Abstract— *The problem of efficiently assigning tasks to machines in heterogeneous computing environments with uncertainty in the availability of the compute resources is a challenging one. Previous research has looked at designing heuristics to maximize the total reward earned by completing tasks in an environment where compute nodes may randomly fail. The rewards associated with the tasks are earned if they are successfully executed before their deadlines. The goal of the resource allocation policies is to maximize the cumulative reward earned. We use heuristics from the literature and improved versions of some of the heuristics to perform the resource allocation decisions. We conduct extensive experiments to compare the performance of these heuristics in a variety of simulation environments. The goal of the study is to be able to recommend a heuristic to use based on the system environment. Our experiments show that different heuristics perform the best in different environments.*

Keywords: mapping, resource allocation, fault-tolerant, heterogeneity, rewards, deadlines

1. Introduction

Distributed computing is currently used to solve a host of problems where different tasks are mapped to separate machines for execution. These environments may be heterogeneous, which means different tasks may have varied execution times on the different machines. This makes it difficult to assign tasks to machines to optimize for a given performance metric. The process of allocating tasks to machines for execution is commonly referred to in the literature as "resource allocation" or "mapping." The mapping and scheduling problem has been known to be NP-Complete [1], and therefore one must use heuristics to get a solution to this problem. It is common for failures to randomly occur in the compute resources of these large-scale distributed systems. As a result, it becomes even more difficult to make resource allocation decisions while being aware of such failures. In this study, the goal of our resource allocation procedures is to maximize the total reward earned while executing the tasks in an environment where the machines may randomly fail.

This work was supported by the National Science Foundation under grant number CNS-0905399, and by the Colorado State University George T. Abell Endowment.

Fault-tolerance in distributed computing environments has been extensively studied. Check-pointing tasks to avoid restarting them from the beginning, in case they fail, is a common method used to alleviate the damage caused by the failure of resources [2], [3], [4], [5]. Replicating tasks is another method used to improve the reliability of the system [6], [4], [7], [8].

Shestak et al. [9] addressed the problem of making resource allocation decisions while being aware of the mean fail rates of the compute resources. To model a harsh environment the machines were made to have high probabilities of failure. They assumed that a bag of tasks is available and ready for execution. Each of those tasks has a reward and a deadline associated with it. The reward of a task is earned if the task is successfully completed by its deadline. If a machine fails while executing the task, the task is returned to the batch and may be re-mapped to another machine for execution. The goal of the resource allocation heuristics is to maximize the total reward that can be earned by executing the tasks before their respective deadlines expire.

The contributions of this paper are: (a) an enhancement in the prediction mechanism for some of the heuristics from the literature [9], and (b) a study of the performance of different heuristics on various environments that differ in their types of heterogeneities, rates for task executions and machine failures, and task re-mapping policies. We compare the relative performance of the heuristics in each of these simulated environments, and recommend the heuristic that one should choose to obtain the highest reward for each environment.

2. Problem Statement

The environment we model in this study and the goal of our resource allocation procedures are based on the work of Shestak et al. [9]. Each task has an associated reward that is earned if its computation is successfully completed by its deadline. The compute resources are assumed to have high probabilities of failure. When a machine failure occurs while executing a task, the task is returned to the batch and is eligible to be mapped to another machine. The task may fail multiple times, and it can be continually remapped to

constant	mach A	mach B	mach C
task class 1	4	4	4
task class 2	4	4	4
task class 3	4	4	4

column-varying	mach A	mach B	mach C
task class 1	5	2	4
task class 2	5	2	4
task class 3	5	2	4

inconsistent	mach A	mach B	mach C
task class 1	6	5	7
task class 2	9	3	4
task class 3	2	10	1

task-mach-consistent	mach A	mach B	mach C
task class 1	1	2	7
task class 2	3	4	9
task class 3	5	6	10

Fig. 1: Sample Estimated Time to Compute (ETC) matrices modelling different types of heterogeneity in an environment with three task classes and three machines

machines as long as its deadline has not expired. The goal of the resource allocation policies will be to map tasks to machines to maximize the total reward earned from all the tasks. In this study, we say that a heuristic is "robust" [10] if it can earn reward in an environment with uncertainties in task execution times and machine failure times. The higher the reward a heuristic earns, the more robust it is to such uncertainties.

We work with a bag of tasks that was available at the start of the simulation. Whether or not failed tasks are allowed to come back for mapping events may be a policy decision. Therefore, we consider both cases (allowing and not allowing failed tasks to re-map), and simulate both environments for experimentation purposes. We also model various types of heterogeneity of the computing environment, and gauge the performance of the various resource allocation procedures.

3. Environment Modeling

3.1 Modeling the Task Execution Times

An Estimated Time to Compute (ETC) matrix is used to model the execution time characteristics of the various tasks in the heterogeneous system. We use task classes to group together tasks that have similar execution time characteristics. Each entry t_{ij} in the ETC matrix gives the mean execution time of tasks of class i on machine j of our heterogeneous suite. The actual execution time of the tasks are modeled using exponential distributions with the means obtained from the entries of the ETC matrix. We use exponential distributions to model task completion times, based on the tests conducted at Ricoh InfoPrint [11]. For simulation purposes, we create and use synthetic workloads, but in real-world environments one could build such a matrix based on historical data.

We model and gauge the performance of various resource allocation policies under different types of ETC matrices. The different ETC matrices are used to model various types of heterogeneity of computing systems. We model four types of ETC matrices. Sample 3 x 3 ETC matrices for each of these types are shown in Figure 1. We model homogeneous workloads and homogeneous compute resources by having a fixed value for all the entries in the ETC matrix. We call this type of ETC matrix *constant*. We model another environment wherein the workload can be considered homogeneous, but the compute resources can be considered to have different computational capabilities. We model such an environment by having unique values for each of the columns of the ETC matrix, and refer to this matrix as *column-varying*. A completely heterogeneous environment is modeled by having random values for each cell in the ETC matrix. In an environment, modeled by such a matrix, it is possible (and likely) for a machine to be better than another machine for a particular task class and worse for another. Such a matrix is referred to as *inconsistent*. If we independently sort the elements within each of the rows of such an *inconsistent* ETC, and then independently sort the entries in each of the columns, we obtain what we call a *task-mach-consistent* matrix. In such an environment, if a machine executes a task faster than another machine, then it will do so for all tasks. Similarly, if a task executes faster than another task on a single machine, then it will do so on all machines. This type of matrix is well suited for some of the heuristics discussed later.

3.2 Modeling the Machine Failures

It has been shown in the literature that exponential distributions can be used to stochastically model hardware failures [12], [13]. In our environment, each machine has an exponential distribution associated with it to model the probability of failure, and for each machine j, we have a failure rate represented by λ_j.

Shestak et al. [9] have shown how a distribution of processor availability can be obtained using the average execution time of tasks on a machine j (referred to as t_j^{av}), and the failure rate of the machine λ_j. This probability mass function consists of as many pulses as there are machines in the environment. The distribution gives the relative probability of each machine to become available

for a mapping event. Machines become available for a mapping event under two scenarios: if they have successfully completed a task, or if they have encountered a failure. The distribution sorts the machines in an ascending order of their "quality." A machine has better "quality" if it has a lower value for $\lambda_j t_j^{av}$. Therefore, a machine that has a lower failure rate and/or a lower value for mean execution time, will be considered better. The Cumulative Distribution Function (CDF) of this probability distribution will be used to guide resource allocation decisions by some heuristics.

4. Resource Allocation Policies

4.1 Overview

In our environment, a mapping decision (deciding which machine to map a task to) is made whenever a machine becomes available for executing a task. Machines become available in two cases: when they successfully complete a task that was assigned to them, or when they have encountered a failure. We make an assumption that failed machines get instantly repaired and are available for executing tasks immediately. We use heuristics from the literature [9] as well as modifications to these heuristics to make mapping decisions.

4.2 Heuristics from the Literature

4.2.1 Reward Heuristics:

There are two heuristics that directly try to optimize the reward [9]. They are the *Reward* heuristic and *Expected Reward* heuristic. In *Reward*, whenever a mapping event occurs, the task that has the highest value for reward is assigned to the machine that just became available. In *Expected Reward*, when a machine becomes available for a mapping event, the task with the highest value for expected reward is assigned to it.

