios where more computing resources are available, and thus, larger ensemble sizes could be used, our results showed that classical EPS does not enhance prediction results by increasing initial ensemble sizes, whereas *G-Ensemble* does. That is, forecast skill in weather predictions could be enhanced almost linearly by *G-Ensemble* scheme as the initial ensemble size increases.

These results encourage us to continue our research efforts by testing our scheme over larger sets of model closure parameters. And we are also planning to design methods that handle real observations during prediction process deciding their injection intervals at run-time in order to get more reliable meteorological predictions.

On The Rearrangeability Of Hypercubes Networks Characterization Of Some Non-1-Partitionable Permutations On 4D-hypercubes

Ibrahima Sakho, Jean-Pierre Jung
LITA EA 3097, Université de Lorraine, Metz, France

Abstract - *This paper addresses the problem of the nD-hypercubes interconnection networks rearrangeability that is the capability of such networks to route optimally arbitrary permutations under queueless communication constraints. The k-partitioning is an unifying paradigm of such routing. For a permutation which is not constituted of two sub-permutations on two disjoint (n-1)D-hypercubes of the nD-hypercube, it consists in decomposing it in an upstream permutation routable in k steps and two independent downstream permutations routable in n-k steps on two disjoint (n-1)D-hypercubes. To do so it is essential to know the minimum value of k for which such decomposition is possible, that is the permutation is k-partitionable. This paper characterizes the permutations which can not be 1-partitioned that is which are non-1-partitionable. The characterization alleviates enough the construction of such permutations for low dimensional hypercubes. The paper lists, if they exist, all the classes of such permutations on nD-hypercubes for $n \leq 3$, and some classes for n = 4.*

Keywords: interconnection network; hypercube; permutation; routing; maximum matching of bipartite graph; graph partitioning

1 Introduction

In the research for interconnection networks (IN), hypercubes constitute a very attractive alternative because of their incremental construction which confers them interesting mathematical properties which allow them to match with most of the IN performance criteria.

Several commercial parallel machines [1] have been built over the years and several theoretical and practical research works [2] have also been done on different aspects of their use as IN. Among the theoretical research, one of the most challenging is their rearrangeability that is, their capability to route any permutation in a number of steps that does not exceed the dimension, say n, of the hypercube. In [3], we proposed the k-partitioning paradigm to solve this still-open problem for high dimensional hypercubes. The paradigm consists in decomposing the permutation in an upstream permutation routable in k steps and two independent downstream permutations routable in n-k steps on two disjoint hypercubes. With this purpose, we gave a characterization of non-1-partitionable permutations which allowed proving, at our knowledge for the first time, formally the rearrangeability of hypercubes of dimension n for $n \leq 3$.

This paper gives a new interpretation of this characterization which alleviates enough the construction and the identification of permutations which are not 1-partitionable qualified in the sequel of non-1-partitionable. Indeed, the paper proves more easily that for $n \leq 2$ there is no non-1-partitionable permutation. For n = 3 it lists all the classes of non-1-partitionable permutations. For n = 4 it exhibits all the non-1-partitionability models then lists some classes of non-1-partitionable permutations.

The remainder of the paper is organised in four sections. Section 2 recalls, from [3], the problem formulation and some basic definitions relative to hypercubes, permutations and routing. Section 3 surveys the state of the art on the optimal queueless routing of arbitrary permutations. Section 4 presents the mathematical foundations of the k-partitioning paradigm. Section 5, firstly establishes the new characterization of non-1-partitionable permutations. Then it analyzes, through this new light on the problem, the non-1-partitionability on hypercubes of dimension n = 4. Section 6 concludes the paper.

2 Problem Formulation

2.1 Definitions

2.1.1 n-dimensional hypercube

A n-dimensional hypercube, nD-hypercube, is a graph $H^{(n)} = (V, E)$ where V, the set of the nodes, is the set of 2^n nodes $u = (u_{n-1}u_{n-2} \ldots u_0)$ with $u_i \in \{0, 1\}$ and E, the set of the edges, is the set of the pairs {u, v} of the nodes such that there is one and only one dimension i for which $u_i \neq v_i$.

It comes from this definition that while a 0D-hypercube is reduced to one node, a 1D-hypercube is obtained in interconnecting two 0D-hypercubes, a 2D-hypercube two 1D, a 3D-hypercube two 2D-hypercubes. More generally a nD-hypercube is obtained in interconnecting two (n-1)D-hypercubes. As the interconnection of the (n-1)D-hypercube can be done in anyone of the n dimensions of the resulting hypercube, any nD-hypercube $H^{(n)}$ can be viewed as anyone of the n

couples ($H^{(n)}_{0,\,i}$, $H^{(n)}_{1,\,i}$) of (n-1)D-hypercubes where $H^{(n)}_{x,\,i}$ is obtained by restricting $H^{(n)}$ to its nodes u such that $u_i = x$. Fig. 1 illustrates a 4D-hypercube viewed as the couple ($H^{(4)}_{0,\,3}$, $H^{(4)}_{1,\,3}$).

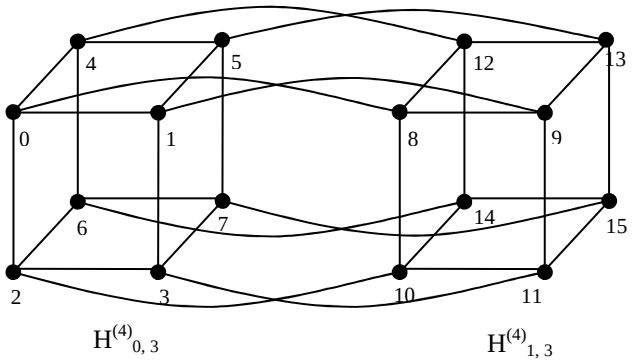

Figure 1. A 4D-hypercube interconnecting two 3D-hypercubes in the dimension 3

2.1.2 Permutation

A permutation on a nD-hypercube $H^{(n)}$ is a one-to-one correspondence π, denoted (π(u); u = 0, 1, ..., 2^n-1), which associates to each node u of $H^{(n)}$ one and only one node of $H^{(n)}$, $\pi(u) = (\pi_{n-1}(u)\pi_{n-2}(u) \ldots \pi_0(u))$.

2.2 Queueless Routing of permutations

Let π be a permutation on a nD-hypercube network with bidirectional links and a set of 2^n messages of the same size each one located at one node u and destined for the node π(u). Routing π under queueless communication constraints consists in conveying all the messages to their respective destination through a sequence of global and synchronous exchanges of messages between neighbour nodes such that no more than one message is located at each node after each exchange step.

Because the messages have the same size, the complexity of such a routing is of the order of the required number of exchange steps. Therefore an optimal routing is the one with the minimal exchange steps. For an arbitrary permutation it is well known, from e-cube routing [4], that at least n exchange steps are required.

3 Related Works

Optimal routing of permutations on nD-hypercubes is, since a quarter of century, one of the most challenging open problems in the theory of IN. It has so been extensively well studied and several communication models and routing paradigms have been used to that purpose.

In [5] Szimansky considers the offline routing in circuit-switched and packet switched commutation under all-port MIMD communication model. Under the circuit-switched hypothesis he proves that, for n ≤ 3, any hypercube is rearrangeable. He also conjectured that routing can be made on the shortest paths, conjecture for which a counterexample has been given in [6] by Lubiw. Under packet-switched hypothesis he shows that routing can be made in 2n-1 steps. Under the single port MIMD communication model, Zhang in [7] proposes a routing in O(n) steps on a spanning tree of the hypercube. In [8, 9] Hwang et al considered online oblivious routing under buffered all port MIMD communication models. They prove that n steps routing is possible for n ≤ 7 and later for n ≤ 12 if local information are used. The better routings under the models viewed above are due to Vöckling [10]. He proves that deterministic offline routing in buffered all port MIMD model can be done in $n+O(\sqrt{n}\log n)$ steps while online oblivious randomized one can be done in $n+O(n/\log n)$ steps.

For the more restrictive models, that is single-port, queueless, and MIMD communication model, the personal communication of Coperman to Ramras, according to Ramaras, and the works of Ramras [11] constitute certainly the leading ones. Indeed while Coperman gives the computational proof that arbitrary permutations can be routed in 3D-hypercube in 3 steps, Ramras proves that if a permutation can be routed in r steps in rD-hypercube, then for n ≥ r arbitrary permutations on nD-hypercubes can be routed in 2n-r steps. Recently, Laing and Krumme in [12] have introduced an approach which simplifies the problem enough to permit a human verification of the possibility of routing in 3 steps arbitrary permutations on 3D-hypercube and computer verification for the 4 steps routing in 4D-hypercube. We also have addressed the problem with a paradigm similar to Laing and Krumme one that we call k-partitioning. However instead of looking explicitly for a partition into 2^k permutations, we look for a partition into two permutations on two disjoint (n-1)D-hypercubes routable in n-k steps. We proved in [3] that for n ≤ 3, arbitrary permutations which are in the worst, 2-partitionable, case can be routed in n steps.

4 Mathematical Foundations

Formally, the k-partitioning process comes down to the computation of a perfect matching in bipartite graphs. So in this section we first recall some basic notions and results on bipartite graphs.

4.1 Bipartite graphs

A bipartite graph is a triplet $G = (V_1, V_2, E)$ where V_1 and V_2 are disjoint sets of nodes and E, the set of the edges, is the set of the pairs {u, v} of the nodes such that $u \in V_1$, $v \in V_2$ and are connected.

The bipartite graph associated to a nD-hypercube is the one where V_1 and V_2 are two disjoint copies of the nD-hypercube nodes and E is the set of the pairs {u, v} such that {u, v} is an edge of the hypercube or u = v.

4.2 Adjacency matrix

The adjacency matrix of a graph is the matrix M whose rows and columns are indexed by the graph nodes and the components M[u, v] are such that M[u, v] = 1 if {u, v}$\in$ E and M[u, v] = 0 otherwise.

For a nD-hypercube, this matrix is anyone of the n (2x2)-blocks matrices whose extra-diagonal blocks, which express the interconnection of its two (n-1)D-hypercubes, are identity matrices and diagonal blocks are the adjacency matrices of its two (n-1)D-hypercubes. Table 1 illustrates the four adjacency matrices of the 4D-hypercubes. In dimension i the indexes of the rows and the columns of the matrix are the boldfaced numbers of the column and the row numbered i in boldfaced italic font.

Table 1. Adjacency matrices of 4D-hypercubes

4.3 Matching of a bipartite graph

A matching of a bipartite graph G is a one-to-one correspondence Γ which associates to each node u of a subset of V_1 a node Γ(u) of V_2 such that the set of all the pairs {u, Γ (u)} constitute a set of two-by-two non adjacent edges of E.

A matching is maximal if it admits no other edge without violating the non-adjacency rule of its components.

A matching is maximum (resp. perfect) if its cardinality is maximum (resp. $= |V_1| = |V_2|$).

The computation of a maximum matching is one of the main problems in the study of bipartite graphs. The main results about this computation come from the theorem of Berge [13] whose implementations led to several algorithms.

4.4 k-partitionable permutations

Given a permutation π on a nD-hypercube $H^{(n)}$, 1et r be its optimal routing steps and, for x = 0 and $0 \le i \le n-1$, let:

- $S_{x,i}$ (resp. $D_{x,i}$) be the set of the nodes u of $H^{(n)}$ such that $\pi_i(u)$ (resp. u_i) = x; in fact $D_{x,i}$ is the set of the nodes of $H^{(n)}_{x,i}$,
- $G_{x,i,k}$ be the bipartite graph ($S_{x,i}$, $D_{x,i}$, E^k), k = 0, 1, 2, …, r-1 where $\{u, v\} \in E^k$ if and only if there is a path of length less than or equal k, from $u \in S_{x,i}$, to $v \in D_{x,i}$, and a path of length less than or equal r - k from v to π(u),
- $M_{x,i,k}$ be the adjacency matrix of $G_{x,i,k}$,
- $\Gamma_{x,i,k}$ be a maximum matching of $G_{x,i,k}$.

π is said to be k-partitionable, for k < n, in dimension i if there is a permutation $\Gamma = (\Gamma_{0,i,k}, \Gamma_{1,i,k})$ on $H^{(n)}$ such that α (resp. β) which associates π(u) to Γ(u) such that $\Gamma_i(u) = 0$ (resp. 1) is a permutation on the (n-1)D-hypercube $H^{(n)}_{0,\,i}$ (resp. $H^{(n)}_{1,\,i}$). α and β are then qualified of downstream permutations relatively to Γ which is qualified of upstream permutation.

π is said to be k-partitionable if there is a dimension for which it is k-partitionable. Otherwise it is non-k-partitionable.

Some remarkable k-partitionable permutations are the ones such that $S_{x,i} = D_{x,i}$, which are the only to be 0-partitionable, and the ones such that $S_{x,i} \cap D_{x,i} = \varnothing$ which are 1-partitionable. As a consequence, in the sequel we will

consider only permutations on nD-hypercubes with $n \geq 1$ and which are such that

$$S_{x,i} \cap D_{y,i} \neq \emptyset \text{ for } y = 0, 1.$$

5 Characterization Of Non-1-partitionable Permutations

The k-partionability is the guaranty for a permutation to be optimally routed, first in k steps and then in n-k steps as two distinct permutations on two disjoint (n-1)D-hypercubes. In this intention, it is essential to identify the classes of non-1-partitionable permutations. In [3] we proved the following characterization.

Proposition 1. A permutation is non-1-partitionable in dimension i of a hypercube if and only if one of the adjacency matrices $M_{x,i,1}$ contains a null column.

Let v be a node of the hypercube which corresponds to such a column in the dimension i. Then by construction of of the bipartite graph $G_{x,i,1}$, no of its neighbour nodes, u can belong to $S_{x,i}$. In other words, u can be a source node of no message destined for a node of $D_{x,i}$. Indeed, otherwise, for any such u, by definition, $M_{x,i,1}[u, v]$ should be equal to 1. Therefore any neighbour node u of v is a source node for a node of $H^{(n)}_{\underline{x},i}$ and necessarily, $\pi_i(u) = \underline{x}$. Reciprocally if v is a node of the sub-hypercube $H^{(n)}_{x,i}$ such that $\pi_i(u) = \underline{x}$ for any of its neighbour node u, then the column associated to v in $M_{x,i,1}$ is null and necessarily, from the proposition 1, the permutation which induced $M_{x,i,1}$ is non-1-partitionable in dimension i. It follows:

Proposition 2. A necessary and sufficient condition for a permutation π to be non-1-partitionable in dimension i, is that there is at least a node v of $H^{(n)}_{x,i}$ such that for any node u, neighbour of v,

$$\pi_i(u) = \underline{x}.$$

In the sequel, a node v of $H^{(n)}_{x,i}$ whose neighbours u, including itself, are such that $\pi_i(u) = \underline{x}$ will be called a $\underline{x}$-node.

It is obvious that for $n \leq 2$, there is no non-1-partitionable permutation on nD-hypercubes. Indeed if such a permutation, say π, did exist then according to the node labelling induced by Proposition 2, there would be at least two distinct nodes, say u and v such that

$$\pi(u) = \pi(v)$$

which contradicts the definition of a permutation.

Now let's examine how the characterization from the proposition 2 comes in various forms for $n \geq 3$.

Firstly we will consider the case of the permutations on the 3D-hypercubes and then the one of certain classes of the permutations on the 4D-hypercubes.

5.1 Non-1-partitionable permutations on 3D-hypercubes

Let π be a non-1-partitionable permutation on $H^{(3)}$. Then for any dimension i, there is at least a 1-node, say v, of $H^{(3)}_{0,i}$ such that for any node u neighbour of v,

$$\pi_i(u) = \pi_i(v) = 1.$$

As $H^{(3)}$ is constituted of 8 nodes then necessarily, for any other node w,

$$\pi_i(w) = 0.$$

In particular

$$\pi_i(\underline{v}) = \pi_i(\underline{v} \oplus 2^j) = 0 \text{ for } j = 0, 1, 2$$

where $\oplus$ stands for the bitwise XOR and $\underline{v}$ for the opposite of v obtained by complementing each bit v_i. In other words, $\underline{v}$ behaves similarly to v and therefore is a 0-node. They are the only nodes which behave such that. Furthermore for any node u of $H^{(3)}$,

$$\pi_i(\underline{u}) = \underline{\pi_i(u)}.$$

Fig. 2 illustrates such a situation for i = 0 with node 0 as 1-node.

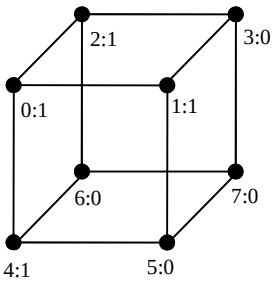

Figure 2. Labelling of the 3D-hypercube nodes according to node 0 as 1-node in dimension 0

Thus, if π is non-1-partitionable on $H^{(3)}$, then for any node u and for any dimension i,

$$\pi_i(\underline{u}) = \underline{\pi_i(u)}.$$

From where

$$\sum_{i=0,2} \pi_i(\underline{u}) * 2^i = \sum_{i=0,2} \underline{\pi_i(u)} * 2^i$$

that is

$$\pi(\underline{u}) = \underline{\pi(u)}.$$

Now let's examine how to choose the x-nodes for each dimension. This is an essential question because any labelling π of the 3D-hypercube such that $\pi(\underline{u}) = \underline{\pi(u)}$ is not a permutation. Indeed, for instance, if the same node is chosen in two different dimensions, then because the neighbour of a node is invariant whatever the dimension,

we obtain 4 nodes whose 2 of the destination addresses bits of the same weight are the same. Consequently whatever the choice for the remaining dimensions the resulting destinations can not lead to a permutation. At least two nodes will have the same destination. Fig. 3 illustrates this case with node 0 as 1-node for both dimensions 0 and 1.

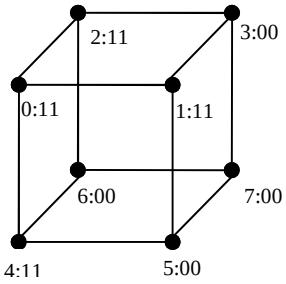

Figure 3. Labelling of the 3D-hypercube nodes according to node 0 as 1-node in both dimensions 0 and 1

So, without loss of generality, we can consider node 0 as the 1-node for the dimension 0. Then, considering the dimension 1, the only choices of 1-nodes are nodes 1, 4 and 5 for which the only choices of 1-nodes for the dimension 2 are respectively 2 and 3, 1 and 2, and 2 and 3; from where the decision tree of Fig. 4 where the numbers of the level dim i stands for the 1-nodes for the dimension i of the hypercube and π^k for the non-1-partitionable permutations classes resulting from each branch.

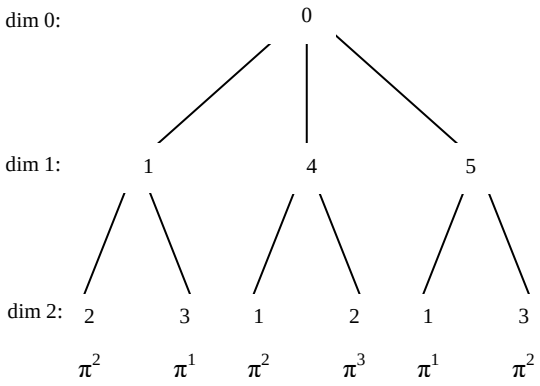

Figure 4. A decision tree for the choice of the 1-nodes in the 3D-hypercube

It can be easily verified that the resulting classes of non-1-partitionable permutations are isomorphic to the following:

$\pi^1 = (3, 7, 5, 6, 1, 2, 0, 4)$,
$\pi^2 = (7, 5, 1, 4, 3, 6, 2, 0)$,
$\pi^3 = (7, 1, 5, 4, 3, 2, 6, 0)$.

Inversely, we can verify that if a permutation is of the class of π^1, π^2 or π^3 then it contains a 1-node for any dimension and then is non-1-partitionable. From where the following proposition:

Proposition 3. A permutation on a 3D-hypercube is non-1-partitionable if and only if it is isomorphic to one of the permutations π^1, π^2, π^3.

5.2 Non-1-partitionable permutations on 4D-hypercubes

Again, let π be a non-1-partitionable permutation on $H^{(4)}$. Then for any dimension i, there is a x-node. On the contrary of $H^{(3)}$, it may exist more than one x-node. Indeed, the labelling of a x-node and its neighbours leaves several alternatives for labelling the remainder nodes. For this reason we have first to determine the maximum number of x-nodes admissible in $H^{(4)}_{\underline{x},i}$ for a given dimension i. Then, in the case of several x-nodes, we have to study the compatibility of all the x-nodes for all the dimensions in the sense that they lead to a permutation and finally to determine the corresponding permutations.

$H^{(4)}_{\underline{x},i}$ admits at most two x-nodes. Indeed the closer the x-nodes are the greater their compatibility is. But the closest three x-nodes are constituted of a sequence of nodes whose binary addresses differ on only one bit which leads to at least 11 destination nodes for 8 available ones. Thus there are two non-1-partitionability models in any dimension: the 1-x-node model and the 2-x-nodes model. In this study we restrict ourselves to the second model. As $H^{(4)}_{\underline{x},i}$ is a 3D-hypercube, three situations may happen according to the distance between the x-nodes: the x-nodes are distant of 1, 2 or 3. Without loss of generality, we can consider the case of the 1-nodes in $H^{(4)}_{0,0}$.

Let node 0 be one of the 1-nodes.

Case 1. The 1-nodes are distant of 1. Let node 2 be the second 1-node. By definition of a 1-node, nodes 0, 2 and all their neighbours, the half of $H^{(4)}$ nodes have to be labelled with 1. Consequently, the other nodes have to be labelled with 0. Fig. 5 illustrates this case.

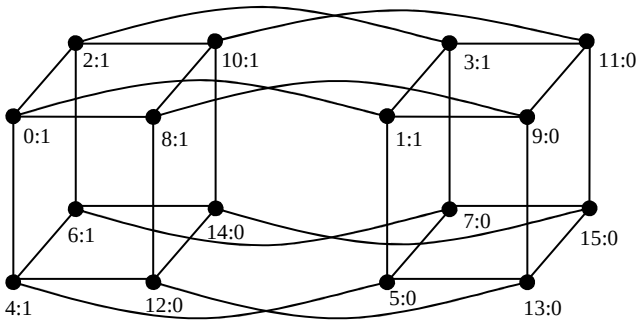

Figure 5. The labelling of $H^{(4)}$ nodes according to the 1-nodes 0 and 2

There is a data flow equilibrium that is a half of the nodes labelled with 1 and the other half with 0. Regarding the queuless constraint, therefore the labelling is consistent. We can observe that the opposites of the 1-nodes in $H^{(4)}$, that is respectively nodes 15 and 13 are 0-nodes. Moreover each x-node in $H^{(4)}$ is a x-node in $H^{(4)}_{x,k}$ where k = 1 is the dimension in which the binary addresses of the x-nodes differ. From the study of 3D-hypercube it comes that in each of the 3D-hypercubes $H^{(4)}_{x,k}$,

$$\pi_i(\underline{u}) = \underline{\pi_i}(\underline{u}).$$

Case 2. The 1-nodes are distant of 2. Let node 10 be the second 1-node. The resulting labelling is illustrated in Fig. 6.

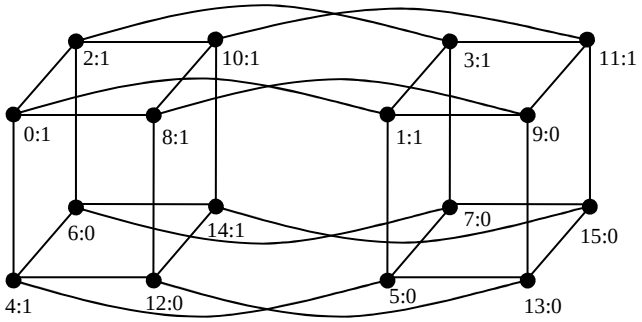

Figure 6. The labelling of $H^{(4)}$ nodes according to the 1-nodes 0 and 10

As previously, the labelling is consistent. We can observe that the nodes 7 and 13 are 0-nodes. Moreover each x-node in $H^{(4)}$ is a x-node in $H^{(4)}_{x,\,k}$ where k=1, 3 is the dimension in which the binary addresses of the x-nodes differ. Again, from the above 3D-hypercubes study, in each of the 3D-hypercubes $H^{(4)}_{x,k}$,

$$\pi_i(\underline{u}) = \underline{\pi_i}(\underline{u}).$$

Case 3. The 1-nodes are distant of 3. Node 0 being one the 1-node in $H^{(4)}_{0,0}$, the only choice for the second 1-node is node 14. The resulting labelling is illustrated in Fig. 7.

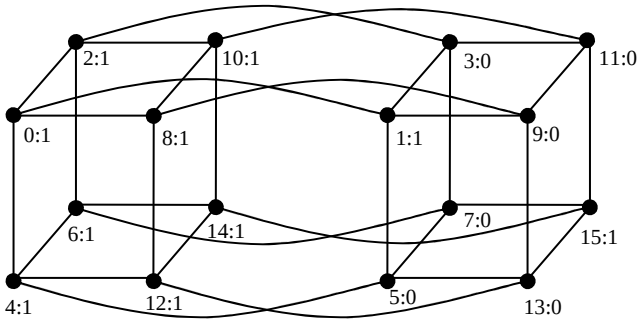

Figure 7. The labelling of $H^{(4)}$ nodes according to the 1-nodes 0 and 14

The labelling is not consistent. There are 10 nodes labelled with 1 against 6 with labelled with 0. This contradicts the fact that π is a permutation on $H^{(4)}$.

This analysis can be summarized by the following proposition.

Proposition 4. If a permutation on $H^{(4)}$ admits two x-nodes in $H^{(4)}_{\underline{x},i}$ then :

a) it also admits two $\underline{x}$-nodes in $H^{(4)}_{x,i}$,
b) both x (resp. $\underline{x}$)-nodes are distant of 1 or 2 in $H^{(4)}_{\underline{x},i}$ (resp. $H^{(4)}_{x,i}$),
c) each x-node remains a x-node in a different $H^{(4)}_{y,k}$ where k is a dimension in which the binary addresses of the x-nodes differ.

In the sequel, we will denote k(i) any dimension k such that each of the two x-nodes for the dimension i remains a x-node in a different 3D-hypercube $H^{(4)}_{y,k}$.

Now we have to study how these two consistent models of non-1-partitionability self combine then how they mingle in the different dimensions of the 4D-hypercubes to lead to a permutation. In this aim, it should be firstly noticed that, similarly to the 3D-hypercubes case and for the same reason, an admissible x-node can not be a x-node in two different dimensions.

First case, suppose that for each dimension the two x-nodes are distant of 1. Then necessarily $k((i) \neq k(j)$ for any $i \neq j$. It can indeed be proved that if, on contrary $k((i) = k(j)$ then in the two remainder dimensions, say r and s, $k((r) = k(s)$. To that purpose, without loss of generality, it suffices to consider that i = 0, j = 1 and that in the dimension 0 the two 1-nodes are the nodes 0 and 2. The decision tree of the remainder 1-nodes choice is illustrated in Fig. 8 where the triplet (u, v):k of the level dim i stands for the two 1-nodes, u and v for the dimension i of the hypercube and k the dimension in which their binary addresses differ.

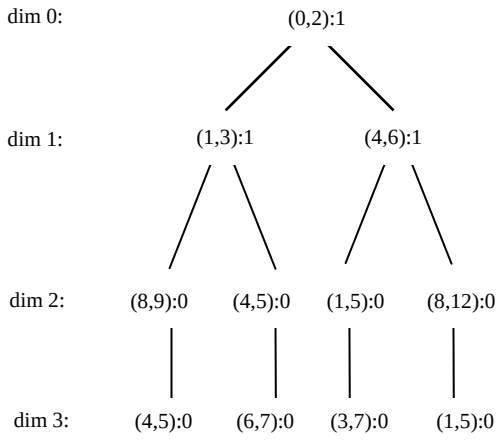

Figure 8. A decision tree of the choice of two 1-nodes distant of 1 in each dimension of the 4D-hypercube

It can be easily verified that no branch of this tree lead to a permutation.

Second case, suppose that for each dimension the two x-nodes are distant of 2. Without loss of generality, let nodes 0 and 10 be the 1-nodes for the dimension 0. Then, in the decision tree of the remainder 1-nodes choice, the only consistent 1-nodes for the dimension 1 are on one side (1,4) which lead to 10 as x-node for a different dimension and on the other side (4, 8) which in turn lead to (1, 2) which lead to 15, the corresponding 0-node of 0 according to Proposition 4, as x-node for a different dimension. In other words, there is no permutation on 4D-hypercube such that there are two x-nodes distant of 2 in each dimension.

Third and last case, suppose that there are two x-nodes distant of 1 for a dimension and two other distant of 2 for a different dimension. Again without loss of generality let 0 and 2 be the 1-nodes for the dimension 0. It can be easily verified that for dimension 1 whatever the x-nodes distant of 2, they lead to a x-node considered for the dimension 0 that is on one side the node 15 as the corresponding 0-node of the 1-node 0 according to Proposition 4 and on the other side the node 2. In other words the x-nodes distant of 1 and the ones distant of 2 can not mingle.

We can conclude this discussion by the fact that the only configurations which could lead to a permutation with two x-nodes in each dimension are the ones with two x-nodes distant of 1 and such that $k(i) \neq k(j)$ for $i \neq j$ for each dimension.

So, let's consider the decision tree of the x-nodes based on these choice criteria. It can then be easily verified that this decision tree leads to permutations which are isomorphic to the following:

π^4 = (3, 11, 13, 15, 1, 10, 9, 8, 7, 6, 5, 14, 0, 2, 4, 12)
π^5 = (7, 15, 9, 13, 3, 14, 11, 10, 5, 4, 1, 12, 2, 6, 0, 8).

The above analysis can then be summarized in the following proposition.

Proposition 6. If a permutation on $H^{(4)}$ admits two x-nodes in each dimension, these x-nodes are distant of 1 and the permutation is isomorphic to π^4 or π^5.

6 Conclusion And Perspectives

This paper has addressed the problem of the characterization of the non-1-partitionable permutations on nD-hypercubes with $n \leq 4$ which is at the heart of the problem of the rearrangeability of the hypercube interconnection networks that is the capability of such networks to realize any permutation without conflict. Non-1-partitionable permutations are the residual permutations which can not be optimally routed under the queueless constraint by the k-partitioning paradigm. So the understanding of their structure is an essential step towards the understanding of how to route them optimally.

We gave a new characterization of the non-1-partitionable permutations which allowed inferring straightforwardly the impossibility of the existence of non-1-partitionable permutations on nD-hypercubes with $n \leq 2$. It also led to easier construction of instances of such permutations on 3D-hypercubes and, to our knowledge for the first time, allows building some classes, the ones with two x-nodes, of non-1-partitionable permutations on 4D-hypercubes without computer simulation.

Our future work will consist in completing this study. It will extend the considered non-1-partitionability models to the 1-x-node ones. Then, beyond the study of how these models self-combine to produce permutations, it will concern the study of how these models mingle consistently with the 2-x-nodes non-1-partitionability models.

Abstract - *In this paper, a performance analysis of a matrix diagonalization algorithm with Jacobi method on a multicore architecture is presented. For this, a block-based sequential algorithm was implemented using the CBLAS library, which improves classic sequential algorithms, and then an algorithm for the parallel resolution of the problem with the shared memory programming tool OpenMP is studied. Next, the experimental work is shown and an improvement in response time is observed as more threads/cores are used. Finally, a performance analysis (Speedup and efficiency) as the dimensions of the input matrix and the number of threads/ cores used increase is presented.*

Keywords: multicore architecture, parallel programming, matrix diagonalization, Jacobi, OpenMP.

1 Introduction

The demand for computational power by a large number of scientific applications has increased so much that the use of parallel platforms for their resolution has become essential. Even though *single-core* cluster architectures have become usual due to their cost/performance ratio versus large shared-memory multiprocessor systems, nowadays machines with more than one processor are quite common.

Multicore architectures appear as a response to the limitations for increasing speed in *single-core* processors due to thermal and energy issues. A multicore processor integrates 2 or more cores in a single chip, which means that applications have to be adapted to be able to exploit the parallelism at a thread level provided by this architecture [1]. Similarly, several multicore machines can be connected through a network, which opens the possibility of having clusters with a large number of processors.

The Jacobi method to diagonalize symmetric matrixes has applications in fields such as biometrics, artificial vision, digital signal processing, and so on [2][3][4]. As the volume of input data increases, the computation time required increases significantly. The combination of linear algebra libraries optimized for the underlying architecture, together with the power provided by a multicore, and a suitable parallel programming tool for such architecture, will allow reducing execution time.

Two of the main performance analysis aspects in a parallel system are the *Speedup factor* (*Sp*) [5][6] and the *Efficiency* (*E*) that relates the Speedup with the number of processors (*P*) used [7].

Scalability is a third, very significant factor in parallel applications: problems usually "scale", i.e., the volume of work to be done increases, and the architectures used can also "scale" by increasing the number of processors used. The effect of scaling workload and/or processors on the performance of parallel algorithms, considering *Sp* and *E*, is of interest. A system is said to be scalable if it can maintain a constant efficiency with increasing work and processors [5][8].

The purpose of this work is to implement a parallel algorithm to diagonalize matrixes with Jacobi method, using the shared-memory programming tool OpenMP [9] and the Linear Algebra CBLAS library [10] in order to exploit the computation power of a multicore machine.

Lastly, experimental tests are presented and an analysis of the performance obtained as the size of the matrix and the number of cores scale, is carried out.

This paper is organized as follows: Section 2 includes a description of Jacobi method for real symmetric matrixes; Section 3 presents various implementations of the classic sequential algorithm, two implementations of the block-based algorithm (one using the CBLAS library), and proposes the parallelization of the block-based algorithm using OpenMP; Section 4 includes a comparative analysis of the execution times for the various sequential implementations with matrixes of different sizes, concluding that the block-based algorithm that uses CBLAS performs better, and it presents experimental evidence and an analysis of the performance (speedup, efficiency) obtained with the parallel algorithm as the input matrix size and the number of threads/cores used are increased.

2 Description of Jacobi Diagonalization Method

The problem of diagonalizing a symmetric square matrix S consists in finding an orthogonal matrix X that causes S to be

reduced to the diagonal form. Jacobi method allows finding a matrix X such that: $X^T*S*X = D$.

The elements in the diagonal of matrix D are called eigenvalues of S, and the columns of matrix X are the eigenvectors of S.

2.1. Specific Case: Diagonalization of a 2x2 Symmetric Matrix

If S is a 2x2 symmetric matrix (Fig. 1.a), it can be diagonalized by means of the orthogonal matrix X that is shown in Fig. 1.b. This matrix is known as *rotation matrix*.

$$S = \begin{pmatrix} s_{11} & s_{12} \\ s_{21} & s_{22} \end{pmatrix} \qquad X = \begin{pmatrix} \cos\alpha & \sin\alpha \\ -\sin\alpha & \cos\alpha \end{pmatrix}$$

a **b**

Fig. 1. a) 2x2 symmetric matrix *S*. **b)** Orthogonal matrix *X*

Since the purpose of the method is obtaining *D*, the values of cosine α and sine α must be such that the elements outside the diagonal of *D* are cancelled out. These values are calculated as shown in Fig. 2.

$$\cos\alpha = \sqrt{\frac{1}{1+\tan^2\alpha}} \qquad \sin\alpha = \cos\alpha\tan\alpha$$

$$\tan\alpha = \frac{sign(\theta)}{|\theta|+\sqrt{1+\theta^2}} \qquad \theta = \frac{s_{22}-s_{11}}{2s_{12}}$$

Fig. 2. Calculation of the values sinα and cosα

2.2 General Case: Diagonalization of an nxn Symmetric Matrix

The general method [11] keeps a matrix X initialized as the identity matrix, where the eigenvectors of S will remain, and in each stage performs a series of rotations that update S and X until the maximum element in the upper triangle of S is lower than a selected threshold.

In each stage, for each element $S_{p,q}$ in the upper triangle, a rotation that cancels out such element is performed. The rotation matrix J (Fig. 3) will have the values cosine α, sine α, -sine α and cosine α at positions $J_{p,p}$, $J_{p,q}$, $J_{q,p}$, and $J_{q,q}$, respectively; it will also have a value of 1 on its diagonal, and 0 on all remaining elements.

The steps to follow for each rotation are:

1. Calculate the elements $S_{p,p}$ and $S_{q,q}$ as follows
   $\mathbf{S_{p,p}} = S'_{p,p} * \cos^2\alpha - 2*S'_{p,q}*\sin\alpha*\cos\alpha + S'_{q,q} * \sin^2\alpha$
   $\mathbf{S_{q,q}} = S'_{p,p} * \sin^2\alpha + 2 *S'_{p,q} *\sin\alpha*\cos\alpha + S'_{q,q} *\cos^2\alpha$
   Notice that $S'_{p,p}$, $S'_{p,q}$ and $S'_{q,q}$ are the values in S before this step. This notation will be used from here on.
2. Cancel out $S_{p,q}$ and $S_{q,p}$.
3. Replace the value in matrix S with the result obtained with the operation J^T*S*J (omitting the positions updated in previous steps).
4. Replace the value in matrix X with the result obtained with the operation X*J.

$$J = \begin{pmatrix} 1 & \cdots & 0 & \cdots & 0 & \cdots & 0 \\ \vdots & \ddots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & \cdots & \cos\alpha & \cdots & \sin\alpha & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & \cdots & -\sin\alpha & \cdots & \cos\alpha & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & 0 & \cdots & 0 & \cdots & 1 \end{pmatrix}$$

Fig. 3. Rotation matrix J for the general diagonalization case.

Thus, matrixes J_i^T and J_i will be multiplied by S until reaching the diagonal form. Matrix X is the result of the product of the J_i matrixes, and X^T is the result of multiplying the J_i^T matrixes (Fig. 4).

$$\ldots J_3^T [J_2^T [J_1^T \, S \, J_1] J_2] J_3 \ldots = D$$

$$\underbrace{(\cdots J_3^T \; J_2^T \; J_1^T)}_{X^T} S \underbrace{(J_1 \; J_2 \; J_3 \cdots)}_{X} = D$$

Fig. 4. Multiplication of S and the rotation matrixes to obtain the diagonal matrix.

3 Implementations of the Algorithm for Jacobi Diagonalization Method

3.1. Classic Sequential Algorithm:

The algorithm to solve the diagonalization problem does not need to have matrix J stored. The updates carried out in S and X during steps 3 and 4 of the method described in Section 2.2 are replaced by the following operations:

$\mathbf{S_{i,p}} = \mathbf{S_{p,i}} = S'_{i,p*}\cos\alpha - S'_{i,q*}\sin\alpha$ for i=1..n, $i \neq p$, $i \neq q$
$\mathbf{S_{i,q}} = \mathbf{S_{q,i}} = S'_{i,q*}\cos\alpha + S'_{i,p*}\sin\alpha$ for i=1..n, $i \neq p$, $i \neq q$
$\mathbf{X_{i,p}} = X'_{i,p} *\cos\alpha - X'_{i,q}*\sin\alpha$ for i=1..n
$\mathbf{X_{i,q}} = X'_{i,q} *\cos\alpha + X'_{i,p}*\sin\alpha$ for i=1..n

That is, during step 3, rows p and q and columns p and q in matrix S are updated; while during step 4, columns p and q in matrix X are updated.

Two optimizations can be carried out in relation to the storage of matrixes S and X in memory:

- Since S is a symmetric matrix, it is possible to store only n*(n+1)/2 elements, n being the row and columns dimension of S, which allows avoiding unnecessary operations due to symmetry.
- Since access to X is always through its columns, if the elements are stored in memory in column-major order, a better performance will be obtained. This is because every time the memory is accessed to look for an element in X, a block of elements that will be used in the short term is moved to cache memory. This is known as optimization by spatial locality.

3.2 Block-Based Sequential Algorithm:

The development of new architectures requires the implementation of new techniques so that algorithms adapt to the underlying platform and thus obtain a better performance. The classic sequential algorithm described in Section 3.1 can be adapted to use linear algebra optimized libraries.

In order to use the matrix operations available in the Level 3 CBLAS library, a sequential algorithm was implemented for the diagonalization of matrixes using the block-based Jacobi method, which will be the basis for the parallel algorithm; for this reason, the matrix S is stored in full.

This algorithm considers that the dimension of matrix S is n = N*r (Fig. 5), where N is the number of blocks in each dimension, and r is the dimension of each block. This algorithm is similar to the classic one. Each element $S_{P,Q}$, with P,Q=0..N-1, will denote a block. Within the block, the elements will be referenced with indexes (p,q), where p,q = 0..r-1. [12]

$$S = \begin{pmatrix} S_{11} & \cdots & S_{1N} \\ \vdots & \ddots & \vdots \\ S_{N1} & \cdots & S_{NN} \end{pmatrix}$$

Fig. 5. Matrix S, whose dimension is n=N*r.

The method keeps a matrix X initialized as the identity matrix, organized by blocks the same as S, where the eigenvectors of S will remain. Each stage of the algorithm performs a series of rotations that update S and X, until the maximum element in the upper triangle of S is lower than a threshold previously selected.

The operations in any given stage consist in cancelling out each block $S_{P,Q}$ in the upper block triangle in S. The steps to follow for each rotation are:

1. Calculate Jacobi with the classic method over the 2x2-block matrix formed by $S_{P,P}$, $S_{P,Q}$, $S_{Q,P}$ and $S_{Q,Q}$. The eigenvectors will be in a 2x2-block matrix called *auxX*.
2. Calculate the transposition of auxX, *transpX*.
3. Apply rotations to matrix S
   a. $S_{I,P} = S'_{I,P} * auxX_{0,0} + S'_{I,Q} * auxX_{1,0}$ for I=0..N, I ≠P≠Q
   b. $S_{I,Q} = S'_{I,P} * auxX_{0,1} + S'_{I,Q} * auxX_{1,1}$ for I=0..N, I ≠P≠Q
   c. $S_{P,I} = transp_{0,0} * S'_{P,I} + transp_{0,1} * S'_{Q,I}$ for I=0..N, I≠P≠Q
   d. $S_{Q,I} = transp_{1,0} * S'_{P,I} + transp_{1,1} * S'_{Q,I}$ for I=0..N, I≠P≠Q
4. Apply rotations to matrix X
   a. $X_{I,P} = X'_{I,P} * auxX_{0,0} + X'_{I,Q} * auxX_{1,0}$ for I=0..N
   b. $X_{I,Q} = X'_{I,P} * auxX_{0,1} + X'_{I,Q} * auxX_{1,1}$ for I=0..N

3.2.1 Implementation with CBLAS.

In the block-based algorithm, the updates to matrixes S and X (steps 3.a, 3.b, 3.c, 3.d, 4.a, and 4.b) involve a sequence of algebraic operations over rxr-sized blocks or matrixes, and copies of blocks to keep auxiliary data that are not carried out in the classic algorithm. The use of the existing linear algebra libraries allows performing matrix operations (Level 3 CBLAS), achieving the best performance for a given architecture. [10]

The function cblas_dgemm was used to reduce block multiplication and addition processing time, and cblas_dcopy was used to optimize block copying.

3.3. Block-Based Parallel Algorithm with CBLAS:

From Section 3.2, it can be observed that a rotation carried out to cancel out an element $S_{P,Q}$ will update rows and columns with index P and Q in S, and columns P and Q in X. Also, if we have two coordinate pairs (P,Q) and (P',Q'), with P≠Q≠P'≠Q', $J_{P,Q} * J_{P',Q'} = J_{P',Q'} * J_{P,Q}$. Based on these two premises, it is concluded that two or more positions can be canceled out in parallel, provided that their indexes are disjoint [13][14].

The parallelization strategy consists in carrying out the rotations simultaneously in each algorithm stage. The number of parallel tasks to be run in each stage is N/2, since their coordinates must be different, and their indexes will be calculated following the *Chess Tournament* strategy [15]. If there are more tasks than threads, they will be equally distributed.

A task whose coordinate is (P,Q) consists in calculating the eigenvectors and eigenvalues of the 2x2-block submatrix formed by $S_{P,P}$, $S_{P,Q}$, $S_{Q,P}$, $S_{Q,Q}$ with the classic sequential algorithm, independently. Then, matrixes S and X are updated as follows:

- Rotations in S: since there may be several threads in this update stage, they must wait before starting (barrier synchronization); then, each of their columns will be updated (since each thread has coordinates whose indexes are disjoint). Then, after a second barrier synchronization stage, the rows in S are updated. The first synchronization prevents a clash between delayed threads currently updating rows in S and other threads that are about to

update the columns corresponding to the next tasks. The second synchronization prevents conflicts in case one thread is modifying its columns and another thread is updating its rows.
- Rotations in X: these rotations modify only the columns and, since all tasks have different coordinates, they can be done in parallel.

After carrying out these rotations, the threads can move on to complete their following task, and so forth until the current stage is finished. Next, the maximum of the upper triangle of matrix S is calculated in parallel, and then one of the threads calculates the set of indexes for the parallel tasks in the next stage (following the *Chess Tournament* strategy). This last step must be done sequentially because of data dependencies.

For the following step, each thread independently verifies the termination condition, from the maximum value of S obtained before, and, based on the result obtained, the algorithm is ended or a new stage is started.

3.3.1 Implementation with OpenMP.

OpenMP [9] is an API for the C, C++ and Fortran languages that allows writing and running parallel programs using shared memory and offers the possibility of creating a set of threads that work concurrently to exploit the advantages of multicore architectures.

The implementation of the parallel algorithm to solve Jacobi method with OpenMP loads the input matrix S and sequentially initializes matrix X.

Next, a set of threads is created, as many as cores are available in the multicore architecture, and they initialize in parallel the structure with the indexes of the tasks to be run in the first stage.

In each stage of the algorithm, each thread will take a consecutive set of parallel task indexes and will follow the steps described in Section 3.3. When all the tasks in a stage have been executed, the threads calculate in parallel the maximum of the upper triangle in S by applying a reduction operation. Then, one of them updates the set of parallel task indexes for the next stage, following the *Chess Tournament* strategy.

4 Results

Tests were carried out in a machine with two Intel Quad Core Xeon E5405, 2.0Ghz processors. Each core has a 32-Kb L1 cache for data and a 32-Kb cache for instructions. Each pair of cores shares a 6-Mb L2 cache. Available memory is 10Gb RAM.

All times were measured with the function omp_get_wtime from the omp.h library. The tests that are compared in Sections 4.1, 4.2 and 4.3 were carried out over matrixes with identical data and identical precision (0.0001), since convergence times depend on the input data and the precision selected. The same is valid for Section 4.4, which assesses the scalability of the parallel algorithm.

4.1. Classic Sequential Algorithm

Four versions with different methods for storing matrix S and matrix X were implemented:

- Version 1: it stores the entire S by rows and X by rows
- Version 2: it stores the entire S by rows and X by columns. Optimization by spatial locality in X.
- Version 3: it stores only the upper triangle for S, and it stores X by rows. Storage optimization for S and lower number of operations by symmetry.
- Version 4: it stores only the upper triangle for S, and it stores X by columns.

Table 1 shows the execution times for each of the versions of the classic algorithm, and matrixes with n=100,200,300,400,500,600,700,800,900,1000. Versions 2 and 3 improve times compared to version 1, the optimization implemented for version 3 being the one with the greatest impact. For this reason, when both optimizations are incorporated in version 4, execution times are reduced even more.

Table 1. Sequential algorithm times with classic Jacobi for various optimizations.

Dimension / Version	Version 1	Version 2	Version 3	Version 4
100	0.21	0.2	0.18	0.18
200	2.1	1.92	1.78	1.62
300	7.56	6.77	6.17	5.54
400	20.51	18.58	17.37	14.97
500	40.8	36.72	34.7	29.57
600	72.4	64.44	60.7	52.4
700	120.7	104.34	98.56	84.2
800	187.3	159.41	151.9	127.4
900	307.03	258.07	250.8	205
1000	387.52	323.5	318.5	256.42

4.2 Block-Based Sequential Algorithm

For the tests with block-based sequential algorithms, the same matrixes from Section 4.1 were used, but their data were organized in consecutive blocks whose possible size will depend on the size of the matrix.

4.2.1 Block-Based Sequential Algorithm (without CBLAS)

The block-based algorithm that does not use CBLAS did not improve the times obtained by the classic algorithm version 4. As the tests included in Table 2 show, the best

response time is obtained with the maximum possible block size. In those cases, the block-based algorithm behaves very similar to the classic algorithm, since it carries out only one stage to obtain the eigenvalues and eigenvectors of the 2x2-block matrix formed by $S_{0,0}$, $S_{0,1}$, $S_{1,0}$ and $S_{1,1}$ applying the classic algorithm, obtaining in this way the eigenvalues and eigenvectors of the entire matrix.

The reason for which the block-based algorithm without CBLAS did not improve response times is due to the extra time used to multiply and copy blocks, and as block size decreases, a larger number of these operations is required.

4.2.2 Block-Based Sequential Algorithm with CBlas

The block-based sequential algorithm that uses the CBLAS library improved the response times of the sequential algorithms assessed in the previous sections. In most of the cases, the best time was obtained with a block size of 10, as shown in Table 3.

To analyze the cause of this improvement, the number of stages carried out by the block-based algorithm in its two versions and the average time needed to perform a rotation were calculated. These tests were done for the matrix of size 1000 with block size 10 and 500.

Both algorithms performed an only stage for block size 500, and 10 stages when using the block size 10. This proves that, when block size is reduced, the algorithm will need more iterations to converge. However, the average time needed for each rotation is different. Taking into account that in each stage, N*(N+1)/2 rotations are done, it is observed that:

- In the case of the block-based algorithm without CBLAS, the average rotation time for the matrix with block-size 10 is 0.011183. The number of rotations in each stage is 5050. Therefore, each stage will take approximately 56.4 seconds, which explains the time measured during the test. On the other hand, the average rotation time for the matrix with block-size 500 is 386.74. This time is similar to the final time obtained, and also to the time obtained with the classic algorithm (version 1). This is because there is only one stage and a single rotation.

- In the case of the block-based algorithm with CBLAS, when using block-size 10, the average rotation time is 0.00229; since there are 5050 rotations in each stage, each will take approximately 11.56 seconds, which explains the time measured during the test. When using block- size 500, the iteration time was 370.81.

The improvement achieved with the block-based algorithm that uses CBlas is due to the use of the functions cblas_dgemm and cblas_dcopy when calculating rotations.

The size of the block that optimizes times must be such that calculating the classic Jacobi for a 2x2-block matrix is not so expensive, since times that are similar to those of version 1 of the classic algorithm will be obtained. The exact ratio must be found, since very small blocks will reduce the average rotation time but will increase the number of rotations. For example: for the block-based algorithm with CBLAS, the average rotation time for the test with the matrix of size 1000 and block-size 5 is 0.001209. The algorithm carried out 10 stages and 20100 rotations in each stage. Each stage in average lasted 24.3 seconds, which ended up in an increase in time.

Table 2. Times obtained with the block-based sequential algorithm without CBLAS.

Dimension / Block Size	**100**	**200**	**300**	**400**	**500**	**600**	**700**	**800**	**900**	**1000**

1024				12963.09		

4.4 Block-Based Parallel Algorithm with CBLAS

Since the scalability analysis was carried out with 2, 4, and 8 threads/cores, matrixes whose size is power of 2 were used, so that the tasks were proportionally distributed among the threads.

Table 4 shows the execution times of the block-based sequential algorithm that uses CBLAS for those matrixes, varying the size of the blocks within the possible values. The test that optimized the execution time for each matrix size is highlighted. Table 5 shows the speedup (*Sp*= Sequential Time / Parallel Time) and the efficiency obtained (*E*= *Sp* / Number of processors) in the parallel tests.

These results show that, if matrix size is kept the same and the number of processors is increased, the speedup obtained is better, that is, the problem is solved in less time. This improvement, however, does not keep a constant efficiency. The decrease in efficiency is due to the overhead of thread creation, synchronization (barriers), and the sequential portion of the problem (the structure with indexes of parallel tasks must be updated in each stage following a *Chess Tournament* strategy in a sequential manner).

When scaling the problem and keeping the same number of processors, as shown in Table 5 and Fig. 6, both speedup and efficiency improve in general, since the overhead mentioned above is less significant in the total processing time.

Table 5. Speedup and Efficiency values as matrix size and threads/cores are increased.

	Speedup			Efficiency		
Dimension (r) / Parallel Tasks	**2**	**4**	**8**	**2**	**4**	**8**
256(8) – 16	1.65	2.91	5.08	0.82	0.73	0.63
512(8) – 32	1.62	2.80	4.91	0.81	0.70	0.61
1024(16) – 32	1.88	3.27	6.30	0.94	0.82	0.79
2048(16) – 64	2.00	3.68	6.65	1.00	0.92	0.83
4096(16) – 128	1.98	3.82	7.07	0.99	0.96	0.88
8192(64) – 64	1.92	3.72	7.07	0.96	0.93	0.88

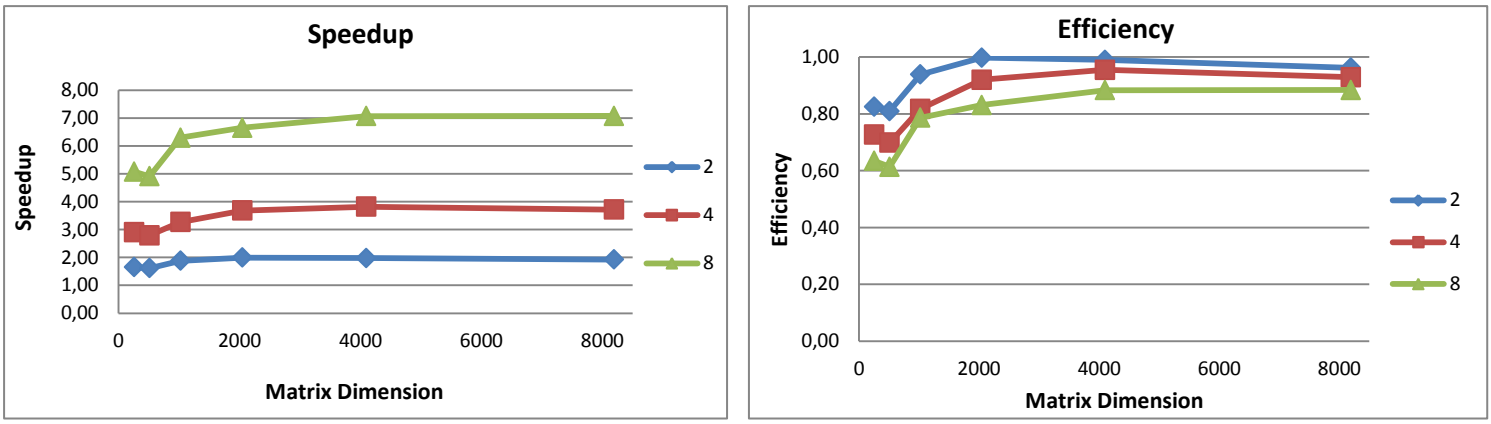

Fig. 6. a) Speedup as matrix size and the number of threads/cores are increased **b)** Efficiency as matrix size and the number of threads/cores are increased.

The behavior described is typical of a scalable parallel system, where efficiency can be maintained at a constant value by simultaneously increasing the number of cores/processors and the size of the problem.

5 Conclusions and Future Work

Various sequential algorithms for the resolution of the matrix diagonalization problem were presented and one parallel implementation that exploits the power offered by multicore architectures was introduced.

The resulting execution times were analyzed for each implementation, and it was observed that the best performance corresponds to the algorithms that use libraries optimized for linear algebra (CBLAS Level 3). It was also observed that performance improves when the algorithm is parallelized on a multicore architecture.

In recent years, GPUs (Graphic Processing Unit) [16] have gained significance due to the high performance achieved in general-purpose applications. One of the future lines of work is based on the migration of Jacobi diagonalization algorithm to be run on GPU, and then systematically study the performance achieved as the size of the problem and the number of threads are increased. Also, an energy consumption analysis for the execution of this parallel algorithm on various multicore architectures is proposed [17].

***Abstract*— For byte memory addressing, we propose using a Memory Area Network for the purpose of multiple processor access to unlimited byte addressed solid state memory on a local, or perhaps a wide area network. We categorize various shared memory computing architectures. We then introduce iPCI to provide the networking and IO virtualization method for shared memory computing. A novel PCI-e switch on a chip with multiple Terabit per second throughput is described. Applications of this shared memory computing approach are explored.**

Keywords- Virtual Shared Memory; IO Virtualization; Memory Area Network; Terabit Switching; Memory Allocation

I. INTRODUCTION TO SHARED MEMORY COMPUTING AND MEMORY AREA NETWORKS

High Performance Computing (HPC) has undergone significant changes, from initial focus of the 1980s of supercomputing based either on ultrafast or massively parallel computing, to network/grid computing of the 1990s based on broadband Internet, to data-centric computing of the 2000s based on data mining methodologies. In recent years, a new paradigm of cloud computing has dominated both computer science research and the information technology industry.