For a task i, $\underline{P_i(t)}$ is the probability (computed at time t) of successfully completing task i through multiple assignments before its deadline expires. The expected reward for a task i is given by the product $r_i P_i(t)$, where r_i is the reward that this task can earn if completed successfully. For any machine j, we represent by $\underline{p_j}$ the probability of machine j being available for an assignment. Also, the term $\underline{V_i(t)}$ is the estimated number of reassignments that task i may undergo starting at time t up to its deadline. The derivations of these terms are shown in [9]. $P_i(t)$ is calculated using the equation shown below.

$$P_i(t) = 1 - \left(\sum_{j=1}^{M} p_j (1 - e^{-\lambda_j t_{ij}}) \right)^{V_i(t)} \quad (1)$$

The term $(1 - e^{-\lambda_j t_{ij}})$ gives the probability of task i failing on machine j. This factor is weighed with the probability of machine j being available for an assignment (p_j), and therefore the weighted sum, $\sum_{j=1}^{M} p_j (1 - e^{-\lambda_j t_{ij}})$, gives the probability of failure when task i is mapped to a machine. Therefore, Equation 1 represents the probability that task i will successfully complete before its deadline, even through multiple assignments.

4.2.2 Matching Heuristics:

There are two heuristics in [9] that use the concepts of the Derman-Lieberman-Ross (DLR) Theorem [14] to guide mapping decisions. We call them the *Matching* heuristic and *Expected Matching* heuristic. A brief overview of the DLR theorem is given below, followed by the *Matching* heuristics that are implemented using the DLR concept.

The DLR theorem [14] provides an algorithm for optimally assigning a set of available workers to incoming jobs. Each incoming job is assumed to have a reward value associated with it. Each worker is assumed to have a probability (that represents the quality and skill of the worker), with which the reward earned for a job is scaled. It is also assumed that one has the distribution from which the reward values for all the incoming tasks are sampled from. Using the distribution of the reward values of the incoming tasks, and the notion of the skill of the workers (determined by their probabilities), the DLR method describes an algorithm that maps high reward tasks to better skilled workers and low reward tasks to lesser skilled workers. The distribution that dictates the reward values of the incoming jobs is vital to making these decisions.

The *Matching* heuristics [9] try to implement the DLR concept within the resource allocation problem. In our environment, machines become available for mapping events, and a task needs to be assigned to them. This is analogous to jobs coming in and looking for a worker that can be assigned to them. The distribution described in Section 3.2 is used to describe the quality and the likelihood of the incoming machine, analogous to the distribution that governs the likelihood of various reward values for the incoming job. The only other factor that needs to be accounted for is the ranking of the tasks, analogous to the ranking of the workers. It is in this aspect that the *Matching* and the *Expected Matching* heuristics differ. In *Matching*, the tasks are sorted based on their reward values. In *Expected Matching* the tasks are sorted based on their value of expected reward. As before, expected reward of a task i is given by the product $r_i P_i(t)$.

4.3 Modifications to Heuristics

We modify Equation 1 to incorporate the knowledge of the machine that just became available for a mapping event. Let us call the machine that just became available to be machine J. The probability that this machine will become available p_J will be 1, and by a similar logic $p_j = 0, \forall j \neq J$. Therefore, the summation term for this mapping event will reduce to $(1 - e^{-\lambda_J t_{iJ}})$. We know that this counts as an assignment for task i, and therefore we extract the term

$(1 - e^{-\lambda_J t_{iJ}})$ out, and reduce the count of the number of reassignments of task i (denoted by $V_i(t)$) by one. This gives us our new equation for $P_i(t)$.

$$P_i(t) = 1 - (1 - e^{-\lambda_J t_{iJ}}) \times \left(\sum_{j=1}^{M} p_j (1 - e^{-\lambda_j t_{ij}}) \right)^{V_i(t)-1} \quad (2)$$

We create the *Latest Expected Reward* and the *Latest Expected Macthing* heuristics that are similar to the *Expected Reward* and *Expected Matching* heuristics, but with the difference that they use Equation 2 for their expression of $P_i(t)$ instead of Equation 1. This is to denote the fact that they use the latest information to compute $P_i(t)$.

For experimentation purposes, we also model an environment where tasks are not allowed to come back when the machine they were assigned to failed. In such an environment, the value of $P_i(t)$ is simply calculated using the equation given below.

$$P_i(t) = e^{-\lambda_J t_{iJ}} \quad (3)$$

5. Simulation Setup

In this study, the workload that we are modeling consists of independent tasks, i.e., no communication is required between the individual tasks, and there are no precedence constraints. Each task is sequential (i.e., not decomposable into parallel parts). It is also assumed that each machine can handle only one task at a time (no multitasking).

We modeled different ETC matrices, as described in Section 3.1. The entries of the ETC matrix represent the mean execution time values of the different task classes on the different machines. We modeled two types of environments; the *narrow* and the *broad* environments. For the *narrow* environment, the entries of the ETC matrix were uniformly picked at random from the range [0.5, 4.0], whereas for the *broad* environment they were uniformly picked at random from the range [0.5, 9.5].

The values of the mean times to failure for the machines were also randomly picked from a range depending on the environment that was being modeled. For the *narrow* environment, the range was [0.6, 1.0], whereas, for the *broad* environment, the range was [0.6, 2.375]. Therefore, the *broad* environment has wider ranges for the possible values of the execution times of the tasks and the times between failure for the machines in comparison to the *narrow* environment.

Similar to the environment studied by Shestak et al. [9], we model an environment with 200 tasks, six machines, and five task classes. Each task is randomly assigned to one of the five task classes. The ETC matrix has task classes along its rows, and machines along its columns, and therefore the size of the ETC matrix is 5 x 6. For each task, the reward value was assigned by randomly picking an integer in the range [1, 100]. All the tasks in a task class have a common deadline. The deadline for a task class was set to six times the longest execution time of this task class across the machines.

There were three main parameters that we varied to alter the environment being modeled. The first was whether or not we allow failed tasks to return back to the batch for further remapping. The second was whether we use the *narrow* or *broad* environment. The final parameter was the type of ETC matrix used. We modeled four types of ETC matrices: *constant*, *column-varying*, *inconsistent*, and *task-mach-consistent*. We ran tests with all combinations of these various parameters.

6. Experimental Results and Analysis

The goal of this study is to compare and evaluate the performance of the heuristics under a variety of scenarios to be able to choose which heuristic to use for different environments. Therefore, it serves to only compare the relative performance of the heuristics with each other under the various scenarios, as opposed to comparing the absolute performance of a heuristic across the scenarios. It would also be inaccurate to make such a comparison, because the different scenarios have different execution time characteristics and different handling methods for dropped tasks. These can result in different values for the total reward earned by the same heuristic under these varied environments.

For each simulation case, 100 trials were performed and the results were averaged and 95% confidence intervals were calculated. For each trial, new values were used for the following: the entries of the ETC matrix, reward values of the tasks, and fail rates of the machines.

We observed that the *Expected Reward* heuristic did not perform better than the *Latest Expected Reward* heuristic for any of the test cases. The *Latest Expected Reward* heuristic is able to use the most recent information to its advantage while calculating the probability of a task successfully completing. The significant benefit earned by using Equation 2 as opposed to Equation 1 comes from the fact that we are able to factor out the current machine from the summation, thus avoiding distorting the probability of failure for this first mapping event.

From our experiments, we also observed that the *Latest Expected Matching* heuristic performed better than both the *Matching* and the *Expected Matching* heuristics. Therefore, in Figure 2 we only show the results for the *Reward*, *Latest Expected Reward*, and *Latest Expected Matching* heuristics. Each of these three heuristics perform better than the other two heuristics for at least some of the environments.

Figure 2 shows the results for the *Reward*, *Latest Expected Reward*, and *Latest Expected Matching* heuristics for the various types of environments that we modeled. Figures 2(a) and 2(b) show results from the case where re-mapping of failed tasks is allowed. Figures 2(c) and 2(d) shows

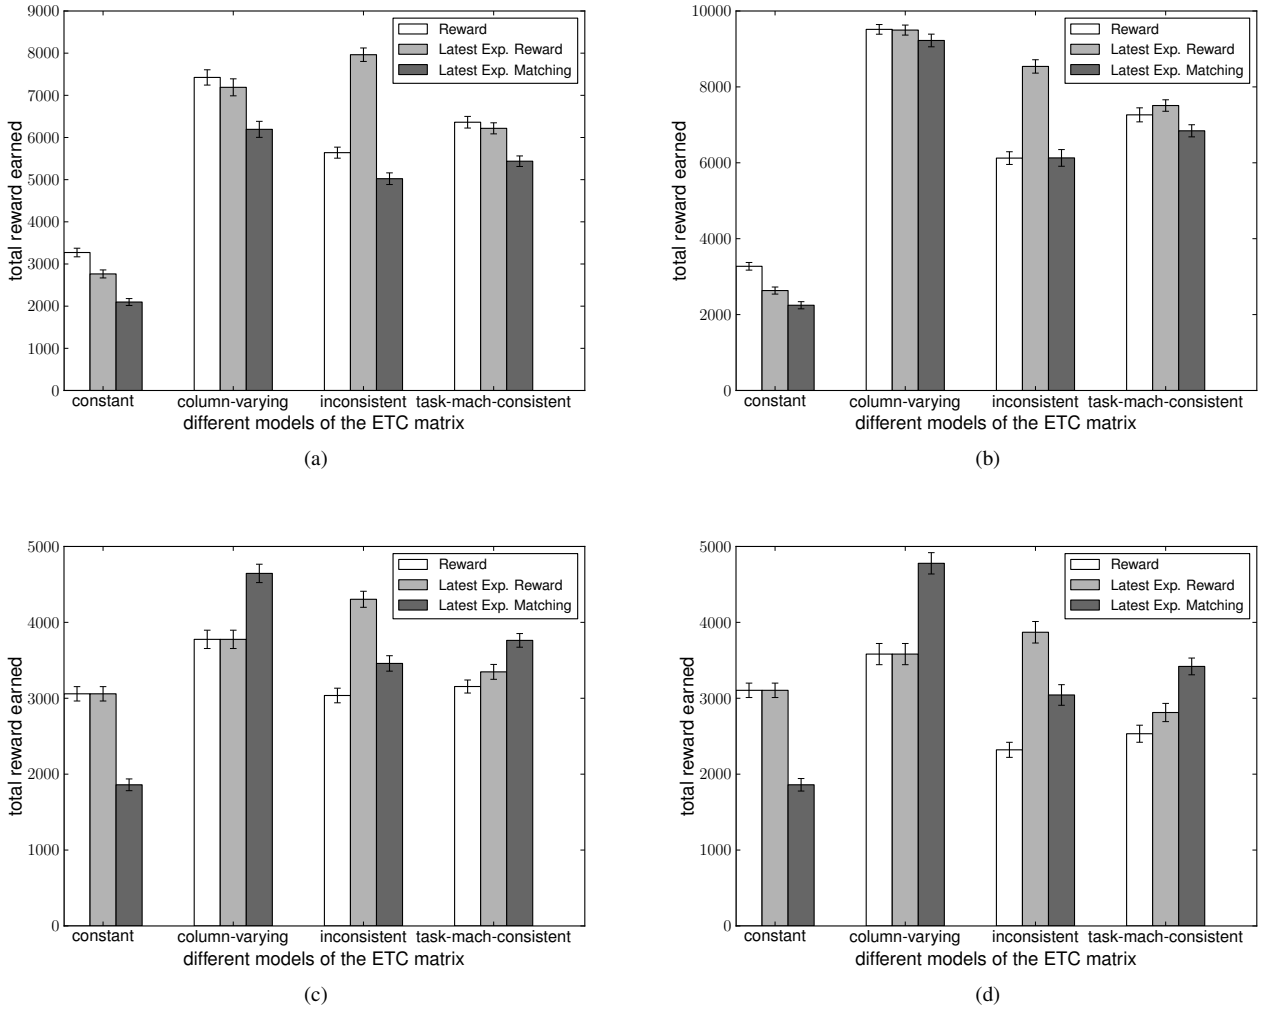

Fig. 2: Results showing the total reward earned by the *Reward*, *Latest Expected Reward*, and the *Latest Expected Matching* heuristics in (a) the *narrow* environment with re-mapping allowed, (b) the *broad* environment with re-mapping allowed, (c) the *narrow* environment with no remapping, and (d) the *broad* environment with no remapping. The results are averaged over 100 trials and the error bars show 95% confidence intervals.

results with the case where each task can be mapped to a machine only once. Figures 2(a) and 2(c) have results from the *narrow* environment. This determines the ranges of the mean execution times of the tasks and the mean fail times of the machines. Figures 2(b) and 2(d) show results for the case with the *broad* environment. For each of these charts, along the independent axis are the results of the three heuristics for the various types of ETC matrices that we modeled, i.e., *constant*, *column-varying*, *inconsistent*, and *task-mach-consistent*. It is worth noting that our goal will be to compare the relative performance of the three heuristics for any given scenario (i.e., comparing the bars within the set of three) as opposed to comparing the results across scenarios.

The *Reward* heuristic performs the best among the three heuristics when we have a completely homogeneous environment (i.e., modeled by the *constant* ETC matrix) irrespective of whether or not tasks are allowed to come back, and whether we use the *narrow* or the *broad* environment. Note that in the case when tasks are not allowed to come back (Figures 2(c) and 2(d)) and when the *constant* or the *column-varying* ETC matrices are used, the *Latest Expected Reward* and the *Reward* heuristic have equal results. On average, the total reward earned by the *Reward* heuristic was at least a 45% improvement over that earned by the *Latest Expected Matching* heuristic when the *constant* ETC matrix was used. This can be attributed to the fact that the *Reward* heuristic directly optimizes for reward, and in an environment where all tasks perform similarly across all machines, the benefits

obtained by performing a matching of tasks and machines is reduced.

In cases where the environment is heterogeneous (i.e., models of the ETC matrix other than *constant*), the *Reward* heuristic beats the *Latest Expect Matching* heuristic when failed tasks are allowed to come back for mapping events (Figures 2(a) and 2(b)). This trend is reversed when failed tasks are not allowed to come back (Figures 2(c) and 2(d)). The *Latest Expected Matching* always does better than the *Reward* heuristic (except the case with the *constant* ETC) when failed tasks are not allowed to come back for re-mapping. Also, in general the relative performance of the *Latest Expected Matching* heuristic is better in such environments. Unlike the other heuristics, the *Latest Expected Matching* heuristic, tries to match "better" tasks (those that have a higher value for expected reward) to "better" machines (those that execute faster, and fail less often). This is particularly helpful when re-mapping is not allowed, because in this case, each task only gets one chance to be mapped to a machine. The *Latest Expected Matching* heuristic performs the best in this case because it holds on to the better tasks until a good machine comes in for a mapping event. The *Reward* (or the *Latest Expected Reward*) heuristic simply assign the task with the highest reward (or expected reward) to the next available machine.

The *Latest Expected Matching* heuristic performs better than the *Latest Expected Reward* heuristic when the environment uses the *column-varying* ETC matrix or the *task-mach-consistent* ETC matrix and when failed tasks are not allowed to re-map. This is because in such environments it becomes easier for the *Latest Expected Matching* heuristic to be able to designate some machines as being better than the others. This helps the heuristic rank the machines in terms of their "quality" and as a result provides better mapping decisions. Moreover, when we use the *broad* environment as opposed to the *narrow* environment, the relative performance benefit of this heuristic increases. This is because there is more variance in the performance of the machines and the *Latest Expected Matching* heuristic is able to use that to its advantage as it makes its decisions by ranking machines in terms of their goodness. The more the difference between the performance of the "good" and "bad" quality machines, the more the benefit of using the *Latest Expected Matching* heuristic.

When we use an *inconsistent* ETC matrix it becomes hard for the *Latest Expected Matching* heuristic to rank the machines. This is because in a highly inconsistent heterogeneous environment, a machine may perform better than another machine for one task, but may perform worse for another task. This makes it harder for the *Latest Expected Matching* algorithm to be able to rank the machines in a global manner in terms of their "quality." Therefore, we see that the *Latest Expected Reward* heuristic always performs better when we model the environment with an *inconsistent* matrix. It performs much better than the *Reward* heuristic in all *inconsistent* ETC matrix cases, because it calculates the expected reward (viz. the probability of earning some reward amount) by looking at the execution time values of the tasks. The *Reward* heuristic fails to look at the heterogeneity of the system while making its mapping decisions, and therefore performs poorly.

In summary, the *Latest Expected Matching* heuristic performs the best when the environment being modeled is similar to the environment of the DLR theorem [14] (on which this heuristic is based), i.e., re-mapping of tasks is not allowed, and the machines can be ranked clearly in terms of their performance (modeled by *column-varying* and *task-mach-consistent* types of ETC matrices). The *Reward* heuristic performs the best when the environment is completely homogeneous (modeled by the *constant* type of ETC matrix), because the execution times are the same for all tasks and machines. The *Latest Expected Reward* heuristic performs the best compared to the other heuristics in a highly heterogeneous environment (modeled by the *inconsistent* type of ETC matrix) because it optimizes for not just the reward value but also the likelihood of earning that reward.

7. Related Work

The scheduling problem has been widely studied in heterogeneous computing environments (eg., [15], [16], [17]). It is important to make the resource allocations be fault tolerant, especially in distributed and grid computing environments. Various techniques have been used to cope with the ill-effects of failures of compute resources. Checkpointing and rollback-recovery are common techniques used to avoid having to restart failed tasks from the beginning (e.g., [2], [3], [4], [5]) (as mentioned in Section 1). Another method used to improve the reliability of the system, in terms of increasing the chances of completing tasks, is to run replicas of the tasks on multiple compute resources (e.g., [6], [4], [7], [8]).