The key technological foundation of cloud computing is virtualization of physical resources in the cloud, including servers, desktop computers, data storage, computer memory, computer IO [1], data networks, and application software. A focus of our research is on memory virtualization in the cloud [2], in short cloud memory, which we believe to be significant for scientific computing in a paradigm called shared memory computing or memory area networks (MeMAN).

Virtual memory has been a foundation of computer engineering from the early days when operating systems were developed around the management of computer memory. Hypervisors, essentially cloud based operating systems, can allow byte address memory space anywhere in the cloud to be allocated to physical machines (PM), virtual machines (VM), or application software compiled and executed anywhere in the cloud.

The intellectual framework of cloud memory is the deconstruction of the physical computer and associated operating system, so that the cloud now comprises a wide area memory network shared and addressed globally for purposes such as data mining. Data-structures then become global, byte-addressed by any program or user in the cloud. This paradigm is sometimes referred to as shared memory computing (SMC). SMC is an HPC method, a competitor to methods of massively parallel computing (MPC) based on message passing among processors.

SMC has its limitation due to latency and throughput impairments in the cloud. Network protocols, such as the Internet Protocol (IP) are unreliable and slow, and therefore fail to meet the nanosecond requirements of computer memory read and write. Cloud memory faces a similar problem that was encountered by data storage, such as NFS, SAN (storage area network), and iSCSI (internet SCSI), only the response time is orders of magnitude faster (tens of nanoseconds instead of tens of microseconds for SAN).

Therefore significant research is needed to first classify types of cloud memory and second to invent high performance cloud memory, a focus of our research.

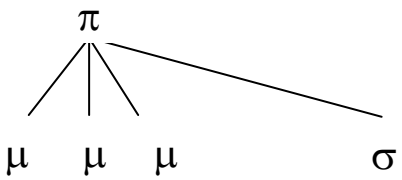
II. CLASSIFICATON AND USE OF SHARED MEMORY COMPUTING

Classification of Memory Sharing

Various classification of memory sharing is proposed here from the simplest to the most general and powerful. Using Greek nomenclatures, processors are represented as π, memory as μ, storage as σ, and bridges/switches as β.

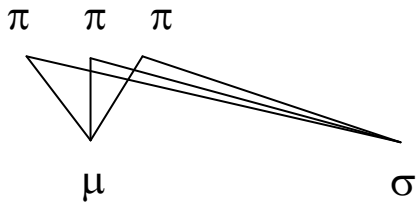
One-to-Many Access

In the simplest form, we have one processor that is directly attached to a multiplicity of memory banks, achieving a scaling of memory capacity for a single powerful processor as shown below. In storage technology, this is analogous to direct attached storage (DAS).



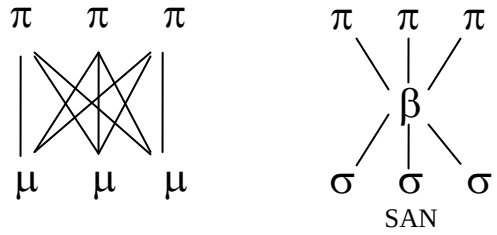
Many-to-One Sharing

Multiple processors share a large memory for the purpose of effective allocation of memory on demand as shown following. This is analogous to the concept of network attached storage (NAS) such as used for network file servers (NFS) accessing a shared data store. However, access to the memory can only be one file or block at a time by servers.



Many-to-Many Sharing

In this more general scheme, multiple processors can access multiple memory banks simultaneously as shown in the left figure in the following. This is analogous to the concept of storage area network (SAN), in which multiple storage servers can serve data retrieval requests on the Internet, while these servers can access simultaneously multiple storage banks through a dedicated switching fabric of a SAN as shown in right figure in the following. Performance is high because of dedicated hardware based protocol processing, such as the use of the Fiber Channel (FC) protocol.



SAN

Exclusive versus Shared Memory Allocation

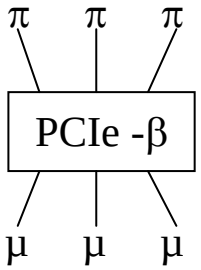
In the above discussions, it is assumed that PM or VM uses memory location exclusively. This is the traditional role of an operating system allocating memory to devices. At the software or program level, a compiler can allocate memory (e.g. the malloc procedure call in C) that can be shared by different procedures or objects in programs. The allocation of memory in this case is facilitated by a compiler prior to further allocation by the operating system. Memory locking mechanisms such as semaphores may be required to ensure memory consistency in conflicting memory access. Examples of research on shared memory computing are shown in references [6-14]

Protocol Adaptation

Virtual memory allocation in the cloud requires IO virtualization, also in the cloud. This is analogous to virtual storage allocation by the iSCSI protocol, whereby the physical SCSI bus for disk drives is extended by the Internet (hence the term Internet SCSI). In the case of cloud or networked virtual memory, the prevailing memory access IO mechanism nowadays is the PCIe (Peripheral Computer Interface) bus. In our previous patented research efforts, we invented various techniques to extend the PCIe bus, for example via wireless networking, via Ethernet switching, via optical networks, and most extensively via the Internet. The choice of protocol for which PCIe adapts to depends on the geographic extent of the cloud, as well as the latency and throughput requirements for cloud memory.

Memory Switching

Many-to-many cloud memory requires a memory switch amongst processors and memories. The memory switch allows highly parallel access of memory banks by processors. Since memory banks and processors can be extensively connected by PCIe bridges, our research focuses on building large PCIe bridges. In previous patented research, we have invented a Terabit switch on a chip with no queuing delay [3, 4, 5]. We are extending the research into memory switching applications. The memory area network (MeMAN) [2] architecture is shown in the following figure.



MeMAN
(Memory Area Network)

III. VIRTUALIZATION OF PCI-E AS A FORM OF SMC

PCI Express (PCI-e) has the ability to be virtualized using the PCI Express relay over an Ethernet channel that uses MAC addresses and Ethernet switches. PCI Express supports the following transaction types: memory, I/O, and data configurations. The virtualization can be implemented by using a native PCI Express host bus adapter on a computer and a scalable network (preferably 1-10 Gbps or higher). In terms of shared memory computing (SMC), the PCI Express architecture is ideal due to the large density of computers and storage.

The PCI Express can be broken down into three separate layers: transaction layer, data link layer, and physical layer. The transaction layer deals with application data. In PCI-e virtualization, the transaction layer can be virtualized through

packet based protocols known as TLPs (Transaction Layer Packets) [23]. A header can be added to the TLP which creates the exchange of protocol specific configuration and synchronization information between the host bus adapter (HBA) and the remote bus adapter (RBA). The resulting PCI-e transaction layer packet is then encapsulated within an Ethernet frame [22].

The data link layer's primary function is to handle the communication protocols of acknowledge (ACK) and negative acknowledge (NAK) supplied from the transaction layer [23]. The data link layer can be translated into an Ethernet implementation of the protocol data units known as DLLPs (Data Link Layer Packets). When data transactions are being processed over an Ethernet switched network, the transaction layer packets are verified for data integrity by the data link layer logic of the receiving end. The proprietary receiving port responds with a either an ACK or NAK, which is then passed to the PCI-e protocol logic. After, a MAC address is then generated that corresponds to the source. The MAC address is parsed with the protocol data to the MAC core. Data integrity is ensured for DLLPs by using a cyclical redundancy check (CRC). A CRC is included with each packet sent across the link [22]. The following are the two plausible cases:

Case 1: ACK is received. The native MAC core transmits a Link ACK packet that informs the receiving port of the next packet what to look for. The MAC core at the other end of the link, receives a Link ACK packet and passes it to the PCI-e DLLP handler. The PCI-e DLL handler that received the Link ACK packet translates the packet into a PCI-e ACK packet and passes it back to the original sending port. The port then processes the ACK and removes the associated TLPs from its replay buffer due to a successful transmission [22].

Case 2: NAK is received. The native MAC core transmits a Link NAK packet stating that the last packet of the receiving packet was received successfully. The remote MAC core then receives a Link NAK packet which is passed to the PCI-e DLLP handler. The PCI-e DLLP handler receives the Link NAK packet and translates it into a PCI-e NAK packet, passing it to the original sending port. The port processes the NAK and resends the outstanding TLP(s) in the replay buffer [22].

The physical layer processes the packets that arrive from the data link layer. The physical layer converts the packets into a serial bit stream. The physical layer connects to the motherboard of the computer. The link created is referred to as a PCI Express Link. The PCI Express Link communicates with the root bus of the native host computer. A PCI Express Link must consist of lanes in parallel (i.e. x1, x4, x8, x16, etc.). The physical layer can be divided into two sub-blocks: a logical and an electrical sub-block. The logical sub-block has a Receive section that identifies and prepares any received data before it is passed to the data link layer. The electrical sub-block has a Transmit section that prepares outgoing data from the data link layer for the electrical sub-block [24].

IV. A TERABIT PCI-E SWITCH FOR SMC FABRIC

In this paper, we also present a large number of input/output ports on the PCIe switch ASIC for SMC applications. The switch is designed as a 128x128 Clos-network crossbar switch which can provide a throughout of 1.024Tb/s for PCIe 2.0 system [24]. Instead of switching at Transaction Layer, PCIe signals are transmitted as is through the crossbar fabric. Without regeneration and buffering of PCIe packets, much of the processing and delay is removed. We also propose a new output contention resolution algorithm utilizing an out-of-band protocol to control the crossbar switch before sending PCIe packets. The proposed switch becomes a switching physical medium for PCIe packets.

In the proposed switching system, electrical PCIe signals are transmitted as is through a three-stage Clos-network crossbar switch called Physical Plane (PP). As a result, without regeneration and buffering of PCIe signal and data, much of the processing and delay is removed within the switch fabric. This requires a shift of accessing, routing and other functions to the endpoints. We employ contention resolution in both space and time to route data through the Physical Plane. The endpoint interface translates the destination PCIe address into routing address. The routing address is sent prior to sending PCIe packets.

The block diagram of the proposed PCIe Switch Board (SB) is shown is Figure 1. PCIe endpoint named Host Bus Adapter (HBA) that generates PCIe signals are connected to the proposed switch ASIC via PCB traces. Each port has 2 pairs of traces for which one pair is responding for transmitting and the other is for receiving. As an illustration in Figure 1, 2 pairs of wires carrying Low-Voltage Differential Signaling (LVDS) for PCIe 2.0 [25] are switched in a Physical Plane (PP). The HBA, Control Plane and Physical Plane are connected through an interface named CC/PP Interface which provides different connections among these components.

128 HBAs are numbered sequentially in binary representation, i.e. the inputs are numbered in the figure as 0000000 to 1111111, respectively. This number is referred to as an Input Segment Address (ISA).

A three-stage Clos-network is built in the PP with a total number of 24 16x16 sub-crossbar switches named Switch Plane (SP). Each stage has 8 Switch Planes numbered as 000 to 111. The structure of Physical Plane and 16x16 Switch Plane is shown in Figure 2. HBA transmitter side (TX+/-) is connected to receiver side (RX+/-) through the three-stage Clos-network switch. It can provide alternative end-to-end connections by routing in different Stage 2 SPs. In each 16x16 SP, X-Y based crossbar switch is structured. The connection between two ports is established using a CMOS Transmission Gate (TG) with low on-channel resistance. The connection status of TG is controlled by the Control Lines.

The step-by-step and out-of-band control architecture allows the initiating endpoint to choose alternative paths in the second stage switch planes to avoid blocking. Previous work [26-27] has been done to analyze the throughput of the proposed switching system.

To verify the proposed switching concept and evaluate performance, we designed the layout of the 16x16 crossbar switch using TSMC 0.25μm CMOS process. With a total number of 256 NMOS transistors used as crosspoints, the layout size is 0.54mm x 0.74mm. Post-layout simulation is

preformed to verify the signal integrity of transmitting PCIe signals.

For the three-stage switch fabric, an approximate area of 5.4mm x 2.4mm is needed. Counting the size of Control Plane, it is not difficult to fabricate the proposed switching system on a single chip with today's ASIC packaging technology.

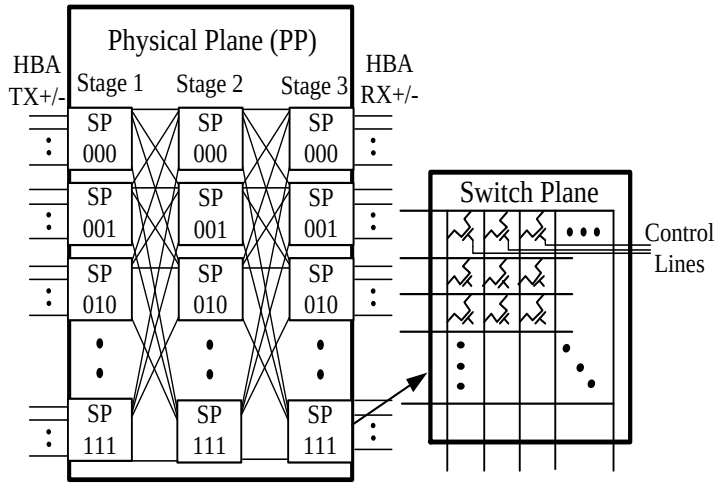

Figure 2. The structure of Physical Plane

V. Conclusion and Applicatons

Our research addresses the need for a byte addressed memory area network (MeMAN). This cloud memory architecture promises to remove the barrier that is currently limiting virtualized computing CPUs from scaling and having proximity beyond the memory bus architecture. This research addresses the various cloud memory architectures and explores the hypotheses involved, the scale or scope for each architecture, as well as the associated limitations (delay, throughput, and maximum size).

Applications for MeMAN are diverse. Our current research focuses on a primary application of cloud memory whereby the memory associated with a user's personal virtual data storage is extended to a personal private device [15]. The academic community, such as the large educational network of King AbdulAziz University, is one subject of research of how a new concept of personal cloud memory interacts with the larger public and private clouds.

Virtual desktops (VDT) are virtual machines for which personal data, personal applications, and hardware and software resources (CPU, OS, memory, and data storage) are provided and shared in the cloud. The concept is analogous to virtual servers which are essentially files that can be instantiated on physical servers as needed. Virtual server migration is facilitated by hypervisors that are network based operating systems on top of computer OS and hardware. VDT, similar to desktop and notebook computers, carries the personal data, software, and computing resources within the network, accessed through thin clients connecting the VDT users to the cloud.

While the replacement of desktop (DT) with VDT in the cloud has numerous advantages, such as data, hardware, and apps sharing; backup and reliability assurance; as well as reduced operational cost, VDT is often constrained by security issues as well as network and bandwidth bottlenecks. The combination of a personal cloud and a public cloud provides the benefits of personal computing and cloud computing, namely a social context while maintaining privacy and security through local and encrypted data storage [18].

As an example, students can carry their personal data and virtual machines loaded with their personal applications on a thumb drive[15], plug the thumb drive into thin clients that may perform local computation, and when needed, access the public cloud for social computing and data synchronization. Our research involves defining the level of privacy, security, and applications needed by students for the application of personal cloud memory. Given the user requirements, cloud memory architectures are being evaluated for implementing a personal memory cloud.

The research is aimed at social networking as well, aiming first to look at how a personal memory cloud enhances the educational and social experience in a large university such as KAU, as well as the cost reduction possible without massive investment by students on computers and data storage, made worse with the lack of data backup, software administration [16], and disaster recovery. While this research is practical in nature, the research impact can be significant for providing a broader cloud memory experience at KAU.

Real-Time Communication Protocol with Temporally Enhanced Erasure Codes

Seonho Choi[1], Hyeonsang Eom[2]
[1]Department of Computer Science, Bowie State University, Bowie, Maryland, U.S.A.
[2]School of Computer Science and Engineering, Seoul National University, Seoul, Korea

Abstract— *In Forward Error Correction (FEC) technique, redundant encoded packets are transmitted to and decoded by receiver(s) so that up to a certain number of lost packets can be recovered by using those redundant packets. The way the encoded packets are generated is to, first, divide a stream of data packets into blocks of k packets, and to generate n encoded repair packets for each block using the original packets. The receiver can recover the k original packets as long as it receives at least k distinct packets in each block. Hence, the encoding/decoding in such protocols are performed on block-by-block basis.*

In [20], a new technique, named as Temporally Enhanced Erasure Codes (TEEC), was introduced as an enhancement to the existing erasure coding technique. In TEEC the scopes of encoding/decoding are expanded beyond block boundaries, and they may overlap with scopes of neighboring blocks. In this paper, we apply the TEEC technique in designing a real-time communication protocol whose objective is to increase the packet recovery rate while reducing packet recovery delays as much as possible at the receiver side.

In terms of average packet loss rates and end-to-end delays for packet delivery, it is shown that a protocol employing TEEC outperforms block-by-block based protocols.

Keywords — reliable protocol, error recovery, FEC, erasure codes, protocol, real-time

1 Introduction

A wide range of applications in the future Internet will require both reliable and timely transmission of data packets between a sender and receiver(s). These include network whiteboards and video/audio conferencing systems, etc. Providing both reliability and timeliness in packet transmission is a difficult problem and several approaches have been proposed and used.

Two different mechanisms exist for error control in network applications, Automatic Repeat reQuest (ARQ) and Forward Error Correction (FEC). ARQ technique is based on timeout and retransmission of packets, and has been adopted in TCP protocol.

However, ARQ technique has its limitations especially if there exist timing constraints on packet delivery times as in real-time multimedia applications, or if it is used for multicasting packets to many receivers. FEC can be used in those environments in which ARQ cannot be used effectively [12,10,7,6]. The sender sends additional packets along with the original data packets so that, in cases of packet losses, they can be used to recover the original data packets that were lost during transmission. One advantage of this approach is that no further interaction between the sender and receiver is needed as long as the lost packets can be recovered from the received packets. In FEC, the sender performs encoding and the receiver performs decoding to reconstruct the lost data packets [10,7,18]. One of the well-known codes in FEC is erasure codes [10]. In erasure codes, the encoded packets are generated by, first, dividing a stream of data packets into blocks of k packets, and generating n-k (>0) encoded repair packets for each block using the original packets. The sender sends n packets for each block, and the receiver can recover the k original data packets as long as it receives at least k distinct original or repair packets. Hence, the encoding and decoding in such protocols are performed on block-by-block basis. FEC technique has been used in many applications due to the advantages mentioned above. For example, the applications and performances of FEC were studied for multicast applications, and it was shown that FEC can be a viable solution approach for reliable multicast transmissions [6, 7, 12, 15].

A new technique named as *Temporally Enhanced Forward Error Correction (TEFEC)* was proposed as an enhancement to the existing block-based FEC codes such as erasure and Tornado codes, and it was applied to design a reliable communication protocol [20]. In this paper, we apply the TEEC technique in designing a real-time communication protocol whose objective is to increase the packet recovery rate while reducing packet recovery delays as much as possible at the receiver side.

The basic idea of TEFEC is that the scopes of encoding and decoding may be expanded beyond block boundaries, and they may overlap with scopes of neighboring blocks. The encoding scope factor is defined to be the number of blocks from which the encoded packets will be generated. For example, Figure 1 shows how the encoding is performed in TEFEC with the encoding scope factor 2.

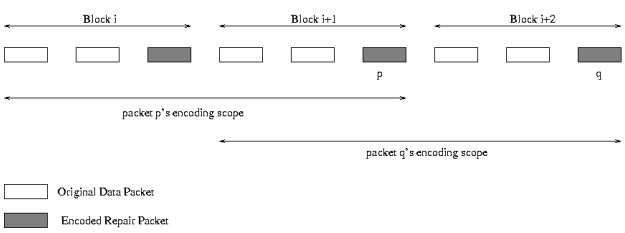

Figure 1 TEFEC with encoding scope factor of 2

In this paper, the detailed algorithm of TEEC is presented with their performances compared to those of the block-based erasure codes. TEEC was developed and implemented by extending erasure codes [10, 20]. To show their applicability, a real-time protocol is developed and simulated by using TEEC technique. It is shown that, in most of the cases, the error correcting capability could be enhanced much while not reducing the average recovery delays at the receiver. The expense we have to pay for this is slightly increased decoding overhead at the receiver. TEEC can be utilized in many applications to enhance the error correcting capability without increasing the bandwidth used for encoded packets and without affecting the real-time aspects of the applications. If the network path has long delays, or if it is expensive to send back NAK packets due to power problems as in mobile communication devices, TEEC can also be used to enhance the performances. For multicast applications, FEC was shown to be a viable solution approach [6,7,12,15]. TEEC can be effectively utilized in such applications as a better solution approach due to the enhanced error-correcting capabilities.

The paper is organized as follows. Section 2 summarizes the erasure codes [10,4]. In Section 3 the encoding and decoding algorithms are presented for TEEC, and the detailed real-time protocol is presented in Section 4 which utilizes TEEC. In Section 5 the simulation settings and results are presented for the reliable protocol with TEEC and traditional protocols with block-based FEC techniques. Finally, in Section 6 the conclusion of the paper follows.

2 Erasure Codes

A brief introduction to the erasure code is given in this section with its principles and computational complexities. A more detailed description of the codes can be found in numerous literatures [1,4,9,10]. The erasure code presented and used in this paper is called *linear block codes* whose principles and implementation techniques are nicely presented in [10].

In erasure codes the original data packets to be sent by the sender are divided into independent blocks whose size (in terms of the number of packets) is denoted by *k*. Using *k* data packets, *n (>k) encoded* packets are generated and transmitted instead of *k* data packets. Thus, the sender transmits total n packets for each block. One important property of erasure codes is that the receiver can *decode* and recover all *k* data packets as long as it successfully receives *k* distinct packets. In other words, up to *n-k* packet losses can be recovered without requiring retransmission of packets. This type of code is called *(n,k)* code.

If the packet size becomes large, then it may become difficult to apply encoding/decoding to entire packets. However, as is shown in [10] large packets can be split into multiple data items, like bytes, and the encoding/decoding process can be efficiently applied by taking one data item per packet. Under this assumption, a block is redefined to be a collection of data items from different packets instead as a collection of data packets. Hence, from a collection of k data packets, σ blocks will be created each of which contains *k* data items where σ is a packet size in terms of data items.

2.1 Linear Block Code

Let $\boldsymbol{x}= x_0\ x_1\ \ldots\ x_{k-1}$ be the source data consisting of k data items. Then an *(n,k)* linear code can be obtained by

$$\mathbf{y} = G\mathbf{x}$$

where *G* is an $n \times k$ generator matrix satisfying some properties that will be explained later, and $\boldsymbol{y}$ is an $n \times 1$ matrix containing *n* data items which will be sent by the sender. This explains how the encoding is performed.

Let $\boldsymbol{y}$ be denoted as $y_0\ y_1\ \ldots\ y_{n-1}$, and suppose that the receiver gets any subset of *k* data items in $\boldsymbol{y}$, and let $i_0\ i_1\ \ldots\ i_{k-1}$ denote the indices corresponding to the data items successfully arrived at the receiver. Then, a $k \times k$ matrix can be obtained from *G* by selecting the rows of *G* whose row indices match $i_0\ i_1\ \ldots\ i_{k-1}$. This new matrix is denoted as *G'* and it is known that any *k* rows of *G* are linearly independent, which is a necessary property for obtaining original data items in $\boldsymbol{x}$ from $\boldsymbol{y}(i_0)\ \boldsymbol{y}(i_1)\ \ldots\ \boldsymbol{y}(i_{k-1})$ by solving

$$(G')^{-1}\ \mathbf{y} = \mathbf{x}$$

where $\boldsymbol{y}(i_h)$ denotes a data item in $\boldsymbol{y}$ whose index is equal to i_h. Hence, the decoding process involves finding an invert matrix of *G'* and multiplying it to $\boldsymbol{y}$. For the purpose of later usages, let $\boldsymbol{x}^m$ and $\boldsymbol{y}^m$ denote vectors of original and encoded data items for a block *m* where $m \geq 0$.

By applying simple algebraic operations we can transform *G* so that upper *k* rows are equal to $k \times k$ identity matrix. This means that the first *k* data items in $\boldsymbol{y}$ are equal to *k* original data items in $\boldsymbol{x}$, and this type of code is called a *systematic code* [10]. If a systematic code is used to encode blocks, the decoding process may be simplified in case the number of lost packets small. In this paper, it is assumed that the systematic code is used and applied.

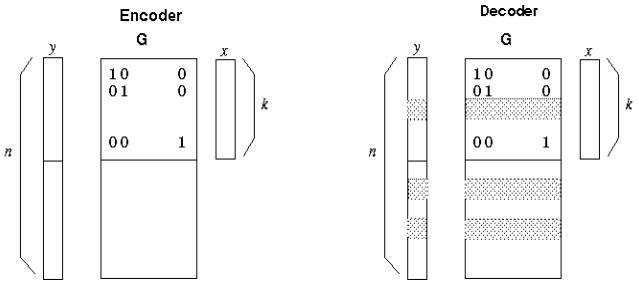

Figure 2. Matrix representation of encoding and decoding using systematic code.

However, there exist some limitations of erasure (or linear block) code. One of them is the precision overhead that incurs during matrix multiplications. That is, consider the matrix multiplication $\boldsymbol{y} = G\boldsymbol{x}$. If the number of bits used for representing one data item in $\boldsymbol{x}$ is α bits, then representing $\boldsymbol{y}$'s data items may require more data bits since they have to be found by multiplying the matrix rows to $\boldsymbol{x}$. This may result in

significant overhead [10], and may invalidate the usage of erasure code despite of its nice loss-recovery capabilities.

This problem can be avoided if the encoding and decoding is performed in a finite field instead of real number field. The algebraic operations are performed in an extension field, $GF(p^r)$, where *GF* stands for Galois Field. The addition and multiplication operations in $GF(p^r)$ can be efficiently performed using XOR operations.

The matrix known as Vandermonde matrix can be used as a generator matrix for encoding and decoding in $GF(p^r)$. The coefficients of the matrix is of the form:

$$g_{ij} = x_i^{j-1}$$

where the x_i's are elements of $GF(p^r)$. If all x_i's are different, the matrix is invertible. Another useful property is that, if no x_i is equal to 0, then the matrix can be transformed into a simpler form which has an identity submatrix in the first *k* upper rows in the matrix. This enables us to build a systematic code.

2.2 Complexity of Encoding/Decoding

When *n-k* repair packets are generated by the sender, the complexity of encoding process is $O((n-k)k\sigma)$ where σ denotes the number of data items in a packet. The total cost of decoding a block is $O(kl^2+kl\sigma)$ where *l* denotes the number of lost packets in the block. Note that $l \le min(k, n-k)$ should hold. These results are presented in more detail in [10].

3 Temporally Enhanced Erasure Codes

The erasure code techniques explained in the previous section usually perform encoding and decoding using blocks as their basic units. The blocks are mutually independent in a sense that encoding and decoding of one block don't affect those for other blocks. The common approach is to divide the entire data packet stream into packet blocks and apply encoding and decoding algorithms to each block.

A new approach, Temporally Enhanced Erasure Codes (TEEC), has been developed to reduce the amount of bandwidths required for additional repair packets, and to reduce the end-to-end delays for packet deliveries. In other words TEEC tries to enhance the repair capacity when the same amount of bandwidth is used for repair packets as in traditional erasure codes while not increasing the recovery delays at the receiver. In this section the conditions and processes for encoding/decoding blocks in TEEC are explained under the assumption that the sender sends *n* encoded (*k* original + *n-k* repair) packets for each block and the receiver tries to recover lost packets if it is feasible.

3.1 Encoding in TEEC

The key idea of TEEC is that the repair packets for a block *m* are calculated from data items that belong to *(v-1)* previous blocks, *m-(v-1), m-(v-2), …, m-1,* as well as from those in the block *m. v (≥1)* is called an *encoding scope factor*. This is represented by the following equation.

$$\mathbf{y}^m = G_{n\times vk}\,[\mathbf{x}^{m-(v-1)}, \mathbf{x}^{m-(v-2)}, \ldots, \mathbf{x}^m]^T \quad (1)$$

where $G_{n\times vk}$ is a generator matrix of size $n\times vk$, and $[\boldsymbol{x}^{m-(v-1)}, \boldsymbol{x}^{m-(v-2)}, \ldots, \boldsymbol{x}^m]^T$ is a $vk\times 1$ matrix that consist of *vk* data items in *v* blocks including block *m*. The generator matrix $G_{n\times vk}$ is obtained from the original generator matrix G^0 which can be found from a Vandermonde matrix in a Galois Field, $GF(p^r)$, as in [10]. Let the size of G^0 be equal to $n_0 \times vk$ where $n_0 \ge n$. Note that the upper *vk* rows of G^0 is equal to an identity matrix. Then, the algorithm is given in the following:

Algorithm 1

Insert an identity matrix of size $k \times k$ as a submatrix into upper right corner of $G_{n\times vk}$, and fill zeros into the remaining part of the *k* upper rows.

Let $r_1, r_2, \ldots, r_{n-k}$ denote *n-k* row vectors[1] chosen from G^0 whose row indices are greater than or equal to *vk*. Also, let $r_i(x)$ and $r_j(y)$ denote the *x*-th and *y*-th elements in the vectors r_i and r_j, respectively, where $1 \le x < y \le vk$. In addition, let *l* be defined as $\lfloor (vk-y)/k \rfloor$. Then, the *n-k* row vectors chosen above can be inserted as the row vectors in $G_{n\times vk}$ with new row indices, $k, k+1, \ldots, n$, if the following relationship is satisfied:

$$\forall\ i,j,t,x,y\ :\ 1 \le i,j \le n\text{-}k,\ \ 0 \le t \le l,\ \ 1 \le x < y \le vk\ ::\ r_i(x)\cdot r_j(y+tk) - r_i(y)\cdot r_j(x+tk) \ne 0\ \vee\ (i=j \wedge l=0)$$

The second step in Algorithm 1 guarantees that, if any two elements (in *x*-th and *y*-th columns) are chosen in an *i*-th row in $G_{n\times vk}$ where $i \ge k$, and if we choose any two other elements whose column indices are *tk* apart from *x* and *y*, respectively, then a 2×2 matrix obtained from these four elements has a rank of 2. If $i=j$ and $l=0$, then this condition is not enforced.

To find out maximum number of rows in G^0 satisfying the above condition, we developed a heuristic algorithm which incrementally builds the set of rows (from G^0) that satisfy the above condition. The Galois Field $GF(2^8)$ was used to generate the original generator matrices. It was shown in [20] that, for large encoding scope factors (*v*) and block sizes, no repair rows may be found. But, for encoding scope factors up to 5 or 6 and for reasonably large block sizes around 10, the valid repair rows could still be found while the more valid rows can be obtained for smaller encoding scope factors and block sizes.

3.2 Decoding in TEEC

The decoding process is more complicated than the encoding process. One important characteristic of the decoding process is that a variable number of consecutive blocks are grouped together and decoding is performed for the lost packets in them. Once the decoding is successfully finished, then all the lost packets are recovered. The minimum number of consecutive blocks that need to be grouped together for decoding is *v* as is seen from the equation (1). For example, the lost packets in the block *m* may be recovered immediately after the packets for *m* arrive when all the data packets for the

[1] The chosen rows don't need to be consecutively located in G^0.

previous *v-1* blocks are available, or after the packets of future blocks arrive at the receiver. A *decoding scope factor*, *w (≥v)*, is defined as the maximum number of blocks which can be grouped together for decoding. The decoding can be performed using less number of blocks than *w* if certain conditions are satisfied, which will be derived in this section.

Suppose that the packets for blocks, *z, z+1, z+2,..., z+c,* are available at the receiver where $0 \le c \le w-1$, and the receiver wants to perform decoding for those blocks. The following assumptions are made regarding the decoding process:

The total number of packets used as input to the decoding process is equal to $(c+1)k$.

Only the repair packets that belong to the blocks $z+v-1, z+v, \ldots, z+c$, are used in decoding. This is because the repair packets that belong to the blocks, $z, z+1, \ldots, z+v-2$, were encoded using the original data packets that belong to the blocks prior to *z*.

If the total number of received packets is greater than $(c+1)k$, then it is assumed that $(c+1)k$ packets are chosen among them[2] and the rest of the packets are discarded. Following notations are defined once the $(c+1)k$ packets are selected:

λ_j denotes the number of received original packets (among *k* packets sent by the sender) for block *j*.

δ_j denotes the number of received repair packets (among *n-k* repair packets initially sent) for block *j*.

Then the following equation should hold:

$$\sum_{i=z+v-1}^{z+c} \delta_i + \sum_{i=z}^{z+c} \lambda_i = (c+1)k$$

As a second step of the decoding process, the matrix of size $(c+1)k \times (c+1)k$ is obtained by Algorithm 2 and is denoted as $G'_{(c+1)k,(c+1)k}$.

Algorithm 2

Assign indices to $(c+1)k$ packets in the range of 1 to $(c+1)k$. Repeat the following steps 2 through 4 for each packet whose index is *p* where $1 \le p \le (c+1)k$.

Let *j* denote a block index in $[0,c]$ and *i* denote a row index in $[1,n]$ for the *p*-th packet. That is, the *p*-th packet belongs to the block $z+j$, and the packet was encoded by using the *i*-th row vector in $G_{n \times vk}$.

From $G_{n \times vk}$ extract a row corresponding to the index *i*. Let this row vector be denoted as r_i.

(i) if the *p*-th packet is a data packet,

→ If $0 \le j \le v-1$, then discard the first $(v-j-1)k$ number of 0 elements from r_i and append *0*s to the end of r_i to make it of size $(c+1)k$

→ Otherwise, add $(j-v+1)k$ number of *0*s to r_i and append *0*s to the end of r_i to make it of size $(c+1)k$.

(ii) if the *p*-th packet is a repair packet,

→ add $(j-v+1)k$ number of *0*s to r_i and append *0*s to the end of r_i to make it of size $(c+1)k$.

4. Place the vector obtained in step 3 as a *p*-th row in $G'_{(c+1)k,(c+1)k}$.

If the obtained matrix, $G'_{(c+1)k,(c+1)k}$, is invertible, then the following equation can be utilized to recover the lost packets in the blocks $z, z+1, z+2, \ldots, z+c$.

$$\mathbf{y}=G'_{(b+v)k,(b+v)k}\ [\mathbf{x}^z,\mathbf{x}^{z+1},\mathbf{x}^{z+2},\ldots,\mathbf{x}^{z+c}]^T$$

where some items in the vectors $x^z, x^{z+1},\ldots,x^{z+c}$ may not be known and should be recovered by the decoding algorithm. The above equation can be rewritten as follows:

$$(G'_{(b+v)k,(b+v)k})^{-1}\mathbf{y}= [x^z,x^{z+1}, x^{z+2},\ldots,x^{z+c}]^T$$

The lost packets in the right hand side may be found by multiplying the inverse matrix to the vector $\boldsymbol{y}$ which contains the arrived packets.

Theorem 1

The matrix, $G'_{(c+1)k,(c+1)k}$, obtained by Algorithm 2 has an inverse matrix only if the following conditions are satisfied:

$$\forall j : 0 \le j \le v-1 ::$$
$$\sum_{i=z+v-1}^{\min(z+v-1+j,z+c)} \delta_i + \sum_{i=z}^{z+j} \lambda_i - (j+1)k \ge 0 \qquad (1)$$

$$\forall j : v \le j \le c ::$$
$$\sum_{i=j}^{\min(j+v-1,c)} \delta_{z+i} + \lambda_{z+j} - k + \min\left(0, \sum_{i=z+v-1}^{z+j-1} \delta_i + \sum_{i=z}^{z+j-1} \lambda_i - jk\right) \ge 0 \qquad (2)$$

$$\forall j : 0 \le j \le c ::$$
$$\sum_{i=z+v-1}^{z+j} \delta_i + \sum_{i=z}^{z+j} \lambda_i \le (j+1)k \qquad (3)$$

Proof: The proof may be found in [20].

The meaning of this theorem is that the three conditions should hold when the obtained matrix, $G'_{(c+1)k,(c+1)k}$, is invertible. That is, those three conditions are necessary conditions for decodability, and it is possible that $G'_{(c+1)k,(c+1)k}$ is not invertible even if the three conditions hold. However, it has been shown from the simulations that the probability of such occurrences is very low when the encoding is performed using $G_{n \times vk}$ obtained by Algorithm 2. This means that the three conditions in Theorem 1 are tight and may be used to detect the invertibility of $G'_{(c+1)k,(c+1)k}$ in most of the cases.

In [20], the detailed explanation of these conditions are given along with how they may be checked in real implementation.

4 Real-Time Protocol Using TEEC

In this section, a real-time protocol is presented which utilizes TEEC encoding/decoding algorithms to recover lost packets during transmission. No retransmission of lost packets are performed. This assumption makes sense especially in real-time applications which has certain timing constraints. It is also assumed that the real-time data packets are generated periodically at the sender and sent to the receiver. The original

[2] How these packets should be chosen will be explained later after the main theorem is presented regarding the decodability conditions.

data packet stream is divided into blocks that contain *k* packets, and the sender also sends *n-k* redundant (encoded) repair packets along with the *k* data packets in each block. These *n* packets are sent to the receiver in a block period.

Suppose that the packets for blocks, *z, z+1, …, z+c*, have arrived at the receiver where $0 \le c \le w-1$, and let $z+i$ denote an index of the first block that has at least one lost data packet where $0 \le i \le v-1$. Again, note that the decoding scope factor, *w*, denotes a maximum number of consecutive blocks that can be grouped together for decoding. The following algorithm is run whenever the transmission of the packets for each block is completed at the receiver[3]. Let $z+c$ denote the block index whose packet transmission is completed now.

Three variables, *SBI*, *EBI*, and *FLBI*, are defined and used, which represent the start block index, the end block index of a decoding scope, and the first loss block index within a decoding scope, respectively. Given *c+1* blocks described above, *SBI* and *EBI* are initialized to *z* and *z+c*. *FLBI* denotes the index of the first block that has at least one lost data packet between *SBI* and *EBI*. This variable is set to $z+i$.

Algorithm 3

Input: *SBI*, *EBI*, and the packets for the blocks in *[SBI,EBI]*
Output: Recovered packets

1. Find out *FLBI* value in *[SBI,EBI]*.
2. If no *FLBI* is found, then the following variables are reset, and exit:
   - *SBI = SBI+1*
   - *EBI = EBI+1*
3. Check condition (3) of Theorem 1 for the last block: find
$$\sum_{l=SBI+v-1}^{EBI} \delta_l + \sum_{l=SBI}^{EBI} \lambda_l - (EBI - SBI + 1)k$$
If the above term is positive, then discard that number of repair packets in the block, *EBI*, since they violate the condition (3) of Theorem 1.
4. If $EBI-SBI+1 \le w$ holds, and (1) ∧ (2) of Theorem 1 holds,
   - Obtain a decoding matrix for the blocks. If the decoding matrix has an inverse matrix, then the lost packets in the blocks are recovered. Recovery of the lost packets are noted. Then, the following variables are reset for the next invocation of the algorithm, and the current invocation is exited:
     - *SBI = EBI-v+2*
     - *EBI = EBI+1*
   - If the decoding matrix is not invertible, then the receiver gives up recovering lost packets in the block, *FLBI*.
     - if $FLBI+1 \le EBI$, the algorithm is repeated for the blocks *FLBI+1, FLBI+2, …, EBI* by performing the following steps:
       - *SBI = FLBI+1*
       - Goto step 1.
     - If *FLBI=EBI*, then set *SBI=EBI+1*, *EBI=EBI+1*, and exit.
5. If $EBI-SBI+1<w$ holds, and the condition (1) ∧ (2) of Theorem 1 doesn't hold,
   - if there is a possibility that (1) ∧ (2) of Theorem 1 will hold after receiving future block packets,
     - In this case, set *EBI=EBI+1*, and exit from the algorithm.
   - if there is no possibility that (1) ∧ (2) of Theorem 1 holds even after receiving future block packets,
     - if $FLBI+1 \le EBI$, then set *SBI=FLBI+1* and goto step 1.
     - If *FLBI=EBI*, then set *SBI=EBI+1* and *EBI=EBI+1*, and exit.
6. If $EBI-SBI+1=w$ holds, and (1) ∧ (2) of Theorem 1 doesn't hold, then, the following steps are performed:
   - if $FLBI+1 \le EBI$, then set *SBI=FLBI+1* and goto step 1.
   - If *FLBI=EBI*, then set *SBI=EBI+1* and *EBI=EBI+1*, and exit.

As can be seen from the above procedure, the receiver may utilize *v-1* previous blocks that are already recovered when decoding the following blocks. This is the ideal case in which the benefits of TEEC can be fully exploited. If, for some reason, the group of blocks can't be decoded, then decoding of the first block that has some lost packets will be given up, and the receiver will proceed the decoding process starting from the next block.

In the step 5 above, it is needed to decide whether it is worthwhile to wait for future block packets or not. That can be decided by examining the following formula.

$$\mu_{EBI} = \max\left(-\begin{pmatrix}\delta_{EBI} + (w - EBI + SBI - 1)(n-k) + \lambda_{EBI} - k + \\ \min(0, \sum_{i=SBI}^{EBI-1}\delta_i + \sum_{i=SBI}^{EBI-1}\lambda_i - (EBI - SBI)k)\end{pmatrix}, 0\right)$$

This formula is obtained from the condition (1) and (2) of Theorem 1. If μ_{EBI} is greater than 0, then it means that the blocks can't be decoded even if the future block packets arrive successfully. If it is equal to 0, then it means that it is worthwhile to wait for more future block packets since there exists a possibility.

5 Simulation

The simulation program was written to test the performance of the reliable protocol utilizing TEEC, and the results are compared with those utilizing the traditional erasure codes. The sender continuously sends the real-time data packets with a period, *P*. Three parameter values are used by the sender for encoding, *n*, *k*, and *v* (for TEEC). Also, for decoding, the receiver has a parameter, *w*. With a set of given parameters, three different cases were simulated:

[3] This time can be detected by observing the packets belonging to the future block arrives at the receiver, or by a timeout.

1. Traditional erasure codes with block size n (k original plus n-k redundant packets).
2. TEEC with parameters, n, k, v, w.
3. Traditional erasure codes with block size vn (vk originals plus $v(n-k)$ redundant packets).

In all three cases, it is assumed that the packets are sent with the same inter-packet departure times. Especially, the time period during which n packets are sent by the sender is denoted as P.

By comparing the performances of the first and second schemes, we can identify how much we can benefit by using the TEEC based protocol instead of using traditional block-based FEC schemes.

Note that the third method uses a large value for block size with the same bandwidth fraction used for sending repair packets as in the first and second methods, and is considered here to see what the advantage is by using TEEC compared to just increasing the block size with the same bandwidth fraction used for repair packets.

The loss models we assumed in this simulation are the independent loss model and the burst loss model which is obtained by a two state Markov chain. The independent loss model has one parameter, p, denting the probability that a packet will be lost during transmission. The Markov chain has two parameters, p_1, p_2, for the transition probability from normal to normal state and the transition probability from loss state to loss sate, respectively.

The metrics obtained and compared in this simulation are as follows:

- Average packet loss rate.
- Average packet recovery delay, i.e., the amount of time taken for the receiver to wait until the lost packet is reconstructed. The delays are measured in units of P, i.e., multiples of P.

The simulation was run for 20000 blocks for each set of parameter values. Figures 3 through 6 were obtained with parameters of $n=8$, $k=5$, $v=5$, and $w=15$, for independent packet loss model and burst packet loss model. Figure 3 shows that the average packet loss rates for TEEC is lower than those for cases 2 and 3 while Figure 4 shows that the average packet recovery delays for TEEC is much lower than those for case 3 and slightly higher than those for case 2. These two figures show the effectiveness of TEEC compared to traditional erasure codes. For burst packet loss model, Figures 5 and 6 show the results with p_1 set to 0.9. Figure 5 shows that, for most of the values of p_2, TEEC has the lowest average packet loss rates and Figure 6 shows that the average packet recovery delays lie between those of case 1 and case 2 up to $p_2=0.65$. It increases after that point and becomes largest for larger p_2 values. Larger p_2 value means longer burst length. Similar results were obtained for different sets of parameter values and models as in this case.

6 Conclusions

A real-time communication protocol utilizing TEEC have been developed in this paper, and its effectiveness was shown through the simulations. The simulation results of the protocol show that TEEC enhances the performances of the protocol in terms of end-to-end delays and average packet loss rates. Even though the experiments were conducted on unicast communication models, more benefits from TEEC can be obtained in multicast applications since many receivers may take advantages of TEEC.

Abstract— In order to introduce more efficient high performance computing (HPC) applications we need to construct a performance model for the complex heterogeneous systems.
Most of the HPC applications, as in the molecular dynamics simulation implement the FFT parallel algorithm that consumes a major portion of the application execution time.
This work constructs a model that can be used to decide the execution plan scalability and highlight major factors that impact directly the algorithm performance.
The parallel FFT algorithm is used as a case study for our modelling procedure.
This paper aims to explore the most impacting parameters of the parallel FFT algorithms execution where other platform and hardware-dependent factors are not included.

Keywords: FFT, Performance, model, parallel, decomposition

1 Introduction

High Performance Computing (HPC) allows scientists and engineers to solve complex science and engineering problems using parallel algorithms on a large number of computing processors and high bandwidth network.

As the scalability is a very important measurement of the applications performance, predicting the algorithm scalability is required in the pre-deploying phase.

The peta-scale computers are the new generation of the HPC platforms as in blue waters project. It delivers 1 peta folps performance [1], the lack of scalability of the parallel algorithms forms a step challenging issue in the new Peta-scale computers.

The scalability issues may prevent the applications from achieving the desired performance hence rise up the importance of the prediction model.

The performance prediction model should address the major factors that affect the performance, however in order to implement a generic model it should not be very detailed to a specific hardware or a specific platform.

The Fast Fourier Transform (FFT) is an enhanced method for calculating the Discrete Fourier Transform (DFT). As it is more efficient, often reducing the computation steps by hundreds. The 3D FFT can be expressed as [2]

$$f(k_x,k_y,k_z)=\sum_z\left[\sum_y\left[\sum_x f(x,y,z)\cdot e^{ik_x x}\right]e^{ik_y y}\right]e^{ik_z z} \quad (1)$$

FFT has been one of the most popular and widely used numerical methods in many areas of scientific computing, including digital speech and signal processing, solving partial differential equations, molecular dynamics many-body simulations and Monte Carlo simulations.

Given its importance, there have been a large number of libraries that provide different implementations of FFT aimed at achieving high-performance in various environments.

The outline of this paper is organized as follows. Section 2 shows the most relevant work related to our work. Section 3 describes the different decomposition algorithms .The experiments test-bed and the analytical model described in section 4 and 5 respectively , section 6 illustrate the experiments results and finally paper conclusion is section 7.

2 Related Work

The steps required to calculate 3DFFT with 2D decomposition add extra computation and communication step while they extend the algorithm scalability [3].

Previous work introduced an analysis of the 3DFFT decompositions methodologies and the performance measurements of each decomposition method [3], the experimental results shown in Table 1 shows a speedup of the 2D decomposition [4], the 2D decomposition theoretical analysis proves a better scalability performance up to the product of the widest two dimensions of the data mesh however it is proven in this work that other factors have a major impact on the algorithm scalability.
The major FFT parallel algorithm cost introduced as a summation of the communication and computation tasks Tfft(N; P;Chunks) = Tcomp(N; P) + Tcomm(Chunks; P)

Where Tcomp(N; P) is the Computation Time, Tcomm(Chunks; P) is the Communication Time [5] . In this paper the analysis model cost equation introduced with more details.

Many intensive studies addressed the FFT algorithm communication cost highlighting BlueGene/L torus and mesh network topologies [6], in our work both computation and communication factors considered along with the different decomposition algorithms and the grid size, the model addressed only the major network parameters aiming to be independent of the network topologies.

A comparison between different FFT libraries and the performance measurements through each decomposition method of the libraries predicts the theoretical scalability enhancements of the 2D decomposition [4], The FFTW [7] is a popular implementation of the 3DFFT; however the FFTW does not support the 2D decomposition however some modifications added to enable the 2D decomposition more details in section IV .

Message Passing Interface (MPI) is a language-independent communications protocol used to program parallel computers especially with the distributed system. MPI communication protocols include both point-to-point and collective communication [8].

There are various models to evaluate the MPI communication performance from the hardware perspective as LogP [9] , LogGP [10] and pLogP [11] where parameters as in Table 2 [12] .

TACC ranger network parameters measured [12] for the blocking and the non-blocking communication (discussed in the analytical model section) as shown in Table 3.

3 3D FFT decompositions

FFT Decomposition is the process of distributing the 3D FFT data mesh and determine the steps of communication and computation across the number of processors grid.

The decomposition way beside the hardware architecture and specifications are the key factors of any FFT algorithm execution plan.

In 1D decomposition shown in Figure **1** which is also called slab decomposition, the 3D data grid is divided into a number of slabs across one dimension

At the first step, the 1DFFT first calculated with respect to two dimensions let's say the x and y direction, and along the third direction z then in the second step a global transpose with all to all communication takes place then the at the last step the 2DFFT is calculated across the last dimension z

In the 1D decomposition, the global transpose (all-to-all communication) takes place only once, however the drawback of this algorithm is the scalability where the number of slabs is limited to the maximum number of processors in one dimension.

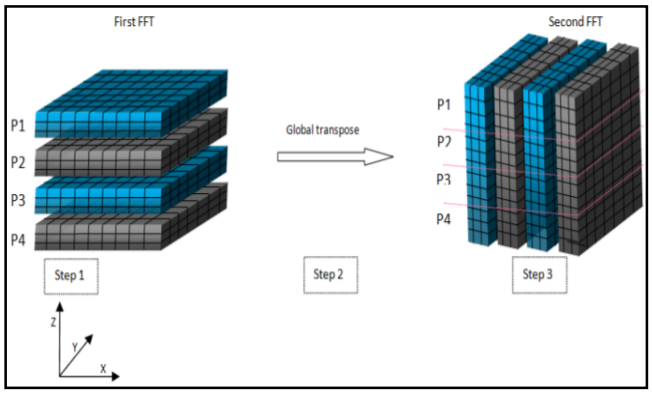

Figure 1 : 3DFFT calculation steps for the 2D decomposition

2D decomposition of the data, which sometimes called the pencil decomposition, is when the data is divided across two dimensions of the 3D data grid. In the first step, the 1DFFT is calculated for each pencil followed by a global transpose in the second step. At the third step, the 1DFFT is calculated along the second dimension then again in the forth step the global transpose takes place. At the last step, a final calculation of the 1DFFT along the last dimension is performed.

The 2D decomposition algorithm is shown in Figure 2 [6]. Two global all-to-all transpose takes place, however

the maximum scalability is up two the product of the widest two dimensions of the 3D data grid.

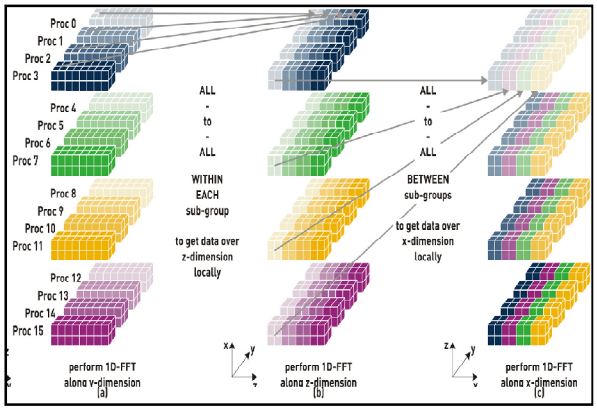

Figure 2: 3DFFT calculation steps for the 2D decomposition

4 Test-bed

Our target platform is the Texas Advanced Computing Centre – Ranger constellation –TACC Ranger. The TACC system consists of 62,976 nodes interconnected through InfiniBand technology providing a theoretical 1GB/sec point-to-point bandwidth, TACC provide a peak performance of 9.2 GFLOPS/core or 128 GFLOPS/node [13]. .

As shown in Figure **3**, every four cores are attached to one socket. Such structure must be considered when measuring the communication performance specially when testing with little number of cores (e.g. 2, 4, 8, and 16) to avoid measuring the intra socket communication instead of the network communication.

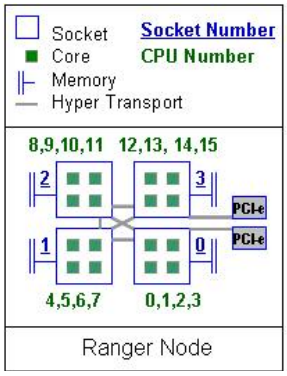

Figure 3: TACC Ranger Architecture

Our experiments code was developed using C++, MPI routines version 1.2.7, PGI 7.1 compiler.

The Fastest Fourier Transform in the West (FFTW) [7] library is selected for computing multiple dimensions of the DFT, FFTW is a MIT developed C subroutine library for computing multiple dimensions of the DFT, FFTW supports only the 1D decomposition however some changes are added to our experimental code to enable the 2D decomposition testing.

In the 1D decomposition, the ***fftw_mpi_local_size*** function used to determine the local size for each processor, ***fftw_plan_dft*** function is used to initialize the plan with the local variables and the input and output data and ***fftw_execute*** function is used to perform the FFT calculation.

In the 1D decomposition, the local size of the processors that are out of boundaries (greater than the largest axis) is equal to zero. In our implementation of the 2D decomposition we overwrite the local size variables to scale it to the number of the product of the widest two dimensions.

In the transposing task, the ***fftw_mpi_plan_transpose*** function used to transpose the global 3D grid over the contributors processors, in the 2D decomposition the transposing action is modified to divide the contributing processors to a set of sub groups that share the required transposing axis as shown in Figure 2. Similar related work in [11] implement the same idea.

Performance Application Programming Interface (PAPI) [14] framework supports several events API, PAPI 3.6.0 is used to measure the number of the floating points instructions needed to calculate the FFT for each processor, however PAPI does not support MPI intercommunication profiling.

Integrated Profiling Monitoring IPM [15] is a portable profiling infrastructure for parallel codes. It provides performance profile from several aspects of the computation communication, and IO of the parallel programs, IPM used to measure the communication time acquired, the message size transferred, and the number of messages for the transposing tasks.

5 The analytical model

This paper aims to explore the most impacting parameters of the parallel FFT algorithms execution to build a high level model for its timing behaviour. The model takes into consideration the major hardware system parameters. However it is not hardware-specific as the more generic parameters we achieve, the more platforms we can use.

For simplicity we can divide the FFT algorithm into two non overlapping stages.

First: the computation part where each processor computes the DFT for the local portion of the data grid, the number of steps per core based on the algorithm order time (N^2, N log N, etc) and data mesh size.

As shown in equation (2) the FFTW algorithm uses O(N log N) [7], the computation time per core depends on several parameters.

The $\boldsymbol{FFC}$ parameter is the floating point factor that reflects the number of flops required for calculating each point.

$\boldsymbol{FFC}$ equals 5 in case of complex number transform as in our experiments and 2.5 in case of real number transform [7], $\boldsymbol{f(Nprocs)}$ is the maximum number of processors scalability considering the FFT algorithm decomposition method where $\boldsymbol{f(Nprocs)}$ in 1D decomposition equals the widest dimension of the data grid. In the 2D dimension, it is equal to the product of the widest two dimensions of the data grid as shown in

equation (3). **Peak Performance** is the peak floating-point operations performance per core, the value of the peak performance equal to 9.2 GFLOPS/core or 128 GFLOPS/node [13]. **Peak Percentage** is the average peak performance percentage measured in our experiments and is found to be around 950 mflops that equivalent to 10% of the theoretical peak performance as shown in Figure 4, the **mflops** is the rate of flops × 10^6 per second where **flipns** stands for the number of floating points measured, **Ndata** is the number of the data grid points.

.

$$\boldsymbol{computation\ time} = \frac{FFC \times \left(\frac{N_{data}}{f(Nprocs)}\right) \log_2 \frac{N_{data}}{f(Nprocs)}}{Peak\ performance \times Peakpercentage} \quad (2)$$

$$\boldsymbol{f(Nprocs)} = \begin{cases} \boldsymbol{Max(N_X, N_Y, N_Z)}, & 1D \\ \boldsymbol{N_i * N_j\ AND\ N_i, N_J \neq Min(N_X, N_Y, N_Z)}, & 2D \end{cases} \quad (3)$$

Second: The communication part that represents the time consumed in the transposing tasks of the algorithm.

Again, the transposing time can be divided into two parts, first the data transmission time, as we have first to figure out the data grid size that will be transposed by each core by dividing the total data size $\boldsymbol{N_{data}}$ on the number of processors $\boldsymbol{f(Nprocs)}$ that depends directly on the decomposition way multiplied by the number of bytes in each data grid point **FFM**, divided on the network bandwidth **BW**. The second part is the overall transpose Message latency $\boldsymbol{MSG_{lat}}$ that equal to the summation of the three overhead parameters multiplied by the number of messages $\boldsymbol{f(Nprocs)}$ as in the transposing task, an all-to-all communication takes place.