Shestak et al. [9] addressed the problem of maximizing the reward earned by the tasks in an environment where the compute nodes may randomly fail. Their work used the concepts of a theorem introduced by Derman et al. [14]. There have been other works on scheduling that look at maximizing reward earned by the tasks [18], but they do not model environments where the machines tend to fail. Our study builds on the work done in [9] to perform a comparative study of the performance of the heuristics under a variety of system environments.

8. Conclusions and Future Work

The goal of this study was to be able to model and characterize various system environments and gauge the relative performance of fault-tolerant heuristics in these environments. This study extends the work of Shestak et

al. [9] by addressing a similar problem, but performing extensive tests on a wide-range of environments. We also modified and improved the prediction mechanism of the *Expected Reward* and the *Expected Matching* heuristics by using the latest information we have about the system. We simulated a variety of environments by changing different attributes associated with the environment. Our results show that the *Reward*, *Latest Expected Reward*, and the *Latest Expected Matching* heuristics have different strengths and weaknesses, therefore performing better or worse depending on the environment.

One direction for future work is introducing a delay before a failed machine returns for a mapping event. This will help us to more closely model a realistic environment. Also, we may try to modify the *Latest Expected Matching* heuristic to make it more heterogeneity-aware. It would also be interesting to modify the workload to have tasks whose reward values degrade with time, instead of having a fixed reward value until a hard deadline.

GPU Acceleration of Genetic Algorithms for Subset Selection for Partial Fault Tolerance

D. Foster
Electrical and Computer Engineering Department, Kettering University, Flint, MI, USA

Abstract - *As reconfigurable logic devices see increasing use in aerospace and terrestrial applications, fault tolerant techniques are being developed to counter rising susceptibility due to decreasing feature sizes. Applying fault-tolerance to an entire circuit induces unacceptable area and time penalties, thus some techniques trade area for fault tolerance. Area-Constrained Partial Fault Tolerance (ACPFT) is a methodology that explicitly accepts a device's resources as an input and attempts to find a maximally fault-tolerant subset, but determining an optimal partition is still an open problem. While ACPFT originally used heuristics for subset selection, a modification called ACPFT-GA has been developed that uses genetic evolution to provide significantly better fault coverage in many applications. However, its running time is substantially longer than standard ACPFT and may be prohibitive. This paper presents a GPU-accelerated version of ACPFT-GA that has executed over 27 times faster than CPU versions, allowing ACPFT-GA to better scale to larger circuits.*

Keywords: Genetic algorithms, partial fault tolerance, reconfigurable logic, GPU programming

1 Introduction

Two options for a system's processing device are general purpose processors (GPU) and application specific integrated circuits (ASIC). The GPU offers great flexibility but low relative computational power. An ASIC can be designed to provide the greatest processing capability, however this requires a lengthy and very expensive design process, and it is extremely costly for small production runs. A reconfigurable logic device such as a field-programmable gate array (FPGA) offers an attractive third alternative. They provide high levels of computational power like ASICs, yet their ability to be reprogrammed gives flexibility like GPUs. They are off-the-shelf devices and therefore do not have the lead times of ASICs. These features make them common choices in the low production runs of aerospace applications, and they are increasingly used in terrestrial systems. However, they may contain millions of bits to store configurations, and this makes them more susceptible to faults caused by electromagnetic radiation than GPUs and ASICs. Aerospace systems are currently concerned with errors due to single event upsets (SEUs), and as transistor feature sizes continue to shrink, terrestrial systems are also becoming wary[1, 2].

Many applications using reconfigurable logic are not safety critical. A failure can be tolerated by ignoring the error and continuing, such as in video playback. In other cases, the operation can be reattempted, such as retransmitting dropped packets in network communication. However, a reduction of faults would clearly improve the user experience. Since systems implemented with reconfigurable logic invariably leave a portion of the device unused, these extra device resources can be leveraged to provide some level of partial-fault tolerance and reduce the fault rate. The problem of applying partial fault-tolerance can then be formulated as follows. The logic cells contained with the original circuit must be partitioned into a protected subset and non-protected subset such that the fault-coverage is maximized given a set amount of additional logic resources. With current logic devices having hundreds of thousands of logic cells, this presents a gigantic solutions space.

A method of partial fault tolerance called Area-Constrained Partial Fault Tolerance (ACPFT) has been developed that accepts a circuit's available area as an input and finds a maximally fault-tolerance version of the circuit. This initial implementation utilizes difference heuristics to determine a partition, and it generally executes very quickly. A second version called ACPFT – Genetic Algorithm (ACPFT-GA) uses genetic evolution to explore the solution space. It was found to produce significantly more fault-tolerant circuits in expected application spaces, but the running times of ACPFT-GA can be two orders of magnitude larger than ACPFT's. To provide the fault coverage of ACPFT-GA with a more acceptable execution time, the research presented here accelerates ACPFT-GA using NVIDIA CUDA, which is a popular programming extension for running scientific computations directly on massively-parallel graphics processors. This results in an average speed-up of around 17 to 18 times over standard ACPFT-GA with some cases showing speedups of over 27 times.

This paper is organized as follows. Section 2 reviews the key concepts of ACPFT-GA, other efforts to accelerate genetic algorithms with CUDA, and the key considerations when developing with CUDA. Section 3 describes the implementation of ACPFT-GA, the tool chain, and the particulars of casting it as a CUDA-based algorithm. Section 4 presents the experimental results, and Section 5 concludes the paper.

2 Background

2.1 Partial Fault Tolerance

Since this paper focuses on the acceleration of ACPFT-GA and not the introduction of ACPFT-GA itself, readers are referred to [3] and [4] for the justifications of partial fault tolerance in reconfigurable logic. These summarize the advances in partial fault tolerance along with alternatives to ACPFT such as the BYU-LANL partial TMR tool [5], partial error masking [6], selective TMR [7], and Automatic Insertion of Partial TMR [8]

Triple modular redundancy (TMR) remains the standard fault-tolerance method for FPGAs [9]. It can be applied to circuits regardless of the function and of the logic cells used, and it often adds a minimal delay compared to other methods. TMR almost completely protects a circuit against a single fault, although voting logic may still be susceptible. However, it more than triples the circuit's size with a corresponding increase in power use. [10]. These advantages make TMR the most common basis for partial fault-tolerance.

Area-Constrained Partial Fault Tolerance is a technique that uses partial TMR to reduce the circuit area susceptible to faults even if the majority voters are not considered ideal, meaning that they can suffer faults also [3]. Ideal voters is an assumption often used for simplification in other methods because when a large subset of the circuit is being protected, the cross-sectional area of the majority voters is significantly smaller than the tripled area, perhaps by several orders of magnitude, and the rate of faults in the voters is considered to be negligible. This assumption is invalid in a fine-grained approach where the protected area and majority voters have comparable areas. ACPFT was originally designed to use several heuristics and metrics to determine a maximally fault-tolerant partition of a circuit's logic cells.

ACPFT maps well to genetic algorithms since it is similar to the familiar knapsack problem. In knapsack, there is a set of items, each with a weight and a value, and a knapsack that can hold a fixed weight. The optimization problem is to select a subset of items that can be carried in the knapsack with the maximum total value. The additional area of the FPGA relates to the knapsack, and the logic cells with their areas and sensitivities to faults relate to items with weight and value. However, the fault-tolerance problem is more complicated since the additional area required by each logic cell is not a constant value. It is a function of the other cells being protected. Previous research demonstrates that even simple genetic algorithms can create more fault-tolerant partitions than heuristic methods under common conditions, namely that the amount of additional resources available for fault tolerance is less than the size of the unprotected circuit [4].

2.2 Fundamentals of CUDA

CUDA is an extension to several common programming languages, prominently C and C++, which requires an NVIDIA-based graphics processor for execution. NVIDIA GPUs are widely deployed and thus represent a very common computing platform. For easy scalability, NVIDIA cards are designed around a generalized processing unit called a streaming multiprocessor (SM). This allows the performance of CUDA applications to scale based on the number and hardware implementation of the SMs contained on a given card. Details of NVIDIA GPUs can be found at [11].