The overhead parameters derived from three parameters l, o, and g. l refers to network latency, o overhead per message transmission and g gap between the successive message transmissions. The three parameters have been measured in previous work [12] as in Table **2** and Table 3, the tables address the latency values for the MPI blocking and non-blocking communication.

The blocking MPI means that the program execution will be suspended till the message buffer is safe to use, however in the non-blocking MPI communication, the call returns immediately after the call is initiated. The FFTW is found to use the non blocking MPI_SENDRECV routine in the transposing communications.

It is worthy to mention that the communication performance has many other parameters that are more hardware-specific; it is out of the scope of this model as the model is designed to be algorithm-oriented.

$$\boldsymbol{communication\ time} = \boldsymbol{MSG_{lat}} + \frac{\left(\frac{N_{data} * FFM}{f(Nprocs)}\right)}{\boldsymbol{BW}} \quad (4)$$

$$\boldsymbol{MSG_{lat}} = \boldsymbol{(L + o + g) * f(Nprocs) - 1} \quad (5)$$

The number of points handled by each core can be calculated as $N_{data}/\ f(Nprocs)$ multiplied by the number of bytes FFM.

6 Model Verification

This section discusses and compares the model and the algorithm performance and scalability.

In the following Figures, the performance results measured in seconds over 2 to 4096 cores, multiple runs executed to calculate the average execution time for 64^3 and 256^3 input grids, respectively.

As discussed in the previous Section, the model and the actual computation time are measured by calculating the number of flops of the FFT calculations for each core divided by the peak performance multiplied by %10 as the peak percentage.

The *MPI_Sendrecv* mpi routine used in point-to-point communication by the FFTW algorithm, the *MPI_Allreduce* used to gather the results of the average number of flops through the running instances, the communication analysis include only the *MPI_Sendrecv* communication in the transposing tasks excluding any other communication overhead used in gathering or synchronizing the data.

The IPM used to profile the messages between the cores, as simple histogram method used to calculate the average message time between cores.

In our platform, TACC Ranger; some parameters should be addressed to submit a job, one of them is the wayness [13] as it determines the number of cores to be used through the whole node (16 cores), for example if the program will run on 32 core and 8 wayness method used, this means that the program will need 4 nodes and then only 8 cores will be used in each node.

As shown in Figure **3** each group of 4 cores are communicated with the other groups through one socket, In the small number of processors (Nprocs < 16), the 1-way job scheduling wayness used to avoid measuring the inter-group communication instead of the InfiniBand socket communication.

6.1 1-D Decomposition

The model successfully predicts the overall trend changes in the FFT execution performance and scalability, Figure 5 and Figure 6 show that the time consumed by the computation part is dominant when the number of cores is less than 64, the communication and computation parts start to be very close when the number of cores are equal to the widest dimension over 2, the results confirms that algorithm scalability extent is equal to the widest dimension in the input 3D grid, when the number of cores is larger than the widest dimension the algorithm divides the data grid on a number of cores equals to the widest dimension and the rest of the cores is not involved in the execution plan.

6.2 2-D Decomposition

The model successfully predicts the overall performance behaviour and scalability, as shown in Figure 7 and Figure 8, the 2-D decomposition success to scale to the product of the widest two dimensions of the data grid as discussed in the previous Section, however the performance drops dramatically when the number of all-to-all messages increased to be more than 128×128 and

the size of the message became very small (less than 32 bytes) where the message latency time is the dominant. The message sizes transmitted for each scenario are shown in Figure 9 that shows the relationship between the message size of each scenario and the decomposition algorithm as well as the data grid size, message size is measured in bytes, the message size of the all-to-all communication step can be derived from the communication analytical equation as $\frac{N_{data}*FFM}{f(Nprocs)^2}$ where the total amount of data required to be transposed on each processor is divided over the total number of the processors engaged in the all-to-all communication.

As shown in equation (5) the number of messages directly impact the time consumed by the messages latency, as shown in Figure 9 the dramatic increase of the messages number along the increase of the number of processors.

As shown in previous work [12] and in Figure 12 the relation between the message size and the G parameter - that introduced in Table 2 - has a Monotonic decrease relationship where the bandwidth affected badly by the message size.

To achieve the desired scalability and performance, the message size and the network latency factors should be considered.

In Figure 10 and Figure 11 the model accuracy for the gap between the predicted time and the measured time is shown for both 1-D and 2-D decompositions with 64^3 and 256^3 data grids inputs, the gap fluctuations may refer to change in the peak performance due to hardware considerations however the overall performance behaviour still predictable.

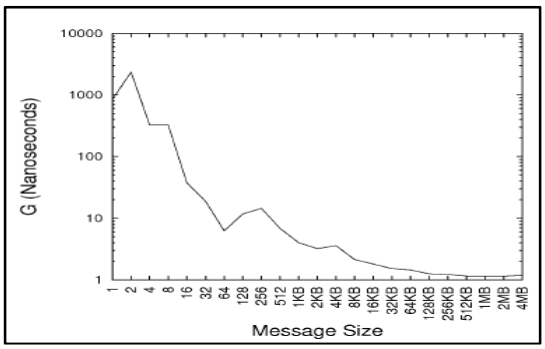

Figure 12: G for Various Message Sizes

7 Conclusions and future work

The paper present a predictive model of scalability and performance of the parallel FFT algorithm, The model successfully predicts the overall scalability performance behavior, although there is a gap between the predicted and measured performance for the very large and the very small message size.

The model scope includes the execution of 3DFFT grid, 1D and 2D decomposition methods. A future work can be done against the 3D decomposition (volumetric decomposition).

The model can be enhanced to include the computation and communication overlapping probability.

The network parameters, as the bandwidth and the message latencies parameters should be known for the target platform; it can be done through 1- System documentation 2- profiling tools.

Apriori-Map/Reduce Algorithm

Jongwook Woo
Computer Information Systems Department
California State University
Los Angeles, CA

Abstract –*Map/Reduce algorithm has received highlights as cloud computing services with Hadoop frameworks were provided. Thus, there have been many approaches to convert many sequential algorithms to the corresponding Map/Reduce algorithms. The paper presents Map/Reduce algorithm of the legacy Apriori algorithm that has been popular to collect the item sets frequently occurred in order to compose Association Rule in Data Mining. Theoretically, it shows that the proposed algorithm provides high performance computing depending on the number of Map and Reduce nodes.*

Keywords: Map/Reduce, apriori algorithm, Data Mining, Association Rule, Hadoop, Cloud Computing

1 Introduction

People started looking at and implementing Map/Reduce algorithm for most of applications, especially for computing Big Data that are greater than peta-bytes as cloud computing services are provided, for example, by Amazon AWS.

Big Data has been generated in the areas of business application such as smart phone and social networking applications. Especially these days, the better computing power is more necessary in the area of Data Mining, which analyzes tera- or peta-bytes of data. Thus, the paper presents *Apriori-Map/Reduce Algorithm* that implements and executes *Apriori algorithm* on Map/Reduce framework.

In this paper, section 2 is related work. Section 3 describes the legacy *apriori algorithm*. Section 4 introduces Map/Reduce and Hadoop and presents the proposed *Apriori-Map/Reduce algorithm*. Section 5 is conclusion.

2 Related Work

Association Rule or Affinity Analysis is the fundamental data mining analysis to find the co-occurrence relationships like purchase behavior of customers. The analysis is legacy in sequential computation so that many data mining books never resist illustrating it.

Aster Data has SQL MapReduce framework as a product [9]. Aster provides *nPath SQL* to process big data stored in the DB. Market Basket Analysis is executed on the framework but it is based on its SQL API with MapReduce Database.

Woo et al [11-13] presents Market Basket Analysis algorithms with Map/Reduce, which proposes the algorithm with *(key, value)* pair and execute the code on Map/Reduce platform. However, it does not use the *apriori property* but instead adopts *joining* function to produce paired items, which possibly computes unnecessary data.

3 Apriori Algorithm

Apriori algorithm shown in Figure 3.1 has been used to generate the frequent item sets in the amount of data transactions in order to produce an association rule.

```
Map transaction t in data source to all Map nodes;
//(1)
C1 = {size 1 frequent items};
// (2) min_support = num / total items; for example: 33%
L1 = {size 1 frequent items ⋂ min_support};

for (k = 1; Lk !=∅; k++) do begin

    // (3) sort to remove duplicated items
    Ck+1 = Lk join_sort Lk;

    for each transaction t in data source with Ck+1 do
        // (4)
        increment the count of all candidates in Ck+1 that
        are contained in t
        // (5) find Lk+1 with Ck+1 and min_support
        Lk+1 = {size k+1 frequent items ⋂
          min_support};
    end
end

return ∪k Lk;
```

Figure 3.1. Apriori Algorithm

The association rule has been used efficiently to manage stock items and products etc analyzing the customer's behavior. It is based on Apriority Property where all subsets of a frequent item set must also be frequent.

For example, minimum support is 2 and there are size 2 item sets generated: *<[coffee, cracker], 3>* and *<[coke,*

cracker], 1> as *<[item pairs], frequency>*. And, when there are size 3 item sets produced as *<[coffee, cracker, milk]>* and *<[coke, cracker, milk]>,* as *Apriority Property*, *<[coke, cracker, milk]>* is eliminated before counting the frequencies of the item sets in the transaction data, which reduce unnecessary computing time.

The time complexity of the algorithm is $O(k \times (k^2 + t \times n))$ when k: size of frequent items, t: transaction data, n: number of item elements in each transaction t. It is simplified to $O(k^3 + k \times t \times n)$ and then $O(k \times t \times n)$ where $t >> k$, $n>>k$.

4 Apriori-Map/Reduce Algorithm

4.1 Map/Reduce in Hadoop

Map/Reduce is an algorithm used in Artificial Intelligence as functional programming. It has been received the highlight since re-introduced by Google to solve the problems to analyze Big Data, defined as more than peta-bytes of data in distributed computing environment. It is composed of two functions to specify, "Map" and "Reduce". They are both defined to process data structured in *(key, value)* pairs.

Inspired by Google's *MapReduce* and *GFS* (Google File Systems) [1], Map/Reduce platform is implemented as *Apache Hadoop* project that develops open-source software for reliable, scalable, and distributed computing. Hadoop can compose hundreds of nodes that process and compute Big Data. Hadoop has been used by a global community of contributors such as Yahoo, Facebook, Cloudera, and Twitters etc. Hadoop provides many subprojects including *Hadoop Common*, *HDFS*, *MapReduce*, *Avro*, *Chukwa*, *HBase*, *Hive*, *Mahout*, *Pig*, and *ZooKeeper* etc [2].

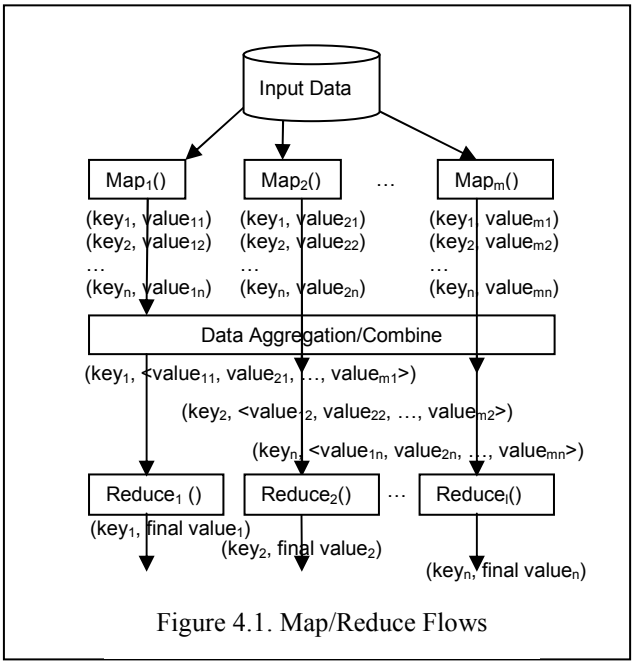

Figure 4.1. Map/Reduce Flows

The map and reduce functions run on distributed nodes in parallel. Each map and reduce operation can be processed independently on each node and all the operations can be performed in parallel. Map/Reduce can handle Big Data sets as data are distributed on *HDFS* (Hadoop Distributed File Systems) and operations move close to data for better performance [5].

Hadoop is restricted or partial parallel programming platform because it needs to collect data of *(key, value)* pairs as input and parallely computes and generates the list of *(key, value)* as output. In map function, the master node divides the input into smaller sub-problems, and distributes those to worker nodes.

Map transaction *t* in data source to all Map nodes;
//(1) In each Map node *m*
C_{m1} = {size 1 frequent items at the node *m*};
// (2) In Reduce, compute C_1 and L_1 with all C_{m1} ;
C_1 = {size 1 frequent items};
// (3) min_support = num / total items; for example: 33%
L_1 = {size 1 frequent items ∩ min_support};

for ($k = 1$; L_k !=∅; k++) do begin

// (4) In each Map node *m*
// L_{mk}: L_k mapped to each node m;
// sort to remove duplicated items
$C_{m(k+1)} = L_k$ *join_sort* L_{mk};

// (5) In Reduce, use Apriori Property
compute C_{k+1} with all sorted $C_{m(k+1)}$;
if (k>=3) prune(C_{k+1});

for each transaction *t* in data source with C_{k+1} do
// (6) In each Map node *m*
increment the count of all candidates in $L_{m(k+1)}$ that are contained in *t*
end
// (7) In Reduce, find L_{k+1} with $L_{m(k+1)}$ and
// min_support
L_{k+1} = {size *k+1* frequent items ∩ min_support};
end

return ∪k L_k;

Figure 4.2. Apriori-Map/Reduce Algorithm

Figure 4.1 illustrates Map/Reduce control flow where, as m is map node id, each valuemn is simply 1 and gets accumulated for the occurrence of items together, which is clearly illustrated in Market Basket Analysis Algorithm of Woo et al [11-13]. Map function takes inputs (k_1, v_1) and generates $<k_2, v_2>$ where < > represents list or set. Combiner function that resides on map node takes inputs $(k_2, <v_2>)$ and generates $<k_2, v_2>$. Reduce function takes inputs $(k_2, <v_2>)$ and generates $<k_3, v_3>$.

Map/Reduce approach, especially for big data set, gives us the opportunity to develop new systems and evolve IT in parallel computing environment. The approach started a few years ago but many IT companies in the world already have adapted to Map/Reduce approach.

4.2 Apriori-Map/Reduce Algorithm

Figure 4.2 is the proposed *Apriori-Map/Reduce Algorithm* that runs on parallel Map/Reduce framework such as Apache Hadoop. *prune*(C_{k+1}) function is to remove the non-frequent item set C_{k+1} by eliminating non-frequent item sets C_k as non-frequent item sets cannot be a subset of frequent item sets.

The algorithm starts with (1) that calculates frequent item set for each map node as the time complexity $O(t/m \times n)$ when t: number of transactions, n: number of items in the transactions, m: num of map nodes. Then, (2) are to collect the frequent item set and (3) is to remove items that does not meet the minimum support in reduce nodes as $O(t/r \times n)$ when r: number of reduce nodes. The time complexity of (1-3) can be simplified initially to $O((t/m + t/r) \times n)$ and then $O(t \times n / x)$ when $m = r = p$.

(4) is to calculate frequent item set with an additional item by joining, sorting, and eliminating the duplicated items in each map node where *join_sort* is $O(k \times k / m)$ when k: size of frequent items and *prune* is $O((k-1) \times k / r)$ that is simplified to $O(k^2/r)$. Similarly, (5) is to collect the frequent item set at the reduce nodes. (6) is to count item frequencies that do not meet the minimum support at the map nodes as $O(t/m \times n)$. (7) is to remove items that does not meet the minimum support in reduce nodes as $O(t/r \times n)$ that is initially simplified to $O((t/m + t/r) \times n)$ and then $O(t \times n / p)$ when $m = r = p$.

4.2.1 Time Complexity

The overall time complexity of *Apriori-Map/Reduce Algorithm* is calculated as $O(k \times (k2 + t \times n)/p)$ where k: size of frequent items, t: number of transactions, n: number of items in the transactions, p: number of map and reduce nodes assuming the node sizes are the same. And, it becomes $O((k3 + k \times t \times n)/p)$ and then $O(k \times t \times n/p)$ where $t >> k$, $n >> k$. It theoretically shows that the time complexity is p times less than the sequential *apriori algorithm*.

4.2.2 Example of the Algorithm

Figure 4.3 is the example transaction data at a store to explain how the proposed algorithm works.

Transaction 1: cracker, beer
Transaction 2: chicken, pizza,
Transaction 3: coke, cracker, beer
Transaction 4: coke, cracker
Transaction 5: beer, chicken, coke
Transaction 6: chicken, coke

Figure 4.3 Transaction data at a store

Suppose that minimum support is 2/6 that represents two items out of 6 transactions as 33%.

(a) The first step
Assuming there are three Map nodes, two transaction data are distributed to three map nodes, that is, map node 1 has transaction data 1 and 2. Node 2 has transaction data 3 and 4. Node 3 has transaction data 5 and 6. Therefore, we can generate size 1 frequent items C_{m1} with an item pair set <*item, frequency*> at the map node m.

C_{11} = {<cracker, 1>, <beer, 1>, <chicken, 1>, <pizza, 1>}
C_{21} = {<coke, 2>, <cracker, 2>, <beer, 1>}
C_{31} = {<beer, 1>, <chicken, 2>, <coke, 2>}

From all C_{m1}, reduce nodes collect and compute C_1 that is size 1 frequent item pairs and L_1 that is size 1 frequent item pairs that meet minimum support. Thus, *[pizza, 1]* of C_1 is eliminated in L_1.

C_1 = {[cracker, 3], [beer, 3], [chicken, 3], [pizza, 1], [coke, 4]};
L_1 = {[cracker, 3], [beer, 3], [chicken, 3], [coke, 4]}

(b) The second step
In the loop, L_1 is mapped to each map node m for L_{m1}.

L_{11} = {cracker, beer}
L_{21} = {chicken}
L_{31} = {coke}

Then, size 2 frequent item pair sets can be generated by joining and sorting L_1 to each item sets of the map node m as $C_{m2} = L_1$ *join_sort* L_{m1} where the duplicated item sets are eliminated:

C_{12} = {<beer, cracker>, <chicken, cracker>, <beer, chicken>, <coke, cracker>, <beer, coke>}
C_{22} = {<chicken, cracker>, <beer, chicken>, <chicken, coke>}
C_{32} = {<coke, cracker>, <beer, coke>, <chicken, coke>}

From all C_{m2}, *reduce* nodes collect C_2 that is size 2 frequent item pairs.

C_2 = {<beer, cracker>, <chicken, cracker >, <beer, chicken>, <coke, cracker>, <beer, coke>, <chicken, coke>};

C2 is mapped to each map node as C_{m2} as follows:

C_{12} = {<beer, cracker>, <chicken, cracker >}
C_{22} = {<beer, chicken>, <coke, cracker>}
C_{32} = {<beer, coke>, <chicken, coke>}

Now, we can generate size 2 frequent items with an item pair set [*item, frequency]* at the node *m* that contains all transaction data as presented in Figure 4.2.

C_{12} = {[<beer, cracker>, 2], [<chicken, cracker>, 0]}
C_{22} = {[<beer, chicken>, 1], [<coke, cracker >, 2]}
C_{32} = {[<beer, coke>, 2], [<chicken, coke>, 2]}

From all C_{m2}, the reduce nodes collect and compute C_2 that is size 2 frequent item pairs and L_2 that is size 2 frequent item pairs that meet minimum support. Thus, *[<chicken, cracker >, 0]* and *[<beer, chicken >, 1]* are eliminated from C_2 for L_2:

C_2 = {[<beer, cracker>, 2], [<chicken, cracker >, 0], [<beer, chicken >, 1], [<coke, cracker>, 2], [<beer, coke>, 2], [<chicken, coke>, 2]};
L_2 = {[<beer, cracker>, 2], [<coke, cracker>, 2], [<beer, coke>, 2], [<chicken, coke>, 2]};

(c) The third step
In the loop, L_2 is mapped to each map node *m*.

L_{12} = {<beer, cracker>, <coke, cracker>}
L_{22} = {<beer, coke>}
L_{32} = {<chicken, coke>}

Then, size 3 frequent item pair sets can be generated by joining and sorting L_2 to each item sets of the map node *m* as $C_{m3} = L_2$ *join_sort* L_{m2} where the duplicated item sets are eliminated:

C_{13} = {<beer, coke, cracker>, <beer, chicken, coke>, <chicken, coke, cracker>}
C_{23} = {<beer, coke, cracker>, <beer, chicken, coke>}
C_{33} = {<beer, chicken, coke>, <chicken, coke, cracker>}

As the item size *k* is or greater than *3*, *prune*(C_{mk}) deletes non frequent item sets that violates *apriori property* that all subsets of a frequent item set must also be frequent:

C_{13} = {<beer, coke, cracker>}
C_{23} = {<beer, coke, cracker>}
C_{33} = {}

C_{13}, C_{23}, C_{33} eliminate <*beer, chicken, coke*> and C_{13}, C_{33} removes <*chicken, coke, cracker*> as <*beer, chicken*> and <*chicken, cracker*> respectively are not a member of L_2, that is, non-frequent items.

From all C_{m3}, reduce nodes collect C_3 that is size 3 frequent item pairs and L_3 that is size 3 frequent item pairs that meet minimum support:

C_3 = {<beer, coke, cracker>}
L_3 = {}

Since L_3 does not have any element, the algorithm ends. Therefore, we have frequent item sets L_1 and L_2 with size 1 and 2 respectively:

L1 = {[cracker, 3], [beer, 3], [chicken, 3], [coke, 4]}
L2 = {[<beer, cracker>, 2], [<coke, cracker>, 2], [<beer, coke>, 2], [<chicken, coke>, 2]};

The item sets L_1 and L_2 can be used to produce association rule of the transaction.

5 Conclusion

The paper proposes *Apriori-Map/Reduce Algorithm* and illustrates its time complexity, which theoretically shows that the algorithm gains much higher performance than the sequential algorithm as the map and reduce nodes get added. The item sets produced by the algorithm can be adopted to compute and produce Association Rule for market analysis.

The future work is to build the code following the algorithm on Hadoop frame and generate experimental data by executing the code with the sample transaction data, which practically proves that the proposed algorithm works. Besides, the algorithm should be extended to produce association rule.

Hybrid Algorithms for Matrix Multiplication on Multicore Clusters

Fabiana Leibovich, Marcelo Naiouf, Laura De Giusti, Fernando G. Tinetti[1] and Armando De Giusti

Instituto de Investigación en Informática LIDI (III-LIDI), Facultad de Informática, Universidad Nacional de La Plata, 50 y 120 2do piso, La Plata, Argentina.

Abstract - *Hybrid programming (through messages and shared memory) has gained importance since the appearance of multicore cluster architectures, fruit of the technological advance of processors and the physical limitations imposed by traditional architectures. This new programming paradigm allows exploiting the new memory hierarchy offered by the architecture.*
The purpose of this work is to carry out a comparative analysis between two hybrid algorithms that use two different parallel programming libraries for shared memory (PThreads and OpenMP). Both algorithms use MPI as message passing mechanism. For the experiments, the classic matrix multiplication problem is used, which is the basis for numerous applications.
The test architecture used for the experimental analysis is a multicore cluster. The performance obtained and programming tools are compared.

Keywords: parallel architectures, hybrid programming, cluster, multicore, message passing, shared memory.

1 Introduction

Parallel architectures have evolved to offer better response times for applications. As part of this evolution, clusters, then multi-cores, and currently multi-core cluster architectures, can be mentioned. The latter are basically a collection of multi-core processors interconnected through a network.

Multicore clusters allow combining the most distinctive features of clusters (use of message passing in shared memory) and multicores (use of shared memory). Also, they introduce modifications in memory hierarchy and further increase computer system capacity and power.

Taking into account the popularity of this architecture, it is important to study new parallel algorithms programming techniques that efficiently exploit its power, considering the hybrid systems in which shared memory and distributed memory are combined [1].

When it comes to implementing a parallel algorithm, it is very important to consider the memory hierarchy available, since this will directly affect algorithm performance. Figure 1 below shows the evolution.

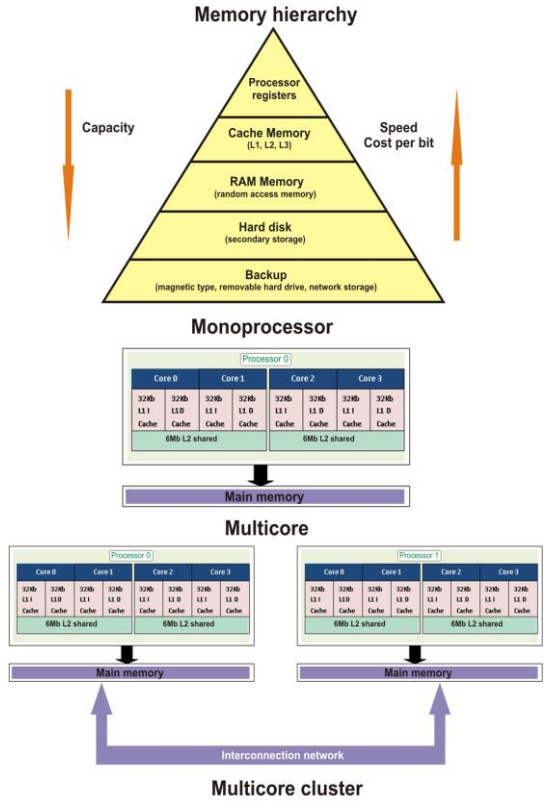

Figure (1) Memory hierarchy

Memory hierarchy performance is primarily determined by two hardware parameters: memory latency (time elapsed from the moment a piece of data is required and the moment it becomes available) and memory bandwidth (the speed with which data are sent from the memory to the processor). In the case of traditional clusters (both homogeneous and heterogeneous), there are memory levels in each processor (processor register and cache levels L1 and L2), but a new level is also included: network-distributed memory.

When considering a multi-core architecture, there are, in addition to register and L1 levels corresponding to each

[1]Investigador Comisión de Investigaciones Científicas Prov. de Bs. As.

core, two memory levels: cache memory shared by pairs of cores (L2) and memory shared among the cores of the multi-core processor [2]. Currently, the new architectures include one additional memory level, L3 cache.

In particular, multi-core clusters introduce one additional level to the traditional memory hierarchy. In addition to the cache memory shared between pairs of cores and the memory shared among all cores within the same physical processor, there is the distributed memory that is accessed through the network. This can also be seen in Figure 1.

This paper is organized as follows: Section 2 presents the objectives, then, Section 3 analyzes the parallel programming libraries used for the experiments. In Section 4, the existing mapping techniques used in this paper are discussed, while Section 5 presents the study case selected for testing and the solutions implemented. Finally, Section 6 discusses the results achieved, and Section 7 details the conclusions and future work.

2 Objective

The purpose of this paper is to carry out a comparative analysis of two hybrid solutions [3][4][5] that use the two shared memory libraries most commonly used nowadays in parallel computing: Pthreads and OpenMP.

Even though there is a large number of parallel applications in various areas, one of the most traditional and widely studied in parallel computation, and used in this paper, is matrix multiplication. It allows analyzing application scalability in two ways: by increasing the size of the problem and increasing the number of execution cores.

3 Parallel Programming Libraries

3.1. Pthreads

Over time, hardware manufacturers have implemented their own versions for thread management and administration. These versions are very different from each other, which makes it difficult for programmers to develop multithread applications that are portable. For this reason, in 1995 the IEEE established the POSIX (Portable Operating System Interface) standard. Its last version is IEEE Std 1003.1, 2004 Edition [6].

Pthreads is a library that implements the POSIX standard defined by IEEE, and is composed by a set of types and calls to procedures in programming language C that includes a header file and a thread library that is part, for example, of the libc library, among others. It is used for programming parallel applications that use shared memory.

The subroutines that form the API in Pthreads can be classified in four large groups: thread management, mutex (routines that handle synchronization and mutual exclusion), condition variables, and synchronization.

3.2. OpenMP

OpenMP is a programming interface (API) defined by a set of hardware and software manufacturer including the following: Sun Microsystems, IBM, Intel, AMD, among others [7].

It provides a portable and scalable interface for the developers of parallel applications that use shared memory.

This API supports C/C++ and Fortran in multiple architectures, including LINUX and Windows NT. It provides several builders and directives to specify parallel regions, shared work, synchronization, and environment variables.

It is formed by the following three components:

1. Compilation directives
2. Running time routine library
3. Environment variables

3.3. OpenMPI

MPI is a message passing interface that defines both the syntax and the semantics of the set of routines that can be used in the implementation of programs that use message passing. It was created to solve the issues that appeared after each hardware manufacturer defined its own communication interface, which in general were incompatible with all others. The purpose of MPI is to solve this problem by defining a standard [8].

MPI is a library that can be used to develop programs that use message passing (distributed memory) and uses the programming languages C or Fortran.

One of the implementations of this standard is OpenMPI, which is used in this paper, because it provides manual mapping mechanisms to assign processes to cores for their execution. This is discussed in Section 4.

3.4. Pthreads vs. OpenMP

It should be noted that *OpenMP* generates a pool of n threads (n is defined by the programmer) that is going to be re-used as needed in a very efficient manner. Thus, there is no need to create and remove threads when entering/leaving each parallel section. This is extensively exploited when the algorithm has several parallel sections.

In the case of Pthreads, threads would have to be created and destroyed for each of these sections, or a pool of threads would have to be created and kept from the algorithm. Also, if the algorithm required synchronization among threads, or more complex

parallelizations, such as shared variables reduction operations, combination of critical and non-critical sections, etc., OpenMP would in theory yield better results than Pthreads, since the library itself provides specialized and optimized mechanisms to do so, whereas Pthreads would require a manual implementation using semaphores or condition variables.

For this reason, one of the advantages of Pthreads over OpenMP is that the programmer has greater control over thread creation, destruction and behavior, since thread management is at a lower level than in OpenMP.

4 Thread and Process Manual Mapping

The traditional operating systems map threads and processes to processors and cores using various scheduling techniques.

However, there are mechanisms that allow application programmers to manually map these threads and processes. In the case of threads, the code of the application has to be modified, whereas in the case of process mapping, it can be done while it is running by using directly the binary.

Based on the architecture used in this paper, that is, multicore cluster, both mapping alternatives were used and combined to obtain a better global system performance. This can be done because the algorithms being studied use a hybrid model, combining shared memory and message passing.

4.1. Process Mapping

Open MPI is an open code project that implements the MPI standard and offers the added functionality of providing directives for explicitly mapping processes to processing cores. To do so, it requires two files called rankfile and hostfile.

The hostfile file defines the number of cores available in the system and the name of the machine in the network. The format of this file is the following:

hostNameX slots = number of cores
hostNameY slots = number of cores

The rankfile file defines an input for each process, as shown below:

rank N = hostNameX slot = number of CPU
rank M = hostNameY slot = number of CPU:number of core

Figure 2 shows a diagram explaining the parameters number of CPU and number of core.

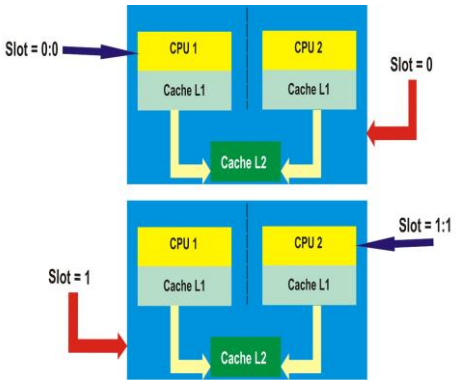

Figure (2) Manual mapping

These two files must be passed as parameter upon execution.

The advantage of this alternative is that the source code is untouched, there is no need to modify it to add this functionality, and as a consequence, the mapping process does not consume execution time. The disadvantage is that mapping is static and cannot be dynamically modified because it is passed as parameter upon execution.

4.2. Thread Mapping

In shared memory systems there is no specific function to assign a thread to a given processing core. Instead of this, there is a function that allows defining the affinity for each task.

Affinity allows specifying which, of all existing cores in a system, can be assigned a certain process or thread. To be able to assign these processes or threads to any given specific core, the core in question must be set as the only schedulable processor/core for such assignment.

Unix-based operating systems offer a system call that allows explicitly defining affinity. This should be used in shared memory environments, since it can manage the cores and processors in the machine on which the operating system is being run. The heading of this function is as follows:

sched_setaffinity(pid_t pid, unsigned long cpusetsize, cpu_set_t *mask)

Where:

- pid: is the process identifier for which affinity is defined. If its value is 0, it represents the process being run. It should be noted that the threads belonging to a same process share the same PID; however, the affinity belongs to each separate thread and is stored in the thread context.

- cpusetsize: this is the length (in bytes) of the data noted by the mask parameter.

- mask: this represents the affinity mask. It is a bit mask where each bit represents a (logical) processor in the system. Bits are sorted from the less significant one, corresponding to the first logical processor, to the most significant one, corresponding to the last logical processor in the system.

  If bit = 0, the processor is non-schedulable

  If bit = 1, the processor is schedulable

By default, when a thread/process is created, it is schedulable for all existing cores in the system. To map a process or thread to a specific processor, such processor must be set as the only schedulable processor.

One of the advantages of this scheduling technique is the possibility of dynamically modifying (during the execution) the schedule of any given thread/process. This is possible because the system call can be included in the application code.

5 Study Case

Given two matrixes A and B having dimensions m*p and p*n elements respectively, the multiplication of both matrixes consists in obtaining matrix C of dimension m*n elements (C = A*B), where each element is calculated with equation (1):

$$C_{i,j} = \sum_{k=1}^{p} A_{i,k} * B_{k,j} \qquad (1)$$

The implemented solutions can be classified in two classes: traditional matrix multiplication (I), and block-based matrix multiplication (II) (matrix C is calculated in blocks). In both cases, the implemented solutions are hybrid, combining shared memory with message passing, and use the master/worker interaction pattern. These were both developed using C language – in the case of message passing, the OpenMPI library [8] was used, while Pthreads [6] was used in one case of shared memory and OpenMP [7] was used in the other.

The testing architecture used should be noted, since it affects the implementation of the algorithms. The hardware used to carry out the tests was a Blade with 16 servers (blades). Each blade has 2 quad core Intel Xeon e5405 2.0 GHz processors; 2 Gb of RAM memory (shared between both processors); 2 X 6Mb L2 cache shared between each pair of cores by processor. The operating system used is Fedora 12, 64 bits [9][10].

5.1. Traditional Matrix Multiplication

There is one process per blade and each blade has 8 execution units – 7 threads are used for processing activities, added to the processing activities from the process itself that acts as a worker (one thread per core). A master/worker structure is used, with one of the processes acting as master, dividing the rows equally among all processes. Once this is done, it generates the corresponding processing threads (acting as worker). The other worker processes act in a similar way and send their results to the master process.

The algorithm can be summarized as follows:

Master process:

It divides the matrix into blocks of n rows/number of blades used for processing

It communicates the corresponding rows from matrix A and all of matrix B to worker processes.

It generates the threads and processes its own block

It receives results from worker processes.

Worker processes

They receive the corresponding rows from matrix A and all of matrix B.

They generate the threads to process the data.

They communicate the results to the master process.

Figure 3 shows an explanatory illustration. The numbers placed on matrix C indicate the number of the thread processed by each cell.

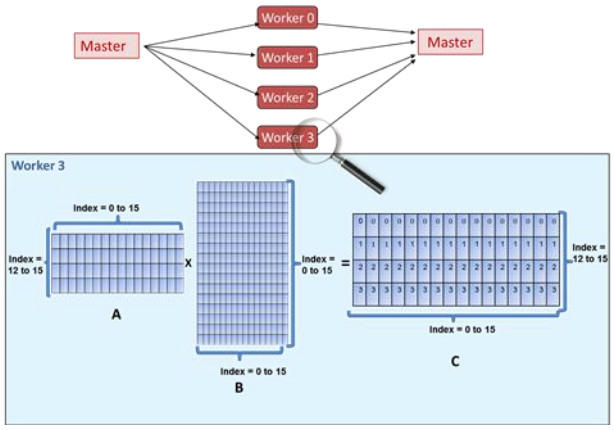

Figure (3) Classic matrix multiplication

5.2. Block Matrix Multiplication

Matrix C is calculated in blocks. To do so, each process receives the rows from matrix A and the columns from B required for calculating the block of matrix C that was assigned to it. The number of blocks into which matrix C is divided is divisible by the number of processes. The algorithm uses a master/worker-type interaction, where the master works both as coordinator and as worker. It divides matrix C into blocks to be processed and then generates processing phases. The same as in the traditional solution, each process is assigned to a blade and each thread to a core within the corresponding blade. Figure 4 shows an explanatory illustration. The numbers placed on matrix C indicate the number of the thread processed by each cell.

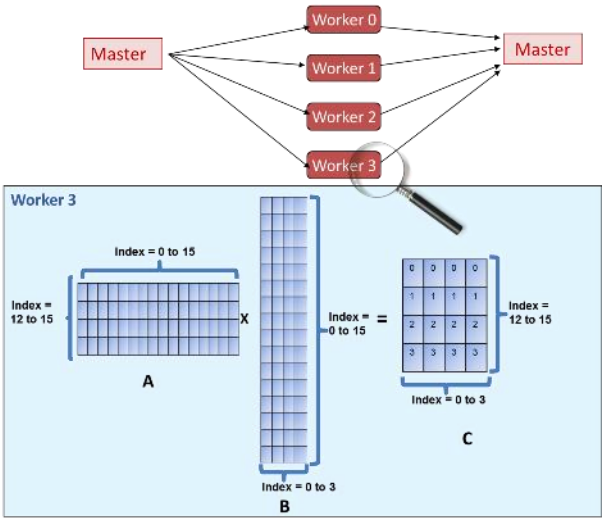

Figure (4) Block Matrix multiplication

Since all processors have the same computation power and all blocks to be processed are the same size, they will all be processed at (approximately) the same speed. Thus, for each processing phase, the master distributes the rows from matrix A and the columns from matrix B based on the block corresponding to each worker, including a block for itself. The master then processes its block and receives all the other results to move on to the next processing phase. The number of processing phases is calculated as follows: if b is the number of blocks that have to be processed and w is the number of workers (including the master, who also operates as a worker), the number of phases is b/w.

It should be noted that each process must store the rows from matrix A to be processed, the columns from matrix B, and the block from matrix C that it generates as a result.

In each phase, once the master distributes the blocks to the workers, it generates the corresponding threads to process its own block, dividing it into rows for each thread to process a subset of rows. The other worker processes act in a similar way, receiving data and sending their results to the master process.

The algorithm can be summarized as follows:

Master process:
It divides matrix C into blocks.
For each phase:
It communicates the corresponding rows from matrix A and the corresponding columns from matrix B to worker processes, based on the block assigned to each of them.
It generates the threads and processes its own block.
It receives results from worker processes.
Worker processes
For each phase:
They receive the data to be processed
They generate the threads and process the data.
They communicate the results to the master process.

6 Results obtained

The following tables show the execution times (expressed in seconds), the difference in time between both implementations, and the percent difference, (based on *Pthreads*) obtained for solution (I) explained in the previous section for 16 (Table 1) and 32 (Table 2) cores, and the results obtained by solution (II) for 16 (Table 3) and 32 (Table 4) cores.

Also, two charts are shown comparing solution execution times for traditional multiplication (Figure 5) and block multiplication (Figure 6).

Size	Pthreads	OpenMP	Difference	Percentage

Figure (6)

7 Conclusions and future work

As it can be observed, the difference in the times obtained by both implementations is not significant – it is never greater than 10%, – but in most of the cases for this problem, *Pthreads* yields slightly better results than *OpenMP*.

According to a report published by Intel, *OpenMP* has an initial *overhead* in its primitives as in the case of *#pragma omp parallel for*. This *overhead* will be significant or not depending on how much it represents, percentage-wise, in relation to the total execution time of the algorithm. It should be noted, however, that this *overhead* is initial and is not related to the operations executed later on [11].

In algorithms that efficiently exploit optimized operations of *OpenMP*, the difference between running the same algorithm with *Pthreads* or with *OpenMP* will in principle be more significant in favor of the latter [12].

However, from a programming effort standpoint, OpenMP markedly simplifies algorithm implementation thanks to the directives it provides. It allows parallelizing a sequential solution in only a few steps, given its high abstraction level. In fact, a solution that has been parallelized with OpenMP allows running the algorithm as if it were the original sequential solution just by disabling the library. The abstraction level provided by OpenMP greatly facilitates the learning and use of the library. Also, the programming directives themselves document the parallelization of the application.

As future line of work, we will work in adapting the algorithms to be run on a heterogeneous architecture, both from the point of view of processor speed and memory hierarchy. Thus, the algorithms will have to respond to new challenges such as load balancing and dynamic work distribution, among others.

Modeling of Hierarchical Multiprocessor Database Systems*

Pavel S. Kostenetskiy, Leonid B. Sokolinsky
South Ural State University, Chelyabinsk, Russia

Abstract - *The paper is devoted to the issues concerning with modeling and simulating of hierarchical database multiprocessor systems. The requirements for a model of parallel database systems are defined. A new computational model of the hierarchical database multiprocessor architecture is described. This model is called DMM (Database Multiprocessor Model) and designed for OLTP workload. It allows us to simulate and analyze an arbitrary multiprocessors configuration for database application. The practical experience of exploiting the DMM model is discussed.*

Keywords: parallel query processing, database multiprocessor model.

1 Introduction

Modern multiprocessor systems mostly have a hierarchical topology. So, the modern computing clusters have three-level multiprocessor architecture. The multicore processor forms the first level of hierarchy. Each computing node of the cluster is a multiprocessor with shared memory. It is the second level of hierarchy. The third level of hierarchy is presented by computing cluster consisting of homogeneous computing nodes interconnected by high-speed network. Another source of multiprocessor hierarchies is presented by Grid-technologies. Grid-system can consist of several clusters interconnected by LAN. Grid-systems can be divided into three classes in accordance with communication network size: intragrid, extragrid and intergrid. Intragrid system incorporates the set of clusters interconnected by LAN inside one organization. Extragrid system is built on interconnection of several intragrid systems. Intergrid system can integrates dozens of extragrid systems in united computational meta-system by the Internet. The general structure of the multiprocessor hierarchy is shown in Fig. 1.

In the nearest future, big organizations will exploit databases which contain many petabytes of information [2]. The hierarchical multiprocessor multicore systems with hundred thousand processors will be needed to manage such huge volumes of data. Therefore the issues of mathematical modeling, simulating and analyzing of the new hierarchical database multiprocessors architectures are important. The first papers devoted to parallel database modeling are the following [1, 3, 4, 5, 6, 7, 8]. All the models proposed in these papers took into account the peculiarity of database

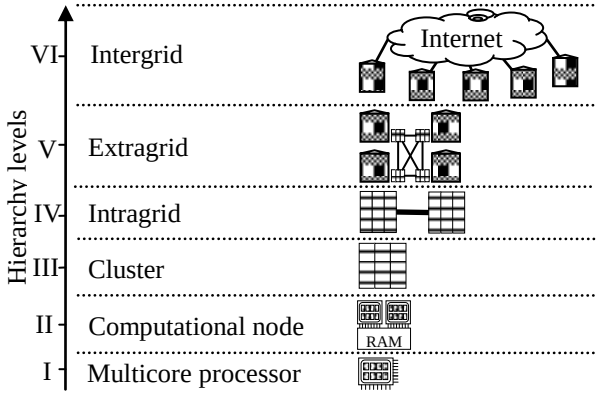

Fig. 1. Structure of multiprocessor hierarchy

applications. However, all these models ignored communication overhead, which is very important for parallel database systems. The first work taking into account the communication overhead was the paper [10]. In this paper, the model of Gamma database machine [9] for multiprocessor system InteliPSC/2 Hipercube consisting of 32 processor nodes was described. The modeling language DeNet [12] was used for description of the model. The model had a network structure. The nodes were presented by abstract modules generating discrete events. The arcs represented the data flows. The certain message type could be associated with each arc.

The further development in modeling of parallel database systems is related with appearance of the hierarchical systems. In paper [14], the model of two-level architecture was described. This model included the transaction, system and queue submodels. In accordance with classification described in work [13], this architecture can be classified as CE (*Clustered Everything*). In such a case, the system consists of *N shared everything* clusters interconnected by the global communication network in *shared nothing* manner.

The database is simulated as a collection of relations, each of which is uniformly partitioned between disks. For every attribute, the set of attribute values is simulated by means of specifying the probability distribution function and the number of unique attribute values. It is supposed that distribution function can be uniform or normal. In addition, it is expected that the attribute distribution function is the same for all the disks and every unique value is presented on every disk. There are two types of transactions in the transaction model: 1) update transactions, 2) query transactions.

Update transactions are simulated as a sequence of the read/write page operations. Query transactions correspond to

* Supported by the Russian Foundation for Basic Research under Grant 12-07-00443-a and by the Federal Program 07.514.11.4036.

relational operators. They are simulated as a sequence of read operations, because the intermediate result is saved in the main memory or in the temporary file and doesn't change the database. Each transaction is represented by the set of processes that run on different nodes and use data interchange. The proposed model doesn't support the data replication. It doesn't also support Zipf's distribution and 80/20 rule. Moreover, this model does not admit a generalization on the arbitrary number of hierarchy levels.

The remainder of the paper has the following outline. In Section 2, the new computational model for hierarchical database multiprocessor architecture is described. This model is called *DMM* (Database Multiprocessor Model). In Section 3, the results of simulating database applications in various multiprocessor configurations are proposed. The last section gives summary of the basic results obtained and conclusions, as well as discusses directions of future research.

2 Database Multiprocessor modules

The *DMM* model includes the following sub-models: *hardware model*, *software model*, *cost model* and *transaction model*.

2.1 Hardware model

The set of multiprocessor system modules is divided into three non-overlapping subsets:

$$\mathfrak{M} = \mathfrak{P} \cup \mathfrak{D} \cup \mathfrak{N},\ \mathfrak{P} \cap \mathfrak{D} = \varnothing,\ \mathfrak{P} \cap \mathfrak{N} = \varnothing,\ \mathfrak{D} \cap \mathfrak{N} = \varnothing.$$

There, $\mathfrak{P}$ is the set of *processor modules*, $\mathfrak{D}$ is the set of *disk modules* and $\mathfrak{N}$ is the set of *hub modules*. The *DMM* model does not provide a representation of memory modules, since in *OLTP* workload, the disk access time is much more then memory access time.

The *DM-graph* is connected acyclic graph $\mathfrak{W}(\mathfrak{M}, \mathfrak{E})$, where the set of edges $\mathfrak{E}$ meets the following restrictions:

$$\mathfrak{P} \cup \mathfrak{D} \neq \varnothing, \mathfrak{N} \neq \varnothing; \quad (1)$$

$$\forall P \in \mathfrak{P}\left(\forall M \in \mathfrak{M}\left(\left(\exists E(A,A') \in \mathfrak{E}\begin{pmatrix}(\text{init}(A) = P \wedge \text{fin}(A) = M)\\ \vee(\text{init}(A') = P \wedge \text{fin}(A') = M)\end{pmatrix}\right) \Rightarrow M \in \mathfrak{N}\right)\right); \quad (2)$$

$$\forall D \in \mathfrak{D}\left(\forall M \in \mathfrak{M}\left(\left(\exists E(A,A') \in \mathfrak{E}\begin{pmatrix}(\text{init}(A) = D \wedge \text{fin}(A) = M)\\ \vee(\text{init}(A') = D \wedge \text{fin}(A') = M)\end{pmatrix}\right) \Rightarrow M \in \mathfrak{N}\right)\right); \quad (3)$$

$$\forall M \in \mathfrak{M}\left(\left(\forall E(A,A'), \tilde{E}(\tilde{A},\tilde{A}')\left(\left(\begin{pmatrix}(\text{init}(A) = M \vee \text{init}(A') = M)\\ \wedge(\text{init}(\tilde{A}) = M \vee \text{init}(\tilde{A}') = M)\end{pmatrix} \Rightarrow (E = \tilde{E})\right)\right) \Rightarrow (M \in \mathfrak{D} \cup \mathfrak{P})\right). \quad (4)$$

Condition (1) means that simulating hardware model must include at least one hub and at least one processor or disk. Conditions (2) and (3) mean that processor and disk modules are able to connect only with hub modules. Condition (4) means that disk and processor modules may not have any descendants, and thus are always the leaf nodes of *DM*-tree.

DM-tree is the *DM*-graph with dedicated node $\bar{N} \in \mathfrak{N}$ called root hub.

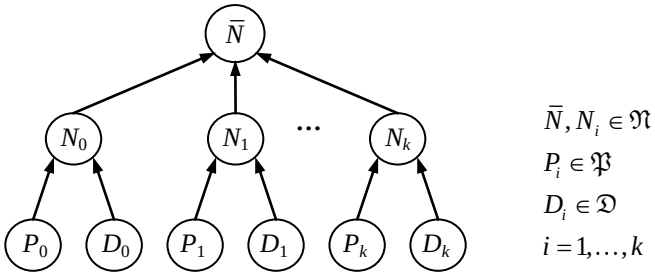

Fig. 2. *DM*-tree example

2.2 Software model

The smallest unit of measuring data in the *DMM* is defined as a "*packet*". We will assume that all packets have the same size. The header of packet includes sender address, the recipient address and some other information. Transfer of a packet corresponds to transfer of one or several tuples in the real databases system.

The *DMM* model does not provide a representation of memory modules, since in *OLTP* workload, the disk access time is much more then memory access time. Any processor module can exchange data with any disk module. Disk modules and hub modules have queue buffers, which are used for packet transfer. The *DMM* model assumes the asynchronous transfer mode. It means that the processor module may start a new exchange without waiting the completion of previous one. However, we suppose that processor module may have not more than s_r uncompleted read operations and not more than s_w uncompleted write operations.

In the *DMM* model, data processing is divided into discrete time intervals called *ticks*. The tick can be defined as a predetermined sequence of steps, which will be described below.

Let $M \in \mathfrak{M}$. We will use the following denotations: $F(M)$ – parent module of node M, $T(M)$ – subtree, which has M as a root.

Processor module $P \in \mathfrak{P}$ may activate read/write operations. Let's define their semantic as follows.

Read Operation. Let processor module P has to read packet E from disk module $D \in \mathfrak{D}$. If P has already activated s_r uncompleted read operations then P has to be suspended. Otherwise, the packet E has to be put in the queue buffer of disk D. At that case, packet E has $\alpha(E)=P$ as a recipient address and $\beta(E)=D$ as a sender address. This algorithm is shown in Fig. 3.

```
if r(P) < s_r then
  Put packet E with address P in the
    queue buffer D
  r(P)++;
else
  wait;
end if
```

Fig. 3. Processor module read algorithm

```
if w(P) < s_w then
  Put packet E in the queue buffer of
    parent hub module;
  w(P)++;
else
  wait;
end if
```

Fig. 4. Processor module write algorithm

There, $r(P)$ is the number of uncompleted read operations for processor module P, s_r is the maximum number of uncompleted read operations.

Write operation. Let processor module P has to write packet E to the disk module $D \in \mathfrak{D}$. The algorithm is shown in Fig. 4.

There, $w(P)$ is the number of uncompleted write operations for processor module P, s_w is the maximum number of uncompleted write operations.

Hub module $N \in \mathfrak{N}$ permanently transfers packets through interconnect. It performs an algorithm, which is shown in Fig. 5.

```
Remove packet E from queue of N;
if α(E) ∉ T(N) then
  Put E in queue F(N);
else
  Find maximum subtree U of
    T(N): α(E)∈U;
  if T(α(E))==U then
    if α(E)∈𝔓 then
      r(α(E))-- ;
    else
      Put E in queue α(E);
    end if
  else
    Put E in queue R(U);
  end if
end if
```

Fig. 5. Hub module algorithm

```
Remove packet E from queue of module D;
if α(E)∈𝔇 then
        w(β(E))-- ;
else
        Put E in the parent queue;
end if
```

Fig. 6. Disk module algorithm

There, E is a packet, $\alpha(E)$ is the recipient address of packet E, $T(N)$ is a subtree, which has N as a root, $F(N)$ is the parent module for N, $\mathfrak{P}$ is a set of all processor modules, $r(P)$ is the number of uncompleted read operations for processor module P, $R(U)$ is the root of a subtree U.

Disk module $D \in \mathfrak{D}$ permanently executes read/write operations. It performs an algorithm, which is shown in Fig. 6. There, $\beta(E)$ is a sender address, $w(\beta(E))$ is the number of uncompleted write operations of sender.

In the *DMM* model, data processing is divided into discrete time intervals called *ticks*. The tick can be defined as a predetermined sequence of the following steps:

1) each hub module handles all packets, which are waiting for transfer;
2) each active processor module performs one read or write operation;
3) each disk module handles one packet from its queue.

It is obvious that in this case, the queue of any hub module may contain not more then $|\mathfrak{P}|+|\mathfrak{D}|$ packets, and the queue of any disk module may contain not more then $s_r s_w |\mathfrak{P}|$ packets.

2.3 Cost model

Each module $M \in \mathfrak{M}$ has a *cost coefficient* $h_M \in \mathbb{R}$, $1 \le h_M < +\infty$. The time needed for a processor to process one packet for *OLTP* applications is roughly 10^5-10^6 times smaller, than the time it takes to transfer data to or from a hard disk, or from the network. Therefore, for all processor modules: $h_P = 1, \quad \forall P \in \mathfrak{P}$.

Hub module N can send more than one packet in each tick. Therefore the following interference function is associated with each hub module $N \in \mathfrak{N}$: $f_N(m_i^N) = \left\lceil \frac{m_i^N}{\tau_N} \right\rceil \delta_N$.

There, m_i^N – is the number of packets transferred by N in the i-th tick; $0 \le \delta_N \le 1$ – scale coefficient, $\tau_N > 1$ is threshold coefficient (the maximum number of the packets sending at the same time which doesn't slow hub module's work). Therefore, the time it takes for hub module N to process i-th tick can be calculated by the formula:

$$t_i^N = h_N f_N(m_i^N), \qquad \forall N \in \mathfrak{N}.$$

The total time spent by the system to process a mix of transactions over k ticks can be calculated by the formula: $t = \sum_{i=1}^{k} \left(\max_{N \in \mathfrak{N}}(t_i^N) + \max_{N \in \mathfrak{D}}(h_D) \right)$.

2.4 Transaction Model

Serial transaction is the transaction which runs on one processor module. Serial transaction Z is simulated by setting of two process groups ρ and ω: $Z = \{\rho, \omega\}$, $\rho \cup \omega \neq \varnothing$. Group ρ includes *read* processes. Group ω includes *write* processes. These processes are an abstract representation of read/write operations performed during transaction processing. Each read and write process has to make the certain *number of disk accesses*. After making all the accesses the process is removed from ρ or ω respectively. Transaction $Z = \{\rho, \omega\}$ is considered as finished when $\rho \cup \omega = \varnothing$.

In the *DMM* model each transaction $Z = \{\rho, \omega\}$ is divided into the finite sequence of steps: $Z_1, \ldots, Z_s$. There, s is the number of transaction steps. In accordance with this each process $x \in \rho \cup \omega$ of transaction Z is divided into s steps: $x_1, \ldots, x_s$. Each step x_i $(i = 1, \ldots, s)$ is described by the set of three numbers (n_i, p_i, d_i). There, d_i is the disk number the process x exchanges data with, n_i is number of disk accesses, p_i is probability of access by process x to disk D_{d_i} on each tick of the simulator running during i-th step.

* Supported by the Russian Foundation for Basic Research under Grant 12-07-00443-a and by the Federal Program 07.514.11.4036.

Consider the following example. Let transaction $Z=\{\rho,\omega\}$ represent MHJ JOIN of two relations. Let's assume that build relation *R* occupies 10 blocks and might be fully placed in main memory, probe relation *S* occupies 10 000 blocks. Let the result be 1000 blocks. Assume that input relations are placed on disk D_5; result is also being saved on D_5. In this case transaction Z is divided into two steps: on the first step the hash table for build relation is being constructed (read process a); on the second step the scanning of probe relation (read process b) and saving the output relation to the disk (write process c) are occurring. Thus, the set of read processes is $\rho=\{a,b\}$, the set of write processes is $\omega=\{c\}$. Each process is divided into two serial steps.

For read process *a* the decomposition is $a=\{a_1,a_2\}$, where $a_1=(10,1,5)$, $a_2=(0,1,5)$. The process *a* makes ten accesses to disk D_5 with probability of 1 on the first step. This step simulates the constructing of hash table in main memory. On the second step process *a* doesn't make any accesses to the disk.

For read process *b* the decomposition is $b=\{b_1,b_2\}$, where $b_1=(0,1,5)$, $b_2=(10000,1,5)$. On the first step process *b* doesn't make any accesses to the disk. On the second step process *b* makes 10 000 accesses to disk D_5 with probability of 1. This step simulates the scanning of probe relation.