Since the underlying hardware architecture of a GPU is drastically different than a CPU, algorithms must be crafted using several critical concepts in order to make efficient use of the GPUs computational power [12]. Since GPU-based cards have either a small cache system or none at all, they rely on massive thread parallelism to hide memory access latency by executing a different group of threads when one group block on a memory operation. Therefore, an algorithm must be able to extract sufficient parallelism from a problem to occupy the GPU's thread slots and mask this latency. Second, main memory accesses are efficient only when reading from contiguous memory locations. Data structures and memory accesses should be structured to use this coalesced pattern. Third, a GPU offers several different types of physical memory, such as the large global RAM, small local shared memory, constant memory, per-thread registers, and so on. Careful design should use the most appropriate memory type. Finally, an NVIDIA GPU executes threads in groups called warps. For each clock cycle, all of the threads in a warp or half-warp must either execute the same instruction or do nothing. When threads within a warp execute different code, called divergence, more and more threads will remain idle per clock cycle, and the processing power of the GPU is under-utilized.

With well-crafted algorithms designed with the above considerations, GPUs can potentially execute algorithms significantly faster than CPUs. GPUs can also solve problems using an estimated one tenth to one twentieth of the power required by traditional supercomputing systems [13], thereby reducing costs.

2.3 CUDA as a Platform for Evolutionary Algorithms

CUDA is already established as a popular platform for evolutionary computing. Examples can be found for simple genetic evolution [14] and differential evolution [15]. Ant colony optimization has also been explored [16-18] as well as particle swarm optimization [19-21].

In many evolutionary techniques, the execution time to evaluate the fitness function is a significant fraction of the algorithm's overall time, as is the case with ACPFT. Thus, even though there have been many implementations of evolutionary algorithms using CUDA, and the common operations are becoming well-understood, it is still crucial to explore efficient implementations of new, unique fitness functions and common evolutionary operators that support them.

3 Implementation

3.1 Genetic Algorithm Structure

The solution to the partial fault tolerance partitioning problem is coded as an ordered array of bytes in which each byte corresponds to a specific logic cell in the circuit. The byte's value is '0' if it is in the non-protected partition and '1' if it is in the protected partition. One byte is used per gene in the chromosome instead of one bit since other values are used temporarily during the constraint satisfaction check described later.

The algorithm randomly selects some chromosomes for mutation, choosing those with higher fitness functions proportionally more often. Each gene is examined for random mutation. Mutation results in the binary value being flipped. For crossover, chromosomes are selected in pairs. One gene is randomly selected as the location for single point crossover. Two new chromosomes are created from each pair selected. Mutation is not performed on chromosomes created by crossover.

The fitness function is simply the number of 1's in the chromosome, representing the number of logic cells that are in the protected subset. Previous research has shown that this correlates very highly with the actual amount of fault coverage provided. However, the complexity in ACPFT-GA is that the chromosome must represent a circuit that can fit within the available logic resources. Therefore, the chromosome is processed such that it represents a circuit with ACPFT correctly applied. In this format, a gene is '0' if it is unprotected, '1' if it is a protected and tripled cell, and '2' if the cell is tripled and connected to a majority voter. With this format, the amount of logic resources can be calculated and compared to those available. If the resulting circuit violates the constraints, the chromosome's fitness is set to a value lower than any possible valid chromosome. It is not culled since further evolution may result in a valid chromosome again.

3.2 Tool Chain

Each circuit is represented in a net list in the common EDIF format. ACPFT was written in Perl to accommodate reading and processing this input file and altering it for the partially protected output file. When using heuristics, the partitioning is processed with the Perl script. If the genetic evolution is selected, the ACPFT Perl script parses the EDIF net list outputs a condensed version of the net list in a text file. A C++ program then imports this formatted net list, performs the genetic evolution with or without using a GPU, and outputs the best chromosome. The ACPFT in turn uses this chromosome to partition the circuit and creates the proper modifications of the EDIF net list that can then be implemented on an FPGA. The script also generates a user constraint file to prevent the FPGA tools from removing the redundant logic cells. Currently, the ACPFT tools are run manually, but they are designed such that they could be easily inserted into the standard FPGA design flow and automated.

3.3 CUDA Implementation

The chromosomes are stored in a 2-dimenional array of characters in which each row corresponds to a complete solution. The array contains enough rows to hold all the members of the current generation and those created by mutation and crossover for the next. Once this entire array has been scanned to determine which chromosomes should be carried into the next generation in order of decreasing fitness function, the appropriate chromosomes are copied into a second identical array, and this second array is then the source of members for the next loop.

The GPU's constant memory was used to store many invariants of the net list, such as logic cell type, numbers of destination cells, and lists of destinations cells. It was also used to hold many kernel parameters that are fixed for a given evolution. None of these values are required to be in constant memory for the algorithm to function, so they could be moved to global memory if the circuit is too large for constant memory.

The pseudo code below shows the basic steps that are performed per generation by ACPFT-GA.

1. Generate array of pseudo-random values
2. Randomly select chromosomes for mutation and crossover
3. Create new chromosomes by mutation
4. Create new chromosomes by crossover
5. Calculate fitness function and validate constraints
6. Reorder the array of chromosomes.

CUDA has a random number library called cuRAND that has a CPU-only version. It is used in the CPU implementation so that both the CPU and GPU versions use the same pseudo-random sequences and generate identical output. Also, the cuRAND number generator is effective when generating large batches of values, so it is called once at the beginning of the loop to create all random values for that iteration.

In step 2, some random values are used to select chromosomes for steps 3 and 4. The fitness values of the chromosomes are summed, and each chromosome is assigned a range of values equal to its fitness. Each random number is scaled to the sum of fitness values, and then it is compared to the chromosomes' ranges to determine which is selected. In the GPU version, this operation is performed on the GPU. The kernel is written so that each block is 256 threads, each one converting one floating point random number to an integer corresponding to a chromosome. The number of blocks required is the ceiling of the number of chromosomes needed in the next two steps divided by 256. With the values tested, there were far too few blocks to fully occupy the card, but it is more efficient than transferring data to the CPU for computation.

In step 3, the algorithm selects a chromosome based on the indices from step 2, and it checks each gene for a mutation using random values still remaining from step 1. On the GPU implementation, one block is launched for each chromosome being mutated. The block size is set to 256, with each thread

checking every 256th gene for mutation. This allows the SM of a revision 2.0 GPU to hold 6 blocks, and the number of blocks/chromosomes needed to fully utilize the card is only a few dozen to a couple hundred.

The crossover step is similar to the mutation step, using indices from step 2 and the remaining random values from step 1. A pair of chromosomes is handled by one block, and each block uses 256 threads, again with each thread processing every 256th gene. Twice the number of chromosomes is needed to occupy the GPU than in step 3, but this number was easily reached.

Step 5 is by far the most complex. At this point, a chromosome contains only 1's and 0's representing the protected and non-protected subsets of logic cells. In ACPFT, each protected cell must be tripled, requiring three of that type of logic cell. For each tripled cell, all of the cells that use its output and are still classified as non-protected must be tripled and then combined with a majority voter. This step is performed first and is designed for as many coalesced accesses as possible, although some are unavoidable when examining a cell's destinations.

Once cells have been promoted to tripled and voted, each cell with a voter is examined to see if all destination are tripled or voted. If so, the logic cell can be converted to a tripled cell, increasing the size of the protected subset and actually freeing some resources used for voters. This step also has coalesced and non-coalesced accesses.

After this step, the fitness function is calculated with a reduction from the CUDA thrust library. The sum consists of the sensitivities for all cells that are in the protected subset, ignoring cells that are single or tripled. Next, the constraint condition is checked. Each logic cell adds a count to the logic cells used based on its state. Single cells add one to the like type, tripled cells add three to the like type, and voted cells add three to the like type and one to the type used for voters. These counts are contained in shared memory and require atomic addition instructions to avoid races.

Once all of the logic cells are accounted for, one thread compares the needed resources to the available resources. If the constraints aren't met, the fitness value is adjusted to 1.0, so that the invalid chromosome still has a small chance of being selected in the next generation. Further mutation and crossover may again result in a valid cell.

The CUDA thrust library is used in step 6. The fitness values are sorted and the new chromosome order is determined using these optimized sorting functions. Another thrust function calculates the prefix sum used for the chromosomes ranges. Finally, a kernel uses the new order to copy the best chromosomes from the current chromosome array into the second array, and the pointers to these arrays are swapped in preparation for the next generation.

4 Testing and Results

ACPFT-GA was tested using the *alu4*, *apex2*, and *pdc* circuits from the ACM/SIGDA "Big 20" benchmarks. These circuits were chosen since they show a range of circuit sizes with 597, 1056, and 1328 logic cells respectively. They have also been used in previous research, and data exists for comparisons.

As with previous ACPFT experiments, the performance given different amounts of available resources is accomplished by creating an array of theoretical FPGAs of varying sizes. The number of logic cells in each circuit is used as a "perfect-fit" FPGA. Larger devices are emulated by increasing the number of each resource by a constant multiplier and rounding down. This method created up to 23 theoretical FPGAs, from 10% to 230% in increments of 10%. Between 210% and 230% depending on the test circuit, there were sufficient resource for full TMR, and partial fault-tolerance would no longer be necessary.

The genetic algorithm parameters were selected to match those used in [4]. The test used a set of 4096 chromosomes. For each circuit, the mutation factor was the reciprocal of the number of logic cells. In each generation, the top 256 chromosomes were carried over into the next generation. 1920 were selected using elitism for mutation, and each gene was checked for a mutation. The remaining 1920 chromosomes were generated by crossover. Mutations were not applied to chromosomes created through crossover. Like the previous work, each initial chromosome was initialized to a string of "0"s, representing a fully unprotected circuit. Three more experiments were performed using the output of a heuristic method from previous research to initialize the chromosomes. The fanout method was chosen since it yielded very good results and had a low execution time. For the second experimental setup, all additional resources were supplied to the fanout method, and then the result was refined with the genetic algorithm. In the third and fourth setups, the fanout method was supplied 10% fewer and 20% fewer resources than available respectively. In these cases, there were still some unallocated logic cells when the genetic algorithm was applied.

The test computer used a Core i7 processor at 2.8 GHz, 6 GB of RAM, a GTX 480 graphics card, and CUDA SDK 4.0. ACPFT-GA was run ten times on each simulated FPGA using just a CPU and then using the GPU. Each test was allowed to run for 1000 generations. The times required for mutation, crossing, and calculating the fitness functions and constraint conditions were logged for all runs.

The mutation time, crossover time, fitness function and constraint checking time, and total execution time are shown in the following tables. Times are shown for the CPU-only version, the GPU accelerated version, and the speedup of the GPU version relative to the CPU version. The data for *alu4*, *apex2*, and *pdc* are shown in Table 1, Table 2, and Table 3 respectively for the tests that begin with no initialization, i.e. all available resources are unused and selected only by the genetic algorithm. The data for tests in which 20% of the resources are left unused, and the chromosomes are initialized with the output of ACPFT using fanout are shown in Table 4, Table 5, and Table 6 for *alu4*, *apex2*, and *pdc* respectively. The data for the other two tests are not shown due to space limitations, but the results are very comparable to the 20%

used tests. These tables show results from 10% additional resources to 230% additional resources.

The data shows several patterns. First, the amount of time required for mutation and crossover remains fairly fixed for each circuit over the range of additional resources. This is expected, since the work performed for the mutation and crossover steps depends on the number of genes and the number of chromosomes. From circuit to circuit, the differences in mutation times and crossover times for both versions were smaller than the difference in circuit sizes. This indicates that these steps are communication bound, as is expected.

The fitness and constraints checking execution time shows much more variation. The pattern of this variation is shown in Figure 1 for the *pdc* circuit with no initialization accelerated with the GPU, and it is representative of graphs of other tests.
This graph demonstrates that the amount of time required for the fitness function is very dependent on the amount of additional resources made available. This pattern is logical. To evaluate the fitness function, each cell that is within the protected subset must be examined to triple and vote its output cells, followed by examing voters to see if they can be removed. As the amount of available resources increases, the number of cells within the protected partition increases, and thus the execution time required also increases.
The data shows that the mutation and crossover speedups are comparable between circuits. The tables also demonstrate that the crossover time consumes a few percent of the total time, the mutation time is usually within 10% to 20% of the execution time (with lower percentages as more resources are made available), and the fitness function consumes the majority of the processing time. Therefore, the total speedup depends largely on the speedup of the fitness function. The speedups between circuit is also very similar. All three circuits were implemented with the same time of logical device and had about the same average fanout. Therefore, the amount of work per logic cell in the protected subset was roughly the same for all three circuits.

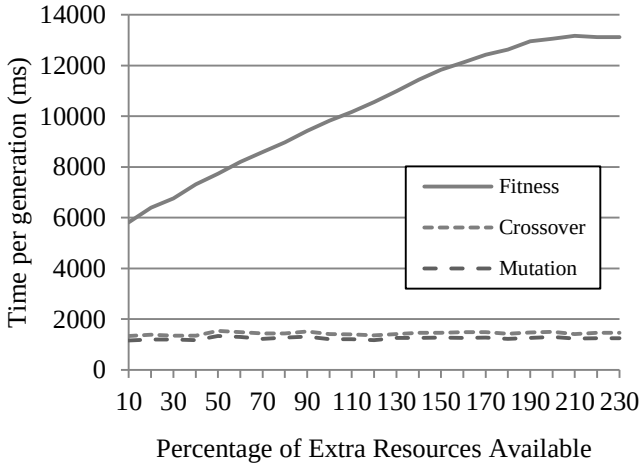

Figure 1 Per Generation Execution Time for the *pdc* Circuit using a GTX 480 and 20% Unused Additional Resources

5 Conclusions

This research presents a significant acceleration of the partial fault tolerance method area-constrained partial fault tolerance using genetic evolution by employing NVIDIA CUDA to execute the algorithm on massively parallel graphical processing units. This speed up allows this method to be much more efficiently applied to larger circuits, and it will benefit from additional acceleration as the processing power of graphics processors tracks that of reconfigurable logic devices.

Abstract— *As the mean time between failures has decreased, applications should be able to handle failures avoiding performance degradation if possible. This work is focused on a decentralized, scalable, transparent and flexible fault tolerant architecture named RADIC an acronym for Redundant Array of Distributed and Independent Controllers. As MPI is a de facto standard used for communication in parallel computers, RADIC have been included into it. RADIC's default behavior is to restart failed processes on already used nodes, overloading them. Moreover it also could be configured to keep the initial process per node ratio, maintaining the original performance in case of failures. In this paper we propose a transparent and automatic management of spare nodes in order to avoid performance degradation and to minimize the mean time to recovery – MTTR when using them. Our work provides transparent fault tolerance for applications that are written using the MPI standard. Initial evaluations show how the application performance is restored as it used to be before a failure, minimizing the MTTR by managing faults automatically.*

Keywords – RADIC, MPI, Fault Tolerance, Decentralized, Spare Nodes, Uncoordinated Checkpoint.

1 Introduction

Considering the many long-running parallel applications that are executed on High Performance Computer – HPC-clusters and the increase in the failure rate [1] on these computers, it becomes imperative to make these applications resilient to faults.

Hardware failures may cause unscheduled stops to applications. If there are not any fault tolerant mechanisms to prevent it, these applications will have to be re-executed from the beginning. If a fault tolerant mechanism is used, failures could be treated. In such environment an automatic and application transparent fault tolerance mechanism is desirable. It could also reduce the complexity of applications development. Failure treatment and management are crucial to maintain the performance of HPC applications that are executed over several days.

One of the most commonly used approaches to deal with failures in HPC parallel applications is the rollback-recovery approach based on checkpoint and restart protocols. Rollback-recovery protocols periodically save processes states in order to rollback in case of faults.

Checkpoints could be performed using a coordinated or uncoordinated checkpointing protocol. Coordinated checkpointing protocols create a consistent set of checkpoints by stopping all the processes in the parallel application in a consistent state and then taking a snapshot of the entire application. This approach minimizes the overhead of fault free execution, but in case of faults, all processes (even those that have not failed) must rollback to the previous consistent saved state. All the computation time used to progress the parallel application execution before the fault and after the last snapshot is loosed.

In uncoordinated checkpointing protocols, each process is checkpointed individually, and it could happen in different moments of the execution. Thus, there is not a global consistent state. The advantage of this method is that in case of faults only the affected processes must rollback. In order to avoid the domino effect [2], this approach should be combined with an event logging protocol.

When a parallel application is executed, we usually seek for executions with an optimal amount of resources to maximize the speedup or efficiency. When a failure occurs and the application loses some resources all the initial tuning effort is loosed.

In this paper we present new RADIC [3] enhancements to avoid performance degradation when failures occur. The objective is achieved using automatic spare nodes management to maintain the initial amount of resources when node failures occur. We also try to minimize the MTTR after a failure is detected by managing faults without human intervention. For that reason, every fault tolerant tasks and decisions are made automatically. The RADIC architecture has been integrated into the Open MPI library to allow execution of real scientific parallel applications and to be application-transparent.

Our approach considers the consequences that node failures bring to parallel applications. A physical failure affects computing components. If these components are not replaced properly there is a loss in computational capacity.

This paper is addressed to the **PDPTA'12** Conference

Running a parallel application with fewer resources than the optimal, causes this degradation.

This work is presented and divided as follow: section 2 describes the RADIC architecture, its components and how it operates to protect an application against failures. In section 3 we introduce the related work on fault tolerant systems. The section 4 presents the integration of RADIC into the Open MPI library to provide user-transparent fault tolerance. Next, section 5 illustrates the initial results obtained with the described implementation. Finally, section 6 presents the conclusions and future lines.