For write process *c* the decomposition is $c=\{c_1,c_2\}$, where $c_1=(0,1,5)$, $c_2=(1000,0.1,5)$. On the first step process *c* doesn't make any accesses to the disk. On the second step process *c* makes 1000 accesses to disk D_5. Herewith on each tick of simulator the probability of disk access is 0.1. The last number is obtained as result of dividing the number of blocks of build relation on the number of blocks of probe relation. We suppose here that values of join attribute are uniformly distributed. For simulation of nonuniform distribution (e.g. the 80/20 rule) it is necessary to use more steps.

Parallel transaction is the transaction that requires two or more processor modules for processing. Parallel transaction *Z* that is being processed on *l* processor modules is simulated as *l* serial transactions $Z^1,\ldots,Z^l$, each of which is processed on the separate processor module. So we can consider that only serial transactions are being processed in the system.

The algorithm that simulates the processing of one transaction on the processor module is described below. Let transaction $Z=\{\rho,\omega\}$ consist of *s* steps $Z_1,\ldots,Z_s$. Let *X* be the set of all read and write processes that compose transaction *Z*: $X=\rho\cup\omega$. Let $X=\{x^1,\ldots,x^r\}$. Each process x^j ($j=1,\ldots,r$) is divided into *s* steps: $x_1^j,\ldots,x_s^j$. Suppose that the *i*-th step of transaction Z is started. Assume that the process x^j obtained the control. Let *i*-th step of process x^j be $x_i^j=(n_i^j,p_i^j,d_i^j)$. It's supposed that process x^j is able to obtain the control in the *i*-th step only if $n_i^j>0$. Then the following sequence of actions runs on the current tick.

1) The value of n_i^j decrements by one.
2) Process x^j initiates exchange operation with disk d_i^j.
3) If $\sum_{j=1}^{r} n_i^j=0$ and $i<s$, then increment i (current transaction step number) by one.

State $n_i^j=0$ corresponds to the ending of *i*-th step of process x^j. State $\sum_{j=1}^{r} n_i^j=0$ corresponds to the ending of *i*-th step of transaction *Z*. Thus, only when all the processes of transaction *Z* finished the processing of *i*-th step, the transaction transfers to step *i*+1.

DMM model allows the processing of *serial transaction mix* $\{Z^i\,|\,i=1,\ldots,k\}$ on one processor in the time-sharing mode. In this case each transaction Z^i $(i=1,\ldots,k)$ appears as its own pair of read and write processes group: $Z^i=\{\rho^i,\omega^i\}$. All the quantity of processes that simulate transaction mix processing on the processor $P\in\mathfrak{P}$ is defined by the following formula: $\Phi_P=\bigcup_{i=1}^{k}(\rho^i\cup\omega^i)$.

The read and write processes that describe the transaction are dynamically appended to the set Φ_P when the new transaction runs on the processor *P*. If some process is finished, it is being deleted from the set Φ_P.

Let's consider the processing of transaction mix Φ_P on processor *P* in the *DMM* model. Processor *P* must initialize one disk access operation on each tick. In accordance with this processor must choose the process $x\in\Phi$ and perform the read or write operation with disk that associated with *x* during the current step. We will call such process *active*. All the processes in the set Φ are organized in the list. Let the pointer to the current list element be (its initial position might be random). In the Fig. 7 the algorithm for defining the active process is shown.

```
//Loop on processors:
for (P = P.begin(); P != P.end(); P++){
   prob = 0; // Summary probability
   //Loop on processes:
   for(x= P.Φ.begin(); x!= P.Φ.end(); x++){
      if (n(x,i(x)) == 0) continue;
      prob += p(x,i(x));
      if (g(prob)) return x;
   };
};
```

Fig. 7. Active process *x* choosing procedure

There, $\mathfrak{P}$ is the set of all processor modules of *DM*-tree, *s(x)* is the number of process *x* steps, *n(x,i)* is the number of disk accesses that process *x* still has to make during *i*-th step, *p(x,i)* is the probability of process's *x* disk access during *i*-th step, *g* is the actuation function and defined by the following description. For each step *i* of process $x\in\Phi$ the probability of access by process *x* to disk associated with this process on *i*-th step is known. The actuation function $g(p_i^x)=G$ is

* Supported by the Russian Foundation for Basic Research under Grant 12-07-00443-a and by the Federal Program 07.514.11.4036.

described by the function of discrete random variable G, which defined by the following distribution law:

G	1	0
P	p_i^x	$1-p_i^x$

Let's review the *transactions creation* in *DMM* model using *MHJ* (*Main memory Hash Join*) algorithm as the example. This algorithm is intensively used in modern DBMS for query processing in cases when one of the relations is completely placed in main memory. MHJ algorithm is divided into "*build*" and "*probe*" *phases*. The hash table for the relation *R* is being constructed on the "*build*" *phase*. Herewith each processor node makes the following operations:

1. Sequential scanning of tuples of the own fragment of relation *R*. For each input tuple the distribution function ψ is calculated. This function calculates the number of the cluster node where this tuple has to be processed. The tuple is transferred to this node.
2. The hash table is built in the main memory of the node using hash function *h*(*t*) for tuples that received during step 1.

The processing of the relation *S* and joining with the tuples from relation *R* are made on the "*probe*" *phase*. Herewith each processor node makes the following operations:

1. Sequential scanning of tuples of the own fragment of relation *S*. For each input tuple the distribution function ψ is calculated. The tuple is transferred to the cluster node where this tuple has to be processed.
2. The tuple from step 1 is received and joined with tuples from step 2 of build phase. The output tuple is created.

Exchange operator redistributes the tuples among the processor nodes on each algorithm phase. The parallel query plan for MHJ operation is shown in Fig. 8. *Scan* operator scans the relation. *Exchange* operator is inserted as the left son and right son of MHJ operator and redistributes the tuples from *scan* operator among the processor nodes during the query processing.

Suppose that we need to create the model of the parallel transaction which is the natural join of *R* and *S* relations on their common attribute *A*. We suppose that the values of attribute *A* are uniformly distributed among fragments of relations *R* and *S*. For both relations we used the skew coefficient μ. According to this coefficient the tuples are divided into two classes: "own" and "alien". μ coefficient determines the percentage of "own" tuples in the fragment. The "own" tuples should be processed on the same cluster node where they are being stored. The "alien" tuples should be transferred to another cluster node on the basis of uniform distribution. For example, if $\mu = 0.5$ the relation is formed in such a way that each parallel agent passes to the other agents about 50% of the tuples of its fragment during the join processing. Herewith all the other agents receive about the same number of tuples.

We suppose that relation *R* is divided into equal-sized fragments $R_i\,(i = 0,\ldots, N-1)$. Each of these fragments is placed on the node which number coincides with the fragment number. Herewith any fragment R_k is able to be placed in main memory of the node. Similarly *S* is divided into equal-sized fragments $S_i\,(i = 0,\ldots, N-1)$. Each of these fragments is placed on the node which number coincides with the fragment number.

Parallel transaction is represented as the set of one-type serial transactions. Each of these transactions is processed on the distinct cluster nodes. Let the cluster node #0 process transaction $Z = \{p\}$. Transaction *Z* and all the processes occurring in it are divided into two steps. The first step simulates the build phase, the second step simulates the probe phase. The set of read processes of transaction *Z* is $\rho = \{a^0,\ldots,a^{N-1}, b^0,\ldots,b^{N-1}\}$.

Processes $a^0,\ldots,a^{N-1}$ conform to build phase. Process a^0 simulates the reading of "own" tuples of relation *R* from own disk D_0. It consists of two steps: $a^0 = \{a_1^0, a_2^0\}$, where $a_1^0 = (\frac{\mu |R|}{N}, \mu, 0)$, $a_2^0 = (0,0,0)$. Processes $a^j\,(j = 1,\ldots, N-1)$ simulate the reading of "own" tuples of relation *R* from alien disks. Each such process consists of two steps: $a^j = \{a_1^j, a_2^j\}$, where $a_1^j = (\frac{(1-\mu)|R|}{N^2 - N}, \frac{(1-\mu)}{(N-1)}, j)$, $a_2^j = (0,0,j)$.

Processes $b^0,\ldots,b^{N-1}$ conform to probe phase. Process b^0 simulates the reading of "own" tuples of relation *S* from own disk D_0. It consists of two steps: $b^0 = \{b_1^0, b_2^0\}$, where $b_1^0 = (0,0,0)$, $b_2^0 = (\frac{\mu |S|}{N}, \mu, 0)$. Processes $b^j\,(j = 1,\ldots, N-1)$ simulate the reading of "own" tuples of relation *S* from alien disks. Each such process consists of two steps: $b^j = \{b_1^j, b_2^j\}$, where $b_1^j = \{0,0,0\}$, $b_2^j = (\frac{(1-\mu)|S|}{N^2 - N}, \frac{(1-\mu)}{(N-1)}, j)$.

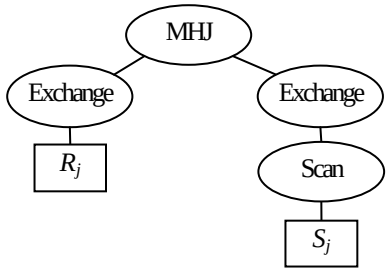

Fig. 8. MHJ query parallel plan

The transactions that are being processed on other cluster nodes are formed analogically.

3 DMM model usage

The *Database Multiprocessor Simulator* is developed on the basis of *DMM*. It allows to simulate and investigate various multiprocessor configuration for *OLTP* workload. The source

* Supported by the Russian Foundation for Basic Research under Grant 12-07-00443-a and by the Federal Program 07.514.11.4036.

code of the simulator is available on the Internet at http://kps.susu.ru/science/dms/sources/DMS-sources.zip. The simulation experiments for transaction processing on existing cluster configurations were performed with the simulator. Then these transactions were performed on the real cluster systems. They demonstrate that the simulator demonstrates the results that are identical to the result of real parallel DBMS processing on the cluster with the simulated architecture. It confirms the adequacy of *DMM*. In this section we are exemplifying the usage of simulator to evaluate the effectiveness of purchasing and upgrading decision of database oriented multiprocessor systems.

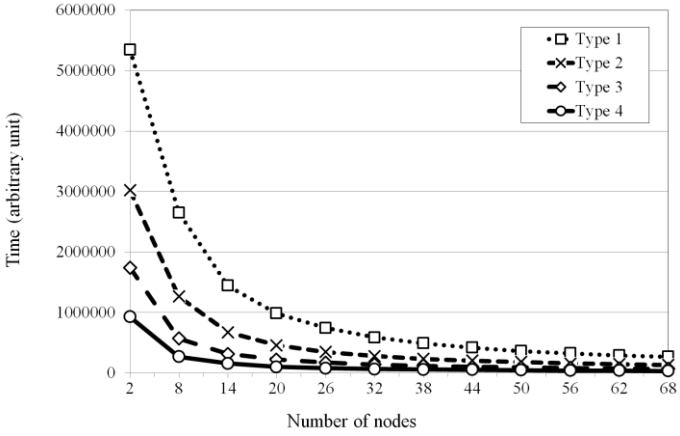

Fig. 9. The dependence of the query processing time from the number and type of nodes

In our experiments we processed natural join for relations *R* and *S* by the *MHJ*. The number of tuples of R and S, respectively, were 6 000 000 and 600 000 000 tuples.

The diagrams of dependence of query processing time from the number and type of nodes were obtained with emulator. They are shown in Fig. 9. The four types of nodes with characteristics and price given in Table 1 were simulated. The price consists of the price of infrastructure (UPS, cooling system, InfiniBand QDR communication network, cases, power supply units, racks, etc.).

Table 1. Prices of computing nodes

Node type	Main characteristics	Price (€)		
		year 2009	year 2011	year 2013 (forecast)
1	One single core CPU and one SAS disk	7,100	6,650	–
2	One double core CPU and two SAS disks	7,775	7,450	7,375
3	Two double core CPU and four SAS disks	8,725	8,125	7,750
4	Two quad-core CPU and eight SAS disks	10,425	9,875	8,650

Table 2. Performance of computing clusters

Number	Configuration	Transaction processing time (in arbitrary units)
1	37 type 1 nodes	496032
2	33 type 2 nodes	265325
3	30 type 3 nodes	146713
4	25 type 4 nodes	78520

Let's exemplify the usage of *DMS* simulator for solving the problems of long-term planning of development of computational capacities in data processing centers.

Example 1. Suppose that the organization has €250,000 for purchasing a computer cluster for database applications. We have to select the most productive hardware architecture, varying the configuration and number of nodes in the system. The cost of this architecture should not exceed that sum of money. Based on dependencies that shown in Fig. 9 we constructed Table 2. It contains different variants of cluster configurations, which cost about €250,000. The transaction processing time in arbitrary units is shown for each configuration. On the Table 2 we can determine that at a given price, the best performance will provide the configuration 4, that consists of 25 type 4 nodes.

Example 2. Let the organization have purchased the computing cluster for database application in 2009. This cluster consists of 20 type 3 nodes. Assume that by 2011 the size of database application has increased by 1.5 times and it became necessary to expand the system. We have to determine how many type 3 nodes should be purchased to increase the system performance by 1.5 times. The current system processes the transactions for 222700 arbitrary units of time, according to Fig. 9. Respectively, the system with 1.5 times higher performance should process equal mix of transactions for 148467 arbitrary units of time. Using Fig. 9 we can determine that the system that consists of 31 type 3 nodes will provide the specified performance. Thus, it is necessary to purchase 11 additional type 3 nodes for €89,375.

Example 3. Let the organization have purchased the computing cluster for database application in 2009. This cluster consists of 26 type 2 nodes. Assume that by 2011 the size of database application has increased by 1.5 times and we know that we know that the same growth dynamics of database size will continue in the next two years. We have to make the first step of system upgrade in such a way that total cost of the two steps of extension (in 2011 and 2013) was minimal.

Table 3. Performance requirements

Step	Year	Time (in arbitrary units)
1	2009	346722
2	2011	231148
3	2013	154099

Table 4. Variants of configuration

Node types	Number of nodes		
	Year 2009	Year 2011	Year 2013
2	26	39	57
4	–	10	15

The requirements for the performance of computing cluster in 2009, 2011 and 2013 are shown in Table 3. These requirements are based on dependencies in Fig. 9. The variants of allowable configurations that will provide the required performance are shown in Table 4.

We consider two variants of the first upgrade step (year 2011):

A.1) expansion of the current system by adding the necessary number of type 2 nodes;

B.1) replacement of the current cluster to the new with type 4 nodes.

Using Table 4 we can see that in case of variant A.1 we have to purchase 13 type 2 nodes. Using Table 1 we calculate that the cost of variant A.1 is €96,850. Analogically we get that the

* Supported by the Russian Foundation for Basic Research under Grant 12-07-00443-a and by the Federal Program 07.514.11.4036.

variant B.1 is the purchasing of 10 type 4 nodes, which cost €98,750.

In line with what variant we choose, we may get two variants on the second step of upgrade in 2013:

A.2) expansion of the system by adding the necessary number of type 2 nodes;

B.2) expansion of the system by adding the necessary number of type 4 nodes.

Using the similar calculations we get that variant A.2 is to purchase 18 type 2 nodes, which cost €13,2750, and variant B.2 is to purchase 5 type 4 nodes, which cost €43,250.

Table 5. Upgrade cost

Upgrade variant	Step		In total (€)
	1	2	
A	96,850	132,750	229,600
B	98,750	43,250	142,000

The total cost of two types of upgrade is shown in Table 5. We can see that variant A is more profitable on the first step, but after step 2 it is more expensive than variant B for €87,600.

4 Conclusion

In this paper, we introduced the new computational model of the hierarchical database multiprocessor architecture. This model is called *DMM* (*Database Multiprocessor Model*) and designed for *OLTP* workload. It allows us to simulate and analyze an arbitrary multiprocessors configuration for database application.

The *Database Multiprocessor Simulator* is developed on the basis of *DMM*. It allows to simulate and investigate various multiprocessor configuration for *OLTP* workload. The experiments for search for optimal hardware architectures of parallel database systems were performed with the simulator.

The main directions of future work are the following. First, it is interesting to use *DMM* for simulating parallel database systems' processing on the petascale multiprocessor systems based on NVIDIA Tesla and Intel Many Integrated Core (MIC) accelerators [11]. Second, we plan to apply *DMM* model for simulating the parallel database systems processing in grid. Third, we suppose to extend the *DMM* model for OLAP applications.

School of Computer Engineering, Iran University of Science and Technology, Tehran, Iran

Abstract - *Ever-increasing growth of high performance computing applications requires employment of novel methods in all aspects of computing systems. The response time of file storage and retrieval operations is one of the most important factors of storage systems and improving that will result higher computational power. Consequently, breathtaking efforts have been done and various file systems with different architectures have been proposed. Most of them are not aware of clusters' execution state and do not consider variety of I/O operations' response time on machines with different storage media, network traffic, and processing load. In this paper, we have proposed a mechanism to store and retrieve files with respect to the execution state of storage nodes and network topology of the cluster. Finally, the proposed architecture has been implemented and evaluated using Hadoop distributed file system.*

Keywords: File System, Response Time, Adaptive Storage and Retrieval, HPC

1 Introduction

Exponential growth of the volume of stored data has made conventional methods of storage and retrieval inefficient which require new ways with higher performance to deal with [1]. Performed estimations show that the size of electronic data was about 1.8 zeta bytes in 2011 that illustrates the need to store tremendous amounts of data [2]. Furthermore, improving the performance of these operations in various aspects such as scalability and reliability must be considered [3]. In this way, three different approaches including improving the performance of each computational element, revising the algorithms, and making use of a series of ordinary computing elements could be followed [4].

In the field of HPC computing, improving overall performance is mainly focused on reducing response time and increasing processing power of the system [4]. In order to fit in with the requirements of these environments and avoid becoming the bottleneck, file system designers have used several techniques to reduce the response time [5] [6]. Numerous file systems, such as HDFS and PVFS, have been proposed to cope with these issues and used novel algorithms and load balancing techniques to improve the overall system performance with the aid of distributed computing [7] [8].

Heterogeneous storage clusters are made of various computational elements with different performance levels. This diversity leads to different response times of computational nodes to a single request. Moreover, the response time of each node depends on other parameters such as processor load, network traffic, and remaining storage space changing during time and will affect the performance of the node [9]. Network topology and the distance between data consumer and data provider is another important parameter that can affect the performance of I/O operations. In many HPC clusters, applications and their respective data are placed as closest as possible and data access is performed using a high-bandwidth and low-latency communication network. However, communication cost between two adjacent nodes is far less than two nodes which are located in different parts of the communication network, i.e. two different racks [7].

In these clusters, data replication is performed in order to improve reliability and response time [7]. If the number and the place of replicas are determined with respect to the execution state of computational nodes, the response time and scalability of the cluster will be improved. In addition, the load will be distributed among the nodes and data will not aggregate in particular parts of the cluster. In this manner, an adaptive mechanism that replicates and distributes replicas in the cluster according to the execution state of cluster's nodes has been proposed in this paper.

2 Related works

Various usages of file systems are possible in computing systems. For example, resources could be represented, accessed, and managed by files in distributed computing systems [10]. Moreover, files could be used to store, retrieve, name, structure, protect, and manage user and system data. Our proposed mechanism considers file systems as the module which is responsible for the mentioned responsibilities in the second definition.

Remarkable efforts have been done in the field of file systems which can be categorized in three classes including centralized, decentralized, and distributed file systems. Traditional file systems like FAT belong to the first class and are inefficient for high performance applications [11]. Extremely low scalability and the limitations of storage media like disks' seek time lead to the appearance of the other two classes. Decentralized file systems were mainly proposed to increase the number of master nodes in file systems and avoid consequences of having a single point of failure. NFS is one of the centralized file systems that a decentralized version of it has been proposed to increase its scalability [12].

Computation requirements of today's applications need a level of scalability which is far from what decentralized approaches can reach. As a result, numerous file systems with distributed architectures have been presented including HDFS and GFS which are used to maintain organizational data at

Yahoo and Google respectively. These two are also good examples of the successful experiences in increasing scalability [7] [13].

PVFS was introduced for parallel storage and retrieval of files in Linux clusters and parallel execution of applications which were previously performed using parallel machines. This file system was designed to support different file system interfaces like POSIX, facilitate installation and use of the file system, and provide features to store and retrieve files in a parallel and concurrent manner by several processes. Moreover, scalability and robustness were among other goals in the design process of this file system [8]. PVFS has been developed as a base for research and development in the field of parallel file systems in Linux [1] [5] [14]. Furthermore, a branch of PVFS called OrangeFS has been developed to consider issues like metadata operations, blocks replication, and access control in more depth [15].

In 2003, Google presented GFS which had been used before that time by Google's applications and designed according to their storage requirements. In addition to different aspects of performance which were addressed in other distributed file systems, GFS has paid special attention to efficient execution of its applications [13]. GFS do not support POSIX standard, has larger basic storage blocks comparing to traditional file systems, and is mainly focused on the optimization of append operations because of the nature of its applications [13] [16]. Moreover, using commodity and cheap hardware in the implementation process of GFS made hardware failure such as network devices and storage media a probable event rather than unexpected. In order to prevent the consequences of these failures, several innovative methods have been considered in the design of GFS.

Ceph is another distributed file system which is proposed to provide a scalable, reliable, and high performance storage cluster [17]. It separates the management of data and metadata and supports more than 250,000 metadata operations in every second by using a pseudo-random distribution function, called CRUSH, instead of allocation tables [18]. Moreover, it distributes the replication, fault detection, and recovery operations among storage nodes, where data and metadata are stored. Ceph is composed of three major parts including client, storage cluster, and metadata cluster. It also provides a near-POSIX file system interface which is a remarkable feature for a distributed file system.

Another project called HDFS is currently in progress in Yahoo that is similar to GFS in various aspects and is published as an open-source file system [7]. HDFS performs as a reliable and high performance storage cluster and used several concepts proposed in GFS. More detailed information about this file system is available in section 3, where implementation platform of our proposed mechanism has been introduced.

Common file systems in this area have not effectively considered execution state of the cluster and computational nodes. In addition, heterogeneity of storage media is another parameter that affects response time and has not properly addressed in these file systems. Our proposed mechanism, discussed in more detail in section 4, has considered these parameters and introduced a method to improve the response time of storage and retrieval operations.

3 Implementation platform

In order to implement and evaluate our proposed mechanism, we have used Hadoop Distributed File System as our implementation platform. HDFS is designed to reliably store large data sets and stream these data to user applications at high bandwidth. Distributing stored data and computations among several processing and storage nodes in HDFS leads to a scalable and economic cluster that can grow to any size on demand [7]. This file system has being used by Yahoo to manage 25 petabytes of application data and has been successful in this way [2]. We have stated our motivations to use it as our implementation platform in section 3.2 and after a brief introduction to HDFS.

3.1 Overview

Every HDFS cluster at least consists of a NameNode and one or more DataNodes. The cluster can grow to any size by adding more DataNodes to it [19]. Moreover, other nodes such as BackupNode and CheckpointNode can join the cluster to improve its reliability [7]. User applications, usually executed on DataNodes, are other pieces of the architecture and interact with HDFS using a programming library. This file system does not support POSIX standard and its interfaces are provided via HDFS client which is a code library [2].

In this architecture, NameNode maintains and manages namespace. Moreover, it manages DataNodes and replicas of each data block. The namespace is a hierarchical structure of directories and files which are represented by inodes. Each file is divided into large data blocks which could be replicated independently and stored on various DataNodes. Besides maintaining the file system namespace, NameNode stores required information to perform the mapping between data blocks and DataNodes [7].

DataNodes are responsible for maintaining the replicas of data blocks in their local storage media and store two files for each replica. One of the files is used to store the data and the other maintains block's metadata. Each DataNode performs a handshake with the NameNode at the startup. During this operation, namespace identifier and software version of the NameNode are compared with respective values of the DataNode. Consequently, the consistency of the file system will be preserved [7]. DataNodes send block reports to the NameNode after joining the cluster and periodically to inform it about their hosted replicas. Moreover, the NameNode receives another kind of control messages from DataNodes that indicates their presence in the cluster and accessibility to their hosted replicas [2].

3.2 Motivations in using HDFS

Availability of user manuals and books besides its open source implementation made it feasible to use HDFS as the implementation platform [2]. In addition, it is widely used in extraordinary computing environments and has the potential to be applied on high performance computing clusters.

Performing the replication under the supervision of the NameNode provides required information for adaptive distribution of replicas over the cluster and makes it a good choice to run the proposed mechanism in this node. Moreover, the execution state of computational nodes can be send along with control messages which are periodically sent by DataNodes to the NameNode.

The mechanism used by HDFS to provide user applications with the block replicas list can be changed to consider the execution state of DataNodes and perform adaptively. HDFS has also provided an interface to consider the network distance between data providers and consumers in order to sort hosts in the replica lists [7]. Furthermore, this file system is designed to use commodity hardware that makes evaluation feasible. HDFS is implemented using JAVA programming language that facilitates source code modification and makes it possible to run it on a wide variety of operating systems [2]. Considering these facts, we have chosen HDFS as our implementation platform in order to evaluate our proposed mechanism.

4 Proposed mechanism

The goal of our proposed mechanism is to consider the execution state of DataNodes and the topology of communication network in storing and retrieving data blocks. Adapting file system operations to the execution state of the cluster will improve the overall performance and distribute the I/O load across the storage cluster. Moreover, selecting least loaded nodes to host replicas can improve the response time of I/O operations.

The execution state of DataNodes including remaining storage space, available network bandwidth, and I/O speed of storage media and where it is placed in the communication network are considered with regard to selecting an appropriate node. Besides adapting I/O operations to execution state of nodes, our proposed mechanism introduces a method to automatically detect the network topology that will help data blocks distribution in the storage cluster.

4.1 Architecture

Adapting reading and writing data blocks to execution state of DataNodes and the network topology is performed by three modules. One of these modules concerned about the network topology and is responsible for maintaining the Network Tree which is used by the other modules. Construction of the Network Tree is performed according to relative distance between computational nodes and communication switches. For instance, direct connection of two nodes to a switch means both of them belong to a same rack. In the same way, relative distance between different racks is estimated using the communication delay between their computational nodes. Section 4.3 contains detailed information about this module.

Adaptive generation of the list of DataNodes hosting replicas of a data block is performed by another module which is described in more detail in section 4.2. This module estimates transfer time of the replica according to the last known load of the DataNodes and the network distance between each DataNode and the client.

The other module of the proposed mechanism selects destination DataNodes to host replicas of each data block. In order to select more appropriate nodes, a priority value is assigned to each DataNode and is continually being updated based on its workload. Using these priority values and the network distance between DataNodes and the client, this module will choose the best node to host the replicas. More information about this module has been stated in section 4.4.

4.2 Adaptive Generation of Replica-Hosts List

Once the NameNode receives a request from a client for reading a data block, it provides the client with a list of DataNodes hosting replicas of the requested data block. HDFS only considers the network distance between the client and replica hosts in construction of this list and ignores the execution state of DataNodes [7]. Our proposed mechanism estimates the time that C_i will spend for reading B_k from D_j and orders the replica-hosts list by these estimated values. As a result, the overhead of read operations will distribute across DataNodes that will improve the overall response time of the cluster. Moreover, some required computations of this mechanism are performed by DataNodes that avoids addition of a considerable overhead to the NameNode.

$$EstReadTime(C_i, D_j, B_k) = size(B_k) \times ReadLatency(D_j) + NetDist(C_i, D_j) \quad (1)$$

Equation 1 is used to estimate the time required for reading a data block called B_k from D_j by the client that is running on C_i in seconds. The value of $size(B_k)$ is stored on the NameNode and can be fetched by one memory access. Furthermore, required computations for $ReadLatency(D_j)$, the amount of time in seconds to read one megabyte of data from D_j, is performed by the respective DataNode and the result is sent to the NameNode via heartbeat messages. Equation 2 shows how this value is calculated. The network distance between C_i and D_j is estimated based on the network topology using $NetDist(C_i, D_j)$. Section 4.3 contains detailed information about this function and the way it detects the network topology.

$$ReadLatency(D_j) = \frac{1}{ReadSpeed(D_j)} + \frac{1}{(1-NetUt(D_j)) \times netSpeed(D_j)} \quad (2)$$

In order to estimate $ReadLatency(D_j)$ in Eq. 2, we need to be aware of the execution state of D_j including the transfer speed and the utilization of its NIC besides the I/O speed of its storage media. The momentary I/O speed of the storage media can be estimated based on the current data streams of the DataNode. In order to rate the maximum I/O speed of the storage media, a shell script will be executed at each startup of the DataNode. Using this information, Eq. 3 estimates $ReadSpeed(D_j)$ in megabytes by calculating a weighted-average of the capacity of all local storages in D_j. Similarly, network transfer speed is evaluated by multiplication of network utilization and total transfer speed of the NIC in MB/s. In this manner, the total transfer speed of each network

interface is determined by parsing the respective output of *ethtool* in Linux. Finally, the addition of inverse of these values represents the time required for reading one megabyte of data from D_j by any other node in the cluster.

$$ReadSpeed(D_j) = \frac{\sum_{i=1}^{n} UsedSpace(S_i) \times (TotalSpeed(S_i) - UsedSpeed(S_i))}{\sum_{i=1}^{n} UsedSpace(S_i)} \forall S_i \in D_j \quad (3)$$

4.3 Dynamic network topology detection

In order to estimate the network distance between DataNodes, an n-ary tree called Network Tree is used. The interior nodes of this tree represent communication switches, while its leaves contain DataNodes of each rack. The branching factor of this tree is the maximum number of ports of all communication switches and is denoted by *BF*. As a result, the height of this tree can be calculated by $h=\lceil \log_{BF} n \rceil$ for some positive *n* that reflects the number of racks in the cluster. Moreover, every leaf of the Network Tree is assigned with a unique identifier called RackID which is used for indexing all the DataNodes belonging to a same rack [20].

Once a DataNode joins the cluster, it is considered to be a member of a new rack and is added to the Network Tree as the immediate successor of the root. After that, the Network Tree and the indexed list of DataNodes will be sent to the newly joined DataNode to find its place in the network. Fig. 1 contains the pseudo-code of the search algorithm a DataNode follows to find its place in the network along with the structure of the Network Tree. The result of the performed search in the newly joined DataNode will be sent to the NameNode in order to update the Network Tree.

```
INPUT: N_c = current DataNode
INPUT: p = the root of NetworkTree
OUTPUT: R_id = null
while (R_id == null) do
    last_RTT = 0
    for each node_i in childs(p)
        N_D = select one of the descendent DataNodes of node_i in a random manner
        new_RTT = eval_RTT(N_c, N_D)
        if (new_RTT < last_RTT) {
        if (childs(node_i) == null) R_id = node_i
        p = switch_i
        break
        }
        last_RTT = new_RTT
```

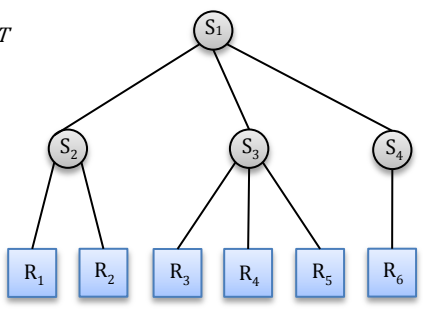

Figure 1: The structure of Network Tree and pseudo-code of its search algorithm

By identifying the nearest common predecessor of two DataNodes in the Network Tree and counting the number of interior nodes in their communication path, the NameNode can estimate the communication latency between every two DataNodes in the cluster. The NameNode assumes a constant communication delay for each switch in the communication path in order to estimate the total communication latency. The running time of this algorithm is $O(\log^{BF}{}_{n})$. Considering the large values of *BF*, its overhead could not be remarkable. As an example, assuming *n*=350 and *BF*=16, the height of the Network Tree would be 3 that supports our point.

4.4 Adaptive selection of replication hosts

Once a new data block is created or an existing one is going to be replicated, the NameNode should select some DataNodes to host the newly created replicas. This selection can be performed based on various considerations such as reducing replication time, improving data distribution, reducing the distance between data provider and consumer, and hosting replicas in the nearest racks. Our proposed mechanism assumes that reader processes are uniformly distributed across the cluster, so it tries to select the more appropriate DataNodes from the nearest racks to the data source. In addition, it obeys the replication rules of HDFS and stores a data block in a rack that contains at most one of its replicas. At the final step of selection, qualified DataNodes are ordered by their remaining storage space and available network bandwidth using Eq. 4. After that, the most proper nodes will be chosen to host the recently created replicas.

$$NodeRate(D_j) = Min\left(\alpha \times \frac{FreeSpace(D_j)}{maxStorageSize}, \beta \times \frac{AvailBW(D_j)}{maxNetBW}\right) \forall D_j \in Cluster \quad (4)$$

The selection priority of every DataNode is determined by comparing its free storage space and available network bandwidth with the total storage space and maximum network bandwidth of the cluster. *FreeSpace*(D_j), *AvailBW*(D_j), *maxStorageSize* and *maxNetBW* are calculated using the information which is being periodically received from DataNodes. Moreover, the effect of free storage media and available network bandwidth on *NodeRate*(D_j) can be adjusted using α and β constants. Here, we have used α=1 and β=1 for the sake of simplicity.

The respective statistics and information of all DataNodes of each rack is stored in a max-heap according to their selection priority value [20]. These max-heaps are referenced by the leaves of the Network Tree and are accessible in this way. As a result, selection of the most proper DataNode of a rack can be performed in O(1). Fig. 2 shows the pseudo-code of the algorithm for selecting the DataNodes to host the recently created replicas of the data block hosted by *Di*.

Once a new data block is created in a DataNode, the first replica is stored in the same node. The other two DataNodes to store replicas are selected using the algorithm shown in Fig. 2 and a pipeline will be organized by HDFS to transfer replicas to the selected hosts. By default, this algorithm stores the replicas in the nearest racks to the data source. However, other policies to select replication hosts could be used in order

to improve reliability of the cluster. For example, storing a replica in another part of the cluster can keep the data block accessible on the event of communication switch failures.

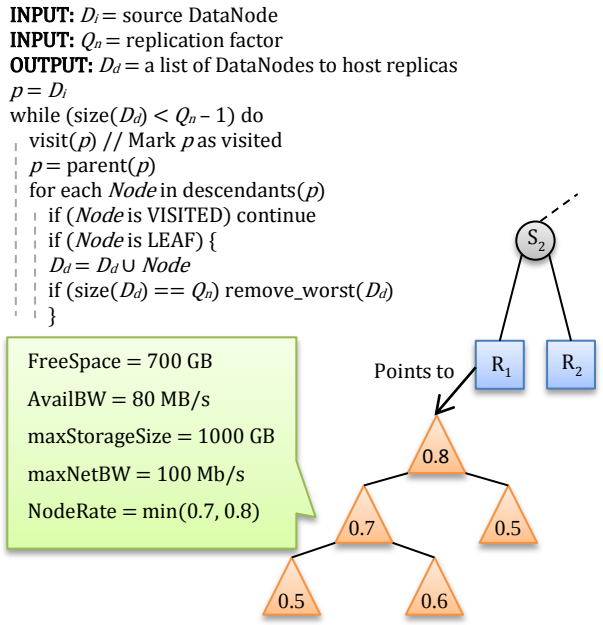

Figure 2: The structure of leafs of Network Tree and the psuedo-code of host selection algorithm

Replication of an existing data block is performed in a similar way. In order to find the proper DataNode to host the new replica, every DataNode that hosts one of the replicas of the data block selects a host using an algorithm similar to the one shown in Fig. 2 with Q_n=1. Next, the proper host for the new replica will be chosen from the selected hosts in the previous step and replication will be performed by the nearest DataNode to it. HDFS performs the replication whenever one of the replicas of a data block becomes corrupted, so the execution rate of this mechanism cannot be remarkable. Moreover, this mechanism can be used to adapt the number of replicas with a dynamic replication factor in storage clusters.

5 Evaluation

We have measured the performance of the proposed mechanism using three distinct criterions. The first two evaluations were performed using HDFS benchmarks in order to demonstrate the improvements in I/O performance of DataNodes and response time of the NameNode. The third one was performed to verify the low computational cost, network traffic and execution time of the algorithm proposed for Network Tree construction. According to the evaluation results, the proposed mechanism can improve the response time of file storage and retrieval operations in heterogeneous clusters with long-term I/O operations.

5.1 I/O performance

In order to evaluate the I/O throughput of HDFS in presence and absence of our proposed mechanism, we have used TestDFSIO benchmark, one of the benchmark packages of hadoop-test-1.0.1. In this manner, a cluster of one master node and three slave nodes is used. Hardware configuration and OS specification of these systems is shown in Table 1.

Table 1: Hardware and OS specification of cluster nodes

	OS	CPU	RAM	Disk (RPM)
Master	Mac 10.6.8	Intel Core 2 Due 2.8	4 GB	5400
Slave	Ubuntu 10.04	Intel Pentium IV 3 GHz	2 GB	5400

TestDFSIO is a MapReduce job and proceeds in two distinct phases. First, it creates some map and reduce tasks to write a number of files which is specified as an input parameter. After that, some other tasks are created to estimate the read performance of the cluster by reading specified number of files. In each phase, the benchmark prints some statistical information about the I/O operation performance of the cluster. In order to examine the effect of our proposed mechanism on HDFS I/O performance, TestDFSIO is executed in the presence and absence of the mechanism using various input parameters and the results are shown in Table 2.

Considering the presented evaluation results, our proposed mechanism is more beneficial for storage clusters with long-term I/O operations. As a result, increasing the size of files will magnify the effect of adaptive selection algorithms on the performance of storage clusters.

Table 2: Evaluated I/O throughput using TestDFSIO

Number of files		10	100	10	100
File size (MB)		100	100	1000	1000
Read (MB/s)	HDFS	7.006	7.421	8.983	9.603
	HDFS + AM	7.043	7.492	9.217	10.039
Write (MB/s)	HDFS	4.893	5.161	6.037	6.958
	HDFS + ASM	4.923	5.202	7.686	7.278

5.2 Cluster scalability

Execution overhead of the proposed mechanism can degrade the number of metadata operations that the NameNode is capable of performing in every second. Once the NameNode reaches its resource limits as a result of an extraordinary number of metadata operations, presence of the proposed mechanism can increase response time of metadata operations and decrease overall performance of the cluster. For investigating this issue, one of the benchmark packages of hadoop-test-1.0.1 called NNBench is used. This benchmark performs in four distinct phases including *create_write*, *open_read*, *rename*, and *delete*. Moreover, NNBench supports a wide variety of input parameters including *sizeOfBlocks* and *numberOfFiles*. Fig. 3 shows the execution results of NNBench in the presence and absence of our proposed mechanism.

As it can be seen in Fig. 3, execution overhead of the proposed mechanism can have a slight impact on the NameNode performance only when the NameNode is overwhelmed with user requests. Indeed, this performance degradation is a direct outcome of centralize nature of the

NameNode in Hadoop clusters and can be avoided on the first sight by downscaling the cluster or improving hardware specification of the NameNode. However, using the proposed mechanism looks economical and effective with regards to how much it improves the system performance by spending a slight amount of processing power and memory space.

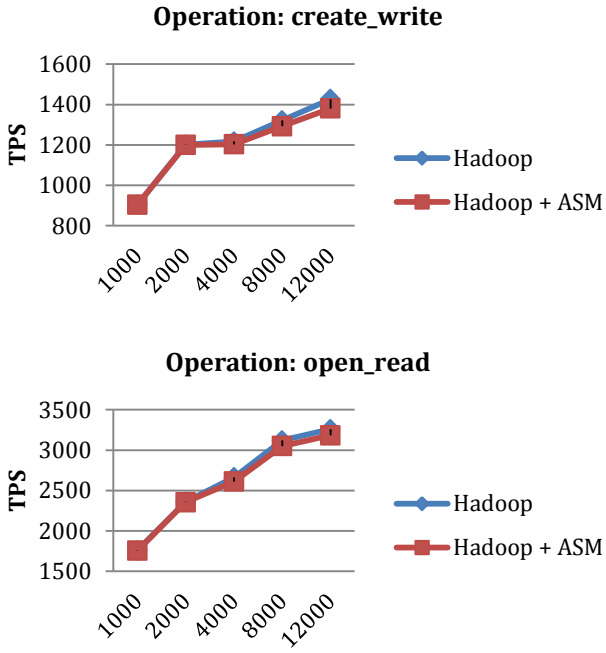

Figure 3: NameNode TPS evaluation using NNBench

5.3 Construction cost of Network-Tree

Construction of Network Tree is performed using ICMP network messages and the Ping utility. To evaluate the performance of our proposed method, we have examined the total network traffic and construction time of this method. Total network traffic of each run is monitored using Wireshark [21]. Searching the Network Tree is a one-time operation and every DataNode have to perform it just after joining the cluster. D-Link switches with a total bandwidth of 100 Mbps have been used to from the communication network and connect computational nodes running a Linux distribution. The height of the Network Tree is two that demonstrates a two level network topology including the core switch and rack switches which are directly connected to the core switch. Fig. 4 shows our experimental results, in which total network traffic and the execution time are in KB and seconds respectively.

The execution time of this algorithm, which is used for searching the Network Tree, directly depends on the branching factor and the height of the tree. Height of the tree does not vary much and even in extra-large clusters, it can hardly ever reach a value more than 3. For instance, using 16-port switches in building a communication tree with the height of 3 will lead to a cluster of size 16^3. The largest operational Hadoop cluster at Yahoo contains 3500 DataNodes which is far less than 4096. Moreover, the branching factor does not exceed 16 most of the times. In most of the clusters, network switches with more than 16 ports are used as rack switches that have no effect on the branching factor of the Network Tree. Considering how this method can facilitate joining of new DataNodes to the cluster, it can be inferred that its execution time and network traffic are reasonable.

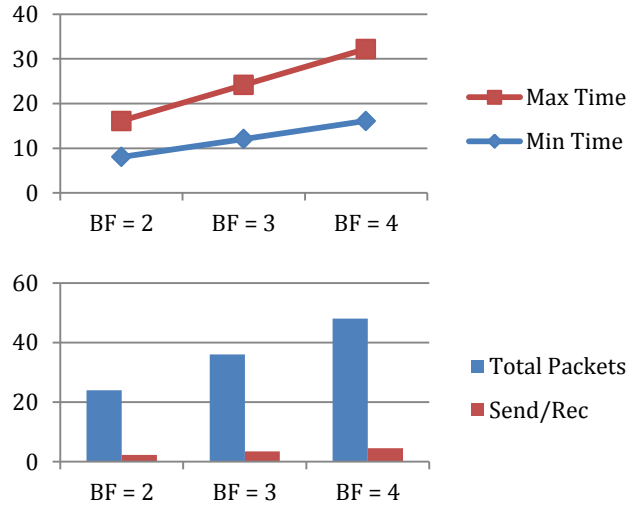

Figure 4: Evaluation results of the tree construction algorithm

6 Further works

Besides the proposed mechanism, distributed file systems can adapt with the execution state of the cluster in some more ways. Using dynamic replication factors and popularity domains for files are two of these ways that can benefit the storage cluster in both reliability and response time.

Considering the concept of files' popularity which is widely used in P2P file sharing systems, the replication policy can be improved. Thus, each file will be replicated in every neighborhood that contains more reader or writer nodes. In this way, a popularity domain will be assigned to each file containing the DataNodes that will probably read or write from/to it in the future. This mechanism can be used along with the task distribution mechanism of Hadoop which executes every task near to its required data. The cooperation of these two can lead to better distribution of load in Hadoop clusters. As a result, the behavior of file system users will affect the replication of data blocks and the file system will adapt with users' activity.

Besides being used for determining proper replication factor of each file, the concept of popularity domains is beneficial for improving reliability of the NameNode in Hadoop clusters. As each popularity domain normally contains the list of DataNodes sharing the respective file, the global namespace can be divided into many popularity domains and distributed across several NameNodes. Consequently, reliability of the central mechanism which is currently in use in Hadoop clusters to maintain file system metadata will be improved by increasing the number of metadata servers. This mechanism follows the same idea as namespaces in Plan 9 and uses popularity domains in exchange of per-process namespaces. Reducing the computational overhead of the NameNode will directly improve the response time of storage and retrieval

operations of files. Indeed, this mechanism can improve both reliability and response time of distributed file systems.

7 Conclusion

Our proposed mechanism considers the execution state of the storage cluster in performing data blocks replication. Various aspects of the cluster such as network topology and different state variables of computational nodes like network traffic and remaining storage space are considered to find the proper host for storing replicas. As the first step in the replication process, the NameNode specifies the required number of replicas for each data block. Next, the replication roadmap is designed based on the performed calculations and the selected host will store the newly created replica. The host selection algorithm will choose the proper nodes to store the new replica by looking at their execution state, available resources, and distance to the source of data. As a result, the load of storage and retrieval operations will be uniformly distributed across the cluster.

A similar method is used in order to find proper replica hosts to provide read operations with requested data blocks. In this manner, our proposed mechanism estimates the cost of reading a data block from every host and uses the results to generate an ordered list of hosts. Some execution variables of storage nodes including available network bandwidth, disk read speed, and current data streams are considered in evaluating the cost of reading every data block. The network distance between the replica host and reader node is also considered in this selection algorithm.

HDFS has been used as our implementation platform. Several facts like easy to use interfaces and open source implementation of HDFS lead to this decision. Performed evaluations show that our proposed mechanism improves the response time of file storage and retrieval operations in heterogeneous clusters running long-term I/O operations. Furthermore, its computational overhead will not have a remarkable effect on cluster scalability.

A Learning Algorithm of Threshold Value on the Automatic Detection of SQL Injection Attack

Daiki Koizumi*, Takeshi Matsuda*, Michio Sonoda*, and Shigeichi Hirasawa*
* Faculty of Information Technology and Business, Cyber University, Tokyo, Japan

Abstract— *The SQL injection attack causes very serious problem to web applications that involve database including personal data. To detect the SQL injection attack, the parsing and the blacklist built based on the known attacks have been widely used. Those approaches, however, have some problems in terms of the size of list or calculation costs as the number of attacks increases. For these problems, the authors have previously proposed a simple automatic algorithm to detect SQL injection attack. This algorithm requires to calculate the ratio of suspicious characters contained in an input sequence. This rate is compared with a known real-valued threshold. This paper proposes the learning algorithm to choose the real-valued threshold from training data sets. Furthermore, some criteria will be considered and their performances will also be examined.*

Keywords: SQL Injection Attack, Automatic Detection, Web Application, Learning Algorithm, Pattern Recognition

1. Introduction

The SQL injection attack was firstly reported in 1999 [2]. It consists of insertion or "injection" of a SQL query via the input data from the client to the application [3]. It causes very serious problem to web applications that involve database including personal data. To detect the SQL injection attack, the parsing and the blacklist built based on the existed attack have been widely used. However, the conventional methods based on blacklist built approaches have confronted at least two problems. The first is the huge cost of updating large blacklist built, the second is the calculation cost for automatic attack detection with large blacklist built.

For these two problems, the authors have already proposed the online algorithm for automatic detection of SQL injection attack [4]. This algorithm requires to calculate the contained rate of suspicious characters with input sequence. This rate is compared with a known real-valued threshold. In the authors' previous research [4], this threshold was empirically determined as a known constant. However, in general, this threshold is an unknown value and should be learned from a given training set of data. This paper proposes a learning algorithm to choose a real-valued threshold. Furthermore, some criteria will considered and their performances will also be examined.

The rest of this paper is organized as the followings. Section 2 gives some definitions and automatic detection algorithm of SQL injection attack which was previously proposed where its threshold value is defined as a known constant. Section 3 proposes the learning algorithm of the threshold value with some formulations. Section 4 shows some leaning examples with artificial data. Section 5 gives their discussions. Finally, Section 6 concludes this paper.

2. The Automatic Detection Algorithm of SQL Injection Attack [4]

2.1 Preliminary

Suppose that l is an input sequence through web application to the SQL database. Note that each input l has a label either attack or normal. The purpose of automatic SQL injection attack detection is to estimate the label of l correctly. Our proposed algorithm requires some known finite characters $s_i, s_{ii}, s_{iii}, \cdots$. These are suspicious characters contained in SQL injection attack inputs such as space, semicolon, single-quotation, left and right round brackets, and so on. Furthermore, let S_k, $k = 1, 2, \cdots, m$ be power sets of known characters $s_i, s_{ii}, s_{iii}, \cdots$ where they are defined as sets of characters except for the empty set. If s_i and s_{ii} are defined as space and semicolon, then three power sets of known characters can be $S_1 = \{s_i\}$, $S_2 = \{s_{ii}\}$, and $S_3 = \{s_i, s_{ii}\}$.

2.2 The Automatic Detection Algorithm

With the above definitions, the automatic detection algorithm was proposed [4]. Furthermore, the theoretical performance was analyzed in terms of statistical prediction problem [1]. The following is the brief description of the automatic detection algorithm.

1) Setting up known values

a) Choose a set of characters S_k.
b) Set a threshold as a real value $\alpha \in [0, 1]$.

2) Calculating the content rate of suspicious characters $x_{k,l}$ which is defined as,

$$x_{k,l} = \frac{\#S_k}{|\,l\,|}\,, \tag{1}$$

where $\#S_k$ denotes the size of S_k.

3) Automatic detection
Determine each input's label (normal or attack input) by the following function $d\,(x_{k,l}, \alpha)$:

$$d\,(x_{k,l}, \alpha) = \begin{cases} 0 & if \;\; x_{k,l} \leq \alpha; \\ 1 & if \;\; x_{k,l} > \alpha. \end{cases} \tag{2}$$

Eq. (2) means that if detection result is normal, then its value is zero, otherwise the result is attack and its value is one.

Example 2.1 (Automatic Detection of Attack Input): Let $l =$ "DROP sampletable;--" be an attack input where its length $|\,l\,| = 19$. Suppose that a character set S_{13} contains space, semicolon, and left round brackets. Furthermore, the threshold value α is set to 0.10.

Since the input l contains one space and one semicolon among characters in S_{13}, a numerator in Eq. (1) becomes $\#S_{13} = 2$. Therefore, according to Eq. (1),

$$\begin{aligned} x_{13,l} &= \frac{2}{19} \\ &= 0.1052\cdots \end{aligned}$$

With the above $x_{13,\,l}$, the detection result by Eq. (2) becomes the following:

$$\begin{aligned} d\,(x_{13,l}, \alpha) &= d\,(0.1052, 0.10) \\ &= 1\,. \end{aligned}$$

Thus l is detected as an attack input.

■

2.3 Performance Evaluation with Artificial Data

For evaluation of the above algorithm, the artificial data was composed [4]. Those data cover the typical types of SQL injection attack input as well as normal input among common web forms. The number of types of attack inputs was 624, on the other hand, that of normal inputs was 234. Those data were converted to the fields of single and multibytes characters, wiki, emoticon etc. These types were assumed to be input as IDs, passwords, names, and addresses etc. [4].

If the real operating situation is considered, the label of each input (either normal or attack) is unknown. Therefore, the mixture data of both labels were used for simulations in evaluations [4]. Let $0 \leq P_N \leq 1$ be the correct detection rate for normal input and let $0 \leq P_A \leq 1$ be the correct detection rate for attack input. Furthermore, if the ratio of the number of the normal input against attack input is $0 \leq \beta \leq 1$, the total detecting rate $0 \leq \mu \leq 1$ can be calculated by the following:

$$\mu\,(S_k, \alpha, \beta) = \beta P_N + (1 - \beta)\, P_A\,. \tag{3}$$

For evaluation, the value of α was empirically chosen as a constant. On the other hand, various values of β were taken with its interval $0 \leq \beta \leq 1$. For the remained S_k, the following objective function was assumed to chose the optimal character set of S^*.

$$S^* = \arg\max_{S_k} \left[\mu\,(S_k, \alpha, \beta)\right]\,. \tag{4}$$

With the above Eq. (4), the sensitive analysis was considered for discussions [4].

3. The Proposed Threshold Learning Algorithm

3.1 Formulation and Criterion

In general, the threshold value is unknown and should be learned from real observed data. If S^* has been already determined and the candidates of $\alpha_j,\; j = 1, 2, \cdots, N$ have been obtained, then the following can be defined as similar form of Eq. (4).

$$\alpha^* \;\; = \;\; \arg\max_{\alpha_j} \left[\mu\,(S_k, \alpha_j, \beta)\right]\,. \tag{5}$$

Since the label of input l is unknown at the real operation, the value of β, which is the weight of normal input against attack input is also unknown. Therefore, Eq. (4) and (5) can be achieved with several criteria. One of them is that assuming the probability distribution of $p(\beta)$ to take the expectation of $\mu\,(S_k, \alpha_j, \beta)$ with respect to β. For numerical approximation, suppose $\beta_m\,, m = 1, 2, \cdots, M$ is sampled on the interval $0 \leq \beta \leq 1$. Then, such criterion can be formulated as the following:

$$\begin{aligned} &\{\alpha^{**}, S^{**}\} \\ &\quad = \arg\max_{\alpha_j} \max_{S_k} \left[\sum_{m=1}^{M} p\,(\beta_m)\;\mu\,(S_k, \alpha_j, \beta_m)\right]\,. \end{aligned} \tag{6}$$

Note that α^{**}, S^{**} maximize the expected total detecting rate $\mu\,(S_k, \alpha_j)$ in Eq. (6).

For the other criteria, both the expected total detecting rate and the absolute value of slope of regression line can be considered which is more

restrictive. This criterion also takes into account the stability of $\mu(S_k, \alpha_j)$ with respect to β.

$$\begin{aligned}
&\{\alpha^{***}, S^{***}\} \\
&= \arg\max_{\alpha_j}\max_{S_k}\left[\sum_{m=1}^{M} p(\beta_m)\ \mu(S_k, \alpha_j, \beta_m)\right. \\
&\quad - \left|\frac{1}{M\sum_{m=1}^{M}(\beta_m)^2 - \left(\sum_{m=1}^{M}\beta_m\right)^2}\right| \\
&\quad \times \left|M\sum_{m=1}^{M}\beta_m\,\mu(S_k, \alpha_j, \beta_m)\right. \\
&\quad \left.\left. - \left(\sum_{m=1}^{M}\beta_m\right)\left(\sum_{m=1}^{M}\mu(S_k, \alpha_j, \beta_m)\right)\right|\right].
\end{aligned} \tag{7}$$

Note that α^{***}, S^{***} maximize the sum of the expected total detecting rate and the slope of regression line. In Eq. (7), the second, third, and fourth terms on the right hand side express the absolute value of slope of the regression line $\mu(S_k, \alpha_j)$ where β is its domain.

3.2 The Proposed Algorithm

With training data set that contain pairs of input sequence l and its label, the following learning algorithm of threshold value α^{**} or α^{***} would be proposed.

1) With various candidate pairs of S_k and α_j, execute automatic detection algorithm with Eq. (1) and (2).
2) Calculate the total detecting rate $\mu(S_k, \alpha_j, \beta)$ with P_N, P_A, and $0 \le \beta \le 1$.
3) Taking β_m for numerical approximation to choose the optimal set of S^{**} and α^{**} by Eq. (6)(or S^{***} and α^{***} by Eq. (7)).

4. Evaluations of the Proposed Algorithm

4.1 Conditions

For evaluations, the artificial data mentioned in subsection 2.3 was used. The number of types of attack inputs is 624, those of normal inputs is 234 where the data cover the single and multibytes characters, wiki, emocticon etc. Note that the data was assumed IDs, passwords, names, and addresses etc.

For known finite characters, the five characters were chosen as Table 1. These characters are same as our previous simulations [4].

With the above five characters, the following twenty six power sets can be defined as,

Table 1: Known Characters

Name	Character
s_i	Space
s_{ii}	Semicolon (;)
s_{iii}	Single Quotation (')
s_{iv}	Right Parenthesis ())
s_v	Left Parenthesis(()

$S_1 = \{s_i, s_{ii}\}, S_2 = \{s_i, s_{iii}\}, S_3 = \{s_i, s_{iv}\},$
$S_4 = \{s_i, s_v\}, S_5 = \{s_{ii}, s_{iii}\}, S_6 = \{s_{ii}, s_{iv}\},$
$S_7 = \{s_{ii}, s_v\}, S_8 = \{s_{iii}, s_{iv}\}, S_9 = \{s_{iii}, s_v\},$
$S_{10} = \{s_{iv}, s_v\},$
$S_{11} = \{s_i, s_{ii}, s_{iii}\}, S_{12} = \{s_i, s_{ii}, s_{iv}\},$
$S_{13} = \{s_i, s_{ii}, s_v\}, S_{14} = \{s_i, s_{iii}, s_{iv}\},$
$S_{15} = \{s_i, s_{iii}, s_v\}, S_{16} = \{s_i, s_{iv}, s_v\},$
$S_{17} = \{s_{ii}, s_{iii}, s_{iv}\}, S_{18} = \{s_{ii}, s_{iii}, s_v\},$
$S_{19} = \{s_{ii}, s_{iv}, s_v\}, S_{20} = \{s_{iii}, s_{iv}, s_v\},$
$S_{21} = \{s_i, s_{ii}, s_{iii}, s_{iv}\}, S_{22} = \{s_i, s_{ii}, s_{iii}, s_v\},$
$S_{23} = \{s_i, s_{ii}, s_{iv}, s_v\}, S_{24} = \{s_i, s_{iii}, s_{iv}, s_v\},$
$S_{25} = \{s_{ii}, s_{iii}, s_{iv}, s_v\}, S_{26} = \{s_i, s_{ii}, s_{iii}, s_{iv}, s_v\}.$

4.2 Simulations

1) Simulation 1
   Choose five pairs of $\{\alpha^{**}, S^{**}\}$ in descending order according to the criteria in Eq. (6).
2) Simulation 2
   Choose five pairs of $\{\alpha^{***}, S^{***}\}$ in descending order according to the criteria in Eq. (7).

4.3 Results

Table 2 and 3 were obtained for Simulation 1 and 2, respectively.

Table 2: Result of Simulation 1

Rank	S^{**}, α^{**}	Value in Eq. (6)
1st	$S_{22}, \alpha = 0.08$	0.9170
2nd	$S_{12}, \alpha = 0.08$	0.9154
3rd	$S_{22}, \alpha = 0.09$	0.9147
4th	$S_{21}, \alpha = 0.08$	0.9142
5th	$S_{14}, \alpha = 0.02$	0.9135

Table 3: Result of Simulation 2

Rank	S^{***}, α^{***}	Value in Eq. (7)
1st	$S_{12}, \alpha = 0.09$	0.9032
2nd	$S_{12}, \alpha = 0.08$	0.8994
3rd	$S_{22}, \alpha = 0.11$	0.8930
4th	$S_{23}, \alpha = 0.10$	0.8903
5th	$S_{21}, \alpha = 0.11$	0.8879

5. Discussions

From Table 2 in Simulation 1, we can see that the pair S_{22} and $\alpha = 0.08$ maximizes the expected total detecting rate $\mu(S_k, \alpha_j)$ in Eq. (6). In our previous research [4], the pair $S_{12}, \alpha = 0.08$ was empirically chosen. According to Table 2, relatively superior pair was discovered with the criterion in Eq. (6). Figure 1 shows the plot of the top three pairs of S^{**} and α^{**} where the vertical axis is the value of μ and the horizontal axis is $0 \leq \beta \leq 1$. According to Eq. (6), the superior μ of the pair S_{22} and $\alpha = 0.08$ can be observed comparing to the empirically chosen pair S_{12} and $\alpha = 0.08$ in Figure 1. In Figure 1, the pair S_{12} and $\alpha = 0.08$ gives the most flattest line among three lines, however, the other two pairs give the relatively superior values according to Eq. (6).

From Table 3 in Simulation 2, S_{12} and $\alpha = 0.09$ are obtained as the optimal pair according to Eq. (7). The second is the pair of S_{12} and $\alpha = 0.08$. Figure 2 shows the same sort of plot as previous Figure 1. Since Eq. (7) emphasizes the absolute value of the slope, more flatter line can be chosen. In this criterion, S_{12}, which contains three characters, was superior to the others, whereas S_{22} was superior to them in the criteria Eq. (6).

Figure 3 shows the effect of various values of α in S_{12}. From Figure 3, the more the value of α increases, the more larger the value of slope of the line becomes. Since Eq. (7) gives the penalty of the larger value of the slope, $\alpha = 0.09$ is more likely to be chosen.

Figure 4 shows the effect of various values of α in S_{21}. Figure 4 also shows that the more the value of α increases, the more the value of slope of the line becomes larger. But the increasing degree of the slope in S_{21} is relatively larger than that of S_{12}. This result can be interpreted as the effect of the character of Right Parenthesis which is the only contained character in S_{21}.

Figure 5 shows the effect of various sets among S_{12}, S_{21}, and S_{24} where those thresholds are the constant $\alpha = 0.08$. From Figure 5, the detecting performances of S_{12} and S_{21} are similar, however, that of S_{24} is the relatively poor. It can be observed that S_{24} is the only set which does not contain Semicolon.

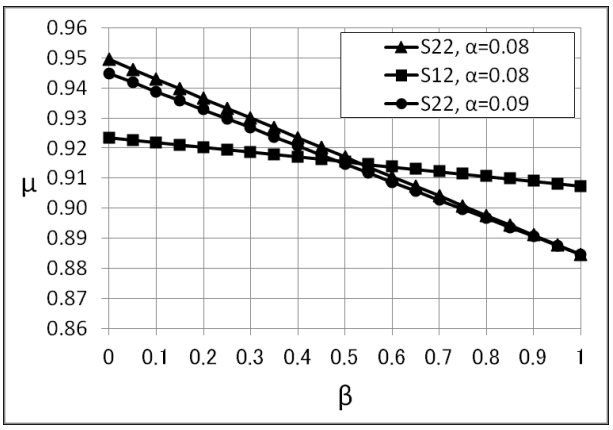

Figure 1: Learning Results based on Eq. (6)

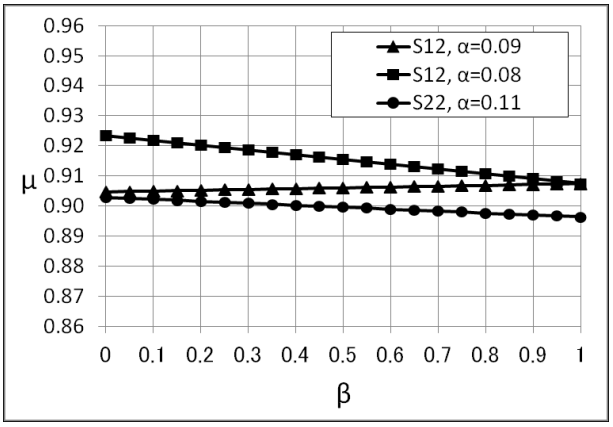

Figure 2: Learning Results based on Eq. (7)

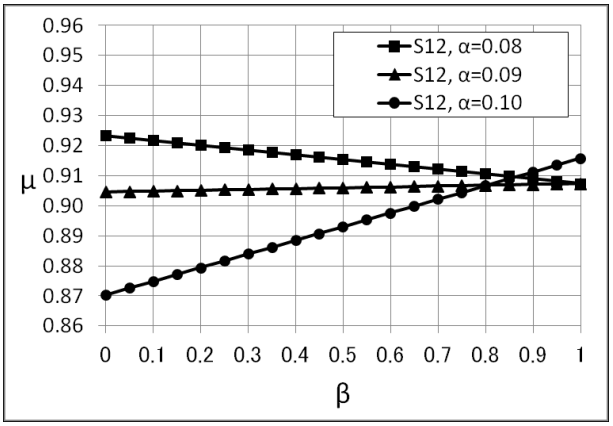

Figure 3: Detecting Performance of S_{12} with various thresholds

6. Conclusions

This paper proposed the learning algorithm to choose the real-valued threshold for automatic detection of SQL injection attack. Furthermore, some

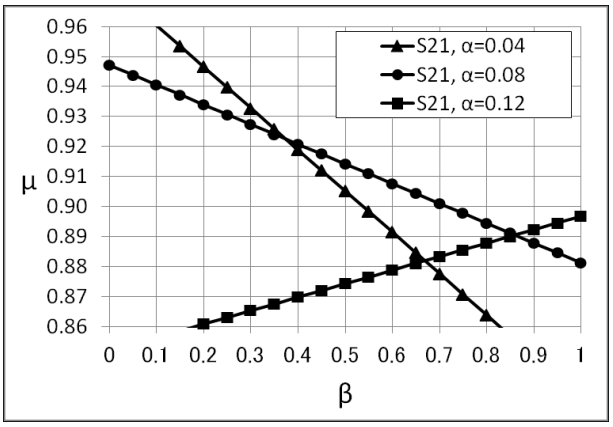

Figure 4: Detecting Performance of S_{21} with various thresholds

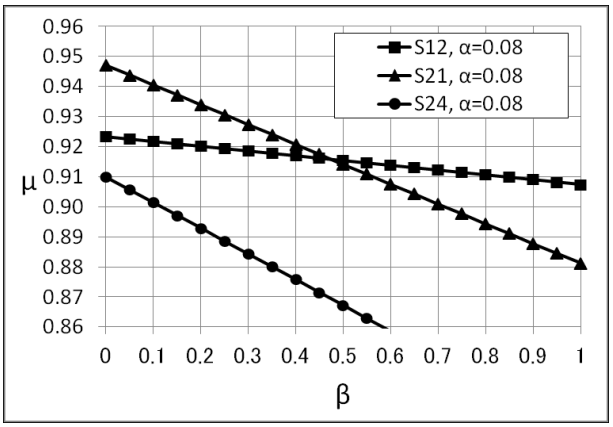

Figure 5: Detecting Performance of S_{12}, S_{21}, and S_{24} with a constant thresholds ($\alpha = 0.08$)

learning criteria were considered and their performances were also examined with artificial data. As a result, the certain effectiveness was observed with the proposed algorithm and thus seeking the unknown threshold value can be possible with training sets of data.

For future research, predictive performance should be examined with unknown data sets. Furthermore, the detecting performance with the real SQL injection data should also be considered.

Abstract - *Service-Oriented Architecture (SOA) has become a common technology for provisioning infrastructure services on-demand. Service-Oriented Architecture (SOA) allows managing, maintaining and accessing heterogeneous and geographically sparse resources in a unified way. This paper introduces GEMBus (GEANT Multi-domain Bus), a service-oriented middleware platform that allows flexible services composition, and their on-demand provisioning and deployment to create new specialized task-oriented services and applications. GEMBus is built upon state-of-the-art Enterprise Service Bus (ESB) technologies and extend them with new functionalities that allow dynamic component services deployment, composition and management.*

The GEMBus architecture incorporates different ESB instances at different management domains, orchestrated by the GEMBus core, constituted by the elements which provide the functionality required to maintain the federation infrastructure: service registry, message infrastructure, security service, accounting service, and composition services. The current paper also discusses the general case for integration of Service-Oriented Architecture (SOA) principles and technologies with the provision and deployment mechanisms to support on-demand infrastructure services provisioning.

This architecture has been validated with a series of use-cases in the GÉANT environment and is about to be applied to similar infrastructures in a wide range of application fields within the academic and research community.

1 Introduction

This paper presents the framework and general architecture of GEMBus (GÉANT Multi-domain Bus), the federated multi-domain service-oriented infrastructure being developed in GN3 [1] project. GEMBus is based on a Composable Service Architecture (CSA) [2], a general framework for composite services, and on the industry-adopted Enterprise Service Bus (ESB) [3], extended to support dynamically reconfigurable virtualized services. The architecture addresses multi-domain issues and distributed heterogeneous services composition and orchestration. The possible users for GEMBus could be the network and service operators who wish to install the GEMBus platform and its core services in their administrative domain, and the users who wish to develop new services and integrate them with the GEMBus platform, enhancing their usability. Both types of users can benefit from the Composable Service Architecture.

Service-Oriented Architecture (SOA) [4] allows managing, maintaining and accessing heterogeneous and geographically sparse resources in a unified way by providing standardized interfaces and common working environments to their users. The heterogeneous nature of these resources spans not only across different providers or administrative domains, but also across different application domains, aiming, for example, at the integration of bandwidth reservation mechanisms with storage allocation procedures into what users should perceive as a single service.

The bus paradigm provides the additional advantage of freeing service developers from dealing with common aspects such as authentication, authorization, accounting, service discovery and message management. This enables them to concentrate on the direct implementation of business processes. Most current ESB frameworks are oriented to

single-enterprise deployment that relies on a central top authority. GEMBus aims to bring the advantages of these ESB frameworks into an open collaborative environment, taking a step further into federated infrastructures and supporting the definition of a multi-domain ESB infrastructure, a "bus of buses".

This paper is structured in the following way. In section 2, we describe GEMBus architecture, placing particular emphasis on GEMBus core components. In section 3, we state the successfully integrated services within the GEMBus infrastructure and in the last section finally, we present our conclusions.

2 GEMBus architecture

In Figure 1 below, is illustrated the general GEMBus architecture, where different ESB instances at different management domains are federated. Services deployed in one of the instances can seamlessly access those services made available by the others.

The GEMBus Core is comprised of those elements that provide the main functionality required to maintain the federated GEMBus infrastructure. The GEMBus Core includes specific functional components and services: GEMBus Registry, GEMBus Messaging Infrastructure (GMI), GEMBus Security Service, Composition Service and GEMBus Accounting Service.

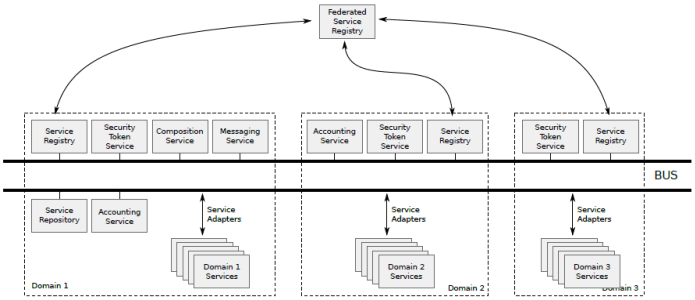

Figure 1: General GEMBus architecture, showing core elements

2.1 GEMBus Registry

In a highly dynamic and multi-domain infrastructure a mechanism to keep track of dynamic deployments is absolutely vital. The GEMBus registry is expected to provide essential functionality to serve as a global information service to keep information about both component infrastructure services and the composed services infrastructure, including also their lifecycle metadata.

Federated Registry should be able to handle all the service description formats that are available because of the variety of services. This includes, but is not limited to, Web Services Description Language (WSDL) [5], Web Application Description Language (WADL) [6] and OSGi [7], [8] bundles.

More specifically, the GEMBus Registry (Federated Service Registry) talks to the local registries to retrieve the list of services from the local domains and to announce them globally (for all participating domains). This registry has the capability to request additional information about the services. The GEMBus registry is responsible for the mapping among the initial description of requests and the requested services.

2.2 GEMBus Messaging Infrastructure (GMI)

Existing ESB frameworks and implementations incorporate a centralized model for message handling, where a domain central message processor (that also provides inter-domain message routing when required) processes all intra-domain messages. Message processors in this case act as a collapsed messaging backbone. This means that to send or receive messages, all services need to connect to one of the adapters supporting specific service related/defined message-level protocols. These adaptors are typically connected to an assigned port.

The GMI extends this functionality in the multi-domain environment considered by GEMBus. The Registry will store and provide the GMI components with service information on location, configuration and properties. These components will make use of the Registry either by using the local, internal ESB registries for local component services, or by directly querying the common GEMBus Registry service. These components will make direct use as well of the GEMBus Accounting Service facility to track message exchange in a way that is transparent to service developers and operators.

2.3 GEMBus Security Services

The GEMBus uses the Security Token Services (STS) defined in WS-Security [9] and WS-Trust [10] as a security mechanism to convey security information between services that can also be easily extended to the federated security required by the GEMBus composable services. The STS makes it possible to issue and validate security tokens, also support services (identity) federation and federated identity delegation.

In the GEMBus STS, different elements support token issues and validation, as shown in Figure 2. The Ticket Translation Service (TTS) is responsible for generating valid tokens in the system according to the received credentials, renewing and converting security tokens. Token validation is performed by the Authorization Service (AS), which can also retrieve additional attributes or policy rules from other sources to perform the validation.

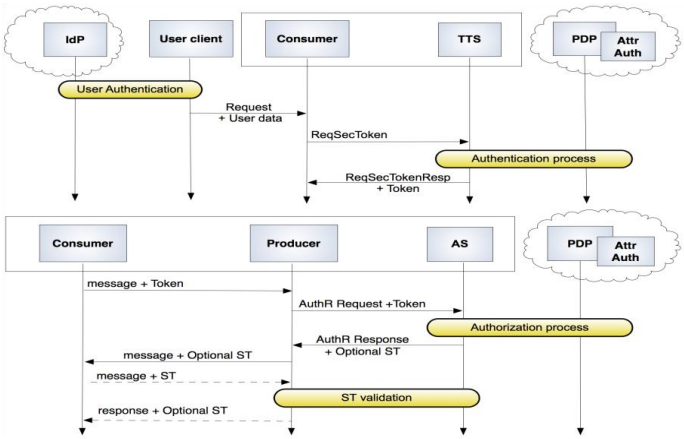

Figure 2: Authentication and authorization processes in GEMBus security services

2.4 Composition Service

In the GEMBus aim follow existing procedures and standard mechanisms, extending them to support multi-domain operation, Business Process Execution Language (BPEL) and available ESB-based execution engines are being used for service orchestration. They are connected with a specific description and control tool (first prototype implemented as an Eclipse plug-in) based on Business Process Modelling Notation (BPMN).

In addition to the orchestration service, a workflow management system will be provided by integrating the Taverna [11] environment, a cross-platform set of tools enabling users to compose not only web services, but also local Java services (Beanshell scripts), local Java APIs, R scripts and import data from Excel or in CVS format.

2.5 GEMBus Accounting Service

The GEMBus multi-domain nature requires specific mechanisms for producing and processing meaningful accounting information. The Accounting Service Architecture for GEMBus consists of a Common Accounting Repository, where all collected data from each ESB instance is stored and an Accounting Module (AM) instance is deployed at every participating ESB.

Services integrated in GEMBus use the message-oriented middleware infrastructure offered by the GMI to communicate. The function of AM is to catch and record every message exchanged (interaction between services) through the GMI, as those messages are precisely the source of information to evaluate GEMBus services behavior and performance. To capture those messages interactions exchanged through the GMI, message interceptors need to be implemented (in most of the cases, SOAP messages).

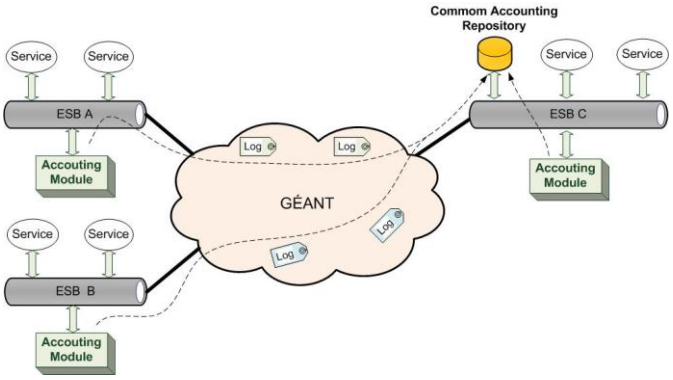

Figure: 3. Accounting Service Architecture

The accounting information will be saved using RDF ontology. RDF is an emerging language and there are several reasons for selecting RDF ontology as a data model, such as is based on open source, languages and standards. Also it can be extended and grown incrementally without impacting the existing data store. Finally, its conceptual closeness to the relational data model is an advantage. It is possible to represent RDF in a relational database and vice versa, the use of set-based semantics and queries and, via its SPARQL query language, easy mechanisms to drive faceted search and other browsing and viewing tools.

3 Using GEMBus for service integration

This section presents a use-case of service integration used during the definition of the GEMBus architecture to validate it and provide a demonstrator of its functionalities.

Use-case is related to the integration of existing GÉANT services: AutoBAHN [12] (for bandwidth on-demand provisioning) and PerfSONAR [13] (for distributed and autonomous network monitoring). Both services have followed integration patterns associated to the creation of specific adaptors to existing service interfaces, taking into account the requirements imposed by service architectures and their interactions with their supporting infrastructures.

The third case is intended to show GEMBus composition mechanisms and how they can be applied to realize an Autonomous Computing scenario. Providing Autonomic Computing (AC) capabilities within the GEMBus framework can benefit the behavior of the services and applications connected to the bus. Applications deployed on GEMBus can consume the AC services provided by the framework to gain self-management capabilities.

3.1 AutoBAHN/perfSONAR Integration as a Service

AutoBAHN service will enable the dynamic integration of bandwidth allocation mechanisms at different domains with other network services (such as monitoring services, other link

management services, and network topology and status information) and application services requiring such capabilities.

Two adaptors have been developed, providing a single entry point to the AutoBAHN infrastructure:

- The Reservation Client Adaptor, handling the user request for path reservation/cancellation/modification.

- The Reservation Service Adaptor, responsible for deploying the reservation service inside the GEMBus platform and publishing it as a service available for others to see and call it.

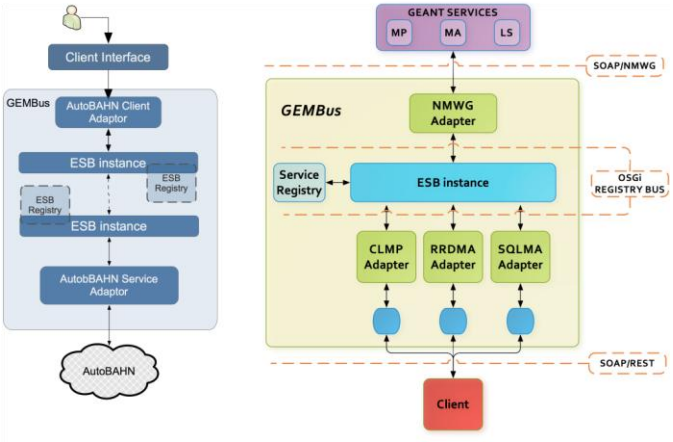

Figure 4: AutoBAHN and PerfSONAR integration within GEMBus

PerfSONAR service is based on a per-service integration pattern that takes advantage of the perfSONAR module software architecture. The per-service integration pattern assumes that each service is integrated as implementation of a separate adaptor. This solution provides several advantages such as easy management of services. Since the ESB framework manages the lifecycle of the adaptors the process related to deployment as well as stopping and restarting each of the services will be easy to perform. Having each of the services in separate adaptors also provides easy access restriction, keeping statistics of the service usage or logging all service events. This pattern offers an easy way for clients to access the services too. The usage of ESB binding elements makes it possible to put out many types of ready-to-use endpoints (such as SOAP or REST protocols) for clients, as well as easy reconfiguring.

The current version of the integration architecture prototype provides four adapters. The Network Measurement Working Group (NMWG) Adaptor is an interceptor that sends requests and receives responses to/from MA (Measurement Archive) and MP (Measurement Point) in the NMWG schema. This component is used by other GEMBus perfSONAR adapters to exchange messages between ESB and the current running services. The three other adaptors are the CLMP (Command Line Measurement Point), which is used for executing command line tools such Ping, traceroute, One-Way Active Measurement Protocol (OWAMP) and Bandwidth Test Controller (BWCTL), RRDMA (Round Robin Database Measurement Archive), which provides the capability to read measurement data stored in RRD files and SQLMA (SQL Measurement Archive).

4 Conclusions

GEMBus attempts to bring the advantages of SOA into the highly heterogeneous, open multi-domain environment that currently characterizes scientific e-infrastructures. GEMBus commitment to openness and the support of high heterogeneity allows making it useful also for environments in which a full SOA deployment is challenging by proposing and enabling some core services that can create a basis for further migration to more consistent service oriented environment.

The GEMBus architecture has been validated with a series of use-cases in the GÉANT environment and is about to be applied to similar infrastructures in a wide range of application fields within the academic and research community. The results achieved so far are encouraging and the integration of composable services in an integrated and federated infrastructure can provide a high quality of services to the academic and research community.

Fast Algorithms for Simultaneous Optimization of Performance, Energy and Temperature in DAG Scheduling on Multi-Core Processors

Hafiz Fahad Sheikh[1] **and Ishfaq Ahmad**[1]
[1]Department of Computer Science and Engineering, University of Texas at Arlington, Arlington, TX, USA

Abstract - *We have proposed two algorithms for simultaneously optimizing performance, energy, and temperature while scheduling a set of tasks on a multi-core system (PET-Scheduling). The proposed algorithms differ in the way they use task allocation and voltage selection decisions to obtain multiple schedules (trade-off solutions) with a wide range of values along each objective. PET-PPF combines a power and performance-aware allocation scheme with probabilistic voltage selection to obtain these trade-off solutions. PET-DCP, on the other hand, first adjusts the task execution times using probabilistic voltage selection before leveraging a performance-optimal scheduler to generate the final schedule. Our results on several application task graphs demonstrate that both of the proposed algorithms can obtain the trade-off curves comprising of multiple solutions to the PET-Scheduling problem. PET-DCP, however, is able to achieve identical energy and thermal improvements as that of PET-PPF but at the same time degrades the performance by as much as 1.5 times less than that of the PET-PPF.*

Keywords: dynamic thermal management, frequency allocation, multi-core systems, task scheduling, DVFS.

1 Introduction

The rapidly scaling multi-core architecture has already spanned to 100 cores on a single chip [20]. However, this quick performance gain has resulted into the complex problems of energy and thermal management. Amplified chip temperatures not only require extra efforts for cooling in the form of expensive thermal packaging or larger fan size but can also lead to problems which can affect lifespan, reliability and performance of these modern systems. For example, a higher temperature can degrade the lifespan of a system to half of its value with a nearly 10^{o}C increase in the operating temperature [2]. It has also been found that in addition to the higher temperatures, large magnitude of thermal gradients can also adversely affect the performance of the interconnects and thus can limit the performance of a system [3]. Therefore, scheduling schemes that can help to control or maintain the temperature below a given threshold are an essential requirement for the extensive use of these systems. A lot of research in the last few years has focused on temperature management, temperature-aware scheduling and performance issues related to these schemes [5], [9], [10]. Most of the research contributions target to satisfy an energy budget or a thermal constraint while minimizing the consequential performance degradation [1], [11]. While these schemes can serve to meet the imposed system-based constraints, they are unable to explore the best possible trade-off between performance and energy or performance and temperature. In addition, some important issues cannot be addressed by constraint-satisfying approaches. For example, for a certain margin of trade-off in performance, what are various improvements possible in energy and thermal profile? For different possible energy budgets and thermal constraints, what is the maximum value of performance that can be achieved? Given a set of schedules with varying values of performance, energy, and temperature, how to select the best trade-off solution? These questions demand a holistic approach for integrating performance (*P*), energy (*E*), and temperature (*T*) (*PET quantities*) into the scheduling process. For this, we address the problem of simultaneously optimizing performance, energy, and temperature while scheduling tasks on a multi-core system (*PET-Scheduling*). Such joint optimization of performance, energy, and temperature is not only complex and challenging but is also a rather unexplored problem.

PET-Scheduling problem is an aggregate of task allocation, task scheduling, and voltage selection problems with the goal of minimizing the performance, energy and temperature. We have developed novel algorithms namely PET-PPF and PET-DCP that can judiciously trade-off performance with energy and temperature. PET-PPF generates a set of probability distributions for selecting a voltage level for each task. Each distribution corresponds to a different value of expected voltage level and thus enables PET-PPF to obtain several trade-off solutions. PET-DCP, uses the same voltage selection scheme as PET-PPF, however, a significant difference is that PET-DCP performs the voltage selections before the task allocation phase. In contrast to PET-PPF, PET-DCP first updates the execution times of the tasks based on the corresponding voltage level selected for each task and then uses a performance-optimal scheduler (DCP [19]) to generate the complete schedule. The key strength of our proposed methods is that they do not aim to provide a single solution to the problem. Rather several trade-off solutions are determined for the *PET-Scheduling* problem. This approach to the *PET-Scheduling* problem is correct as in the presence of multiple conflicting objectives one solution can dominate the other along

different objectives. And for such cases, where all quantities are equally important, one quantity cannot be directly preferred over the other.

The rest of the paper is organized as follows: Section II covers the related work on energy and thermal-aware scheduling. Section III presents the details of the problem under consideration. Section IV explains the proposed algorithms for the solution of the problem and Section V highlights the evaluation setup. Section VI explains the results of the simulation while Section VII concludes the paper.

2 Related Work

Most of the research efforts in the energy and thermal-aware scheduling, target to satisfy a given thermal or energy constraint at the cost of some loss in performance. Primarily, dynamic voltage and frequency scaling (DVFS) is used to adjust the voltage levels of the cores to reduce the power consumption and thus the energy and temperature. The methods in [6], [9], [10], [15] aim to meet the thermal constraints for different kinds of workloads and systems under consideration. A solution for maximizing performance under the imposed power and thermal constraints, by solving the frequency assignment problem for multi-core systems is presented in [9]. Another frequency planning method leveraging combinatorial optimization framework to maximize performance of multi-core systems with thermal limits is developed in [10]. An Event based scheduling method that can improve the peak temperature along with the total number of DTMs without excessive computation overhead is presented in [15]. The scheme proposed in [6] uses a non-DVFS approach to calculate the optimal core states for the given thermal constraints. For tasks represented as DAGs (Directed Acyclic Graphs), several iterative techniques in terms of performance degradation and computational complexity are compared in [11]. These techniques aim to find the most suitable task for the voltage adjustment to satisfy the given thermal constraint. There are also several methods that handle DTM with an alternate perspective, instead of considering temperature as a form of constraint, they try to improve thermal profile of the system within the allowed performance margins [5], [8], [14]. Similarly, there are numerous research efforts which aim to meet the given energy budget while sacrificing as little performance as possible. A power shifting method in [25] that controls the power of the different components of a server system is shown to improve the power budget based on workload conditions. A method to minimize schedule length under an energy constraint by determining the optimal power supplies on each processor is outlined in [18].

However, there are far lesser number of contributions in the pursuit of joint optimization of performance and energy or performance and temperature. The scheme presented in [4] minimizes the energy consumption and performance penalty leveraging Complier-Driven techniques. A hybrid hardware-software approach can improve performance loss consequential to the application of DVFS by leveraging reconfigurable fetch, issue, and retirement units etc., without exceeding the thermal limit [12]. The impact on the thermal profiles of cores due to the power activation at different locations of the chip represented as look-up tables have been used in [16] to allocate tasks to different cores. The proposed approach targets to improve the peak temperature as well as guarantee the thermal limit while at the same time decreases the rejection ratios under thermally constrained CMPs. A few research efforts report improvements in performance and energy under an efficient DTM policy [13]; however, these improvements are usually the by-products of the thermal management.

In contrast to the above mentioned research contributions we have targeted the simultaneous optimization of performance, energy, and temperature for allocating tasks on a multi-core system. We have compared our solutions to the schedules which only target to achieve maximum performance and do not take energy and temperature into consideration. This comparison can help to quantify the actual performance loss exhibited by various solutions in the pursuit of energy and temperature minimization.

3 PET-Scheduling Problem

Given a task graph with N tasks, the total number of cores (M) and the set of available voltage levels ($\boldsymbol{L}$), we aim to minimize makespan, energy consumption and temperature simultaneously while solving the task allocation, task scheduling, and voltage selection problem for the given task set. Thus the required objectives are:

$$Minimize \quad \max_{1 \le i \le N} ft_i \tag{1}$$

$$Minimize \quad \sum_{i=1}^{N} P_i . et_i \tag{2}$$

$$Minimize \quad \max_{1 \le i \le N} \max_{1 \le j \le M} T_i^j \tag{3}$$

ft_i represents the finish time of the ith task. P_i is the power dissipated during the execution of the ith task and et_i is corresponding execution time. T_i^j is the temperature of the jth core during the execution of the ith task (details of thermal model will be presented in Section V). Our goal is not to only produce one solution for solving the above mentioned min-min-min problem but to explore the whole Pareto front that exists between performance, energy, and temperature (*PET quantities*). These trade-off solutions can be used to guide the overall scheduling process to meet the required objectives. For workload, we considered tasks with precedence relationships represented as directed acyclic graphs (DAGs). Several scientific and multimedia applications can be conveniently represented as DAGs. A DAG consists of weighted nodes and edges, where the

weight of the node represents the cost associated with the computation of the task and the weight on an edge represents the communication cost between the two tasks or nodes. Critical path in a DAG is defined as the path of longest length in the graph and hence governs the latest finishing time of a scheduled DAG [7]. The nodes constituting critical path are known as critical path nodes (CPNs) and the cores on which these tasks are scheduled are called the critical cores. Nodes having successors on critical path are known as In-bound nodes (IBNs). All other nodes are called out-bound nodes (OBNs) [7].

4 Proposed Solution

We will explain the algorithms proposed for solving the *PET-Scheduling* problem by highlighting their task allocation and voltage selection phases followed by their computational complexities. While doing so, it is assumed that there are *M* cores in the system which can switch across *K* voltage levels and the DAG to be scheduled has *N* tasks/nodes.

4.1 PET-PPF

For DAG scheduling, the decision space for the *Pet-Scheduling* problem spans not only the task allocation decisions but also include task ordering and voltage selection decisions. PET-PPF solves the problem in a hierarchical manner. For task allocation, PET-PPF aims to minimize the product of total power consumption of the cores and their available time for allocating the upcoming task. The intuition is to include performance and power directly into the allocation decisions as both energy consumption and temperature are related to the power dissipation. In other words, while allocating ith task we select the core with minimum PP^j_i which is defined as:

$$PP_i^j = s_{i-1}^j \, P_{i-1}^j, \;\; \forall 1 \le j \le M \tag{4}$$

where, s_{i-1}^j represents the finish time of the jth core after allocating i-1 tasks to all the cores. P_{i-1}^j is the total power consumption of the jth core just before allocating ith task. Therefore, ith task is allocated to the core such that:

$$y_{i,j} = \begin{cases} 1 & for\ j = \arg\min_{1 \le \delta \le M} (PP_i^{\delta}) \\ 0 & otherwise \end{cases} \tag{5}$$

In (5), $y_{i,j}$ is set to 1 if ith task is allocated to the jth core. The makespan of a scheduled DAG varies significantly with how tasks are prioritized during the allocation phase. We assigned priorities to the tasks according to their classification in the DAG. CPNs are given the highest priority followed by IBNs while OBNs are kept at the lowest priority. The list of tasks generated by this classification is usually termed as CPN Dominant Sequence (CPN-DS) [7]. However, while constructing CPN-DS the precedence constraints are evaluated to ensure that the parent nodes are added to the list prior to the task itself. In voltage selection

Figure 1: PET-PPF

phase, a set of probability distributions is generated. Each probability distribution is used to select the voltage level for every task in the DAG, thus generating a potentially different schedule in the objective domain. In other words, to obtain τ trade-off solutions, we generate τ probability distributions. For generating this set of distributions, we start with a uniform distribution (allowing each voltage level to have the equal chance of getting selected for every task). We then transform the distribution in each step to first shift the peak of distribution towards the maximum voltage level and then repeat the procedure starting with uniform distribution to shift the peak of distribution towards the lowest available voltage level. In other words, we start with a uniform probability distribution in first step, as:

$$\Pr(x = L_i) = \frac{1}{K}, \;\; \forall L_i \in \mathbf{L} \tag{6}$$

In the above equation **L** represents the set of available voltage levels. Now, to adjust the peak of this distribution we define a *partition index* on the set **L**. Such that in each

13:endfor
```

Figure 2**:** PET-DCP

transformation step the probabilities corresponding to the voltage levels with indexes up to the *partition index* are reduced by a certain factor and the collective reduction is then distributed to the probabilities of voltage levels present in the second partition. If α represents the *partition index* over the set of available voltage levels and η defines the fractional reduction in the probability values corresponding to the selected voltage levels. Then the new distribution can be given by:

$$\Pr(L_i)=\begin{cases}\Pr(x=L_i)/\eta & \forall\, i\le\alpha\\ \Pr(x=L_i)+\dfrac{L_i}{\sum_{r=\alpha}^{K}L_r}\sum_{m=1}^{\alpha}(\eta-1)\Pr(x=L_m) & \forall\ \alpha\le i\le K\end{cases}\qquad(7)$$

In the above equation the parameters α and η can be adjusted to control the computational complexity of the overall approach. We found empirically that with α set to the middle of set **L** and η=2, several unique distributions can be obtained when size of **L** is not very large ($|\mathbf{L}| \le 10$). It must be noted that (7) represents the adjustments done for gradually shifting the probability distribution to favor the maximum voltage level and may be repeated τ times, where τ can be selected based on the value of η. In addition, the increase in the probability of selection for each level is proportional to the value of its voltage. The required modification is straight forward for the case where we need to favor the lowest voltage level. Figure 1 presents the overall procedure used by the PET-PPF.

4.1.1 Computational Complexity of PET-PPF

The total number of adjustments steps can be controlled by τ for each direction, therefore, the probability distribution adjustment phase is $O(\tau K)$. In the task allocation phase, a single term as in (4) is evaluated for every core per each task. Hence, the complexity of task allocation phase is $O(M)$. So, for a DAG with N tasks, the overall complexity of PET-PPF is $O(\tau N (M+K))$.

4.2 PET-DCP

PET-DCP takes an opposite approach to that of the conventional DTM and energy improvement schemes. Most of such schemes adjust a performance-optimal schedule to satisfy the given thermal and energy requirements. However, PET-DCP, starts with the task adjustment phase using the given trade-off margin, and then leverages a performance-optimal scheduler to generate the final schedule. In other words, initially a set of probability distributions (similar to PET-PPF) for voltage selection phase is generated. Each distribution is then used to select the voltage level for every task in the DAG. Based on the selected voltage levels, the execution time of each task is updated. This updated DAG is then used as input to the DCP (Dynamic Critical Path) scheduler [21] which generates the final schedule. DCP is a performance-optimal scheduler which keeps track of the critical path after every task allocation and assigns priorities to the remaining tasks accordingly. DCP has been shown to generate schedules with near-optimal makespan [7]. As the expected voltage level varies across the probability distributions generated in the voltage selection phase. Therefore, each distribution allows a different level of performance trade-off which translates into possibly different energy and thermal improvements. It should be noted that any change in the execution time of tasks can result into a possible modification of the critical path and thus the initial schedule as generated by DCP no longer remains optimal. Therefore, starting from a performance-optimal schedule and then iteratively updating it for the desired energy and thermal requirements may potentially lose more performance in the pursuit of energy and temperature improvements. However, the use of performance-aware scheduler by PET-DCP as a second step ensures maximum performance for the modified task graph. Thus, PET-DCP can potentially achieve the performance-energy and performance-temperature trade-offs without excessive performance degradation. Figure 2 briefly outlines the PET-DCP approach.

4.2.1 Computational complexity of PET-DCP

The computational complexity of DCP to generate a schedule for a DAG of N tasks is $O(N^3)$. The total number of adjustments steps are 2τ, therefore the complexity of probability distribution adjustment phase is $O(\tau K)$. Ignoring the time-complexity of drawing N levels from the given distribution ($O(KN)$) and the time to update the DAG ($O(N)$), the overall complexity of PET-DCP will be $O(\tau K N^3)$.

5 Experimental Details

We assumed a 16-core system with cores arranged in a grid layout of 4x4. However, the proposed approach can be used for any number of cores and voltage levels. Each core was assumed to be able to switch across 5 different voltage levels in active mode, thus changing the power consumption and frequency of the system. The values of frequencies at different voltage levels along with their power consumption are outlined in Table 1. It should be noted that the frequency-power scaling relationship used in our evaluation

TABLE 1
DVFS PARAMETERS

f(MHz)	1600	2000	2200	2400	2600

TABLE 2
SYSTEM PARAMETERS

Parameter	No. of Cores	Layout	Freq. Switching	Partition index (α)	Adj. factor/step (η)	Total adj. steps (τ)	Total no. of solutions
Value	16	Grid 4x4	Independent	3	2	10	27

is not very aggressive in terms of reducing the power with the change in frequency/voltage level. Similar scaling relationships have been observed by other research efforts based on actual multi-core systems [17]. Various other parameters related to the system under consideration and the proposed algorithms are listed in Table 2.

5.1 Thermal model

To estimate the temperature of the cores with various power dissipation levels, we can use a steady state thermal model as:

$$T_j = R_{th} P_j + T_A \quad (8)$$

In the above equation, T_j represents the temperature of the jth core due to a power dissipation of P_j watts. R_{th} is the thermal resistance and T_A represents the ambient temperature. Though the model in (8) has been frequently used in various DTM related research efforts, however, it does not take into account the power consumption of the neighboring cores while calculating the temperature of each core. In order to cater for the power dissipation of the neighboring cores we can modify (8), similar to [24] as:

$$T_j = R_{th} P_j + \sum_{\forall m \in neighbor_j} \gamma R_{th} P_m + T_A \quad (9)$$

In (9), $neighbor_j$ represents the set of cores which are adjacent to the jth core. The correlation between the power consumption of the neighboring cores and the temperature of a particular core can be controlled by γ. Though the model in (9) is still simplistic, however, it should be noted that any thermal and system model can be used in conjunction with the proposed algorithms. Since, the presented algorithms provide a mechanism to explore trade-off surfaces that exist between performance, energy, and temperature, therefore, the values of these quantities can be obtained from any complex and detailed models without having an impact on the results reported in Section VI.

5.2 Task model

We used task graphs of various applications including Fast Fourier Transform [22], Laplace Equation [23], Gauss Elimination [22], Fpppp [21] and a Robot Control application [21]. Details of these task graphs can be found in the provided references.

6 Results

Figures 3-5 compare the trade-off regions obtained by the proposed algorithms for various application task graphs. While figures 6-8 present the corresponding performance-

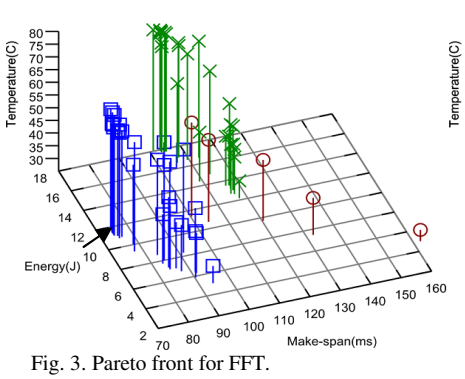

Fig. 3. Pareto front for FFT.

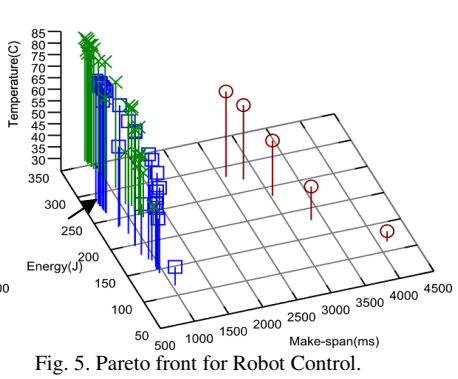

Fig. 5. Pareto front for Robot Control.

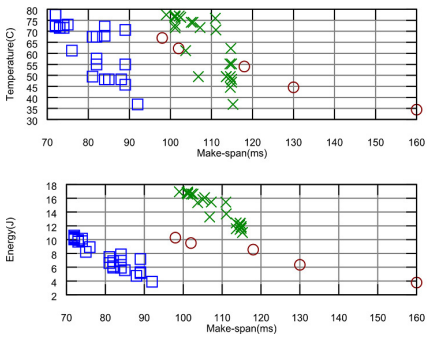

Fig. 6. Trade-off curves for FFT.

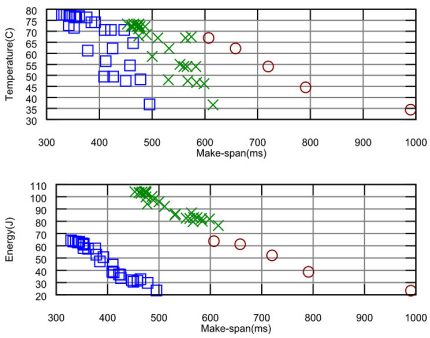

Fig. 7. Trade-off curves for Gauss Elimination.

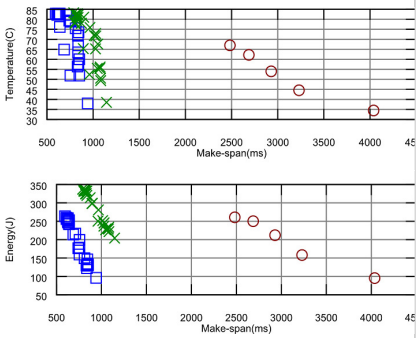

Fig. 8. Trade-off curves for Robot Control.

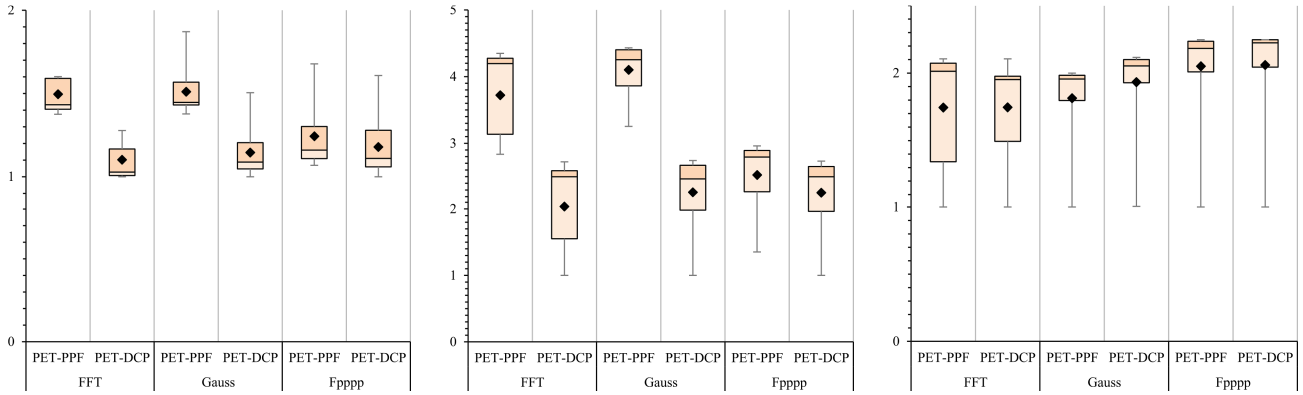

Fig. 9. Comparison of PET-PPF and PET-DCP for various task graphs along (a) Performance, (b) Energy, and (c) Peak temperature.

energy and performance-temperature trade-offs possible by leveraging the Pareto-fronts obtained from the proposed algorithms. Due to the space considerations, we have only presented the selected figures and tables. For comparison, we used an efficient temperature-aware allocation scheme called Post-Tm [16]. We used each of the available voltage level from Table 1 along with the Post-Tm allocation scheme to generate a base-line trade-off surface. A direct comparison of these Pareto surfaces (Figures 3-8) proves that both of the proposed algorithms can obtain trade-off solutions with wide range of values and with better spread along each objective as compared to the modified Post-Tm approach. However, a contrasting difference is that PET-DCP is able to generate the Pareto fronts or trade-off surfaces which are much closer to the performance optimal point (shown by arrows in Figures 3-5). Since, the spread of solutions generated by the PET-DCP is not inferior to both PET-PPF and Post-Tm along energy and temperature axis, therefore, the closeness to origin along performance axis translates into energy-performance and temperature-performance trade-offs with lesser performance degradation. Figure 9 compares the algorithms in terms of the distribution of the solution points (normalized to the minimum value obtained) along each objective. We can observe that PET-DCP was able to achieve a range of values comparable to PET-PPF but on the other hand, attains a significantly lower mean value for most of the cases.

To further analyze the quality of trade-offs, Table 3 compares the amount of performance degradation for the corresponding improvements in energy and temperature for each algorithm. While calculating the performance degradation as well as energy and temperature reductions for each trade-off solution, the values of *PET quantities* corresponding to the performance-optimal schedule as generated by DCP were used as reference. $\Delta P_m/\Delta E_m$ represents the ratio of percentage performance degradation to the percentage decrease in energy and $\Delta P_m/\Delta T_m$ is the ratio of percentage performance degradation to the percentage reduction in peak temperature (averaged over all solutions generated by each algorithm for a given task graph). Negative values for $\Delta P_m/\Delta E_m$ and $\Delta P_m/\Delta T_m$ in Table 3 represent an average decrease in the energy and temperature consequential to the corresponding performance degradation. From the values in Table 3, it can be observed that both the PET-PPF and Post-Tm degrades the performance by a larger percentage than the corresponding percentage decrease in energy and temperature. For example, for Gauss Elimination task graph the values of $\Delta P_m/\Delta T_m$ for PET-PPF and Post-Tm are -3.04 and -3.99 which means that for every 1% reduction in peak temperature, performance has to be degraded by 3.04% and 3.99% respectively. However, PET-DCP needs to degrade the performance only by 1.43% for every 1% improvement in peak temperature for the same application. Similar comparison exists for other task graphs. Figure 10 highlights this trend pictorially for all the task graphs used in our experiments. We also observe that PET-PPF, yields positive values for $\Delta P_m/\Delta E_m$ for some of the task graphs. This points out that, PET-PPF is unable to obtain large number of trade-off solutions that can improve energy consumption as

TABLE 3
TRADE-OFF RATIOS

compared to the base-line performance-optimal schedule.

Based on the performance of PET-DCP, we can note that in general, it may be potentially better to pre-adjust the tasks according to the system's state and the given requirements of energy and temperature before targeting the maximal performance to obtain better trade-off solutions. It may also be noted that once the trade-off solutions are available, an operating point or schedule can be selected from them according to the imposed constraints and the given preferences.

7 Conclusion

We proposed two schemes to explore the trade-off regions that may exist while trading loss in performance with the improvements in energy and peak temperature. Both algorithms were able to generate trade-off curves comprising of schedules that result into diverse range of values for makespan, energy consumption and peak temperature. Our evaluation results indicate that PET-DCP, which pre-adjusts tasks probabilistically for energy and thermal improvements before using a performance-optimal scheduler, can produce multiple schedules that are very close to the performance-optimal point. This leads the PET-DCP to achieve *trade-off ratios* better than the other algorithms (PET-PPF and Post-Tm) by a factor of 2 on average. The work presented in this paper is an inaugural effort to jointly optimize performance, energy, and temperature while scheduling tasks on a multi-core system and can be used as a framework to attain efficient trade-offs among the *PET quantities*.

Parallelization Strategies for Local Search Algorithms on Graphics Processing Units

Audrey Delévacq, Pierre Delisle, and Michaël Krajecki
CReSTIC, Université de Reims Champagne-Ardenne, Reims, France

Abstract— *The purpose of this paper is to propose effective parallelization strategies for Local Search algorithms on Graphics Processing Units (GPU). We consider the distribution of the 3-opt neighborhood structure embedded in the Iterated Local Search framework. Three resulting approaches are evaluated and compared on both speedup and solution quality on a state-of-the-art Fermi GPU architecture. Solving instances of the Travelling Salesman Problem ranging from 100 to 3038 cities, we report speedups of up to 8.51 with solution quality similar to the best known sequential implementations and of up to 45.40 with a variable increase in tour length. The proposed experimental study highlights the influence of the pivoting rule, neighborhood size and parallelization granularity on the obtained level of performance.*

Keywords: TSP, ILS, Parallel Metaheuristics, 3-opt, GPU

1. Introduction

Iterated Local Search (ILS) is a metaheuristic that successively applies a given Local Search (LS) procedure to an initial solution and incorporates mechanisms to climb out of local optima. This method finds good solutions to many optimization problems in a reasonable time which may still remain too high in practice. However, it offers an interesting parallelization potential when extended to a population-based approach where different individuals improve their solution by executing the same algorithm on several computing units [1].

At present time, the best known implementations of the ILS framework are dedicated to conventional, CPU-based sequential and parallel architectures. However, as recent years have shown the potential to use the GPU as a high performance computational resource, it becomes important to deliver GPU-based optimization methods that are efficient in both solution quality and execution speed. However, recent research has shown that this goal is often difficult to achieve.

The purpose of this paper is to propose parallelization strategies for ILS to efficiently solve the Travelling Salesman Problem (TSP) in a GPU computing environment. The 3-opt exchange procedure used within the algorithm is decomposed on processing elements along with required data structures. Pivoting rules based on first-improvement and best-improvement schemes are also evaluated. Important algorithmic, technical and programming issues that may be encountered in this context are finally highlighted.

This paper is organized as follows. First, we present k-opt LS algorithms, the ILS metaheuristic and their application to the TSP. After a fairly complete review of the literature on parallel LS and ILS, the proposed GPU parallelization strategies are explained. Finally, a comparative experimental study is performed to evaluate the performance of the resulting algorithms.

2. Iterated Local Search for the Travelling Salesman Problem

The Travelling Salesman Problem (TSP) may be defined as a complete weighted directed graph $G = (V, A, d)$ where $V = \{1, 2, ..., n\}$ is a set of vertices (cities), $A = \{(i, j) \mid (i, j) \in V \times V\}$ is the set of arcs and $d : A \rightarrow \mathbb{N}$ is a function assigning a weight or distance d_{ij} to every arc (i, j). The objective is to find a minimum weight Hamilton cycle in G, which is a tour of minimal length visiting each city exactly once.

Local Search (LS) generally aims to iteratively improve an initial solution by local transformations, replacing a current solution by a better neighbor until no more improving moves are possible. In that case, a local optimum is reached and the procedure stops. Most well-known LS algorithms for the TSP are based on k-opt exchanges which delete k arcs of a current solution and reconnect partial tours with k other arcs in all possible ways. Figure 1 describes the specific 3-opt [2] procedure. Among the other popular ones, we may cite the 2-opt [3] and Lin-Kernighan [4] algorithms.

One of the key elements of LS is the pivoting rule which dictates the choice of the neighbor solution that will replace the current one [5]. The most commonly used methods are best-improvement and first-improvement. In the first case, all neighbors of the current solution are evaluated and the one which produces the greatest improvement is selected. In the second case, the first improving move is accepted and the others are discarded. Less popular alternatives are random-improvement and least-improvement which respectively choose a neighbor randomly or with minimal improvement of the objective function. Anderson [6] defines a parameter k associated to the number of improving moves found before choosing the best one. When $k = 1$, the algorithm uses a first-improvement strategy and

the more k increases, the more thorough is the exploration of the neighborhood. He deduces that first-improvement is generally the best choice for TSP.

In order to accelerate the execution of LS algorithms for the TSP, various mechanisms are usually used to reduce the neighborhood of the current solution. First, candidates lists, which comprise the cl nearest cities for each city, may be used when reconnecting partial tours instead of the whole set of cities. Second, fixed-radius neighbor search reconnects tours only with arcs for which the sum of weights is potentially lower than the sum of weights of the arcs to be deleted. Third, *don't look bits* are associated to each city in order to drive the search away from arcs which have recently led to unimproving moves. A complete description of these methods may be found in Bentley [7] and in Johnson and McGeoch [8].

A LS procedure becomes trapped in a local optimum when no improving moves are possible in the neighborhood of the current solution. A way to partly counter this problem is to embed it in a guiding construction such as Iterated Local Search (ILS) [9]. This metaheuristic is divided into four main steps that are highlighted in Figure 2. The first one is the generation of an initial solution S, usually with constructive heuristics or randomly. The second one is the LS procedure that is applied to S to bring it to a local optimum. The third one is a perturbation move which transforms S into S' in order to get it out of that local optimum. Finally, an acceptance criterion is evaluated to choose which solution between S and S' will be used to resume the search. The three last steps are then repeated until an end criterion is reached, for example a maximum time limit or iteration count.

```
while S is not a local optimum do
    for each combination of a, b, c ∈ [0; n] do
        Delete arcs (a,a+1), (b,b+1) and (c,c+1)
        Produce neighbors of S by reconnecting partial tours
        Evaluate neigbors of S
    Replace S by the best neighbor chosen by the pivoting rule
Return best solution S
```

Fig. 1: 3-opt LS pseudo-code.