2 RADIC Architecture

RADIC [3] is a fault tolerant architecture for message passing systems based on *rollback-recovery* techniques. These techniques rely on uncoordinated checkpoint protocol combined with a receiver based pessimistic event log [4]. The approach that was chosen does not need any coordinated or centralized action or element to carry out their fault tolerance tasks and mechanisms, so application scalability depends on the application itself.

The RADIC architecture acts as a fault tolerant layer between the MPI standard and the parallel machine (fault probable). This fault tolerant layer provides a fault-resilient environment for parallel application even when the application runs over a fault-probable parallel machine.

Our work is focused on providing an application-transparent fault tolerant middleware within a message passing library, specifically, Open MPI [5].

Critical data such as checkpoints and event logs are stored in a different node than the one in which the process is running. Processes that were residing in a failed node will be restarted in another node from their latest checkpoint, and will consume the event log in order to reach the before fault state. RADIC policies provide a transparent, decentralized, scalable and flexible fault tolerance solution.

2.1 RADIC components

RADIC provides fault tolerance based on two main components: *protectors* and *observers*. In the Figure 1 we illustrated computing nodes (Ny), application process (Px), the protectors (Ty), and the observers (Ox) where the sub-index *x* represents the process number and *y* represents the node number. Protectors and observers work together with the aim of building a distributed fault tolerant controller. Both components are described below:

- *Observers*: are responsible of process monitoring and fault masking. Each application process has one observer attached to it. The observers performs event logging of received messages in a pessimistic manner, they also take periodic checkpoints of the process to which it is attached. Checkpoints and logging data are sent and stored in their protectors located in another node (Figure 1). During recovery, the observers are in charge of processing with the event log, replaying them in order to reach the same state before fault.
- *Protectors*: on each node there is a protector running, their main function is to detect node failures via a heartbeat/watchdog protocol. Protectors also store checkpoints and event logs sent by observers. When a failure occurs, the protector has to restart the failed processes that it protects; they also have to reestablish the heartbeat/watchdog protocol since it gets broken due to node failures.

2.2 RADIC Operation

Fast failure detection is one of RADIC priorities, since it is one of the variables that affect the MTTR. RADIC first detection mechanism is a heartbeat/watchdog protocol that allows protectors to learn about neighbor's protectors faults.

As every communication goes through the observers, they have absolutely control of messages exchange between peers. Observers can also detect and mask faults. Each protector maintain a data structure called *radictable*, where each entry (an entry per process exists in the application) of the structure is composed of a process id, the URI of the process, URI of its protector, and a unique clock of received and sent messages. When a process fails and get restarted, the observers consult the *radictable* in order to find about the node where the process has been recovered by asking the process's protector. The protectors updated the *radictable* on demand when they identify any processes failures.

In the Figure 2a it is possible to see a fault free execution using RADIC without spare nodes support.

When a failure occurs (Figure 2b), the parallel application execution will continue with one less node. The node failure is detected by the heartbeat/watchdog mechanism. After the failure, the heartbeat/watchdog mechanism is reconstructed, and T4 indicates T2 as the new protector of P4 (Figure 2c). O4 needs to take a checkpoint of P4, because its latest checkpoint gets lost when T3 fails. T2 restarts and re-executes P3(Figure 2d), and also will indicate that the new protector of P3 is T1. Then O3 will take a checkpoint of P3 and send the data to T1. Finally, O3 we erase old message logs.

The protectors have two operating modes: active or passive. Active is when they form part of the detection scheme and there are some application processes running on its node (all nodes of Figure 2). Protectors may be in a passive state when they are running in a spare node, this is a low consumption state (to avoid node and network overload).

2.3 Spare Nodes in RADIC

When a failure occurs and the failed process is restarted in the same node its protector is running, if this node already has application processes running on it, the node becomes overloaded. This could slow down the execution of both

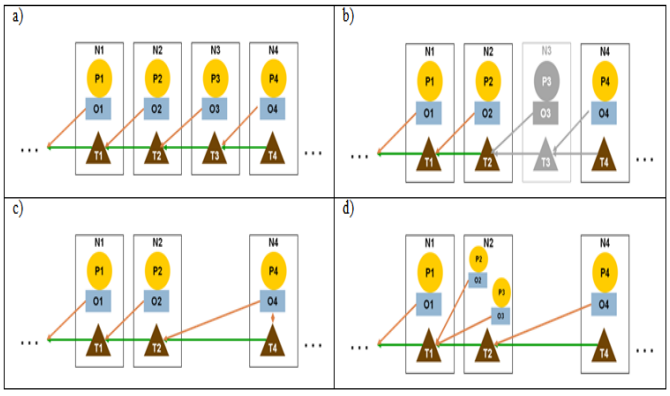

Figure 2. a) Fault free execution. b) Failure in Node 3.
c) Heartbeat/watchdog restoration and assignation of a new protector to P4.
d) Restart of the process P3 in node N2.

processes. As a consequence of this, the performance of the entire application could be affected, increasing its execution time.

One method to maintain the initial performance in such a scenario is to use spare nodes to restart failed processes [6] instead of overloading the non-failed nodes. Spare nodes are that initially are not used by the parallel application.

In the Figure 3a, we can observe the execution of a parallel application using 4 nodes and having 1 spare node (NS). When a failure occurs in the node N3 (Figure 3b) the protector T2 will detect the failure of protector T3 and it consult a table to find the information about the spare nodes location and state (*sparetable*).

The *sparetable* (Table 1) is replicated among all protectors. Spares are assigned as failures occur, and the replicated information is updated on demand, so all the operations are made in a decentralized and transparent manner. Eventually, these tables could be outdated, however it does not affects the RADIC operation, since this information will be checked before using any spare.

After consulting its *sparetable* the protector T2 confirms the availability of the spare NS (Figure 3c) and if it is available T2 transfer the latest checkpoint and event logging data of process P3 to NS (Figure 3d). Finally, the protector TS restart P3 and become an active protector by joining the heartbeat/watchdog protection scheme (Figure 3e).

3 Related Work

Many proposals have been made to provide fault tolerance for message passing applications. Most strategies are based on a coordinated checkpointing approach or an uncoordinated checkpointing strategy combined with a logging mechanism.

Currently, there are several checkpoint-restart tools available. We can highlight BLCR (*Berkeley Lab's Checkpoint/Restart*) [7] and DMTCP (*Distributed MultiThreaded Checkpoint*) [8]. DMTCP works at user space and BLCR works at kernel level. BLCR is one of the most used libraries to provide fault tolerance in parallel systems. To use BLCR in parallel applications, MPI libraries should at least reopen communication channels after restart [9].

Table 2 highlights the features of three of the most popular fault tolerant frameworks integrated into MPI libraries and our approach. Most solutions use a centralized storage. However, due to scalability reasons, it is desirable to avoid any centralized element.

Our approach differs from MPICH-V2 [10] because we do not use any centralized storage because with RADIC, every computing node could stores critical data from process residing in another node. Also we use a pessimistic receiver based logging protocol. MPICH-V2 is now a deprecated implementation.

MPICH-VCL is designed to reduce overhead during fault free execution by avoiding message logs. It is based on Chandy-Lamport algorithm [11]. MPICH2-PCL [12] uses a blocking coordinated checkpointing protocol.

LAM-MPI [13] is previous to Open MPI. It modularizes a *checkpoint/restart* approach to allow the usage of multiple *checkpoint/restart* techniques. The implementation supports communications over TCP and Myrinet in combination with *BLCR* and *SELF* checkpointing operations. *LAM-MPI* uses a coordinated checkpoint approach and needs a communication thread between the checkpoint/restart system and the process *mpirun* to schedule checkpoints.

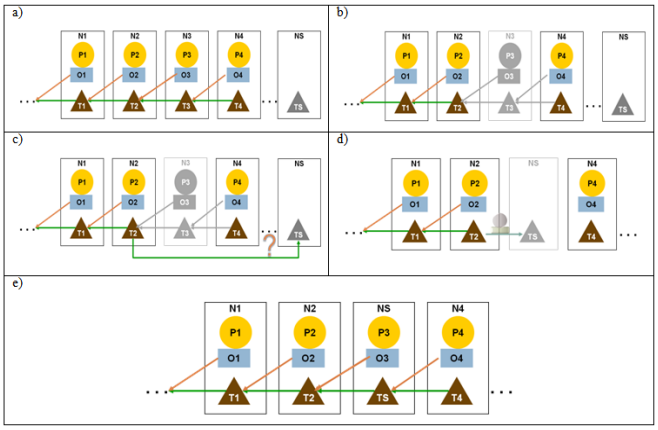

Figure 3. RADIC with spare nodes. a) Execution before failure with one spare node. b) Failure in node 3. c) The protector T2 check availability of spare node NS. d) Protector T2 transfer the checkpoint of process P3 to spare node NS. e) Protector TS restart process P3 and also the communications.