```
Generate solution S
Apply LS procedure on S
Evaluate length L of solution S
while end criterion is not reached do
    Transform S into S' by a perturbation move
    Apply LS procedure on S'
    Evaluate length L' of solution S'
    if L' < L then replace S by S' // acceptance criterion
Return best solution S
```

Fig. 2: ILS pseudo-code.

The ILS metaheuristic is considered as one of the most powerful approximate methods for the TSP [1]. In fact, the works of Stützle and Hoos [10] and Lourenço *et al.* [9] show its competitiveness in solving various TSP problems varying from 100 to 5915 cities. However, faced to large and hard optimization problems, it may need a considerable amount of computing time and memory space to be effective in the exploration of the search space. A way to accelerate this exploration is to use parallel computing.

3. Literature review on parallel LS

Verhoeven and Aarts [11] proposed a classification that distinguishes *single-walk* and *multiple-walk* parallelization approaches for LS algorithms. In the first category, one search process goes through the search space and its steps are decomposed for parallel execution. In that case, neighbors of a solution may be evaluated in parallel (*single-step*) or several exchanges may be performed on different parts of that solution (*multiple-step*). In the second category, many search processes are distributed over processing elements and designed either as *multiple independent walks* or *multiple interacting walks.*

Johnson and McGeoch [8] defined three parallelization strategies for k-opt algorithms. The first one uses *geometric partitioning* to divide the set of cities into subgroups that are sent to different processors to be improved by a constructive algorithm and a LS procedure. As this partitioning has the drawback of isolating subgroups without reconnecting subtours intelligently, the second strategy favors *tour-based partitioning* to divide tours into partial solutions that includes a part of the edges of the current solution. The third approach is a simple parallelization of neighborhood construction and exploration.

Works on parallelization of ILS for the TSP mainly follow the population-based, multiple-walk approach where many solutions are built concurrently. Hong *et al.* [12] designed a parallel ILS which executes a total of m iterations using a pool of p solutions. Martin and Otto [13] proposed an implementation in which several solutions are computed simultaneously on different processors and the best solution replaces all solutions at irregular intervals.

Few authors have tackled the problem of parallelizing LS algorithms for TSP on GPU. Luong *et al.* [14], [15] proposed a methodology for implementing large neighborhood algorithms in which the CPU is in charge of LS processes and the GPU deals with the generation and evaluation of neighbor solutions. It was experimented on TSP with Tabu Search using a swap as the local transformation. Maximal speedup of 19.9 is reported on a 5915 cities problem but solution quality is not provided. O'Neil *et al.* [16] implemented an iterative hill climbing algorithm based on 2-opt local transformations in which random restarts are associated to threads. Maximal speedup of 61.9 is reported on a 100 cities problem. Fujimoto and Tsutsui [17] integrated a 2-opt best-improvement LS into a genetic algorithm executed

on GPU. Maximal speedup of 24.20 is obtained on problems of up to 493 cities. Delévacq *et al.* [18] augmented an Ant Colony Optimization algorithm with a 3-opt local search implemented on GPU. Solving TSP problems from 198 to 2103 cities, they reported speedups of up to 8.03 with solution quality similar to the best known sequential implementation.

These works provide a frame of reference for evaluating the attainable efficiency of GPU-based LS algorithms for the TSP. However, most of them overlook important issues that make it difficult to assess their effectiveness as parallel optimization methods. First, speedups are mostly provided with nonexistent or inappropriate evaluation of solution quality. The proposed implementations are also experimented on TSPs often limited to a few hundred cities without bypassing obvious memory limits of actual GPUs. In addition, as significant implementation details like the pivoting rule and the mechanisms used to accelerate the computations are not provided, algorithms can hardly be reproduced or tested on larger problems. Finally, basic local transformations are most often implemented even though the most effective methods for solving the TSP are based on the 3-opt neighborhood structure and the Lin-Kernighan algorithm [6].

As LS algorithms are key underlying components of most high-performing metaheuristics, a natural fit is to run a guiding metaheuristic on CPU while the GPU, acting as a co-processor, takes charge of running the LS procedure. However, there is still much conceptual, technical and comparative work to achieve in order to design such hybrid parallel combinatorial optimization methods. This paper aims to partially fill this gap by proposing, evaluating and comparing various parallelization strategies for the 3-opt LS on GPU.

4. GPU parallelization strategies for ILS

We propose three parallelization strategies based on the algorithm described in Figures 1 and 2. They mainly differ in the pivoting rule used to select an improving neighbor, the distribution of solutions to processing elements and the use of GPU shared memory. For the sake of completeness, we first provide a brief description of the GPU architecture and computational model.

The conventionnal NVIDIA GPU [19] architecture includes many *Streaming Multiprocessors* (SM), each one of them being composed of *Streaming Processors* (SP). On this special hardware, the *global* memory is a specific region of the *device* memory that can be accessed in read and write modes by all SPs of the GPU. It is relatively large in size but slow in access time. Each SM employs an architecture model called *SIMT* (*Single Instruction, Multiple Thread*) which allows the execution of many coordinated threads in a data-parallel fashion. *Constant* and *texture memory caches* provide faster access to device memory but are read-only. The constant memory is very limited in size whereas texture memory size can be adjusted in order to occupy the available device memory. All SPs can read and write in their *shared memory*, which is fast in access time but small in size and local to a SM. It is divided into memory banks of 32-bits words that can be accessed simultaneously. *Registers* are the fastest memories available on the GPU but involve the use of slow local memory when too many are used.

In the CUDA programming model [19], the GPU works as a co-processor of a conventional CPU. It is based on the concept of kernels, which are functions (written in C) executed in parallel by a given number of CUDA threads. These threads are grouped together into *blocks* that are distributed on the GPU SMs to be executed independently of each other. However, the number of blocks that a SM can process at the same time (*active blocks*) is restricted and depends on the quantity of registers and shared memory used by the threads of each block. In a block, the system groups threads (typically 32) into *warps* which are executed simultaneously on successive clock cycles. The number of threads per block must be a multiple of its size to maximize efficiency. Much of the global memory latency can then be hidden by the thread scheduler if there are sufficient independent arithmetic instructions that can be issued while waiting for the global memory access to complete. Consequently, the more active blocks there are per SM, and also active warps, the more the latency can be hidden. Special care must also be taken to avoid flow control instructions (if, switch, do, for, while) that may force threads of a same block to take different paths in the program and serialize the execution.

The proposed strategies are inspired by the population-based and multiple independent walks general strategies described in Section 3. However, only the LS phase is parallelized on GPU instead of entire walks. In all cases, memory management issues had to be adressed. Data transfers between the CPU and the GPU as well as global memory accesses require considerable time but may be often be reduced by storing the related data structures in shared memory. However, in the case of ILS applied to TSP, one central data structure is the distance matrix which is needed by all solutions of the population while being too large ($O(n^2)$ in size) to fit in shared memory for problems larger than a few hundred cities. It is then kept in global memory. On the other hand, as it is not modified during the LS phase, it is possible to take benefit of the texture cache to reduce their access times. The first two strategies are applied on a first-improvement LS implementation and the last one on a best-improvement scheme over a fixed size neighborhood. Specific details for each strategy are given in the next sections.

4.1 First-improvement LS : $ILS-FI_{thread}$ and $ILS-FI_{block}$

The proposed GPU parallelization strategies applied to a first-improvement LS have been presented by the authors

in the form of preliminary work [20] and are inspired by our previous contributions on Ant Colony Optimization [21], [18]. Their general parallelization model is illustrated in Figure 3(a). The first one, presented in Figure 3(b), is called $ILS-FI_{thread}$ and associates each LS to a CUDA thread. It has the advantage of allowing the execution of a great number of LSs on each SM and the drawback of limiting the use of fast GPU memory. The second strategy, called $ILS-FI_{block}$ and illustrated in Figure 3(c), associates each LS to a CUDA block. Thus, parallelism is preserved for the LS phase, but another level of parallelism is exploited by sharing the multiple neighbors between many threads of a block. As only one solution is assigned to a block, it becomes possible to store the data structures needed to improve the solution in the shared-memory. Two variants of the $ILS-FI_{block}$ strategy are then distinguished : $ILS-FI_{block}^{global}$ and $ILS-FI_{block}^{shared}$.

Currently, most efficient LS methods for solving the TSP are based on the first-improvement pivoting rule and mechanisms to reduce execution times. They were obviously designed and optimized for traditional single processor computing systems. While it may be possible to achieve good efficiency on small multiple processor/core systems with minimal changes to existing algorithms, the parallelization process is not as straightforward for a synchronous, massively parallel architecture like the GPU. On one hand, existing sequential implementations are based on reducing the number of computed neighbors in a single LS step whereas GPU processing is well suited for large data-parallel applications. On the other hand, speedup mechanims are often based on conditional statements which induce thread divergence within warps and then serialization. These observations lead us to propose a new parallelization strategy based on the synchronous evaluation of fixed size neighborhoods.

4.2 Best-improvement LS : $ILS-RKBI_{blocks}$

In a basic best-improvement LS, the whole neighborhood of a given solution is evaluated. In the case of the 3-opt move for a n cities TSP, the number of combinations to delete three edges of the tour is $\binom{n}{3}$. For each combination, there are 7 ways to reconnect the subtours [22] which corresponds to 7 neighbors. Research on TSP show that such a scheme leads to prohibitive execution times and local optima that are much further away from the ones obtained with first-improvement schemes [6]. We then propose the *random-k-best-improvement* pivoting rule which offers a compromise between first-improvement and best-improvement as well as a computation model better suited to GPUs. At each step, arcs to be deleted are randomly selected to generate a total of k neighbors and the one which produces the greatest improvement is kept. By assigning different values to k, one may customize the search behavior and the amount of work performed by the GPU. This leads to the proposition of a third parallelization strategy called $ILS-RKBI_{blocks}$ and illustrated in Figure 4(a).

This strategy splits computations of a single step into two kernels. The first one, described in Figure 4(b), is dedicated to neighborhood evaluation which is the most expensive part of the step. Each solution is associated to several blocks and its neighbors are splitted into groups to be assigned

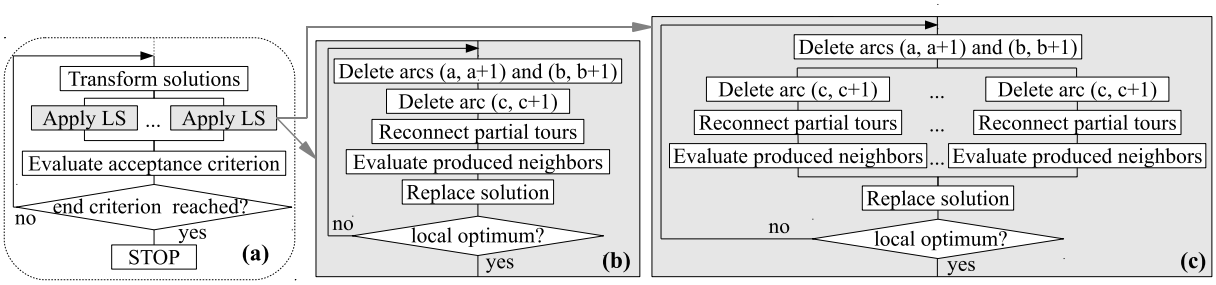

Fig. 3: Parallelization models for first-improvement ILS : general (a), $ILS-FI_{thread}$ (b) and $ILS-FI_{block}$ (c).

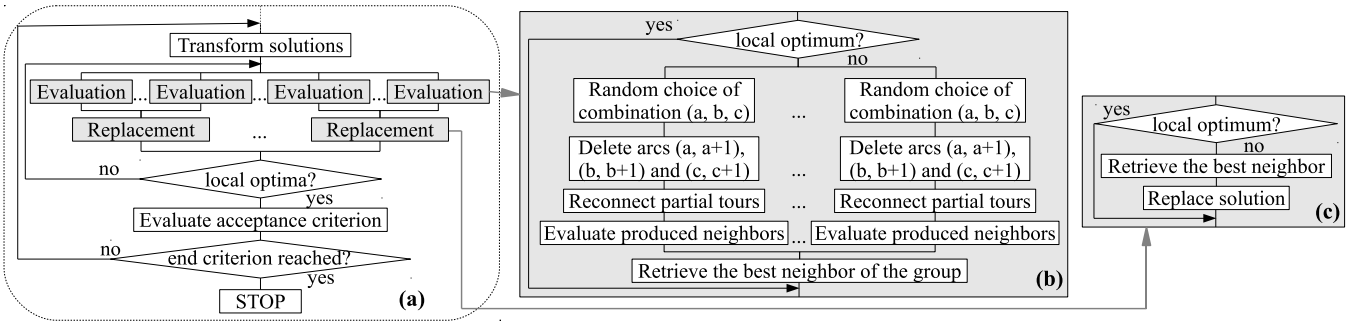

Fig. 4: Parallelization model for random-k-best-improvement ILS (a), evaluation kernel (b) and replacement kernel (c).

to each block. Each thread is then associated to several neighbors. Using the NVIDIA CURAND library, a thread randomly selects the three arcs to break, evaluates possible reconnections and stores the best one in its own space in shared memory. Once all the neighbors have been evaluated, a reduction is performed in the shared memory to find the best neighbor of the block which is stored in global memory.

In the second kernel, presented in Figure 4(c), each solution is associated to a single block which retrieves its best neighbor among the ones produced by the first kernel and replaces the current solution. The two kernels are launched alternately until all solutions are local optima.

5. Experimental results

GPU strategies are experimented on TSP problems ranging in size from 100 to 3038 cities. Speedups are computed by dividing the sequential CPU time with the parallel time obtained with the GPU acting as a co-processor. Experiments were made on a NVIDIA Fermi C2050 GPU containing 14 SMs, 32 SPs per SM and 48 KB of shared memory per SM. Code was written in the "C for CUDA V4.1" [19] programming environment. As a premiminary step, we validated our sequential ILS implementation with a comparative study with Stützle and Hoos [10] and Lourenço *et al.* [9] works.

The parallel ILS parameters are as follows. Initial solutions are built with the nearest neighbor heuristic, improved with 3-opt LS and perturbed with a double-bridge move. A population of nb_{sol} solutions is used, a total number of it_{total} iterations is performed and the ILS procedure is limited to $it_{lim} = \frac{it_{total}}{nb_{sol}}$ iterations for each solution. All speedups are computed for $nb_{sol} = 2^x$ with $x \in \{0, 3, 6, 9, 11\}$ from 20 trials for problems with less than 1000 cities and from 10 trials for larger instances.

5.1 $ILS - FI_{thread}$ and $ILS - FI_{block}$

First-improvement LS algorithms use a *don't look bits* procedure and a fixed-radius neighbor search restricted to candidate lists of size 40. it_{total} is set to 1048576 for each problem to ensure that the same number of LSs are performed for all numbers of blocks and threads. In $ILS - FI_{block}$, the number of blocks is set to nb_{sol} and the number of threads per block is set to the size of candidate lists. In $ILS - FI_{thread}$, the number of blocks and threads are configured to maximize the number of blocks without exceeding the number of active blocks per SM.

Table 1 shows speedup for $ILS - FI_{thread}$, $ILS - FI^{global}_{block}$ and $ILS - FI^{shared}_{block}$. The reader may note that increasing nb_{sol} and so, the total number of threads, leads to increasing speedups for all strategies. Overall, if the number of threads used is too small, GPU resources are not well exploited and memory latency is not efficiently hidden. The reader may also notice that speedups obtained with $ILS - FI_{thread}$ are always lower than with $ILS - FI_{block}$. As this strategy does not execute enough threads in parallel to efficiently hide memory latency, we obtain a maximal speedup of 2.02. In fact, speedups are achieved only with 2048 threads. Furthermore, code divergence induced by computing the neighbors of many solutions/threads on the same block in SIMD mode involves significant algorithm serialization.

Table 1: Speedup for $ILS - FI_{thread}$ (T), $ILS - FI^{global}_{block}$ (BG) and $ILS - FI^{shared}_{block}$ (BS) strategies and solution quality (frequency of finding the known optimum $freq$ and average percentage deviation from the optimum Δ_{avg}) for each problem.

The greater speedups and the maximal value of 7.77 obtained with $ILS - FI^{global}_{block}$ show that sharing the work associated to each solution between several threads is more efficient. For example, when nb_{sol} is set to 2048, ILS_{thread} uses 2048 threads versus 81920 for ILS_{block}. On the other hand, speedups increase from 100 to 318 cities and then slightly decrease. In that case, the larger data structures and frequent memory accesses needed to solve the biggest problems imply memory latencies that grow faster than the benefits of parallelizing available computations. Further improvements are brought by the use of shared memory, introduced in $ILS - FI^{shared}_{block}$, which provides maximal speedup of 8.51. However, results for the three biggest problems show that the limits of this kind of memory are quicky reached. In fact, as it is limited in size, using too much of it reduces the number of active blocks per SM. Associated to the combined effect of the increasing number of blocks required to perform computations, performance

gains become less significative. For the 3038 cities problem, the amount of required shared memory is so high that no block can be active on any SM.

An analysis of the frequency of finding the known optimum and the average percentage deviation from the optimum is also provided in Table 1. It shows that the optimal solution is always found by the parallel implementations for small problems. For medium-sized problems, the more nb_{sol} increases, the less frequently is the optimal solution found. As the number of iterations becomes too low to provide a thorough search, the optimal solution is never found for the bigger problem. This indicates that when choosing appropriate parameters for the parallel algorithms, a compromise must be achieved between speedup and solution quality.

5.2 $ILS - RKBI_{blocks}$ strategy

An empirical study was performed to determine the parameters used for the $ILS-RKBI_{blocks}$ strategy. The number of threads per block is set to 64 as it generally maximizes the number of active blocks per SM. It is also a multiple of 32 as advised in the CUDA specification [19]. Table 2 provides the chosen number of blocks for each solution to evaluate its neighbors. The number of iterations it_{total} and the number of evaluated neighbors k are selected so the sequential execution time is in the same order of magnitude as the ones of the first-improvement strategies when nb_{sol} is set to 64. They are then set to $1,120,000/5,500$ for kroA100, $1,120,000/11,000$ for lin318, $560,000/10,000$ for rat783, $2,240,000/1,200$ for fl1577 and $2,240,000/1,000$ for pcb3038.

Table 2: Number of blocks per solution for each problem and nb_{sol} values.

	1	8	64	512	2048
kroA100	120	70	30	5	2
lin318	110	60	30	5	2
rat783	80	100	60	10	5
fl1577	140	90	60	15	15
pcb3038	120	100	90	20	20

Table 3 presents speedup, frequency of finding the optimum and average percentage deviation from the optimum for the $ILS-RKBI_{blocks}$ strategy. The reader may notice that significant speedups are obtained with all values of nb_{sol} and a maximal speedup 45.40 is achieved with 64 solutions on the 318 cities problem. Also, with the exception of the two smallest problems with $nb_{sol} = 1$ where the amount of work is too small, speedups are in the same order of magnitude with any value of nb_{sol} for any particular problem. This shows the scalability of the neighborhood distribution strategy to different population sizes. However, the more nb_{sol} increases, greater is the deterioration of solution quality in most cases.

Table 3: Speedup and solution quality (frequency of finding the known optimum $freq$ and average percentage deviation from the optimum Δ_{avg}) for ILS_{rkbi}.

Problem	nb_{sol}	Speedup	Solution quality	
			$freq$	Δ_{avg}
kroA100	1	25.06	1.00	0.000
	8	37.21	1.00	0.000
	64	**45.29**	1.00	0.000
	512	42.12	1.00	0.000
	2048	42.32	1.00	0.000
lin318	1	27.55	0.00	0.482
	8	38.35	0.00	0.483
	64	**45.40**	0.00	0.633
	512	43.21	0.00	0.875
	2048	43.58	0.00	0.886
rat783	1	14.76	0.00	1.224
	8	16.74	0.00	1.582
	64	**17.02**	0.00	2.740
	512	16.24	0.00	3.496
	2048	16.74	0.00	3.518
fl1577	1	**30.40**	0.00	1.034
	8	29.47	0.00	1.703
	64	29.52	0.00	1.831
	512	28.02	0.00	1.776
	2048	28.85	0.00	1.741
pcb3038	1	31.23	0.00	4.636
	8	31.20	0.00	4.940
	64	31.70	0.00	5.162
	512	30.31	0.00	5.104
	2048	**33.59**	0.00	4.970

A comparison with Table 1 shows that when speedup is considered, $ILS-RKBI_{blocks}$ clearly performs better than $ILS - FI$ in all cases. The increased neighborhood size, better sharing of neighbors between blocks and reduction of thread divergence allows the resulting algorithm to make a better use of GPU ressources. Using fixed size data structures to store the best neighbors also makes the use of shared memory relevant even for bigger problems. However, the gains in speedup also lead to the deterioration of solution quality. The random choice of neighbors and inhability to use speedup mechanisms of first-improvement strategies makes it difficult for $ILS - RKBI_{blocks}$ to keep the same level of optimization than $ILS - FI_{thread}$ and $ILS - FI_{block}$ in the same execution time. This may indicate either that a compromise must be found between speedup and solution quality when designing parallel ILS algorithms for GPUs or that news ways must be thought to restore - if possible - the delicate balance between all the algorithm components in this context.

6. Conclusion

The aim of this paper was to design efficient parallelization strategies for Iterated Local Search on Graphics Processing Units to solve the Travelling Salesman Problem. The $ILS-FI_{thread}$ and $ILS-FI_{block}$ strategies associated the local search phase to the execution of streaming processors and multiprocessors respectively. They provided maximal

speedups of 2.02 and 8.51 with competitive solution quality as well as major shortcomings in their use of GPU computational resources. In an attempt to overcome these limitations, the $ILS - RKBI_{blocks}$ strategy was proposed to increase neighborhood size and associate multiple blocks to the evaluation of each solution. Significant speedups were then achieved, ranging as high as 45.40, at the cost of a variable deterioration of solution quality. This leads to the idea that solving the TSP and other combinatorial optimization problems on GPU is currently a matter of compromise between speedup and search efficiency.

In future works, we plan to deepen our understanding of the links between neighborhood size, pivoting rules and algorithm parameters in order to improve the search process of our GPU ILS implementation. Also, as this work is part of a greater project related to the parallelization of metaheuristics on GPU, we seek to use the knowledge built in this paper to propose a general framework that can be applied to other metaheuristics. We also plan to propose algorithms to automatically determine effective thread/block/GPU configurations for ILS and other metaheuristics. We believe that the global acceptance of GPUs as components for optimization systems requires algorithms and software that are not only effective, but also usable by a wide range of academicians and practitioners.

Acknowledgment

This work has been supported by the Agence Nationale de la Recherche (ANR) under grant no. ANR-2010-COSI-003-03. The authors would also like to thank the Centre de Calcul Régional Champagne-Ardenne for the availability of the computational resources used for experiments.

Evaluation of power consumption in programming models based on map reduce in shared memory systems

Zahra khoshmanesh[1]
[1]CSE and IT Department, Shiraz University, Shiraz, Iran

Abstract *- One of the most common models in parallel programming is Map reduce. In companies which use Map reduce framework, at each time a lot of computers are executing Map and Reduce functions. These functions are executing many times and we can estimate the effect of any small changes in response speed or consumed power in each execution of the Map reduce model to be very high. On the other hand, power and energy became an important challenge in computer systems with high performance, so that criteria such as consumed Power are as important as performance criteria. Nowadays, because of the generated heat and also because of decrease in energy sources, saving the consumed power is very important. So, finding the parts of the programs which needs more power is of prime Importance, because by finding these parts, we can find the ways to investigate and improves them in terms of power. In this paper, we investigate the available Map Reduce framework and programs in this regard from the point of consumed power, which are implemented in multi-core environment with common memory.*

Keywords: *consumed power, map reduce, multicores, parallel programs, efficiency*

1 Introduction

According to Moore law [5], numbers of transistors on a chip are doubled each two years. As the size of the transistors is reduced, more of them can be placed on the chips, so we can have more cores on a chip. But the problem which arises is the consumed power. One transistor has a low consumed power by itself, but here we have a big number of transistors which cause high amount of the heat. On the other hand, transistors cannot be turned off completely, this means even if they are completely turned off, they will have current leakage, and some currents will pass through them, even when they are turned off. And this will cause gradual loose of energy and the power of connection wires will be too high. Most power saving mechanisms like doing the task slowly, will affect the performance. For two reasons, increasing the speed of the processors by increasing the frequency is not possible. These two challenges are memory wall and heat wall. Memory wall is related to difference in speed between memory and main processor and heat wall related to the fact that as the execution speed of the computer increases, consumed power which is proportional to cubic root of the frequency, also will increase and subsequently more heat will be generated [7]. To overcome these problems and to increase computation power of the system, parallel architecture was recommended among which multi-core architecture was designed as the practical way of overcoming problems. So, we have a number of cores on a processor and in order to be able to use the power of all cores, we should use multi-node programming. But the problem which arises is that common multi-node programming leaves the whole control to the user, and this is a disadvantage.

By increasing the use of information technology and popularity of the issues such as automation and use of digital equipment in business processes, in all cases we face data generation, nowadays we come across with the problem named data volume explosion. For example EBay Company has announced that, it has more than 6.5 petabyte data. This figure is 10 petabyte for Yahoo. The need to analyze the raw data for different uses in increasing which in turn demand appropriate and effective solutions for data analysis.

In 2004, Google introduced its programming model for use in environment with several processor units which is called Map reduce. This model which is inspired from functional programming model does all the operations related to passing, distributing and gathering data between computers and just demands the computing core of the program from user. In today world, in which we deal with a high amount of the data, this programming model is very useful. If we consider each computer in a distributed system as a core in multi-core processors, we come with the conclusion that models such as Map reduce is a good choice for use in this processing unit.

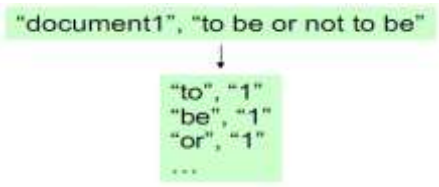
This model is a simple programming model which is used for solving computation problems in big scales and in distributing form. Map reduce was developed by Google in 2003 and is a software framework which provide a safe and scalable bed for development of distributing uses and is implemented in different languages.

In fact, it contains a set of library functions which hide the details and sophistication from the user. These details include: automatic paralleling of the tasks, data load balancing, optimization of network and disk transferring, management of faults in machines. Moreover, each improvement in library will be applied to all the places

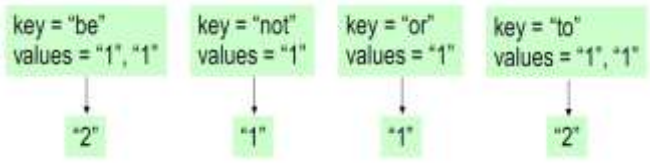
which this library has been used.In this method, two main steps exist: Map and Reduce.

Map step: main node, take the input and divides it into smaller sub-problems and then distribute them between nodes which are responsible for doing the tasks. It is possible that, this node repeats the task and if so, we would have a multi-surface architecture. Finally, these sub-problems are processed and response is sent to the output.

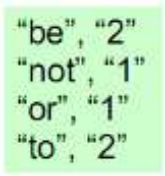
Reduce step: for generating an output, the responses and results which are received by main node, will be merged together. To do so, some operations like filtering and conversion may be applied on the data.
These two main operations are done on a regular pair (key, value). Map function, take a regular pair of the data and convert it to a list of regular pairs. Then, Map reduce framework, gather all the pairs with the same keys from all lists and produce a group. For each generated key, one group is produced. And the reduce function act on all groups. Now, map reduce framework, convert one list of (key, value) to a list of values.
As an example, a framework called Mars is designed for graphical processors for programs based on Map reduce. Also some programs which are designed and developed by Google based on the map reduce and focus on web based search programs for ordinary CPU are tested and implemented GPUs with high computation power and broad band widths.
One of the common examples for solving problems by Map reduce, is finding the number of occurrence of a word in a document. Here document referee to web page. In this problem, input is a file which has a text in each row. Map function takes (key, value) pairs. In this case, key is the address of the web page, and value is web content .[8] Output of the map function will be a list of other regular pairs :(number of occurrence, word) same as figure below:



Now map reduce framework gathers all the pairs with common keys. Then reduce function, merges the value of the pairs with common keys and assign a new value for that which in this case is sum of the values.



And finally, output will be like this:



Word count pseudo codes are shown in following:

```
map(String key, String value):
 // key: document name
 // value: document contents
 for each word w in value:
  EmitIntermediate(w, "1");
reduce(String key, Iterator values):
 // key: a word
 // values: a list of counts
 int result = 0;
 for each v in values:
  result += ParseInt(v);
 Emit(AsString(result));
```

Algorithm 1 .word count pseudo-code

Studies show that direct monthly energy costs and expenses for data center is about 23% of the total monthly operational costs [9]. If we consider costs like power distribution and cooling structure which affect the monthly energy costs indirectly, it will be about 42% of monthly operational costs. Trends show that performance of the processors increase each 18 month in terms of number of cores, while performance is doubled in each wat in each two years. [10]. so, it would not be surprising if a previous study has estimated that servers in USA include 3% of the total consumed energy in 2011. One reason for the high cost of the energy of the servers is that nodes in clusters environment are used 20 to 30% and the performance of the energy in this range is below 50%. This reveals the fact that 42% of monthly operational cost contribute to power, which decrease in it will increases the energy performance. [11]
Since map reduce framework can be used in computers in a data center and its power can be determinable, investigation and analysis of power is necessary in these environments. [12, 13]

2. Previous works

In this part a brief description of the works which have been done before, is presented. In [12] Map reduce programming model for systems with common memory called Phoenix is implemented. Creation of the nodes, dividing the data, dynamic work timing and fault tolerance between nodes of the processors are done automatically by Phoenix. In this paper, codes written by low level APIs such as P-thread were compared with those written by Map Reduce. Conclusion

was that performance of the Map Reduce programming model on systems with common memory is as good as simpler parallel codes. Despite, run time overloads, Phoenix yield the same performance results for most of the applicable programs. Obviously, there still exist programs which give better results in P-thread than in Map Reduce model.

In [8] a framework called Mars is designed for graphical processors for Map reduce based programs. Also some programs are designed and developed by Google based on the map reduce which focus on web based search programs for ordinary CPU. Are tested and implemented in this framework and for CPUs with higher computation power and higher band widths and then are compared with Phoenix which is a modern and updated Map Reduce framework on multi-core CPUs. Above mentioned framework hides the sophistications of GPU programming with map reduce interface. And finally, they came with 16 time faster execution of 6 common web programs compare to executions on a CPU with four cores.

In [14] is focused on power and energy for clusters which use Map Reduce programming model and propose techniques to decrease the consumed energy. This technique is turning off the nodes and attention goes towards the number of nodes to be chosen to be off and have direct impact on the consumed energy. Majority of the works which have been done in this paper is systematic consideration of different strategies for turning off the nodes in Map Reduce model and their impacts on total consumed energy and workloads response time. Two methods investigated are CS & AIS. In the first method some of the nodes with lower loads become off in low load period and the second method is turning off all the nodes in low use period which is proposed by the authors. These two methods are compared to each other and conclusion is that the second method which is proposed by them, give better results in both saving consumed energy and قresponse time which is shown by analytical models and laboratory results.

It is worth noting that in all the papers mentioned above just the performance aspect is taken into account and consumed energy and power are not considered at all and in [14] just the consumed power of Map Reduce programs in distributed environment is investigated. None of the papers dealt with consumed power of Map Reduce base programs in environments with common memory

3. Laboratory results

In this part first a brief explanation will be given about the framework in which the test is done and then the measurement results in multi-core environment with common memory related to Phoenix Map reduce will be presented.

3.1 The Phoenix System

Phoenix implements Map Reduce for shared-memory systems. Its goal is to support efficient execution on multiple cores without burdening the programmer with concurrency management. Phoenix consists of a simple API that is visible to application programmers and an efficient runtime that handles parallelization, resource management, and fault recovery. [12]

The current Phoenix implementation provides an application-programmer interface (API) for C and C++. The API includes two sets of functions. The first set is provided by Phoenix and is used by the programmer's application code to initialize the system and emit output pairs. The second set includes the functions that the programmer defines .Apart from the Map and Reduce functions; the user provides functions that partition the data before each step and a function that implements key comparison. The API is quite small compared to other models. The API is type agnostic. The function arguments are declared as void pointers wherever possible to provide flexibility in their declaration and fast use without conversion overhead.

The API guarantees that within a partition of the intermediate output, the pairs will be processed in key order. This makes it easier to produce a sorted final output which is often desired. There is no guarantee in the processing order of the original input during the Map stage.

3.2 Basic Operation and Control Flow

Figure 1 shows the basic data flow for the runtime system. The runtime is controlled by the scheduler, which is initiated by user code. The scheduler creates and manages the threads that run all Map and Reduce tasks. It also manages the buffers used for task communication. The programmer provides the scheduler with all the required data and function pointers through the scheduler args t structure.

After initialization, the scheduler determines the number of cores to use for this computation. For each core, it spawns a worker thread that is dynamically assigned some number of Map and Reduce tasks.

To start the Map stage, the scheduler uses the Splitter to divide input pairs into equally sized units to be processed by the Map tasks. The Splitter is called once per Map task and returns a pointer to the data the Map task will process.

The Map tasks are allocated dynamically to workers and each one emits intermediate <key, value> pairs. The Partition function splits the intermediate pairs into units for the Reduce tasks. The function ensures all values of the same key go to the same unit. Within each buffer, values are ordered by key to assist with the final sorting. At this point, the Map stage is over. The scheduler must wait for all Map tasks to complete before initiating the Reduce stage. [12]

Reduce tasks are also assigned to workers dynamically, similar to Map tasks. The one difference is that, while with Map tasks we have complete freedom in distributing pairs across tasks; with Reduce we must process all values for the same key in one task. Hence, the Reduce stage may exhibit higher imbalance across workers and dynamic scheduling is more important. The output of each Reduce task is already

sorted by key. As the last step, the final output from all tasks is merged into a single buffer, sorted by keys. The merging takes place in log2 (P/2) steps, where P is the number of workers used. While one can imagine cases where the output pairs do not have to be ordered, our current implementation always sorts the final output as it is also the case in Google's implementation [8].

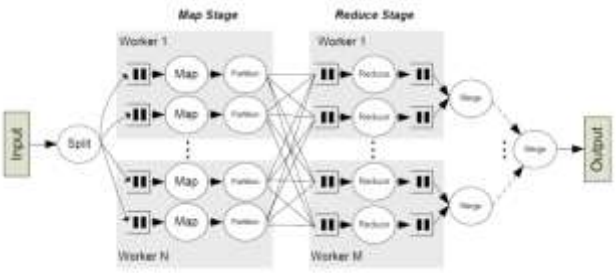


Fig. 1 the basic data flow for the phoenix runtime

For power consumer measurement, we use a power measurement device, applications of study with a brief description of them include:

Word Count: It counts the frequency of occurrence for each word in a set of files. The Map tasks process different sections of the input files and return intermediate data that consist of a word (key) and a value of 1 to indicate that the word was found. The Reduce tasks add up the values for each word (key).
Reverse Index: It traverses a set of HTML files, extracts all links, and compiles an index from links to files. Each Map task parses a collection of HTML files. For each link it finds, it outputs an intermediate pair with the link as the key and the file info as the value. The Reduce task combines all files referencing the same link into a single linked-list.

Matrix Multiply: Each Map task computes the results for a set of rows of the output matrix and returns the (x,y) location of each element as the key and the result of the computation as the value. The Reduce task is just the Identity function.

String Match: It processes two files: the "encrypt" file contains a set of encrypted words and a "keys" file contains a list of non-encrypted words. The goal is to encrypt the words in the "keys" file to determine which words were originally encrypted to generate the "encrypt file". Each Map task parses a portion of the "keys" file and returns a word in the "keys" file as the key and a flag to indicate whether it was a match as the value. The reduce task is just the identity function
.

KMeans: It implements the popular kmeans algorithm that groups a set of input data points into clusters. Since it is iterative, the Phoenix scheduler is called multiple times until it converges. In each iteration, the Map task takes in the existing mean vectors and a subset of the data points. It finds the distance between each point and each mean and assigns the point to the closest cluster. For each point, it emits the cluster id as the key and the data vector as the value. The Reduce task gathers all points with the same cluster-id, and finds their centroid (mean vector). It emits the cluster id as the key and the mean vector as the value.

PCA: It performs a portion of the Principal Component Analysis algorithm in order to find the mean vector and the covariance matrix of a set of data points. The data is presented in a matrix as a collection of column vectors. The algorithm uses two Map Reduce iterations. To find the mean, each Map task in the first iteration computes the mean for a set of rows and emits the row numbers as the keys, and the means as the values. In the second iteration, the Map task is assigned to compute a few elements in the required covariance matrix, and is provided with the data required to calculate the value of those elements. It emits the element row and column numbers as the key, and the covariance as the value. The Reduce task is the identity in both iterations.

Histogram: It analyzes a given bitmap image to compute the frequency of occurrence of a value in the 0-255 range for the RGB components of the pixels. The algorithm assigns different portions of the image to different Map tasks, which parse the image and insert the frequency of component occurrences into arrays. The reduce tasks sum up these numbers across all the portions.

Linear Regression: It computes the line that best fits a given set of coordinates in an input file. The algorithm assigns different portions of the file to different map tasks, which compute certain summary statistics like the sum of squares. The reduce tasks compute these statistics across the entire data set in order to finally determine the best fit line.[12]

3.3 Measurement of consumed power of the programs

In this part each program with different set of the data (small, medium or large) have been executed and the consumed power of the different phases including splitters, map, reduce, partition, sort and hash is measured, if available, and the results are shown in the following graphs.

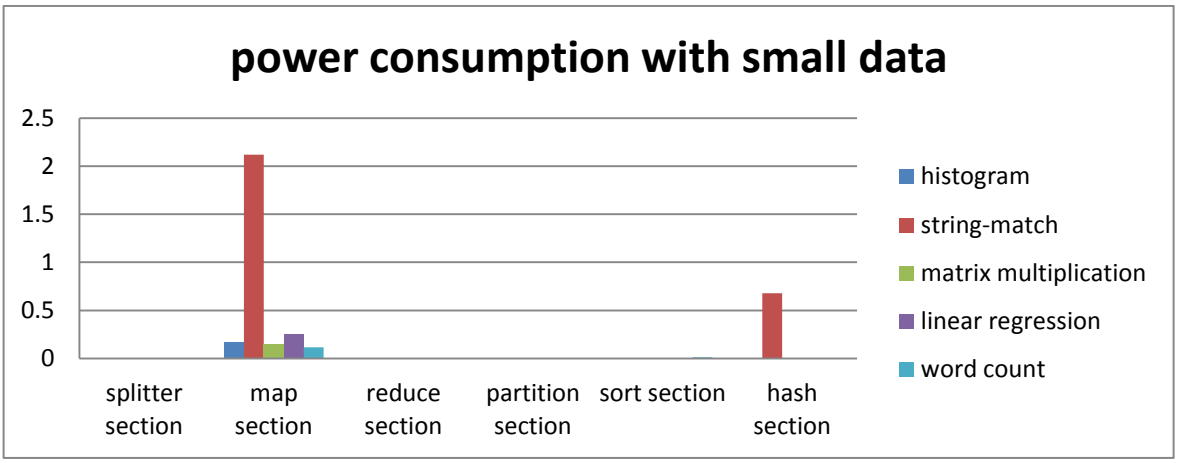

Fig .2 power consumption in small data

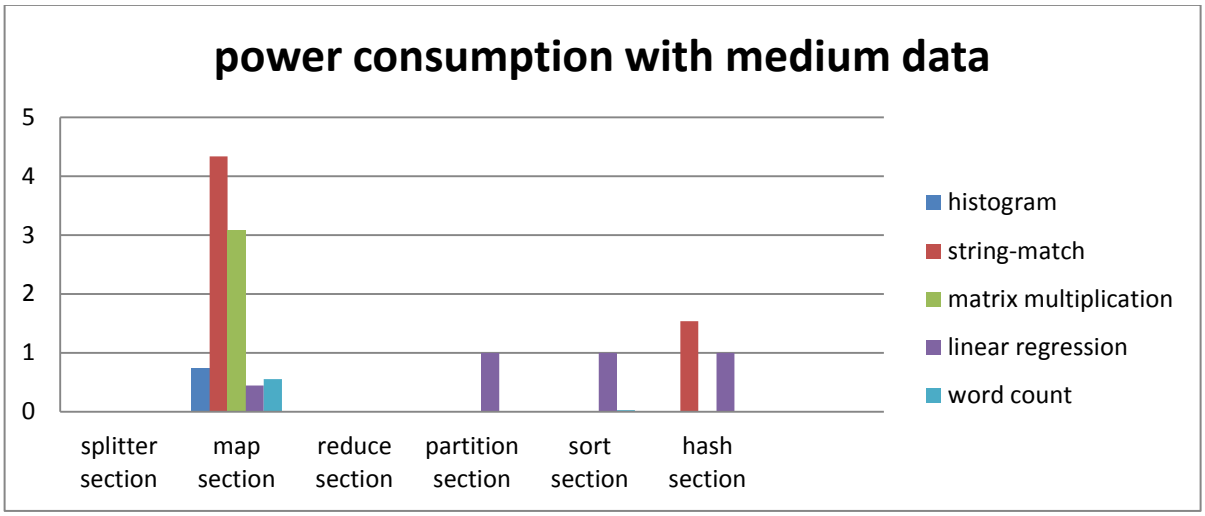

Fig .3 power consumption with medium data

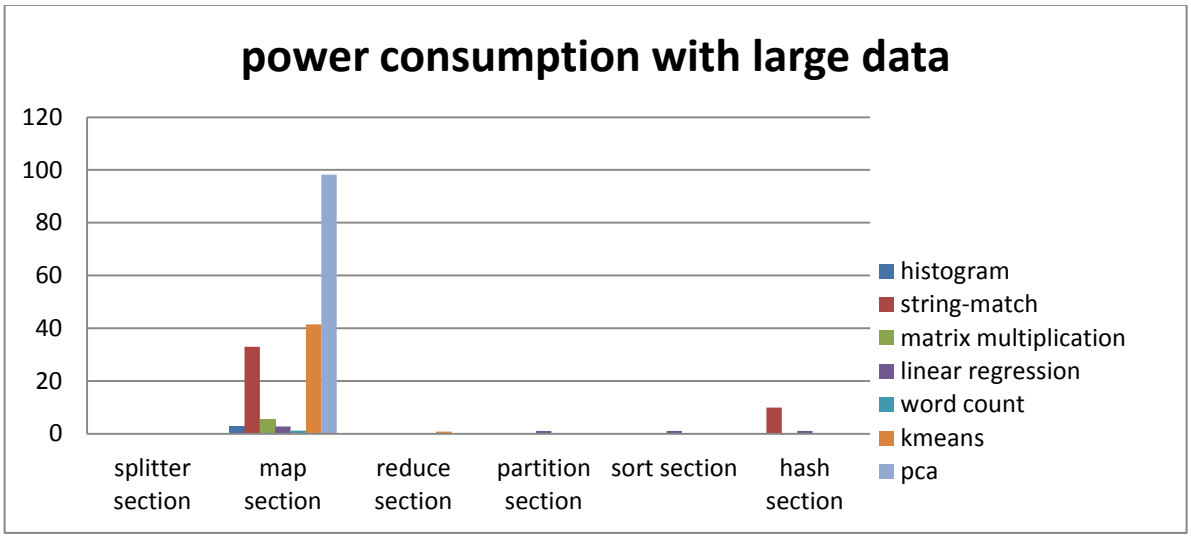

Fig .4 power consumption with large data

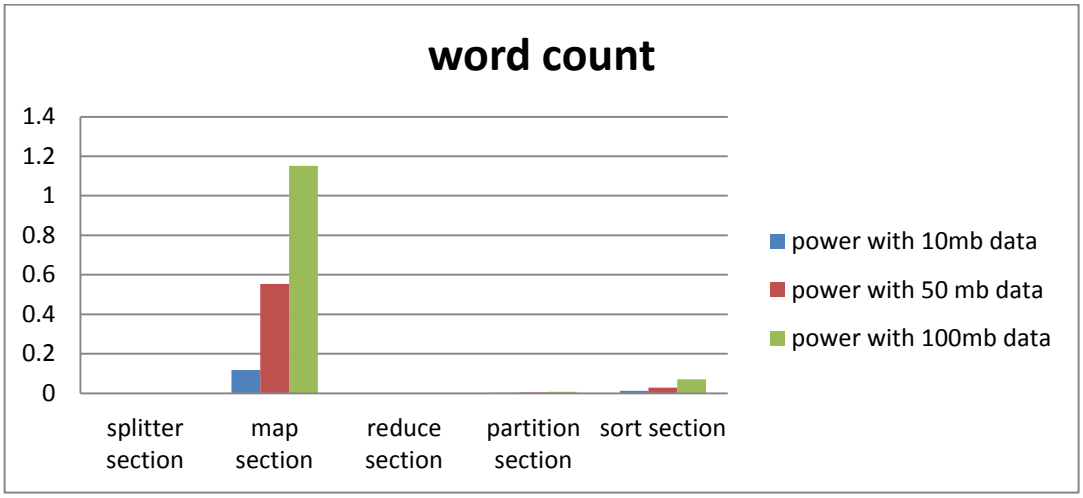

Fig.5 power consumption in word count application

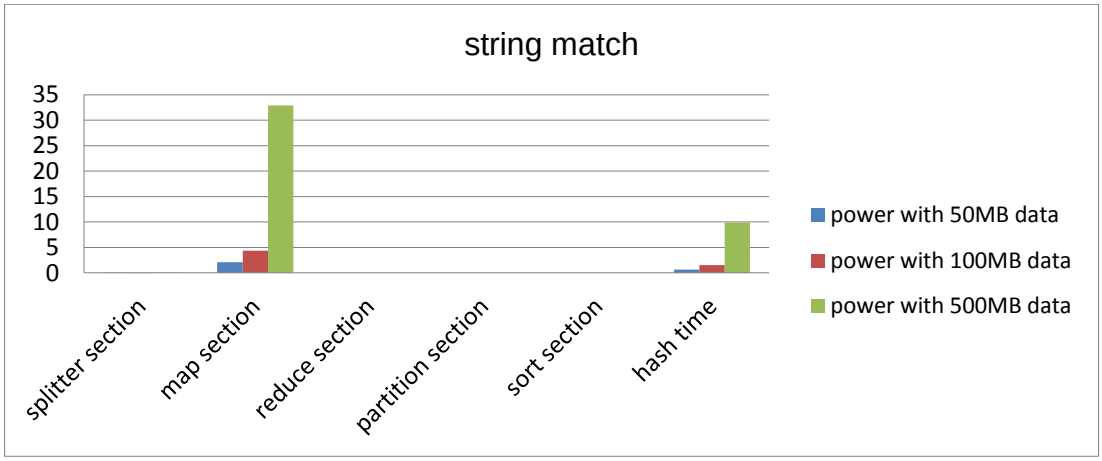

Fig .6 power consumption in string match application

First, data is divided into 3 categories: small, medium and large. And consumed power of each category for all programs under study is measured and recorded. Tables 2 to 4 show these measurements. To see the consumed power better, two more common and more important programs named "word count" and "string match" which cover all parts of the work are shown separately.

It is obvious from the above graphs and tables that most of the activities occurred in the map part and consumed power in map part of different programs is far from other phases of each program. In "word count" program most of the consumed energy is allocated to map. In sort part by changing the size of the data, by doubling the data, consumed energy increases more than two times, unexpectedly. So, it is expected that by increasing size of input data, consumed energy will paramount. In map part by doubling the size of the data, consumed energy also is doubled approximately.

In all programs, by increase in size of the input data, consumed power will be much more evident. In matrix multiplication program, by increasing the size of the data, calculation increased and the consumed power is fixed and by doubling size of the input, consumed power increased by less than 2 times.

In "string match" program, consumed of hash part is considerable and includes about ¼ of the total consumed energy. By increasing size of the input file, the consumed power increase non-linearly.

In programs which contain sort and hash, the rule of consumed power is more evident and by increasing input data, input of these tasks becomes more complicated. consequently, sub-programs of these operations should be

improved and better algorithms should be used in these operations.
In all programs consumed power of reduce part is not considerable. But it should be noted that most of the program either haven't reduce part or a little work is done in this part.

4. Conclusion

Today, consumed energy plays an important role in the world we are living in and we look for the cases which consume less energy. This role is of the same importance in computers and its programs. Moreover, volume of the data which should be processed is increasing such that we face explosion of the data.
Map reduce programming framework is used for processing these huge data. Different implementations of this framework in different environments are proposed.
One of these implementations is in multi-core environments with common memory. Here, measurements are done in this environment.
Based on the measurement following results obtained:
Most of the activities occurred in Map part and consumed power in Map part of different programs is much more than that of other phases of each program. In programs which include sort and hash parts, role of consumed power is more evident and by increasing input data, these tasks become more complicated. So, sub-programs of these operations should be improved and better algorithms should be used for these operations.

5. Future works

Measurement in Mars framework and comparison with Phoenix will be done in the future. And we will try to look for algorithms which improve the sort and hash functions and results of implementation of these algorithms will be investigated.

Evaluation of Encryption Algorithms for Privacy Preserving Association Rules Mining on Distributed Horizontal Database

Ashraf El-Sisi, and Hamdy M. Mousa
Faculty of Computers and Information, Menofyia University, Egypt
{ashrafelsisi@hotmail.com, hamdimmm@hotmail.com }

Abstract - *Encryption algorithms used in privacy preserving protocols can be affected on overall performance. In this paper we study several encryption algorithms with two methods of privacy preserving association rule mining on distributed horizontal database (PPARM4, and PPARM3). The first method PPARM4 computes association rules that hold globally while limiting the information shared about each site in order to increase the efficiency. The second method PPARM3 is a modification for PPARM4 based on a semi-honest model with negligible collision probability. Common encryption algorithms for the two methods of privacy preserving association rule mining on distributed horizontal database selected based on performance metric. So a performance comparison among five of the most common encryption algorithms: RSA, DES, 3DES, AES and Blowfish with the two privacy methods are presented. The comparison has been conducted by running several encryption settings with the two methods of privacy preserving association rule mining on distributed horizontal database. Simulation has been conducted using Java. Results show that, PPARM3 gives better performance with all encryption algorithms implemented. Also PPARM3 with encryption algorithm DES gives best result with different database sizes. Based on the results we can tune the suitable encryption algorithm from our implementations to the required overall performance.*

Keywords: Encryption, distributed data mining, Association rule mining, privacy, security.

1 Introduction

Data Mining (DM) techniques have been widely used in many areas especially for strategic decision-making [1-8]. Apart from its usual benefits, it also has a few disadvantages associated with it. Experts say that data mining in the wrong hands will end up in destruction. The main threat of data mining is to privacy and security of data residing in large data stores [9-15]. Some of the information considered as private and secret can be brought out with advanced data mining tools. It is a real concern of people working in the field of database technology. Different research efforts are under way to address this problem of preserving security and privacy. The privacy term is overloaded, and can, in general, assume a wide range of different meanings. For example, in the context of the Health Insurance Portability and Accountability Act (HIPAA) Privacy Rule, privacy means the individual's ability to control who has the access to personal health care information. From the organizations point of view, privacy involves the definition of policies stating which information is collected, how it is used, and how customers are informed and involved in this process. We can considering privacy as "The right of an entity to be secure from unauthorized disclosure of sensible information that are contained in an electronic repository or that can be derived as aggregate and complex information from data stored in an electronic repository". There are many methods for privacy preserving distributed association rule mining across private databases. So these methods try to compute the answer to the mining without revealing any additional information about user privacy. An application that needs privacy preserving distributed association rule mining across private databases, like medical research. Sensitive information contained in a database can be extracted with the help of non-sensitive information. This is called the inference problem. Different concepts have been proposed to handle the inference problem. The process of modifying the transactional database to hide some sensitive information is called sanitization. By sanitizing the original transactional database, the sensitive information can be hidden. In the sanitization process, selective transactions are retrieved and modified before handing over the database to a third party. Modification of transaction involves removing an item from a transaction or adding an element to the transaction. In some cases, transactions will be either added to or removed from the database as suggested in [16]. The modified database is called sanitized database or released database. The efficiency of a privacy-preserving algorithm is measured based on: (1) the time taken to hide the data, (2) the number of new rules introduced because of the hiding process, and (3) the number of legitimate rules lost or unable to be extracted from the released database. Encryption algorithm used in privacy preserving can be affected on overall performance, so in this paper we addresses the problem of evaluate several encryption algorithms with two protocols of privacy preserving association rule mining (PPARM4, and PPARM3) on distributed horizontal database. The numbers (4 and 3) in

abbreviations (PPARM4, and PPARM3) respectively means the number of computation steps to get the results of protocol. The first protocol (PPARM4) computes association rules that hold globally while limiting the information shared about each site in order to increase the efficiency [17]. The second protocol (PPARM3) is a modification for the first based on a semi-honest model with negligible collision probability [18]. Section 2 gives an overview about the problem and the related work in the area of privacy preserving association rule mining on distributed homogenous databases. In section 3 some details of the two protocols of the algorithms of computing the distributed association rule mining (PPARM4, and PPARM3) to preserve the privacy of users. Sections 4 and 5 describe implementation and results of several encryption algorithms with the two methods of privacy preserving association rule mining on distributed horizontal database. Finally, some conclusions are put forward in Section 6.

2 Association Rule Mining

Association rule mining finds interesting associations and/or correlation relationships among large sets of data items. Association rules show attributes value conditions that occur frequently together in a given dataset. In [19] the association rules mining problem can formally be defined as follows: Let I = {i1, i2, . . . , in} be a set of items. Let DB be a set of transactions, where each transaction T is an itemset such that . Given an itemset , a transaction T contains A if and only if . An association rule is an implication of the form where and . The rule has support S in the transaction database DB if S% of transactions in DB contains. The association rule holds in the transaction database DB with confidence C if C% of transactions in DB that contain A also contains B. An itemset X with k items is called a k-itemset.

2.1 Distributed Association Rule Mining Problem

The problem of mining association rules is to find all rules whose support and confidence are higher than certain user specified minimum support and confidence. Clearly, computing association rules without disclosing individual transactions is straightforward. We can compute the global support and confidence of an association rule knowing only the local supports of AB and ABC, and the size of each database:

$$Support_{AB \Rightarrow C} = \frac{\sum_{i=1}^{numberofsites} Support\_count_{ABC}(i)}{\sum_{i=1}^{numberofsites} database\_Size(i)}$$

$$Support_{AB} = \frac{\sum_{i=1}^{numberofsites} Support\_count_{AB}(i)}{\sum_{i=1}^{numberofsites} database\_Size(i)}$$

$$Confidence_{AB \Rightarrow C} = \frac{Support_{AB \Rightarrow C}}{Support_{AB}}$$

Note that this requires no sharing of any individual transactions. And Protects individual data privacy, but it does require that each site disclose what rules it supports, and how much it supports each potential global rule. What if this information is sensitive? Clearly, such an approach will be secure under secure muti-party computation (SMC) definitions by some modification, a way to convert the above simple distributed method to a secure method in SMC model is to use secure summation and comparison methods to check whether threshold are satisfied for every potential itemset [18]. For example, for every possible candidate 1-itemset, we can use the secure summation and comparison protocol to check whether the threshold is satisfied. Fig. (1) gives an example of testing if itemset ABC is globally supported, it shows determining if itemset support exceeds 5 percent threshold. Each site first computes its local support for ABC, or specifically the number of itemsets by which its support exceeds the minimum support threshold (which may be negative).

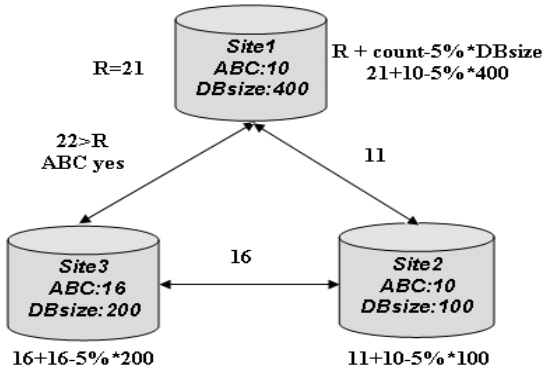

Fig. 1. Computing global support securely

The parties then use the secure summation algorithm (the first site adds a random (R) to its local excess support, then passes it to the next site to add its excess support, etc. and finally when pass to first site subtract the generated random from the result). The only change is the final step, the last site performs a secure comparison with the first site to see if the sum ≥ R. In the example, R -10 is passed to the second site, which adds its excess support (5) and passes it to site 3. Site 3 adds its excess support; the resulting value (22) is tested using secure comparison to see if it exceeds the Random

value (21). It is, so itemsets ABC is supported globally. Due to huge number of potential candidate itemsets, we need to have a more efficient method. This can be done by observing this lemma, (If a rule has support > k% globally, it must have support > k% on at least one of the individual sites). A distributed algorithm for this would work as follows, request that all rules are sent by each site with support at least k, for each rule returned, request that all sites send the count for their transactions that support the rule, and the total count of all transactions at the site. From this, we can compute the global support of each rule, and be certain that all rules with support at least k have been found. This has been shown to be an effective pruning technique. In order to use the above lemma, we need to compute the union of locally large sets. Then use the secure summation and comparison only on the candidate itemsets contained in the union. Revealing candidate itemsets means that the algorithm is no longer fully secure: itemsets that are large at one site, but not globally large, would not be disclosed by a fully secure algorithm. However, by computing the union securely, we prevent disclosure of which site, or even how many sites, support a particular itemset. This release of innocuous information (included in the final result) enables a completely secure algorithm that approaches the efficiency of insecure distributed association rule mining algorithms. The function now being computed reveals more information than the original association rule mining function. However, the key is that we have provable limits on what is disclosed.

3. (PPARM4, and PPARM3) Protocols Details

In secure multi-party computation approaches, given two parties with inputs x and y respectively, the goal of secure multi-party computation is to compute a function f(x, y) such that the two parties learn only f(x, y), and nothing else. In [19] there are various approaches to this problem. In [20] an efficient protocol for Yao's millionaires' problem showed that any multi-party computation can be solved by building a combinatorial circuit, and simulating that circuit. A variant of Yao's protocol is presented in [21] where the oblivious transfers is used to make secure decision tree learning using ID3 with efficient cryptographic protocol and their also two solution of our problem under the secure multi party computation for association rule mining [22], [23]. In [23] an explanation of a much more efficient method for this problem is described. To obtain an efficient solution without revealing what each site supports, they instead exchange locally large itemsets in a way that obscures the source of each itemset. They assume a secure commutative encryption algorithm with negligible collision probability. Intuitively, under commutative encryption, the order of encryption does not matter. If a plaintext message is encrypted by two different keys in a different order, it will be mapped to the same cipher text. Formally, commutatively ensures that Ek1(Ek2(x)) = Ek2(Ek1(x)). The main idea is that each site encrypts the locally supported itemsets, along with enough "fake" itemsets to hide the actual number supported. Each site then encrypts the itemsets from other sites. An example illustrate the protocol in [19] is given in fig. (2). Using commutative encryption, each party encrypts its own frequent itemsets (e.g., Site 1 encrypts itemset ABC). The encrypted itemsets are then passed to other parties, until all parties have encrypted all itemsets. These are passed to a common party to eliminate duplicates, and to begin decryption. (In fig. (2), the full set of itemsets is shown to the left of Site 1, after Site 1 decrypts). Then this set is passed to each party, and each party decrypts each itemset. The final result is the common itemsets (ABC and ABD in fig. (2)), an approach to proof that protocol preserves privacy can be found in [20]. This approach to prove that algorithm reveals only the union of locally large itemsets and a clearly bounded set of innocuous information.

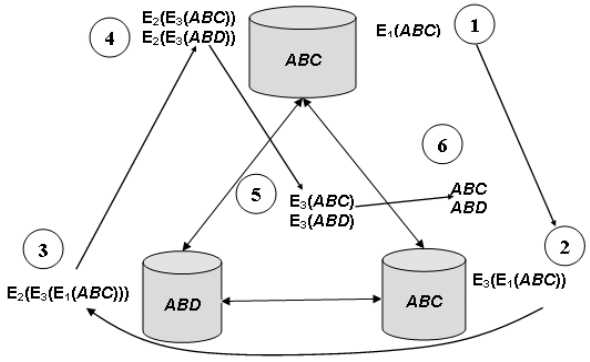

Fig. 2. Steps needed for computing the algorithm in [25]

3.1 PPARM4 protocol

Other method for privacy preserving association rule mining on distributed homogenous databases (PPARM4) in [17], showed that the protocol in [23] employs commutative encryption algorithm so it adds large overhead to the mining process then another protocol improves this by applying a public-key cryptosystem algorithm on horizontally partitioned data among three or more parties. In this protocol, the parties can share the union of their data without the need for an outside trusted party. Each party works locally finding all local frequent itemsets of all sizes. Then use public key cryptography to find the union of a frequent local itemset. We find that this method reduce the number of steps from 6 to 4 to calculate the global candidate item sets as shown in fig. (3) where K1 is private key and k2 public key . In [17] the results showed that this improvement reduces the time of mining process compared to method in [23]. For description this protocol, let P = {P0, . . . , Pn} be a set of N parties where |N| ≥ 3. Each party Pi has a database DBi. With assuming that parties running the protocol are semi-honest. The goal is to share the union of DBi as one shuffled database and hide the link between records in DBComp and their owners. This

employs a public-key cryptosystem algorithm on horizontally partitioned data among three or more parties. In this protocol, the parties can share the union of their data without the need for an outside trusted party. The information that is hidden is what data records where in the possession of which party. Protocol is described for one party as the protocol driver as shown in table [1]. The first party called Alice.

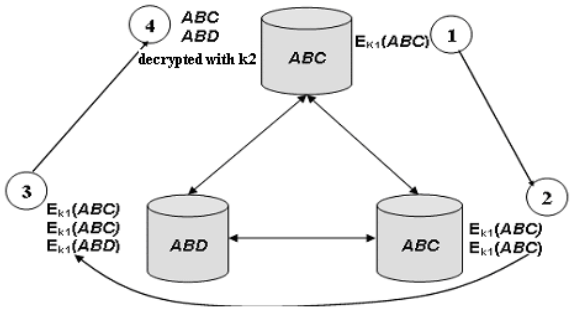

Fig. 3. Steps needed for computing PPARM4 algorithm

Table [1] Description of PPARM4 protocol

1. *Alice generates a public encryption key kPA.*
Alice makes kPA known to all parties (for illustration another two parties called Bob and Carol can be used).
2. *Each party (including Alice) encrypts its database DBi with Alice's public key.*
This means the encryption is applied to each row (record or transaction) of the database. Parties will need to know the common length of rows in the database. We denote the result of this encryption as kPA(DBi). Note that, by the properties of public cryptosystems, only Alice can decrypt these databases.
3. *Alice passes her encrypted transactions kPA(DB1) to Bob*. Bob cannot learn Alice's transactions since he does not know the decryption key.
4. *Bob mixes his transactions with Alice's transactions.*
That is, he produces a random shuffle of kPA(DB1) and kPA(DB2) before passing all these shuffled transactions to Carol.
5. *Carol adds and shuffles her transactions kPA(DB3) to the transactions received from Bob.*
6. *The protocol continues in this way, each subsequent party receiving a database with the encrypted and shuffled transaction of all previous parties in the enumeration of the parties. The i-th party mixes randomly his encrypted transactions kPA(DBi) with the rest and passes the entries shuffled transaction to the (i + 1)-th party.*
7. *The last party passes the transactions back to Alice.*
8. *Alice decrypts the complete set of transaction with her secret decrypt key.*
She can identify her own transactions. However, Alice is unable to link transactions with their owners because transactions are shuffled.
9. *Alice publishes the transactions to all parties.*
If the number of parties is N, then N − 1 of the parties need to collude to associate data to their original owners (data suppliers).

3.2 PPARM3 protocol

In [18] fast privacy preserving association rule mining on distributed homogenous databases (PPARM3), reduces the number of steps from four steps to only three steps for any numbers of clients to calculate the global candidate itemsets. The details of PPARM3 protocol as in fig. (4) and table [2].Table [3] shows a comparison of the three algorithms in [17, 18, and 23].

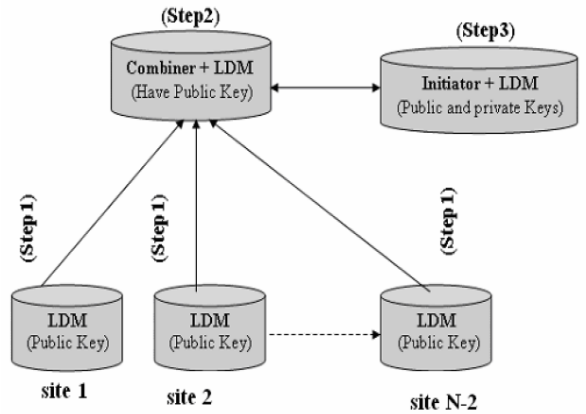

Fig. 4. General structure of PPARM3 algorithm

Table [2] Description of PPARM3 protocol

Protocol: Finding large itemsets of size k and global association rules.
Require: N >3 sites one site is algorithm initiator and another is data mining combiner and other called clients (local data mining) sites numbered (1..N − 2) and we assume negligible collision probability.
Step 1: *All local data mining (LDM) compute the mining results using fast distributed mining of association rules (FDM) [23] as locally large k-item sets (LLi(k)) and local support for each item set in LLi(k) then Encrypt frequent item sets and support (LLei(k)) then send it to the data mining combiner.*

Step 2: *The combiner merge all received frequent items and supports with the data mining combiner frequent items and support in encrypted form then send LLe(k) to algorithm initiator to compute the global association rules .*
Step3: *The algorithm initiator receives the frequent items with support encrypted. The initiator first decrypt it, then merges it with his local data mining result to obtain global mining results L(k), then compute global association rules and distribute it to all protocol parties.*

Table 3. Comparison between algorithms in [17, 18, and 23].

Comparison factors	Algorithm [23]	Algorithm [17]	Algorithm [18]
Steps for computation	6 steps	4 steps	3 steps
Rounds to compute results	2 rounds	2 rounds	1 round
Cryptography used	Communica tive	Public key	Public key
Mining algorithm	Apriori	Apriori	Apriori-Tid

3.3 Encryption Algorithms

Many encryption algorithms are widely available and used in information security. They can be categorized into Symmetric (private) and Asymmetric (public) keys encryption. In Symmetric keys encryption or secret key encryption, only one key is used to encrypt and decrypt data. The key should be distributed before transmission between entities. Keys play an important role. If weak key is used in algorithm then every one may decrypt the data. Strength of Symmetric key encryption depends on the size of key used. For the same algorithm, encryption using longer key is harder to break than the one done using smaller key [24]. There are many examples of strong and weak keys of cryptography algorithms like RC2, DES, 3DES, RC6, Blowfish, and AES. RC2 uses one 64-bit key. DES uses one 64-bits key. Triple DES (3DES) uses three 64- bits keys while AES uses various (128,192,256) bits keys. Blowfish uses various (32-448); default 128bits while RC6 is used various (128,192,256) bits keys [25-28]. Asymmetric key encryption or public key encryption is used to solve the problem of key distribution. In Asymmetric keys, two keys are used; private and public keys. Public key is used for encryption and private key is used for decryption (E.g. RSA and Digital Signatures). Because users tend to use two keys: public key, which is known to the public and private key which is known only to the user. There is no need for distributing them prior to transmission. Asymmetric encryption techniques are slower than Symmetric techniques, because they require more computational processing power.

4. Implementation of (PPARM4 and PPARM3) Methods

We implement PPARM4 and PPARM3 algorithms using java. Because the distributed association rules mining need the mining run in more than one site, we can use the RMI (remote method invocation) to connect the sites with each other. Our application is two parts one name server and other is client so we have two site works as server. First is the protocol initiator and second is the data mining combiner and we need client for every participant in the protocol. The initiator is responsible of the threshold of the mining algorithm so it need to define the support and confidence and also generate the public key (k2)and private key (k1) used in encryption and decryption in protocol and finally compute the final results. The data mining combiner responsible of combining the results of clients sites and mix the results to make better privacy of user data and every client is responsible of making the local data mining and encrypt the results of mining and send to data mining combiner. In our implementation our test in data that represent based on 0/1 matrix. And using Public-Key Cryptography, where each user places in a public file an encryption procedure. That is, the public file is a directory giving the encryption procedure of each user. The user keeps secret the details of his corresponding decryption procedure. There are several examples of commutative encryption; perhaps the most famous being RSA (if keys are not shared) and Pohlig-Hellman encryption. Firstly we use RSA that is useful to fulfill our requirements. After that we repeat the same work with different encryption algorithms (DES, 3DES, AES and Blowfish] to evaluate the best encryption algorithm improving the overall performance privacy preserving protocol.

5. Results of implementations and discussion

By running PPARM4 and PPARM3 algorithms 75 times. Running testing based on 5 homogenous data bases with different size from 2500 bytes to 2500000 bytes by 15 time for every data base. The 15 values are much closed to each other. The values listed in table [4] and tables [5] are the average values of time for PPARM4 and PPARM3 respectively in case RSA, DES, 3DES, AES and Blowfish encryption algorithms. Testing is performed using P4 (2.8 GHZ) with Java (SDK 1.6). Fig. (5) and fig. (6) shown the relation between different database sizes and time consuming of protocols (PPARM4 and PPARM3) for each encryption algorithm (RSA, DES, 3DES, ASE, and Blowfish) respectively. The results show PPARM3 is faster than PPARM4 in case all encryption algorithms implemented by the same ratio. Fig. (7) and fig. (8) show a comparison between time of protocol (PPARM4 and PPARM3) respectively and different encryption algorithms (RSA, DES, 3DES, AES and Blowfish) with variable database size. From these results we can say that the best performance of time for privacy protocols PPARM4 and PPARM3 is in case using encryption algorithm DES. So we can tune the required performance of privacy protocol by control in changing the encryption algorithm.

Table [4] Computation time in ms for PPARM4 with different encryption algorithms

Database size (B)	RSA	DES	3DES	AES	Blowfish

6. Conclusions

In this paper we presented study several encryption algorithms (RSA, DES, 3DES, AES and Blowfish) with different protocols of privacy preserving association rule mining on distributed horizontal database (PPARM4, and PPARM3). Testing is performed using P4 (2.8 GHZ) with Java (SDK 1.6). The results show PPARM3 is faster than PPARM4 in case all encryption algorithms implemented by the same ratio. The results prove that, the best performance of time for privacy protocols PPARM4 and PPARM3 is in case using encryption algorithm DES. So we can tune the required performance of privacy protocol by control in changing the encryption algorithm. In future work we can consider finer tuning by implement many different setting for encryption algorithm using with privacy protocol. For example longer key is harder to break than the one done using smaller key.3DES uses three 64-bits keys while AES uses various (128,192,256) bits keys. Blowfish uses various (32-448); default 128bits.

Abstract - *Dependence on computer networks is now a reality. The networks are continuously becoming larger, heterogeneous and more complex in size and functionality. Any computer network service relies on several component interactions. This might involve mutually communicating hardware and software. The main task is to guarantee network service in the presence of network faults. In this work we present a design of a model to identify, predict, evaluate and neutralize faults on a computer network. The approach incorporates the capability of Dynamic Bayesian Networks to diagnose, predict and forecast faults and evaluate the magnitude of the network service degradation. The model is complex enough to diagnose and yet simple enough to avoid time and space complexity on the network. Fault thresholds to satisfy probability of error occurrence are established. We present model simulated results to demonstrate the applicability of proposed model.*

Keywords: Network reliability, fault, Dynamic Bayesian Network

1 Introduction

Dependence on computer networks has become a necessity to many organizations both profit making and nonprofit making including individuals. There is a whole explosion of services based on the network platform. The computer networks are themselves becoming larger, complex, ubiquitous, flexible and dynamic. Devices may be added, undergo repairs, be upgraded, and be removed from the network at any given time.

In order to access the correct service, a user needs several components to interact at least according to their requirement specification to perform one or more specified operational function. This might involve mutually communicating applications software, system software, protocols and communicating hardware and transmission media. The final output from the network is the sum total of the interaction of all the necessary components and subcomponents and protocols. Each component, each interface, each protocol plays an important role in the overall outcome. How can we guarantee high degree of network service survivability in the presence of network faults, malfunctions, malware attacks and software design flaws? The user is not interested in whether there has been a removal or repair of a device or debugging or upgrade of a protocol but is concerned with the availability of a an expected service at a given point in time as dictated by requirements and needs. Therefore organizations need some solid form of trust from the network. The confidence is brought by the application of sound reliability models.

In this work we present a design of a model to identify, predict, evaluate and neutralize faults on a computer network. In section 2 we present a brief overview of computer network faults classes. The Dynamic Bayesian Network approach to diagnose, predict and forecast faults and evaluate the magnitude of the network service degradation is also presented in section 2. We present model simulation results in section 3 and draw our conclusions in the subsequent section which is section 4.

2 Methodology

The body of work includes in depth analysis of the literature and work that has been done in the field of fault management. The relevant literature review guides the designing of computer network hybrid reliability model. Both secondary and primary sources of information are used to enhance the researchers' knowledge in the field of study and enable them to design a model based on the effort done by other researchers to the same end. Probabilistic techniques, Dynamic Bayesian Networks, and simulation methods are used as the foundation and the building blocks of this work. Network faults are identified using the Network Management error codes, and the Simple Network Management Protocol trap messages.

The simulation is designed and implemented using C++. The data used is collected from management agents via Simple Management Protocol messages (SNMP traps) and network system log-files. For simulation purposes the random occurrence of faults, the minimal standard random number generator as recommended in [1] is used. The probability outcomes are then compared with the statistics from the collected data as experimental control.

2.1 Overview of computer network faults

A network fault is defined as an abnormal condition or defect at the network component, equipment, or sub-system level which may lead to an error which may in turn lead to a failure [2]. Network faults constitute a class of network events that can cause other events but are not themselves caused by other events as explained in [2].

Therefore a network failure is a result of a network system state error and the generator of an error is a fault. An error can propagate through a network and cause hardware and software failure to otherwise faultless hardware and software subsystems. A failure is the manifestation of the error that is observable by the client. The client might be a human being or another network component or system [2].

Systems have faults but as long as that fault is not activated and it has not triggered an error, we cannot talk of a failure. Failure of a computer network is with respect to the abnormality in service provision visible to a client.

Computer network faults can be classified as permanent, transient and intermittent [2]. This is the taxonomy of faults based on their temporary effects. Taking an assumption that the active period of a fault is the interval during which the fault has a negative influence on the network, and benign period is the interval where the fault is not influential. Therefore a formalized classification definition is as follows: The permanent fault has an infinite active period. It reflects irreversible physical changes to a system or subsystem. Transient faults have a finite active time interval followed by an infinite benign period. These are generated by temporary network conditions like loss of signal in wireless network or an active attack by a hacker. Intermittent faults have finite active period and finite benign period, in other words these are recurring. Intermittent faults are internal in nature like network congestion.

Classification of faults based on the behavior are presented in [3], these can be summarized as crash faults (component either completely stops operating or never returns to a valid state); omission faults (component completely fails to perform its service); timing faults (component does not complete its service on time or suffers from synchronization) and Byzantine faults (faults of an arbitrary nature).

Although errors induced by transient and intermittent faults manifest very similarly, two main criteria as observed in [4] may be used to determine the type of the fault that generated the error. Firstly, failures generated by errors induced by intermittent faults tend to occur as a cluster at the same location, when the fault is activated. Secondly, replacement of the culprit component or subsystem removes the intermittent fault; by contrast failures generated by errors induced by transient faults cannot be eliminated by repair. The cause of a transient fault cannot be traced to a defect in a well identifiable part of the network. For simulation purposes we use some Simple Network Management Protocol Management Information Base (NMP MIB) data and network system logs to establish an estimate of transient fault rate and intermittent fault occurrence patterns. However this is highly contextual as each situation is dependent on a myriad of network characteristics from hardware brands and type to software and parameter configuration. A permanent fault induces a permanent error which in turn induces a permanent failure irrespective of the context. On the other hand a transient fault induces a transient error which subsequently induces a transient failure. Lastly an intermittent fault likewise induces an intermittent error which also triggers an intermittent failure.

According to Mouhammd [5], faults can be split into two categories, soft and hard faults. Wear or damage constitutes hard faults. These may be either hardware or software. The soft fault stem from poor engineering principles such as incomplete design. We focus on the soft faults in this study though there is overlapping.

Table 1: Fault classes

Faults Classes		
Permanent	Transient	Intermittent
Hardware clash Power outages Software clash	Malware Software bugs Hackers Buffer overflows	Packet loss Congestion End-to-end delay

The objective of understanding computer network faults is to be able to identify them according to their classes and as such it facilitates the modeling process.

Network reliability is the probability that a network will perform satisfactorily for at least a given period of time when used under stated conditions. It is an important attribute of a computer network as a system. Network reliability mostly deals with long term, or average behavior of the network. It is a property of the network and evaluates characteristics such as failure rate and failure density, architectural properties. The identification of faults is an important step towards reliability modeling of a system. In figure 1 below we show the relationship between failures, errors, and faults. A fault may develop into an error which may develop into a failure. However not all errors can develop into a failure. Some errors may only develop into failures only under certain conditions. The Millennium Bug, in Year 2000 is an example of a failure that was triggered by time.

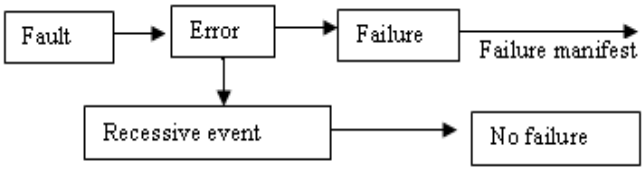

Figure 1: Fault, error failure relationship

A computer network is a repairable system. This means that if a component fails we can either replace the subcomponents that failed; this is referred to as repair maintenance, or replace the whole component by a new one

and this is referred to as preventive maintenance. All this is done to recover from a failure that would have been caused by a fault. In order to design a reliable system we need to specify the faults that the system may be subjected to. Therefore fault assumption is important in the whole system reliability modeling process. We have identified and classified the faults. Now we present methods for dealing with them.

2.2 Bayesian belief network

Bayesian networks provide a complete description of a given problem domain based on causal relationships. The cause-effect relationships enable both forward and backward reasoning. Every entry in the full joint probability distribution can be calculated from the information in the network. Bayesian networks represent full probability models in a compact and intuitive way. These networks can address problems in diagnosis, prediction, forecasting, information retrieval, knowledge representation and many other domains [6].

As well as being a complete and nonredundant representation of the domain, Bayesian networks are more compact than the full joint distribution and their time and space complexity is lower than that of other models like the Markov Chain Models. This property is what makes it feasible to handle domains with many variables. Bayesian networks are sparse systems [6]. This means that it satisfies the property of being locally structured. The premise for locally structured systems is that, each subcomponent interacts directly with only a bounded number of other components; regardless of the total number of components this will imply less complexity exponential explosion.

In the Bayesian Network framework the independence structure in a joint distribution characterized by a directed acyclic graph, with nodes representing random variables (which can be discrete or continuous, and may or may not be observable), and directed arcs representing causal or influential relationship between variables. The conditional independence assertions about the variables, represented by the lack of arcs, reduce significantly the complexity of inference and allow the underlying joint probability distribution to be decomposed as a product of local conditional probability distributions (CPD) associated with each node and its respective parents. The semantics of Bayesian networks can be viewed in two ways that is as networks that represent joint probability distribution or as an encoding of a collection of conditional independence statements. The two views serve to guide the construction of the network and the designing of inference procedures. [6].

2.2.1 The rationale behind employing Bayesian network for this study

As aforesaid Bayesian Networks, are space efficient data structures for encoding all of the information in the full joint probability distribution for the set of random variables that characterize a problem space. It uses the fact that in real-world problem domains, the dependencies between the variables are generally local. The Bayesian network allows one to compute any value in the full joint probability distribution of the set of random variables. It represents all of the direct causal relationships between variables which are an advantage in the determination of failure causes. It can be used to reason forward (top-down) from causes to effects (predictive reasoning) or backward bottom-up) from effects to causes (diagnostic reasoning). In other words we can infer faults sources from errors and vice versa.

2.2.2 Constructing Bayesian network for a network fault

Let X represents faults of arbitrary nature. Let the Bayesian Network for the set of fault variables $X=\{x_1, x_2, \ldots x_n\}$ represent a joint probability distribution: $P(x_1, x_2, \ldots x_n)$. Then we writing the joint probability as a conditional probability using the chain rule we have:

$$P(x_1, x_2, \ldots x_n) = P(x_n|x_{n-1}\ldots x_1)P(x_{n-1}\ldots x_1) \quad (1)$$

Then reducing equation 1 to each conjunctive probability to a conditional probability we have:

$$P(x_1, x_2, \ldots x_n) = \prod_{i=1}^{n} P(x_i | x_{i-1,\ldots.} x_1) \quad (2)$$

The expression is referred to as the chain rule. Therefore for every fault variable X_i in the network provided that Fault-Evidence $(X_i) \subseteq \{X_{i-1}\ldots X_1\}$, we can express its probability as:

$$P(X_i|X_{i-1}\ldots X_1)=P(X_i|\text{Fault-Evidence}(X_i)) \quad (3)$$

Let X_t, denotes a set of unobserved fault state in time t, and e_t denotes the observed error. The observed error implies fault evidence. Therefore to predict the future fault state of X we have to extend equation 3 to obtain the following expression:

$$P(X_{t+k}|e_{1:t}) \text{ for some } k > 0. \quad (4)$$

For example, the expression might mean computing the probability of network buffer overflow fault five time units from now given all the observations of network buffer overflow errors or failures up to now.

It is not only forward reasoning that is of interest but also retrospective reasoning. The diagnostic reasoning in helps establish fault sources. This fault hindsight entails computing the posterior distribution over a past fault state, given all errors or failures to the present point in time. That is, from equation 4, we wish to compute $P(X_k|e_{1:t})$ for some k time units such that $0 \leq k < t$. For instance if we want to compute the probability that there was network congestion five units of time ago given the network congestion based errors or failures up to now. In this case k=5 units of time.

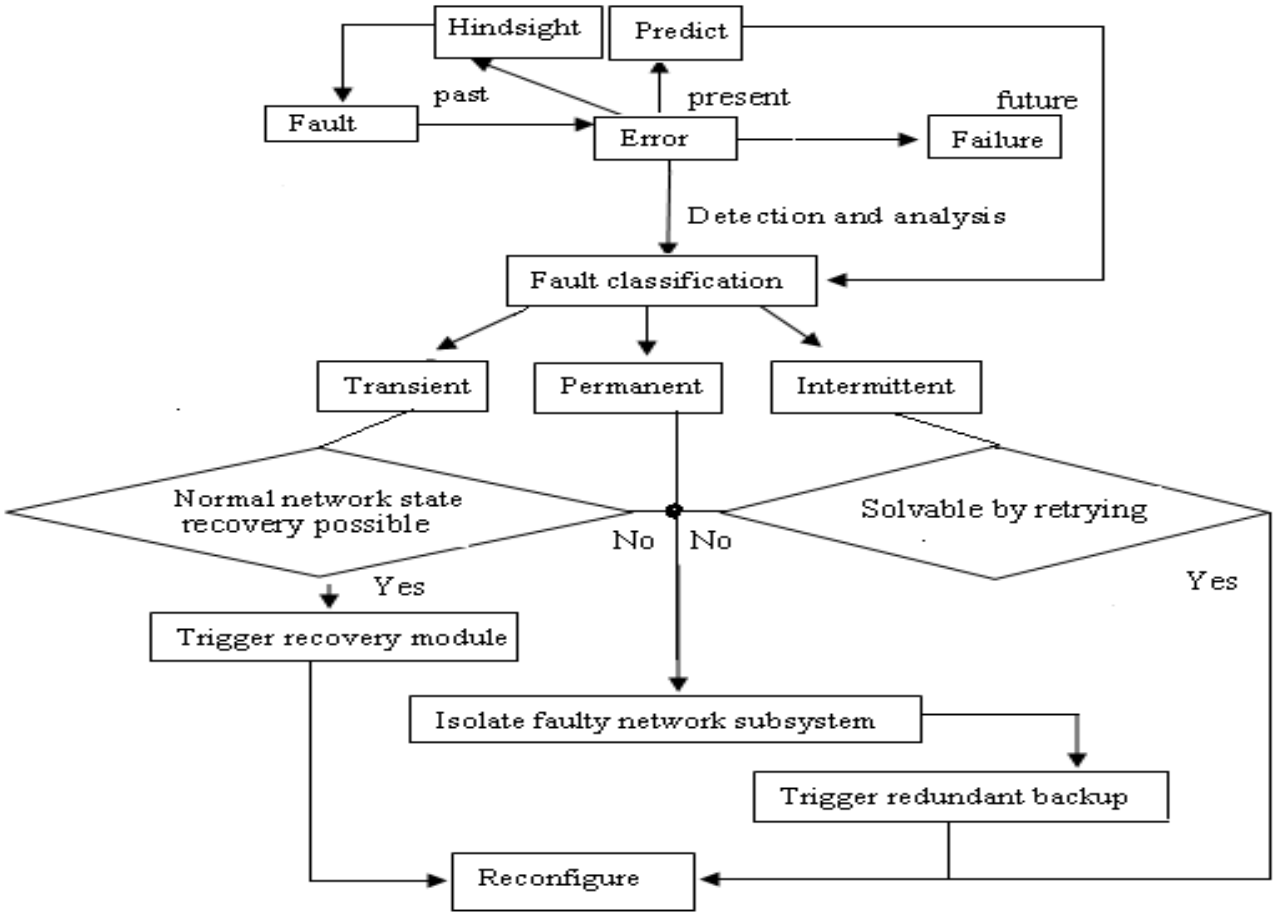

Figure 2: Proposed Reliability architecture

3 Results and discussion

Using the information obtained from a single organizations' network over a period of six months from SNMP, and network log files we obtained the fault rates shown in table 2. If there is a fault the probability that it might be associated with a protocol either poorly configured or corrupted is 0.48.

Table 2: Basic component fault rates from data collected

Basic network component	Fault rate
Switch	0.100
Bridge	0.130
Server	0.260
Network adapter	0.004
Router	0.210
Protocol	0.480
Transmission media	0.340

Let IF_{t-1} represent intermittent fault probability state variable in time t-1, and we also assume that: $P(IF_t|IF_{t-1}=true)=0.013$, $P(IF_t|IF_{t-1}=false)= 0.987$ and $P(IE_t|TF_t=true)=0.46$, $P(IE_t|IF_t=false)= 0.29$. IE_t represents the intermittent error in the network. We predict for the next nine time units (correct to 9 decimal places) and the results are shown in table 3 and figure 3. The results demonstrate the temporary nature of this type of fault. In some cases only a single run will result in the belief that a fault does not exist as proved by our simulation model. However due to its recurrence nature also we found that it can approach absolute values in some probabilistic instances.

Table 3: Intermittent fault probability over time

Time units into the future	Intermittent fault probability changes with time
1	0.110400000
2	0.006791759
3	0.001101247
4	0.000785880
5	0.000768500
6	0.000767543
7	0.000767490
8	0.000767487
9	0.000767487

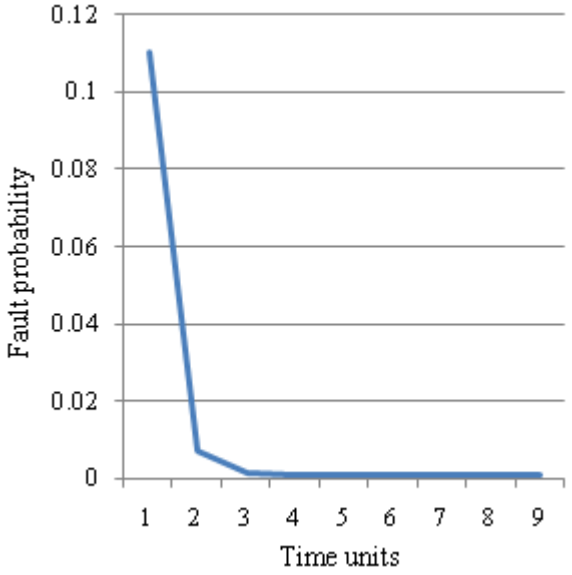

Figure 3: Intermittent fault probability trajectory over time

Given the initial belief that the probability of a transient fault is 0.5, TF_{t-1} represent transient fault probability state variable in a time t-1, and we also assume that $P(TF_t|TF_{t-1} = true) = 0.85$, $P(TF_t|TF_{t-1} = false) = 0.15$ and $P(TE_t|TF_t = true) = 0.49$, $P(TE_t|TF_t = false) = 0.027$. TE_t represents the transient error in the network. We predict for the next ten time units and the results are shown in figure 4. These results demonstrate the persistence of this type of fault and indicate a probability increase on the significant disruption of a particular network service. Figure 4 below shows the graphical representation of the results, this type of fault needs to be eliminated to restore normal service.

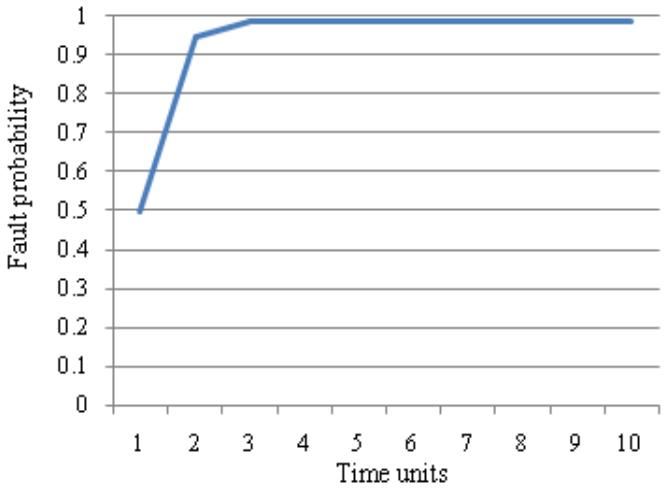

Figure 4: Transient fault probability progression over time

Table 4 was generated by our model simulation. However there is varying degrees of uncertainty when it comes to calculating the probability of a fault and classifying it as a condition necessary and sufficient for a failure occurrence.

Table 4: Forward inference on fault classification

Fault	Error	Failure type	Automated decision
Router interface out of synchronization	Packet loss	permanent	Temporarily isolate router by switching to standby router.
Timing mismatch	Time out	Intermittent, permanent or transient	Retry, or activate standby
Power cut	Blackout	Permanent	Switch to UPS
Broadcasting burst packets	Congestion , Bandwidth saturation	Intermittent	Retry
Network Protocol misconfigurations	Invalid routes	Transient	Switch to alternative node and reconfigure

4 Conclusions

In this paper we have considered the applicability of Bayesian networks for reliability modeling. Faults, errors and failures are probabilistic in nature therefore Bayesian Networks constitute a sound probabilistic rigorous mathematical modeling framework to tackle this domain. Network reliability is a research domain that will continue attracting research efforts as networks continue to grow in size functionality and complexity. Each component of a system can be engineered taking care of reliability; however when the systems are put together as subsystems to interoperate, challenges may immerge. Network configurations and reconfigurations, attacks, upgrades all introduce some level of network service uncertainty which is worthy researching. We have surveyed fault taxonomy in order to understand the characteristics and the dynamics of faults. The understanding will help architects to design networks that a more resilient to faults thereby guaranteeing service. The approach taken is based on the assumption that faults exists in any network what is important is how to handle them. We define network faults as a class of network events that can cause other events but are themselves not caused by other events.

The proposed model is designed to identify, localize, categorize the faults and select as well as initiate a recovery process. Prediction is achieved in order to preplan for the future abnormal behavior of the network. A level of redundancy by replicating some critical devices and network links to facilitate network restoration after localization and isolation of a component affected by a permanent fault is proposed.

In furthering this work it is recommended to research on fault parameter estimation and failure distributions and localization without depending on alarms from network management systems.

Abstract - *A parallel formulation for the simulation of a branch prediction algorithm is presented. This parallel formulation identifies independent tasks in the algorithm which can be executed concurrently. The parallel implementation is based on the multithreading model and two parallel programming platforms: POSIX threads and Cilk++. Improvement in execution performance by up to 7 times is observed for a generic 2-bit predictor in a 12-core multiprocessor system.*

Keywords: branch predictor simulator, parallel formulation, multi-threading, Cilk++.

1 Introduction

A branch predictor is an algorithm implemented in hardware which is intended to improve the performance of instruction execution in the pipeline of modern microprocessors. This algorithm predicts whether a branch instruction should be taken (T) or not-taken (NT) by the microprocessor, based on stored history of execution of previous branches [1]. Prediction accuracy is inherent to the prediction algorithm and is frequently evaluated and quantified by computer simulation, using branch traces as input data. These branch traces contain a set of branch addresses and outcomes which represent every branch instruction seen by a processor when executing a computing task.

Typically, branch traces are collected from the execution of well-known benchmark programs, and stored in very large files with millions of addresses and outcomes. The simulation process executes a software model of the prediction algorithm and relates obtained results with observed outcomes. The analysis computes a prediction to each branch in the trace, compares this prediction with the actual outcome observed, and keeps a global tally of the number of comparison matches, referred to as hits. Behaviour and accuracy analysis of a branch prediction algorithm implies the execution of a batch process for a number of trace files, each one subject to different parameter values. This analysis requires a significant computational time.

In this paper, a parallel formulation of a generic branch predictor algorithm is described. This parallel formulation exploits the inherent parallelism of the algorithm and reduces the execution time of the analysis by simulation of a branch predictor using multiprocessor systems. The implementation of the parallel formulation has three main steps. Firstly, a concurrent classification of the branch traces, according to the branch address, is performed. Secondly, the execution of the predictor algorithm on each class of address proceeds concurrently. Thirdly, a final step to tally global hits is computed. Results show an improvement in execution performance by up to 7 times when this implementation is evaluated on a 12-core system.

2 Generic Branch Prediction Algorithm

Prediction algorithms are basically defined by two processes: a prediction function and an update procedure. The prediction function makes a prediction (T or NT) for a branch instruction based on information stored from previous branches. The update procedure modifies the recorded history of branches based on the prediction and the actual outcome of the branch. A Branch Prediction Buffer (BPB) maintains information of previous branches as a table. BPB is indexed by a hash function of the branch instruction address. BPB typically contains a set of bits indicating whether the branch was recently taken or not [1].

Fig. 1 describes an algorithm of a generic branch predictor simulator, using a BPB table with 2^S entries, with $S > 0$. Each entry in BPB table stores history for a branch instruction address.

Input arrays *A* and *O* in Fig. 1 contain the branch traces for the simulation. Variable *hits* stores the tally on the correct predictions. Every branch instruction in the trace is related with one element of the BPB table and evaluated by

the prediction function (lines 2-3) making a Boolean decision as either taken (T) or not-taken (NT). This value is compared with the recorded outcome (line 4), and matches are stored in *hits* (line5). Finally, BPB table is updated (line 7) at the corresponding entry for the branch instruction address.

```
Input:
   A ← array of addresses
   O ← array of outcomes
Output:
   hits: correct predictions

1. for i=1 to N do
2.  entry ← A_i mod 2^S
3.  p ← prediction(entry,BPB)
4.  if (p=O_i) then
5.       hits ← hits + 1
6.    end if
7.    update(entry,p,O_i,BPB)
8. end for
```

Figure 1. Pseudocode of a generic branch predictor simulator algorithm.

2.1 Parallel formulation

The pattern access to BPB table determines the behaviour of the algorithm in Fig.1: each branch instruction accesses only the entry in BPB corresponding to its address. Therefore, data decomposition can be applied sequentially over branch instruction addresses to classify outcomes. This classification creates a list of arrays, where each item in the list corresponds to outcomes for a specific address value in BPB. Thus, each array in the list can be processed by an independent predictor task, and all these tasks can be executed concurrently, although every individual task performs sequentially.

An example of this data decomposition is shown in Fig. 2. Arrays *A* and *O* represent the input traces. Array *A* contains a set of 13 hash values of branch instruction addresses, for a BPB table with 8 entries (entry values between 0 and 7). Array *O* contains its corresponding set of outcomes (T or NT).

i	1	2	3	4	5	6	7	8	9	10	11	12	13
A	5	6	2	4	6	1	7	1	5	3	5	3	7
O	T	T	NT	NT	T	T	T	NT	NT	NT	T	T	NT

	T	NT	NT	NT	T	T	T
	NT		T		NT	T	NT
					T		

Figure 2. Example of data decomposition of input traces.

The input data is arranged in a list of arrays, *LO*. Each item in list *LO* corresponds to an entry value in BTB table, and contains an array of outcomes ordered by appearance in the trace. For example, for an entry value of 5, *LO* item has three outcomes (T, NT, T) corresponding to the outcomes of elements 1, 9 and 11 in the input trace.

Fig. 3 describes the parallel formulation for the algorithm presented in Fig. 1. In this parallel formulation, outcomes of the branch traces in array *O* are classified in a list of 2^S arrays (*LO*) according to the value of its corresponding address (lines 1-4). Concurrent tasks process *LO* items. Each task *k* executes sequentially the predictor algorithm on the array elements (lines 5-13) and registers correct predictions in $lhits_k$. After all tasks conclude, all *lhits* are accumulated in a global tally (*hits*).

```
Input:
   A ← array of addresses
   O ← array of outcomes
Output:
   hits: correct predictions

1.  for i=1 to N do
2.  entry ← A_i mod 2^S
3.  LO_entry.append(O_i)
4.   end for
5.   for each k in[0..2^S-1] do parallel
6.  while (LO_k.get(O_ki)) do
7.     p ← prediction(k, BPB)
8.     if (p=O_ki) then
9.    lhits_k = lhits_k + 1
10.    endif
11.    update(k,p,O_ki,BPB)
12.  end while
13. end foreach
14. for k=0 to 2^S-1 do
15.  hits = hits + lhits_k
16. end for
```

Figure 3. Pseudocode of the parallel formulation for the simulator of a generic branch predictor.

3 Parallel implementation

The parallel formulation algorithm in Fig. 3 was implemented using a shared memory model for concurrent tasks in multiprocessor systems called multithreading [2]. Multithreading is a parallel programming model that allows concurrent execution of multiple threads in the same process. A thread is a sequence of instructions within a process that can be scheduled for independent execution with other threads. Every program has one main thread. This thread can perform all the tasks by itself, or create other threads with defined subtasks. These subtasks should be designed to encapsulate functionality in order to exploit the inherent concurrency in the algorithm. Thread synchronization operations influence on the overall execution time performance [3]. Two multithreading programming platforms were used to compare performance of parallel implementations: POSIX threads and Cilk++.

3.1 POSIX threads

POSIX threads (*pthreads*) API (Application Program Interface) is a standard approved by IEEE for thread management. *Pthreads* is a portable threading library designed to provide a consistent programming interface across different operating systems platforms. Their main functions focus on thread creation, destruction and synchronization. The most common functions for thread synchronization are the mutual exclusion (*mutex*) locks and barriers. [4]

The *pthreads* version for parallel simulation of the branch predictor algorithm used in this paper encapsulates the classification of the outcomes and the predictor procedure. In the classification step, input arrays are divided in sub-arrays and each thread classifies a sub-array in a local version of *LO* list. After this classification is completed, corresponding arrays from all local *LO* lists are orderly merged in global arrays to create a global *LO* list. Then, the predictor function is executed concurrently, where each thread sequentially processes one item of the global *LO* list at a time. Finally, every thread updates the global tally of correct predictions with its own local tally.

In this implementation, barrier synchronization is used at the end of the input classification and at the end of merging local *LO*s. *Mutex* synchronization is used for concurrent update of the tally of correct predictions.

3.2 Cilk++

Cilk++ is a language extension for programming languages C/C++. Three statements make up the main part of the extension; *cilk_spawn*, *cilk_sync* and *cilk_for*. *cilk_spawn* and *cilk_for* are used to create parallel tasks, either with complete functions or with loop iterations. The *cilk_sync* statement is a local barrier, and is used to synchronize parallel tasks created by *cilk_spawn*. Aditionally, Cilk++ includes a library for mutex locks. Locking tends to be used much less frequently than in other parallel environments, such as *pthreads*, because all protocols for control synchronization are handled by the Cilk++ runtime system. The Cilk++ runtime system is based on a work-stealing scheduler using threads. This is a dynamic load-balancing scheduler and improves the utilization rate of processing units in a system [5].

The Cilk++ version for parallel simulation of branch predictor algorithm used in this paper implements three stages: input array classification, merging of local *LO* and prediction with verification. Every stage is implemented with a *cilk_for* statement. *cilk_for* is a replacement for the conventional C++ *for* statement and executes loop iterations in parallel. Cilk++ compiler converts a *cilk_for* loop into a divide-and-conquer recursive function encapsulating the loop body. This strategy benefits Cilk++ scheduler performance [6]. After the three *cilk_for* loops, the sum of all the partial tally of correct predictions is performed sequentially.

4 Results

Both parallel implementations were executed on an Intel 12-core (dual 6-core Xeon X5690, 3.47GHz) desktop system with Scientific Linux 6.0 (release 2.6.32-131). *Pthreads* version was compiled with gcc 4.4.4 (Red Hat 4.4.4-13), and Cilk++ version was compiled with cilk++ (GCC) 4.2.4 (Cilk Arts build 8503). Branch traces were collected from SPEC 2000 benchmark programs, with sizes of 10 million and 30 million of traces. BPB table was set at 4096 entries. We specifically exercised a 2-bit branch predictor algorithm [1].

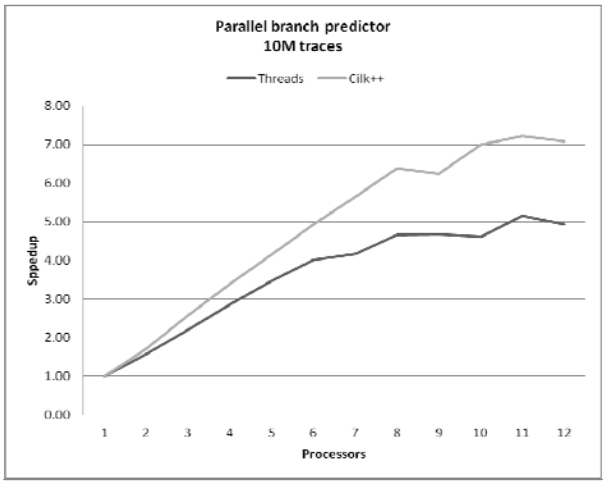

Figure 4. Speedups of the simulation of the parallel branch predictor in a 12-core system with 10 million traces.

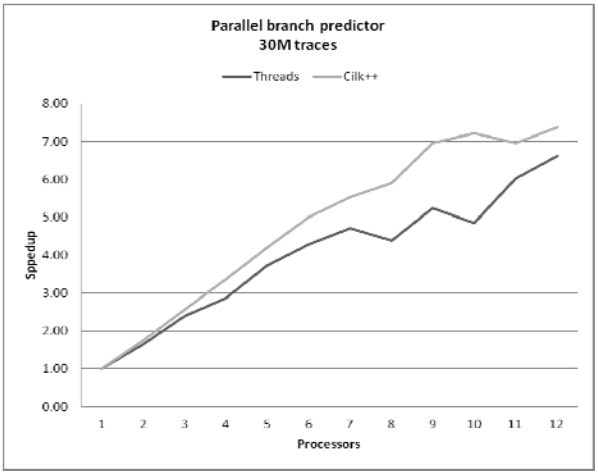

Figure 5. Speedups of the simulation of the parallel branch predictor in a 12-core system with 30 million traces.

Fig. 4 and Fig. 5 show the execution time speedup for *pthreads* and Cilk++ versions with input traces of 10 million and 30 million of elements, respectively.

On each parallel execution, one thread was created for each executing core. The execution time was calculated by the average of 50 executions of every version of the program (sequential, *pthreads* parallel and Cilk++ parallel).

5 Discussion

The Cilk++ implementation shows better performance than the *pthread* implementation for both sizes of branch traces files. Speedup in both implementations exhibits a sustained improvement on the first group of 6-cores. However, this improvement starts to decline with the second group of 6-cores. This behaviour is due to both the distribution of the data on cache memory of each processor and a slower external buffer that interconnects processors and memory.

The speedup tendency is very similar for Cilk++ implementation with both sizes of input traces. However, for *pthreads* implementation, with 10 million input traces, speedup starts to decline when the number of threads increases. With 30 million traces this tendency is not observed. This behaviour reflects how the cost of creating and synchronizing threads influences the execution performance.

The increasing speedup in performance suggests that concurrent independent tasks have been effectively identified from the sequential algorithm.

6 Conclusions

A parallel formulation for the simulation of a 2-bit branch prediction algorithm has been proposed. This parallel formulation was implemented, based on the multithreading model, using *pthreads* and Cilk++ programming platforms. Execution time performance exhibits an improvement with an incremental tendency by up to 7 times for a 12-core multiprocessor system. These results suggest that the parallel formulation effectively identifies inherent parallel tasks in the algorithm.

Future work is aimed at using the parallel formulation of the simulation of the 2-bit branch predictor with other branch predictor algorithms to analyze its performance.

Abstract – *In recent years, the number of Electronic Control Units (ECU) steadily increases which require higher communication bandwidth. Switched fabric has become an active area of research because of its wide uses in industry. In fact, its uses can be a fast and reliable hardware solution for existing CAN-Bus problems like limited bandwidths and throughput.*
In this paper, we proposed and modeled a switched fabric CAN network Architecture based on CAN Controllers and switched fabric by the use of timed colored Petri nets (CPNTools).

Keywords*: Higher communication bandwidth, CAN Bus, Switched fabric, Switched fabric CAN Network, timed colored Petri nets, CPNTools.*

1 Current bussed Network problem and Switched Fabric CAN Network benefit

During last decades, the demand for sophisticated embedded systems requires the use of many connected equipments. A dedicated network bus [1] is used for connecting sensors, actuators in vehicles, robots and industries. Many serial buses were developed by car makers like MOST, J1850, SAE J1708, Byteflight, LIN... and CAN(controller Area Network). Most of them are specific to manufactures and not standardized.CAN is one of the most popular fieldbuses [2,3,4]. More than 400 million nodes were sold worldwide. It is used in those applications that require fast and reliable communication [5]. Nowadays, more sophisticated buses are concurrent to CAN networks like FlexRay [6], recently appeared, and RTethernet. They offer higher speed to satisfy the high bandwidth required for modern vehicles, suitable for x-by-wire application. In contrast the usage of FlexRay [7] is not widely used due to its complex specification and high cost.
Current parallel bus-based [8] solutions present some problems. In fact, it's well known that the physical separation of cards is limited to usually less than 3 feet. There are also limited bandwidths, high protocol overhead and no deterministic performance.

The limitations of a bussed network [2] are eliminated with crossbar switch network. A switched-fabric bus is unique in that it allows all CAN Controllers on a bus to logically interconnect with all CAN Controllers on the bus. The switching fabric is the physical connection within a switch between the input and output ports; it can be proved that all switches need a crossbar inside their switching fabric which allow them to operate at very high speed. Crossbar switches are widely used because of their simplicity and their high-performances [9] which promise to greatly simplify efforts and to add better capability and availability. Crossbar switch [8] can support simultaneously multiple messages. This greatly increases the aggregate bandwidth of the system. Because of the broadcast nature of the CAN protocol (ie: messages are not sent to a specific destination address, but rather as a broadcast), the chosen crossbar switch (as it is shown in Figure 1) is configured by closing all its crosspoints to ensure that the CAN message will be sent at the same time [3,4] for all outputs nodes as it is defined in CAN protocol [5].

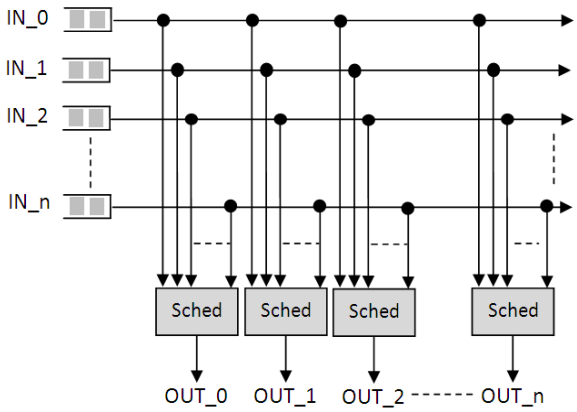

Fig. 1: NxN crossbar Switched Fabric CAN Network supporting broadcast

Each Electronic Control Unit (CAN Controller Node) produces a class priority of messages. For example, ECU_0 produces high level of priority and ECU_n (n in our model is equal 3) produce low level of priority. In fact, Produced CAN messages will be queued in the input queue of the incoming interface (If the input queue is full, the packet is dropped.). Therefore, to respect the CAN protocol philosophy, CAN messages will be broadcasted for all output port through crossbar Switched Fabric [10]. Furthermore, to reduce congested output port and to respect

the priority policy, each CAN message will be queued in the suitable output queue of each outgoing interface according to his level priority. (If the output queue is full, the packet is dropped). Then, each output port scheduler will select the message to be sent among the existing CAN message in accordance with his priority.
In our work, we modeled the switched fabric CAN Network using stochastic colored Petri. Our major contribution is to raise the lack of the bus solutions by proposing switched Fabric CAN. In fact, CAN based Networks using crossbar Switched fabric [11] have yet a well period before its replacement and it can compete the new sophisticated buses.

Our paper is organized as follow:

• The section 2 gives a short overview of Stochastic and Colored Petri Net SCPN [12].

• Based on the proposed architecture and CPNTools software, we model, in the last section, the most important Switched fabric CAN Network modules.

In the fourth section we give some conclusions of our work.

2 Short Recall of Coloured Petri Net

Coloured Petri Nets have been developed by K. Jensen in course of his PhD thesis (Jensen, 1980) to expand the modeling possibilities of classical Petri Nets. Like other forms of Petri Nets a CPN consists of places, tokens, transitions and arcs.
The primary feature unique to CPNs is the inclusion of evolved data structures into tokens [13,14]. These data structures are called coloursets and resemble data structures in high level programming languages; they can range from simple data types such as integers to complex structures like structs or unions in C/C++. Similar to programming languages it is possible to define variables associated with these coloursets such as linked list and queue.
Some examples of colourset and variable definitions are shown in Fig.2. Tokens as well as places of a CPN are always associated with a colourset and a place may only contain tokens of the same colourset as its own. To well understand the SCPN models of our Switched CAN controller, we give a short recall of CPN concepts.

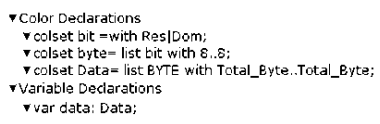

Fig. 2: Coloured and variable definitions

The places in a CPN are depicted as ellipses (Fig.3) with the name of the place written into it and the associated colourset (Id) below. A token in a CPN is represented by a small circle (Fig. 3). Its value (the data stored in the token) is shown in a rectangle attached to the circle. A number in the circle denotes the number of tokens with the same value. Figure 3 for example shows a place called *Buffer_Node_1* associated with the colourset CAN_Messages and holding one token with a value of{ {ID=[Dom,Res,Dom,Dom,Res,Dom,Dom, Dom,Res,Res,Dom,Dom,Dom,Res,Dom,Res,Dom,Dom,Do m,Res,Res,Dom,Res,Res,Res,Res,Res,Dom,Res],DATA=[b yte(4),byte(6),byte(5),byte(1),byte(5),byte(6),byte(6),byte(1)],TS=0}].

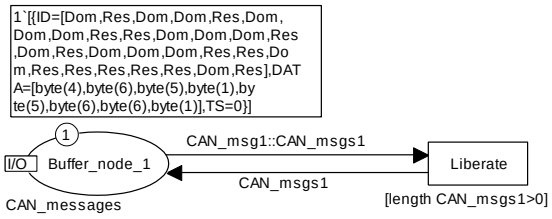

Fig. 3: Graphical representation of a place in CPN

Transitions in a CPN are represented by rectangles (Fig. 4) and can access the data stored in tokens by mapping tokens to variables. There are two possibilities to access this data:

-Guard conditions: The transition is enabled only if a specific condition – called a guard condition – regarding one or more variables is met. Guard conditions are encased in brackets and written above the transition (Fig.4).

-Transfer function: The transition reads and writes variables according to a specified function that can range from simple addition of values to complex conditional commands.

-Transfer functions consist of the definition of input () variables, output () variables and the commands to be carried out (action ()) and are attached below the transition (Fig.4).The example depicted in Figure 4 shows a transition that only fires if the length of variable *CAN_msgs* is less than the value *FIFO_length* and generates an output variable *CAN_msg* without taking any input variables (Fig. 4), the variable *CAN_msg* is filled with the return value of the function defined in the action part, *new_MSG_0*, which in this case is defined in the CPNtools area Declarations.

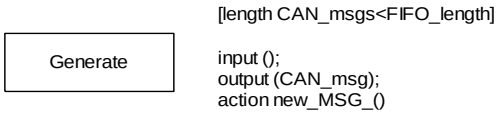

Fig. 4: Transition Generate with guard condition and transfer function

Places and transitions in a CPN are linked by arcs. Arcs in a CPN can be unidirectional or bidirectional. Unidirectional arcs transfer tokens from a place to a transition or vice versa.
Bidirectional arcs transfer the same token from a place to a transition and back. Arc inscriptions define the mapping of tokens to variables. An inscription can either be a constant value or a variable of the colourset that is associated to the place the arc is connected to. If all places connected to a transition by unidirectional input arcs or by bidirectional arcs hold tokens and its (optional) guard condition is met, the transition is said to be enabled. In case of more than one enabled transition in a CPN the one to fire is chosen randomly. Later on, we will add more places to our controller models to avoid arbitrary transitions.

For an analysis of clocked systems it is possible to define timed colourset, defined by the keyword timed and transition or arc delays marked by the characters @+.
If a colourset is defined as timed, a timestamp is added to the tokens of this colourset. The timestamp cannot be accessed by guard conditions or transfer functions. When

using timed colourset the firing of transitions depends on a global clock counter. Transitions can only fire if the clock value is the same as the largest timestamp of its input tokens. When a transition fires with a timed arc, the timestamp of its output token is the sum of the current clock value and the arc delay, in the example in Figure 5 this delay is *Time_sched_delay* clock cycles.

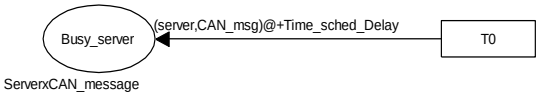

Fig. 5: Timed arc inscription.

3 SCPN Based Switched Fabric CAN Network model

In order to facilitate modeling of Switched CAN Controller, a modular approach was taken making use of hierarchical CPN models. The model of the Switched Controller is built following a hierarchical and modular architecture.

The root of the hierarchical representation of the model is shown in the figure 6.

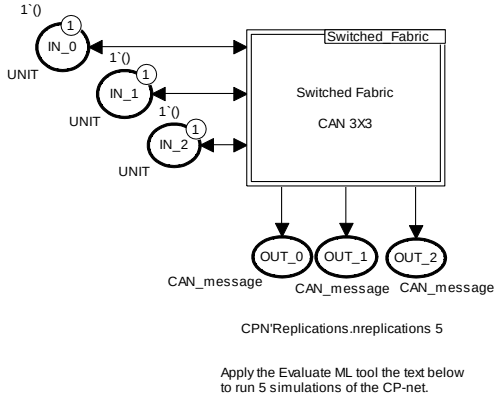

Fig. 6: Root level of the model

The Switched Fabric CAN 3x3 whose activity is modeled by the transition *Switched_Fabric* transmits the CAN message via the Switch Fabric. The places *IN_i* and *OUT_i* (i can be a value between 0:2) play the role of inputs/outputs for sub-models.

Nodes in CAN are identified by their identifier (in this model, colourset *Id* is a list of 29 bits). The coloursets and variables used in this model are shown in Figure 7.

Messages sent through the Switched Fabric CAN are represented by tokens of the colourset *CAN_message*. This colourset is a record of the colourset *Id* that designates the message priority and the colourset Data which represent the data field to be transmitted and the colourset *TS* for saving the time stamp for the birth of the message.

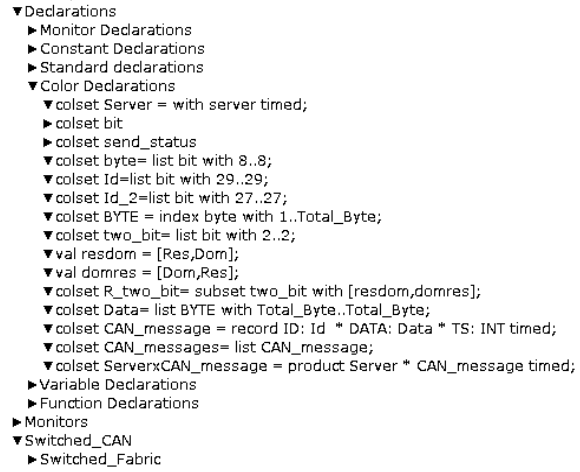

Fig. 7: Coloursets for CAN Network model

The variables (*CAN_msg*, *CAN_msg1* and *CAN_msg2*) are of type of the colorset *CAN_message*. This variable models the messages which cross the different sub-models of Figure 8 (*Node_i*, *Broadcast_i*, *FiFo_i_j* and *Scheduler_i*).

The Switched CAN network model in Figure 8 is composed of three nodes. Each node is represented by a transition and two places. The transition called *Node_i* (i can be a value between0:2) is a hierarchical transition which describes the messages generation within the node, how the messages are stored in buffer. The place *Buffer_Node_i* is used to store the messages already generated.

This place is configured with colourset *CAN_messages* which is a list of colourset *CAN_message*. When a token is present on this place (*Length CAN_msgs* >0) a message is ready for sending. This last fires the hierarchical transition *Broadcast_i*. The originated message is duplicated in three places, one for each output port of the Switch fabric. According to the priority which is associated to the messages (defined by their ID), the messages are stored in the FIFO queue (there is as many queue as of priorities). In this model, three levels of priority are defined: 0: high level of priority; 1: medium priority and 2: low priority.

FiFo_i_j is a substitution transition which presents the queue of *input_i* for the *output_j*. Finally, the scheduler processes the different messages according to its scheduling policy.

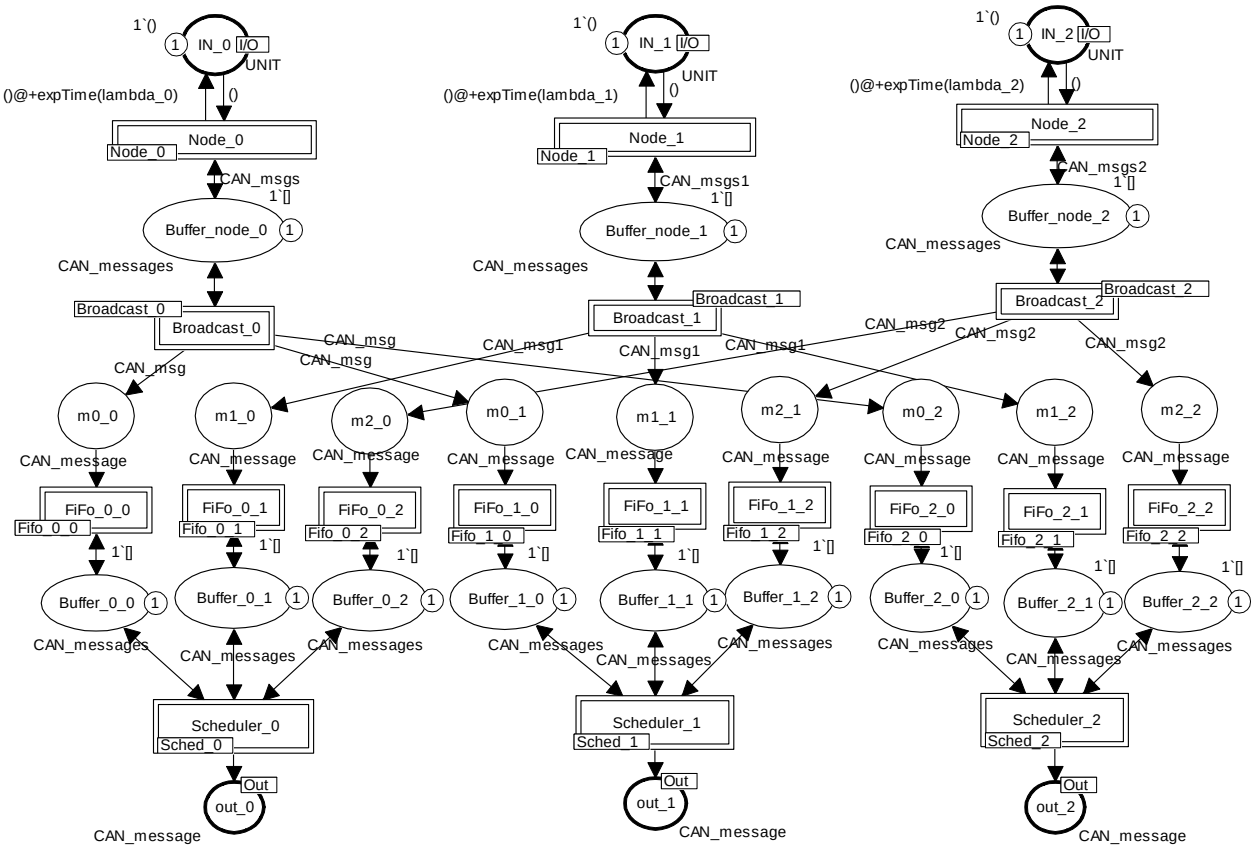

Fig. 8: SCPN Switched CAN Networks model with three nodes having three different priority classes

3.1 Generating CAN Messages (Node_i Transition)

As shown in Figure 9, the load source is modeled by the place *Next* and the transition *Generate*. Initially the place *Next* contain one token and is connected via two arcs to the transition *Generate*, the arc from *Generate* to *Next* is timed using the exponential random function. Thuswe can have a random message with parameterized inter arrival period using the value *lambda_i* (*lambda_0* for node 0: Figure 9).

The place *Buffer_node_i* is used as messages buffer, sized of 4 in our case, to decouple the source message from the Switched CAN controller. When the load source increases and no room is available in the buffer, an overflow occurs and the transition *FIFO_FULL* fires leading to lose the last generated message (due to a congestion or excessive load).

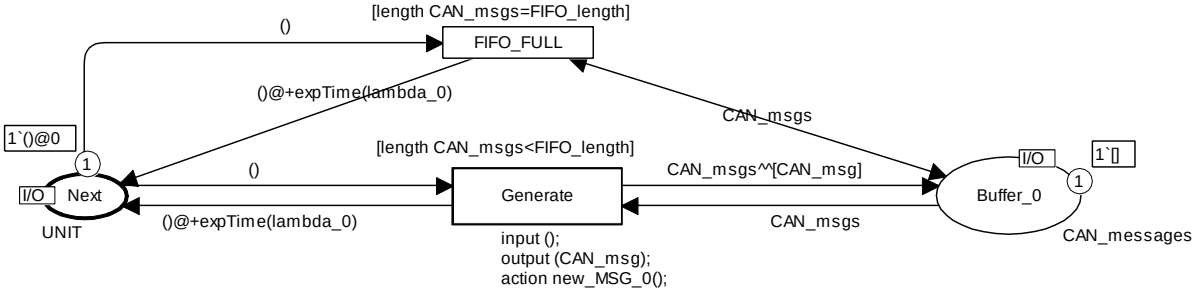

Fig. 9: Generation of CAN Message (Node_0)

3.2 Broadcasting of CAN Message (Broadcast_i Transition)

The set of broadcasting message is represented by the model described in the figure 10. Transition *Liberate* models a message coming from *Buffer_node_i*.

The *Buffer_node_i* place is a list of CAN_Message. When the list length is not null (i.e there is at least a message to send), the *liberate* Transition can be fired if the line is free (there is a token in *Line_Free* place). Otherwise, message coming from *Node_i* has to be delayed *Transfer_Data_Delay* until the previous message will be liberated. If the message is liberated, the *Server* token will be moved from the place *Line_Free* to *Line_Busy*. Then the messages will be duplicated in the right place (queues)

according to their priorities. For example, message of medium priority (*CAN_msg1*) will be routed to the places *m1_0*, *m1_1* and *m1_2*. The CAN message *m1_i* will be queued in the queue 1 of the output port i (*OUT_i*).

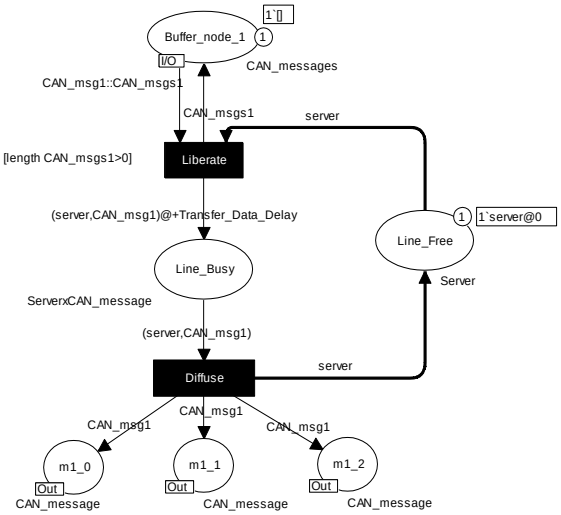

Fig. 10: Broadcasting CAN Messages generated by Node1

3.3 Storing CAN Messages (FiFo_i_j)

FIFO model is represented in the figure 11. It processes the messages in the order of their arrival. The function of the transition *Arrive* is to concatenate incoming message (*CAN_msgi*) to the *Buffer_i_j*. *Buffer_i_j* is a place having *CAN_messages* as colourset: i indicates the level of the message as it was explained previously and j indicates the output port of the model. Thus *Buffer_i_j* is the queue of Message i of the output port j (*OUT_j*). When the buffer is full (in our model *FiFo_length= 4*), the transition *Fifo_i_j_Full* is fired and the incoming message will be rejected.

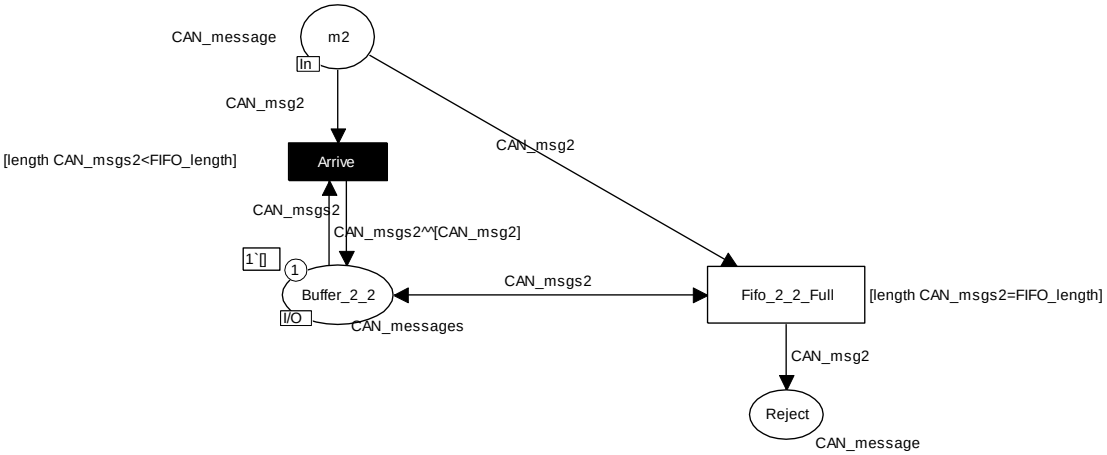

Fig. 11: Storing CAN Messages generated by Node 2 in the queue 2 of output 2

3.4 Scheduling CAN Messages (Scheduler_i)

The model of the figure 12 describes the behavior of a static priority scheduling. The type of messages is classified in three groups:

- High priority messages: These messages are generated by Node_0 and are modeled in the place *Buffer_i_0* as a list of *CAN_Message* (*CAN_msgs*) in the Scheduler of the output port i (*OUT_i*).
- Medium priority message: Those are generated by *Node_1* and are modeled in the place *Buffer_i_1* as a list of *CAN_Message* (*CAN_msgs1*) in the *Scheduler_i*.
- Low priority message; those are generated by *Node_2* and are modeled in the place *Buffer_i_2* as a list of *CAN_Message* (*CAN_msgs2*) in the *Scheduler_i*.

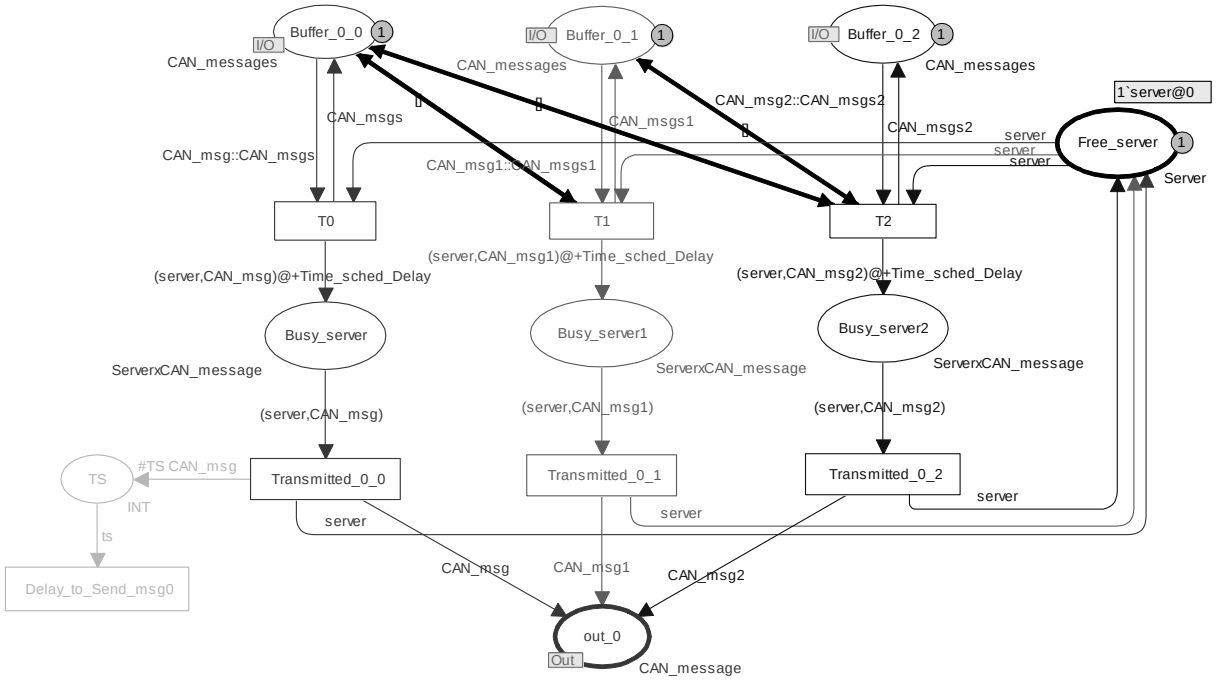

Fig. 12: Scheduling CAN Messages at the Scheduler of Output 0

A message with lowest priorities can be delayed by the other packets due to the non-preemptive characteristics of this kind of message scheduling algorithms [15].
For example, in the case of Scheduler_0, the messages of Buffer_0_2 (low priority messages) has to wait until the messages of Buffer_0_0 and Buffer_0_1 (high and medium priority messages) are fully transmitted. Then, the messages of Buffer_0_1 (medium priority messages) has to wait until the messages of Buffer_0_0 (high priority messages) are fully transmitted.

This scheduling policy is modeled using bidirectional arcs between buffers places and the transitions *T1* and *T2*. These arcs are inhibitor arcs. The method of usage of inhibitor arc is described in more details in [13].
When there is at least a message to transmit, the Ti transition can be fired if the server is free what it means that there is a token in *Free_server* place. Otherwise, the following message (according to the algorithm described above) have to be delayed *Time_Sched_Delay* until the previous message is fully transmitted. After the transmission of the message, the Server token will be moved from the place *Busy_sereri* to *Free_server*. The interest of the static priority algorithms is that it is easy to implement. Other Scheduling algorithms can be studied in future works.

4 Conclusion

In this paper, Switched Fabric CAN architecture is presented and modeled by CPNTools. The SCPN model of the Switched Fabric Controller is presented with three nodes at transmitter side using a switch fabric (3x3). For that, three message priority classes were treated with a clear representation on ID field (high, medium and low priority messages).
The model focuses on queueing, broadcasting and scheduling mechanisms which are the keys factor for the proposed architecture.
The evaluation of throughput, latency and loss probability of the proposed architecture and a comparison with Bussed CAN controller [2] will be studied in the future works to demonstrate that CAN with a crossbar switched fabric has yet a well period before its replacement.

***Abstract*—Nowadays has been observed a large increase in the volume of images generated by medical devices. The manipulation of medical images has one known as DICOM standard that allows interoperability between these images in different devices. The server CyclopsDCMServer was developed in order to work with Hierarchical Data Format (HDF5) for manipulation of medical images (DICOM) on a distributed file system. This work aims to improve the performance of the server through an approach that uses the functions of reading and writing parallel. The experimental results indicate a gain of the proposed approach with respect to the original environment.**

***Keywords*-HDF5; MPI; PVFS; DICOM; Parallel I/O;**

I. Introduction

Databases alternative to conventional database for data storage has been a solution more sought by researchers and companies when it faces to large volumes of data in systems of high performance computing. Among the alternatives that are available and active development, currently the Hierarchical Data Format (HDF) has been highly seeking by researchers. HDF5 is the fifth version of this format, and was developed by the group "HDFGroup" from the University of Illinois in the United States. Since the release of HDF many general purpose and scientific began using it as an efficient alternative and high performance for storing and accessing large files. As examples, NASA use HDF to store data from global monitoring, clinical applications for managing large collections of images of X-rays and oil companies that store large amounts of data from 3D seismic surveys [1].

CyclopsDCMServer is a work being done by the group INCoD at Federal University of Santa Catarina in Brazil [2] and it aims to supply storage of DICOM images [3] provided by medical devices connected on *Rede Catarinense de Telemedicina* (RTCM) [4]. RTCM connects different health institutions such as hospitals and primary care that encompasses 286 cities in the state of Santa Catarina. This network provides service access to more than 10 DICOM modalities, among them are: electrocardiogram (ECG), magnetic resonance imaging (MRI), computed tomography (CT) and computed radiography (CR) [5]. For this integration occur between server and DICOM modalities, the RCTM use Picture Archiving and Communication System (PACS) [6] which includes hardware and software support for most medical equipment masking all part of communication, safety and accessibility. In Santa Catarina, the system is available almost over the state, and trend in few years cover the entire state.

A research mode of this server uses HDF5 as the data format to DICOM images and a distributed file system PVFS (Parallel Virtual File Systems), in order to focus on storage performance, DICOM image queries and solve the problem of scalability generated by storing vast amounts of files generated by PACS system. This work involves on a version of this server that includes the parallelization of the reading and writing DICOM files in HDF5. This study focuses on presents the architecture and experiments of reading and writing in parallel , with the goal of achieving better performance in access to the database and collect communication delays. This work has as motivated some parallel writing function tests performed in work [7], which demonstrated improvements in writing time.

This work is structured in six sessions. The next session begins with a base of how the CyclopsDCMServer works, and in section 3 presents the introduction of the approach of proposed architecture. In Section 4, we describe some related work. In section 5 depicts the hardware and software used in this project, the experiments and results. Finally, in Chapter 6, we ended the study with conclusions and future work.

II. CyclopsDCMServer

CyclopsDCMServer was developed in order to provide service integration of DICOM in PACS environment, in order to provide medical imaging storage and accessibility for manipulating these images through workstations. The application is multiplatform and can run on the Linux machine, Windows and other systems. Currently, in real system, the application CyclopsDCMServer stores all information provided by PACS system in a relational database called PostgreSQL. The DICOM files generated by available modalities on PACS system, generate files with different sizes, ranging from 300 Kbytes to 600Mbytes per image, and should remain stored on the server for at least 10 years. In measuring the increase in volume of data they generate problems such as scalability, latency in queries and maintenance costs.

Based on these problems described above, studies were carried out by Macedo et al [5] seeking to circumvent issues of telemedicine environments based in server with relational database systems. These issues considered are scalability, distribution of information, ability to use techniques for high system performance and operating costs. The result of this research led to a new server architecture based on PVFS and HDF5. Among the usual procedures of the current approach, the contribution was storing all the information hierarchically, such as organize and store data in HDF5 format. The second step was to use a cluster with distributed file system in order to seek high-performance disk access. Another contribution was to create an object called H5WRAP to handling with HDF5 interface.

A. H5WRAP

Due to lack of a procedure that incorporate a DICOM image in HDF5, it was necessary to create a library called H5WRAP, which converts a DICOM file in the format HDF5 data. The library contains an object that is used to create, find, collect and store information related to DICOM images in HDF5 files and this information is represented in Figure 1. Among various metadata contained in a DICOM file [8], for the H5WRAP, were collected only metadata that are importance to the PACS system used in Santa Catarina.

HDF5 files are organized in a hierarchical structure. It is observed that were selected three DICOM layers, each layer represent a group of study, serie and image, where the hospital attributes and patient studies are contained in the study layer. Their primary structures are two datasets and groups [1] . An HDF5 group is a grouping structure that can contain zero or more instances of groups or datasets, while an HDF5 dataset is a multidimensional array of data and also contains metadata that describes the dataset. In the next section, we explain how the read and write in parallel was built in H5WRAP

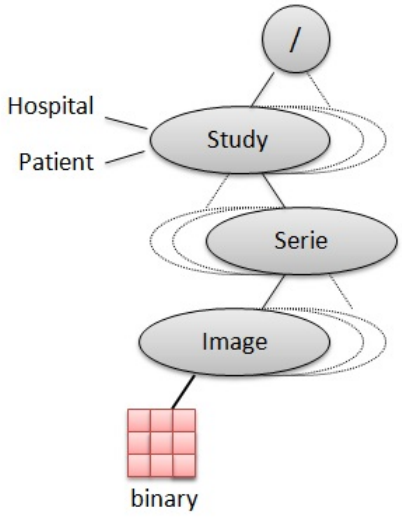

Figure 1. DICOM layers in HDF format

B. PH5WRAP

The PH5WRAP is an architecture oriented to work in reading and writing parallel only the binary. The reason for this restriction is due to the fact that the binary image representing on average 90% of a DICOM file, ignoring the need to parallelize small disk accesses to metadata, which could result in a longer process, due to communication necessary to distributed these layers. This architecture is designed to work in the same environment previously proposed in H5WRAP, based in PVFS and HDF5, with the addition of the Message Passing Interface (MPI).

The parallel access is provided by processes that are initiated at each node. The parallel access comes from the HDF5 API, which uses ROMIO interface to access the file system. ROMIO is a portable implementation of MPI-IO access which was created to provide high performance access to distributed file system. Its development is restricted to support some types of file system and among the most widely used, we have the PVFS and NFS [9]. In terms of characteristics of parallel access, the Parallel Virtual File Systems designed to support multiple access models, such as collective and independent access, as well as non-contiguous access patterns and structured. PVFS has three important structures: the metadata node, data node and client node. A node can represent all the structures simultaneously. The metadata nodes are controllers of permission file, directories and file names. Data nodes store physically data files and the client makes requests to the file system commands using POSIX or through APIs .

The Figure 2 illustrates the architecture of PH5WRAP, which illustrates the communication between the usual H5WRAP with the parallel application. The implementation of parallel application will be used by the server as it needs to perform a read operation or write a binary image DICOM.

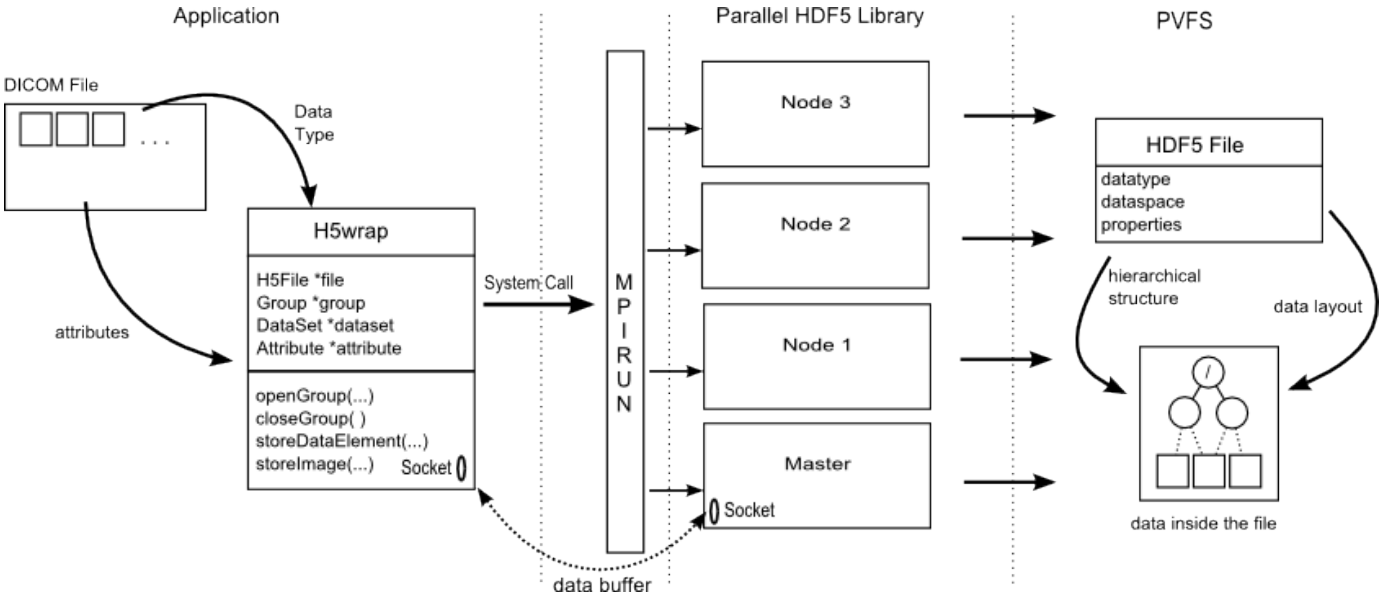

Figure 2. Ph5wrap architecture

Basically, the dicom file is unpacked to the data type and attributes, wrapping these contents into HDF5 format and throwing the binary image to parallel application. In this application, two main procedures are performed, the reading and writing functions. In case of Figure 3, it illustrates the division of binary image between the application processes when the master node receives the buffer from H5wrap. The division it's make simple, based on number of parallel nodes, which more nodes, smaller the buffer to distributed to other nodes.

The next two sections, it's describe the functionality of the both main function.

1) Write function: The write function begins with a request for some DICOM modality available on the PACS for storage an image in CyclopsDCMServer. As the object H5WRAP performs file analysis , it is create indexes in Clucene index table [10]. Before writing the metadata, it is checked whether the study groups, series and image metadata are already available in the HDF5 file, otherwise it is create the layers. Stored metadata, the server creates a connection through socket with the master process, sending the type of operation, the operation path and binary buffer, awaiting return the status of communication process. The Master process distributes the binary partition for nodes according to number of nodes in the system, and they store their respective buffer in system PVFS.

2) Read function: The process of reading function is similar to the writing process. Start with a client application consulting an image. This query is performed on server via Clucene index table where DICOMS images can be filtered by modalities study, series and images. The retrieve for an image is performed after the step above, that returns the

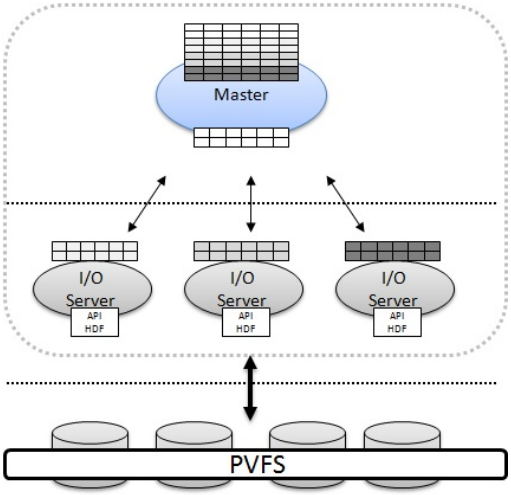

Figure 3. Shows the binary buffer distribution between nodes

object path that will be accessed in HDF5 file. The reading of metadata is performed by H5WRAP, while the binary image is performed by the parallel application. To performing the reading of the binary, H5WRAP create connection with master process, sending only the type of operation and location of the binary access. The Master node distributes to other nodes the location, which each node retrieves a region of binary. After reading their region, the nodes return a binary portion to master process. The Master, taken up all the regions, it sends the binary to H5WRAP. The H5WRAP ends the DICOM file, returning to the client.

III. Related Work

The first two works are themes that seek to resolve I/O performance issue of large amounts of stored data, using the parallel HDF5 library. The first related work [11], is very similar to ours where this work focus on the use of parallel I/O library for scalability problems involving many fermions dynamics for nuclear structure (MFDn). This study used a parallel version of HDF5 and performed tests on the independent and collective models. The results showed that files with size up to 20 GB, parallel HDF5 became more productive than sequential. The work [12] focuses in using parallel-IO for particle-based accelerator simulations that involved large amounts of data and dimensional arrays. They used two different API, the first is well-known MPI-IO and the second is the parallel HDF5 called H5part. He compared the simulations performance of read and write file operation between the API H5part, MPI-IO and the primary (file per process). HDF5 showed good performance in writing, although MPI-IO showed better results in both operations.

The works [13] [14] [15] are interesting because they focused in working with comparisons and performance improvements of I/O in platforms such as Jaguar and Red Storm. These are supercomputing platforms, which provide computer services, such as GTC for spectrum, Parallel Ocean Program (POP) ocean modeling, physics calculations program and others. The work proposed by Yu et al has some interesting comparisons with different types of I/O. They propose to improve and enhance access in a parallel application called Jaguar of Oak Ridge National Laboratory and aimed at several objectives such as, the characterization of performance parallel-IO on storage unit and scalability of the entire system. The results showed a better performance and less scalability in parallel-IO in collective mode and showed that using technique called FLASH I/O, the performance can improve by 34% with certain adjustments on collective I/O .

About the file systems, the work [16] conducted three experiments in an atmospheric model system, distinguishing the access mode on disk. The experiments deal with applying a single application with a differential in system architecture that adds Threads on its processes. The written tests with local disk had the best performance by not requiring communication between the nodes of the file system. The environment with threads had a better performance when used the parallel virtual file system (PVFS), because it has facilities when use MPI interface. The experiments were performed using 30 clients in one PVFS environment with four nodes. As each process accesses the file system constantly to write the atmospheric results, when you have more than one process per machine, they compete for access disk, reducing the execution time. This does not occur with the application threads, since it runs one process per machine and performs better memory used.

IV. Environment And Experimental Results

The environment used for the experiments is a virtualized with eight virtual machines, both PVFS nodes and nodes of the parallel application. Another virtual machine is used to host the server CyclopsDCMServer. For virtualization platform environment, we used VMware vSphere 5. The host machine has an Intel Xeon E5310 with 4 cores at 1.6 GHz each and a total of 10Gbytes of memory and 460 Gbytes of disk. Each virtual machine has virtualized 1077 Gbytes of memory and 23:26 Gbyte disk.

To assemble the virtual cluster, it was necessary to set up an environment with PVFS, MPICH2and HDF5, and their arguments are meant for installation work with parallel features. Each of the parallel application process will also be a PVFS data storage node. We use the same number of PVFS data nodes as parallel application processes in order to use the maximum use of the environment. The graphs bellow shows the number of attempts on y axis and time spent in seconds on x axis to complete the experiments.

In reading experiments were total conducted 24 experiments, 16 collecting only the read time of binary from two DICOM images in HDF file, discarding the communication delay and assembly of the DICOM file. The other eight experiments represent the total value of reading the images, plus the assembly of the DICOM file. The first binary image has 92.16Mbytes while the second has 52.42 Mbytes. Experiments were performed with the serial server, three more experiments with 2, 4 and 8 parallel nodes. These experiments were performed twice, resulting in a total of eight experiments per image. Each reading experiment was repeated 25 times on the same image. From these results, it is collected the average and presented in the comparison chart of the averages in Figure 4.

It can be observed in the first average graph of image 1 on the first attempt, a difference up to 6 milliseconds of average serial reading with 4 parallel nodes. In the second attempt, the parallel reading with 8 nodes have underperformed with a difference of approximately 7 milliseconds compared to the serial reading and near twice worse compared with 4 nodes. The same can be observed in image 2, although the results are better than eight nodes serial reading, the difference between the applications with four nodes is almost twice. Finally, the Figura 6 graph is a noteworthy the impact of the runtime application when used CyclopsDCMServer with 8 nodes.

One important factor that causes the loss of performance of parallel application with 8 nodes in the three graphs is due to be working with one processor with four cores and using 8 vitual machines, running one process. This process will disputed to use one core, therefore, others have to wait. This causes saturation in processor use, rather than working with a virtual machine requires a high processing power. This

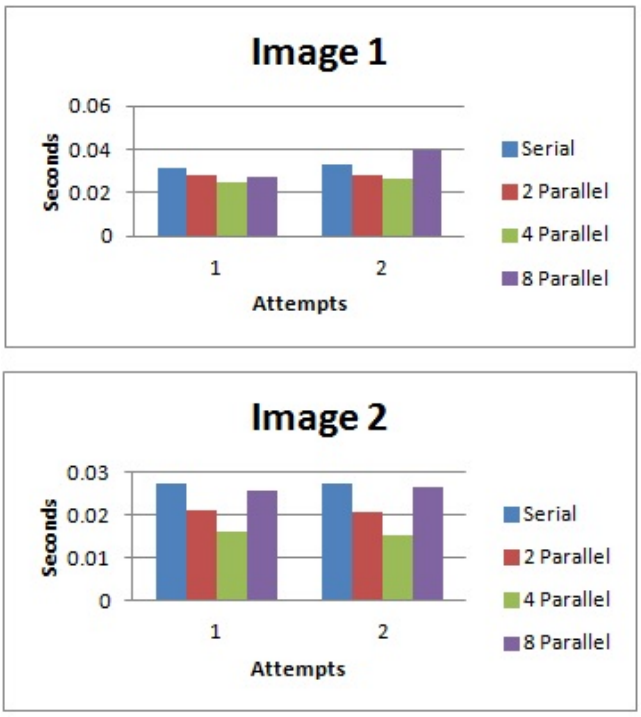

Figure 4. Reading comparisons graphics

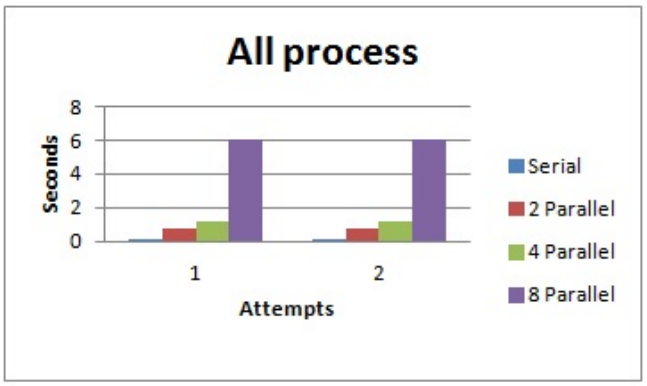

Figure 5. Server runtime

conclusion can be proved also by the fact that when we use only four nodes, no process have to wait, the performance is approximately 2 times faster. This underperformance provide by 8 nodes is also observed in Figures 5.

The next figures illustrate two graphs of average for written experiments performed with about 1000 DICOM images each attempts. These images are sent to the server CyclopsDCMServer, which is responsible to communicate with parallel application.

In Figure 6 shows the average time of writing an image in the HDF. For this first graph, we collected the time of writing only, discarding the time of the system. Among the two attempts, there is the bottleneck described above

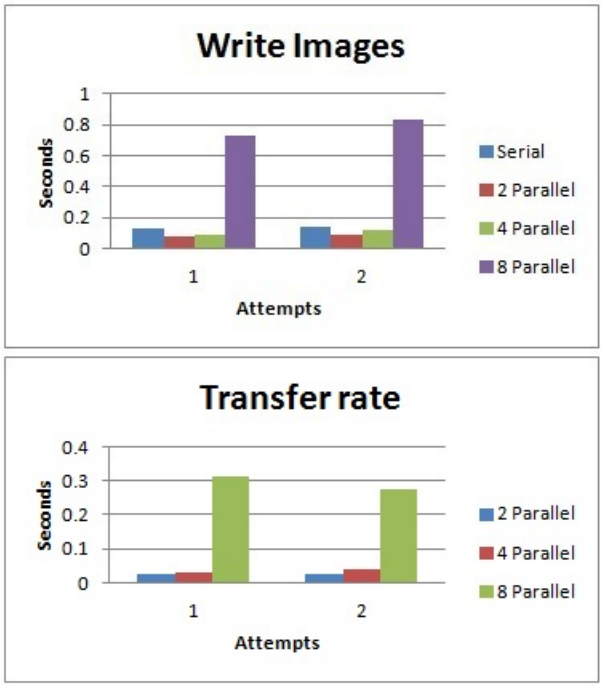

Figure 6. Written comparisons graphics and graph of transfer rate

about the 8 nodes and performance gain of 2 and 4 nodes. This gain is around 50 milliseconds and 33 respectively compared with serial mode. The transfer rate is shown in the second graph. This transfer rate is the measurement of the binary transmission from the server to the MASTER of the parallel application. Unlike the total time of the system, the transfer rate does not take into account other communications between the MASTER and the server, as well as communication between the application processes. Note that the speed of data communication is directly interconnected to the number of processes in the system.

V. Conclusion And Future Work

This work was done in order to show new results for the parallel architecture introduced earlier in [7], in order to detect failures and performance in reading and writing parallel of a DICOM image in HDF format. The environment is virtualized and configured with parallel virtual file system (PVFS) and HDF5, where more tests were realized to collect more consistent results.

The results showed a gain in reading and writing parallel, but the number of nodes exceeds the number of processing from the host machine, the performance of the architecture is low. Other problem in this system is the poor time of runtime system, provided by the communication between the server and parallel approach to transfer binary buffer. One solution to overcome the time problem is to move the H5wrap object to the master process, with goal to remove the necessity of binary transfer.

As future work, we intend that run parallel architecture in a real environment and dedicated to collect results that do not depend mainly on the processing power. Analyze the performance of system access in accordance with increasing the number of nodes. Finally, more tests with different types of DICOM modalities, mainly work with larger files.

Optimizing The Locking Methods in Distributed Database Systems

Mehdi Assefi
Dept. of Computer Engineering
Islamic Azad University, Neyshabur Branch
mhd_asefi@msn.com

Abstract

The main objective of this paper is to analyze the results of evaluation on different capabilities of concurrency control in Distributed databases, and examine different choices for locking and required settings on a sample database.

We have chosen the Oracle database of a paperless filing system as the basis for examining. In this distributed database, different transactions could access to a database through different stations and implement some basic operation on it. As we could assume, using a proper mechanism for concurrency control seems to be necessary. By evaluating possible choices and effect of their performance on the throughput of the system, and mean response time of transactions, we will try to evaluate pro and con for each method.

1. INTRODUCTION

As mentioned earlier, Oracle enables the developers to change the architecture of the database using the programming, and at the background. Host languages will give this chance to developers, by making connection with Oracle. using a proper mechanism for concurrency control seems to be necessary. By evaluating possible choices and effect of their performance on the throughput of the system, and mean response time of transactions, we will try to evaluate pro and con for each method.

2. Manual setting at the background

2.1. Using PL/SQL and Java

As you know, you can use a structural control for grouping SQL commands in a PL/SL block and then send the block to the Oracle.
it is also possible to use PL/SQL and Java procedures and reduce calling of the database in the program. For example, for running one SQL command, 10 calling will be needed, but for running a micro program containing 10 SQL commands, only one calling will be needed. This will reduce the network traffic. We can compile PL/SQL and Java procedures separately and put in a database. These procedures will be passed to PL/SQL motor after calling. Moreover, only one copy of these procedures must be loaded in the memory for being used by multiple user.

PL/SQL can also cooperate with Oracle developing tools such as Oracle Forums and Oracle Reports. By adding processing power, performance will increase. Using PL/SQL will cause calculation to be run more efficient and fast and without being called within Oracle. Result will be reduction of response time and network traffic.

2.2. Using advantages of row locking

Oracle enables databases to lock row of data and avoid locking the whole table. Row locking will make increasing of concurrency possible and many users will be able to access to the rows of a table. By this, performance will increase sharply.

2.3. Configuring parameters of a database

Using the host languages and applicable parameters, we are able to optimize the structure of a database. We hereby mention some of these parameters.

db_block_size

This parameter defines the size of blocks in the database. As we know, block is the scale for transferring information from the disk. By increasing the size of the block, we will have this chance to read all items that are at the same class. This will reduce the mean time needed by disk for accessing a unit of data. This parameter will be defined when we create the database and will be permanent. Precise identifying the size will be useful for preventing the information to become scrappy.`

db_cache_size

This parameter will identify the size of data buffer. Data will be read from disk and will be placed in this buffer in order to minimize access request to the disk. Results show that irregular increase of this buffer will drastically reduce the performance, which would be due to the extra burden posed on the operating system for buffer management and reducing the memory (result of occupying the buffer by data).

db_file_multiblock_read_count

This parameter identifies number of block which will be read in any referral to the disk.

Java_pool_size

In case if a database uses Java codes, proper set up for this section will have positive effect on the performance. This place creates a location in the buffer for putting Aplet Java codes.

large_pool_size

If database is supposed to transfer huge blocks, proper set up for this section will be very helpful. These objects will be considered when online backup is undertaken and object is loaded in the memory. Hereby list of these parameters for our database follows. We will change the parameters to evaluate the results.

3. Optimizing I/O parameters related to data involvement

In order to see the change in the events related to I/O, in any system we can use perfmon. By observing counters related to the system parameters, we could have required changes. Following parameters are available:

Disk reads/Sec	**number of reads per second**
Disk write / sec	**number of writes per second**
Disk transfer / sec	**number of transfers per second**
Avg. Disc Sec/Read	**average time spent for reading**
Avg. Disc Sec/Write	**average time spent for writing**
Avg Disc Sec/Transfer	**average time spent for reading and writing**
Avg Disk Queue/Length	**average number of I/O in I/O sub system**

For example, in the system that we analyze, I/O operations will be complete in 20-30 ms. If this amount increase from 6 ms for a disk, system will halt and database must be optimized.

3.1. Using UTLBSTAT and UTLESTAT

To useful parameters within Oracle are UTLBSTAT and UTLESTAT. There are some documents inside ORANT\RDBMS80\ADMIN folder that use internally by Oracle. When the database is going to be created, CATPROC.ORA and CATALOG.ORA will run from this folder. UTLBSTAT and UTLESTAT also run from this folder.

UTLBSTAT sets up internal tables and creates an instant photo from Oracle's internal counter. It will then create another photo after a high loaded operation by UTLESTAT and compares the results. UTLESTAT introduces number of complete counter values and a full statistical briefing during this period. It must be considered that UTLBSTAT.SQL and UTLESTAT.SQL both have a CONNECT INTERNAL string at top. Obviously both of these documents will have problem in NT. This row must be marked as explanation. For doing this, we put Rem at the beginning of them. UTLESTAT and UTLBSTAT could be run using SVRMGR30 application. After being connected to the database as INTERNA or SYS we can run UTLBSTAT as follow:

D:\ORANT\RDBMS80\ADMIN\UTLBSTT;

After a heavy load operation and after a considerable amount of time UTLESTAT must be implemented using the following pattern:

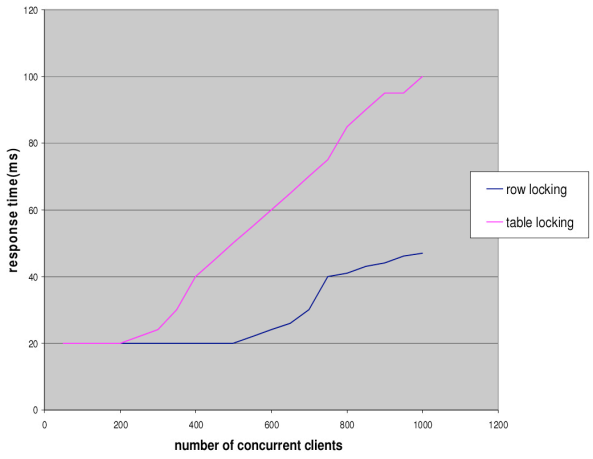
D:\ORANT\RDBMS80\ADMI\UTLESTAT;

4. Evaluating the performance

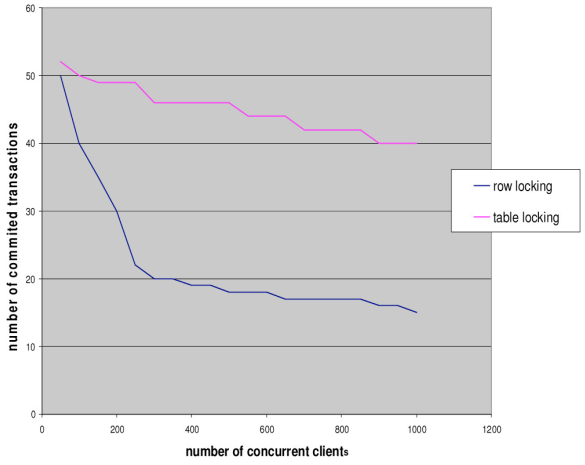
We now want to analyze the implementing time of our database's transaction considering different parameters. For increasing the work content and enhancing the workload, we will run transactions with increasing content on the database. We will then calculate the response time of the transactions, using the introduced calculation tools.

We first apply table locking rather than row locking. Results show that row locking will reduce the time that transactions need to access data, and in result response time will decrease and operational capability will increase. Chart related to the effect of these changes is depicted in the chart below.

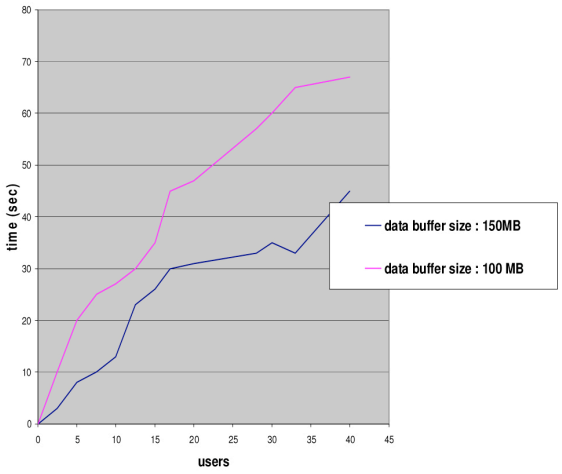
We use 100 MB and 150 MB buffers. Database volumes in both cases were 1.6 GB. We used IMPORT/EXPORT and INSERT commands in this evaluation. Number of clients was vary from 10 to 40. Results show that using a bigger buffer will result in reduction of the time needed by transactions to access the data, wich will reduce the operation time and will increase operational capability. Following charts will depict the effect of these changes.



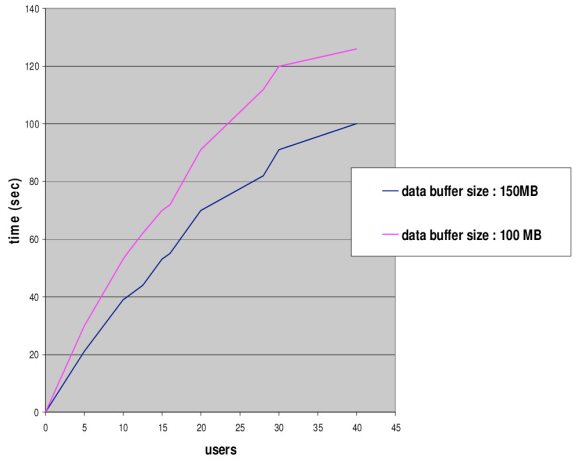
Effect of using row locking on transaction's response time



Effect of using row locking on throughput of system



Effect of using a bigger locking queue on response time of INSERT transaction



Effect of using a bigger locking queue on response time of IMP/EXP transactions

5. Summary

Oracle database is capable of doing manual setting using the programming. Majority of operation related to managing concurrency control is possible to be undertaken manually. The focus will be on increase or decrease on the length of queues and data buffers, and row locking and table locking. By considering system specifications ad proper adjustment for these parameters and other parameters of I/O, we will be able to considerably increase the performance of the database.

Abstract—*Acceleration of FDTD (Finite-Difference Time-Domain) is very important in computational electromagnetic. We propose a hybrid single/double precision floating-point computation to accelerate FDTD on GPUs. We apply single-precision when the dynamic range of the electromagnetic field is low and double-precision when the dynamic range is high. According to the experimental results, we achieved over 35 times of speed-up compared to the CPU implementation and over 1.79 times speed-up compared to the conventional GPU acceleration.*

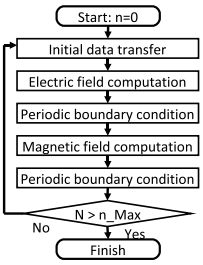
Keywords: GPGPU, FDTD, high-performance-computing

1. Introduction

Computational electromagnetic shows a rapid development recently due to the introduction of processors that have parallel processing capability such as multicore CPUs and GPUs (Graphic Processing Units). FDTD (Finite-Difference Time-Domain) algorithm [1] is one of the most popular method of computational electromagnetic simulation due to its simplicity and very high computational efficiency. It has been widely used in many applications such as coil modeling [2], resonance characteristics analysis [3], etc. Many of these applications require double precision floating-point computation to satisfy the stability condition [4].

There are many works that use GPUs [5] to accelerate FDTD. Such works consider how to parallelize the FDTD computation so as to use many nodes as possible. However, using more nodes means more cost and more power consumption. In this paper, we focus on extracting more performance from the same hardware by using high-precision computation only when it is necessary.

We consider the FDTD method used in resonance characteristics analysis of a cylindrical cavity [3] as the example application. We analyze the characteristics of the application and apply double-precision floating-point computation when the dynamic range is large and single-precision floating-point computation when the dynamic range is small. dynamic range refers to the ratio between the largest and the smallest values of electric (or magnetic) field. According to the experimental results, we achieved over 35 times of speed-up compared to the CPU implementation. This speed-up is almost 1.79 times of the conventional GPU acceleration.



(a) FDTD process

$$E_z^{n+1}(i,j) = E_z^n(i,j) - P_y(i,j)\left\{H_x^{n+\frac{1}{2}}(i,j+1/2) - H_x^{n+\frac{1}{2}}(i,j-1/2)\right\}$$
$$+ P_x(i,j)\left\{H_y^{n+\frac{1}{2}}(i+1/2,j) - H_y^{n+\frac{1}{2}}(i-1/2,j)\right\}$$
$$H_x^{n+\frac{1}{2}}(i,j+1/2) = H_x^{n-\frac{1}{2}}(i,j+1/2) - Q_y(i,j)\left\{E_z^{n+1}(i,j+1) - E_z^n(i,j)\right\}$$
$$H_y^{n+\frac{1}{2}}(i+1/2,j) = H_y^{n-\frac{1}{2}}(i+1/2,j) - Q_x(i,j)\left\{E_z^{n+1}(i+1,j) - E_z^n(i,j)\right\}$$

(b) FDTD computation

2. Hybrid floating-point computation

Figure 1(a) shows the FDTD algorithm [1]. It starts with an initial data of electric and magnetic fields. The initial data are processed to obtain the electric field for the first time step. After that, the boundary conditions are applied. Then the magnetic field data are obtained and the boundary conditions are applied. This process continues for n time steps. Figure 1(b) shows the electric and magnetic field computations. Electric and magnetic fields (in x, y, z directions) are denoted by E and H respectively. The coordinates of the 2D fields are denoted by (i, k).

To increase the speed-up, we observe the characteristics of our application [3]. According to [3], the electromagnetic field outside the cavity is weaker than that inside. Figure 2 shows the computation grid for FDTD calculation. The electric field far away from the grid origin has a small dynamic range. We observed similar characteristics from

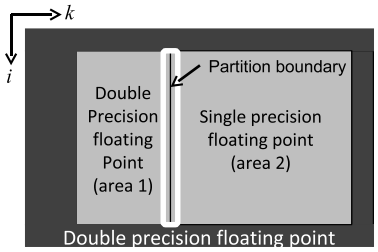

Fig. 3: Partition for single/double precision computation

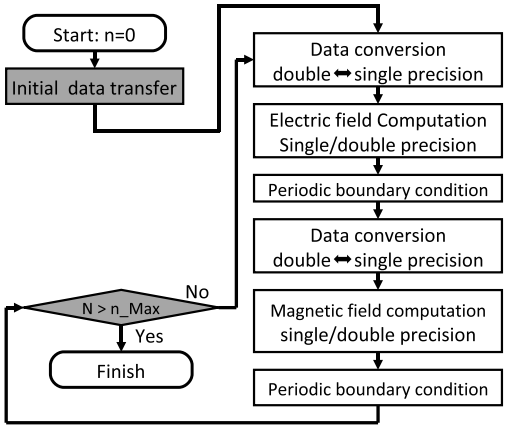

Fig. 4: Hybrid single/double precision computation

the magnetic field data analysis also. Therefore, we use double-precision floating-point when the dynamic range is large and single-precision floating-point when the dynamic range is small. As shown in Fig.3, the entire boundary and "area 1" are done in double precision floating-point while the rest of the computations in "area 2" are done in single precision floating-point. One problem in this method is the float-to-double conversion overhead. As shown in Fig.1(b), calculation of electric field of the coordinate (i, k) requires the magnetic fields at its left and right coordinates. Similarly, calculation of magnetic field of coordinate $(i, k + 1/2)$ requires the electric field at its left and right coordinates. To compute the electric and magnetic fields on the partition boundary in Fig.3, we need both double and single precision values that belong to area 1 and area 2 respectively. Therefore, we need float-to-double conversion and this is an additional overhead. Figure 4 shows the flow-chart of the hybrid single/double precision floating-point computation.

3. Evaluation

For the evaluation, we use Intel core i7 960 CPU and GeForce GTX 590 GPU. As shown in Fig.5, the proposed method is 1.79 times faster than the conventional double-precision GPU implementation [5]. Double-precision floating-point computation requires two CUDA cores while single-precision requires only one. This is the reason for the speed-up of the proposed method.

Figure 6 shows the processing time against the amount of double precision computation. Note that, the "double precision computation area" refers to the percentage of the

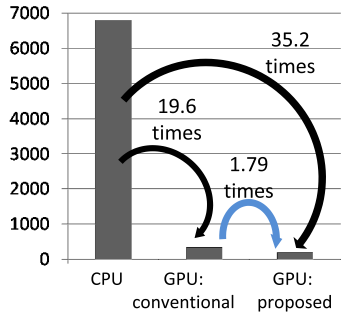

Fig. 5: Processing time comparison

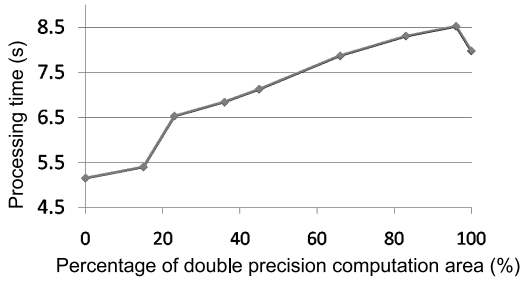

Fig. 6: Accuracy of the hybrid computation

grid area done in double-precision. The processing time increases with the amount of double precision computation. However, the processing time of "95% double precision computation" is larger than that of "100% double precision computation". This is due to the float to double conversion overhead in hybrid single/double precision computation.

4. Conclusion

In this paper, we proposed a hybrid single/double precision floating-point computation to accelerate FDTD on GPU. Since the amount of hardware required for double-precision is two times larger than that of the single-precision, we can increase the performance of the GPU by doing more computation in single-precision. However, due to the double-to-float conversion overhead, at least 85% of single-precision computation is needed for a considerable speed-up.