The current *checkpoint/restart* implementation of the Open MPI library [9] aims to combine the best features from these methods described above. The implementation uses a distributed checkpoint/restart mechanism where each checkpoint is taken independently, but coordination is needed to make a consistent global state, which requires the interruption of all processes at the same time.

Another work that has become important is the Coordinated Infrastructure for Fault Tolerant Systems –CIFTS- [14]. It is a framework that enables system software components to share fault information with other components to take some action in order to get adapted to faults. The main difference with our proposal is that we deal with faults automatically and transparently to applications. This allows us to reduce the MTTR.

4 RADIC in MPI

The first prototype of RADIC was called RADICMPI [15] and it has been developed as a small subset of the MPI standard. As a message passing library is very limited. As this implementation does not have all the MPI primitives, it cannot execute many of the scientific applications available

Table 1. Sparetable

Spare Id	Address	Observers
0	Node5	1
1	Node6	0
…	…	…

RADICMPI does not consider collective operations and other complex functions that many applications use. For that reason, instead of extending the prototype to comply the MPI standard, we decided to integrate the RADIC architecture into a well-established MPI implementation. It allows the correct execution of any MPI application using the fault tolerance policies and mechanisms of RADIC (Section II).

In the next paragraphs we will explain some important features of the integration of RADIC into Open MPI.

4.1 Open MPI Architecture

A depth research about the inclusion of RADIC in Open MPI has been made in [16]. The implementation is named

RADIC-OMPI and integrates the basic protection level of RADIC. It does not include spare nodes management.

Open MPI architecture has been already described in [5]. For that reason, in this paper we will focus only on the components relevant to the RADIC integration.

The Open MPI frameworks are divided in three groups that are: *Open MPI (OMPI)* which provides the API to write parallel applications; *Open Run-Time Environment (ORTE)* which provides the execution environment for parallel applications; and *Open Portable Layer (OPAL)* which provides an abstraction to some operating system functions.

To launch a given parallel application, an ORTE daemon is launched in every node that takes part in the parallel application. These daemons communicate between them to create the parallel runtime environment. Once this environment is created the application processes are launched by these daemons. Every process exchange information about communication channels during the Module Exchange (MODEX) operation which is an all-to-all communication. The *protector* functionalities have been integrated into the ORTE daemon because in Open MPI there is always one daemon running in each node, wich fits the protector requirements.

Table 2. Fault tolerant MPI libraries.

Name	FT Strategy	Detection and Recovery
MPICH-V2	- Uncoordinated Ckpt. - Sender based pessimistic log. - Centralized storage.	- Automatic.
MPICH-VCL	- Coordinated Ckpt. - Chandy-Lamport Algorithm. - Centralized storage.	- Automatic.
Open MPI	- Coordinated Ckpt. - Centralized storage.	- Fault Detection and safe stop. - Manual recovery.
RADIC	- Uncoordinated Ckpt. - Pessimistic Receiver based Log. - Distributed storage.	- Automatic and application transparent.

OMPI provides a three-layer framework stack for MPI communication:

- *Point-to-point Management Layer (PML)* which allows wrapper stacking. The **observer**, because of its behavior, has been implemented as a PML component; this ensures the existence of one observer per application process.
- *Byte Transfer Layer (BTL)* that implements all the communication drivers.
- *BTL Management Layer (BML)* that acts as a container to the drivers implemented by the BTL framework.

The Open MPI implementation provides a framework to schedule checkpoint/restart requests. This framework is called *Snapshot Coordinator (SnapC)*. The generated checkpoints are transferred through the *File Manager (FileM)* framework. All these communications to schedule and manage the transferring of the checkpoint files are made using the *Out of Band (OOB)* framework.

4.2 RADIC Implementation

To define the initial heartbeat/watchdog fault detection protection scheme and protection mapping a simple algorithm is used: each observer sets his protector as the next logical node, and the last node sets the first one as its protector.

All protectors should fill the *radictable* before launching the parallel application and update it with new information when failures occur. The update of the *radictable* does not require any collective operation. Thus many protectors could have an outdated version of the *radictable*. However, the *radictable* will be updated further on demand, when observers try to contact restarted processes.

Regarding to the fault tolerances mechanism and their integration into Open MPI, the following observations can be made:

- *Uncoordinated checkpoints:* each process performs its checkpoints through a checkpoint thread. Checkpoints are triggered by a timer (*checkpoint interval*) or by other events. Before a checkpoint is made, to ensure that there is no in transit messages all communication channels are flushed and remain unused until the checkpointing operation finishes. After a checkpoint is made, each process transfers their checkpoint files using the *FileM* framework and then the communication within processes are allowed again.
- *Message Log:* since the observer is located in the PML framework, it ensures that all communications through it are logged and then transferred to the correspondent protector. The protector only confirms a message reception after the message has been saved. Messages are marked as received by the remote process after the receiver and its protector confirm the message reception (pessimistic receiver based log).
- *Failure detection mechanism:* failures are detected when communications fails; this mechanism requires the modification of lower layers to raise errors to the PML framework where the faults are managed. It avoids application stops. A heartbeat/watchdog mechanism is also used. The protectors send heartbeats to the next logical node and the receiver protector resets the *watchdog* timer after reception.
- *Failure management:* the default behavior of the library is to finalize when a failure occurs (*fail-stop*) Hence RADIC needs to mask failures to continue execution and avoid fault propagation to the application level. When a protector finds out about a failure, the restarting operation is initiated.
- *Recovery:* the recovery is composed of three phases. In the first one, a protector restores the failed process from its checkpoint with its attached observer. Then the restored observer sets its new protector, re-executes the process while consuming the event logging data and then takes a checkpoint. Finally, the process execution is resumed after its checkpoint is sent to its new protector, just to ensure its protection. Protectors involved in the fault also reestablish the protection mechanism. We consider the recovery as an atomic procedure.
- *Reconfiguration:* when the recovery ends, the communications have to be restored. To achieve this

goal the lower layers of Open MPI must be modified to redirect all the communications to the new address of the process. To avoid collective operation this information is updated on demand or by a token mechanism.

4.3 Proposal: Spare Nodes Management in Open MPI

An important aspect that has to be considered when running parallel applications is the performance. The previous implementation of the RADIC architecture [16] allows the successful completion of parallel applications even in presence of failures. However, it does not consider the management of extra resources to replace failed nodes. Including the spare nodes management into RADIC, the applications will not only end correctly but also will avoid performance degradation due to loss of computational resources.

Our proposal is not restricted on avoiding performance lost, we also propose a mechanism for automatically select spare nodes and include them on the parallel environment domain without user intervention. By doing the spare nodes management transparently and automatically, we minimize the MTTR.

When including spare nodes into the RADIC architecture, the restarting and reconfiguration are the most affected mechanisms. To reconfigure the system, a deterministic algorithm to find restarted processes is needed.

When using RADIC without spare nodes (Figure 2), failed processes are restarted in their protectors. If an observer tries to reach a relocated failed process, it will take a look at its *radictable* to find the old protector of the failed process (this information may be outdated). Then, the observer will ask about that process. The old protector will say that it is no longer protecting such a process, and will point who is the new protector (Figure 2).

If a failure occurs and there are spare nodes available, the spare will be included into the parallel environment domain and failed processes should be restarted in it. The heartbeat/watchdog mechanism will be reestablished and the involved protectors will update their *radictable* and *sparetable* (Table 1).

Considering Figure 3e, if process P1 wants to reach P3, O1 will ask T2 about P3. T2 will point that P3 is residing in the spare NS. Then O1 will tell T1 to update its radictable and its sparetable and P1 will finally try to contact P3. The process described above is distributed and decentralized, and each process will do it only when it is strictly necessary, avoiding the costly *Module Exchange* (MODEX) collective of Open MPI.

The main problem when restarting a process in another node is that we need an ORTE daemon running in that node to adopt the new process as a child. Moreover, all future communication with the restarted process needs to be redirected to its new location. For that reason, ORTE daemons are launched even in spare nodes, but no application process is launched on it until it be required as a spare node.

An additional problem that must be addressed is that a sender observer must not consider as a failure the lack of communication with other processes when the receiver process is doing a checkpoint or is restarting. The sender observer will fail to communicate, and will consult the receiver's protector to find about the state of the receiver. The protector will indicate that the process is checkpointing or restarting, and the communication will be retried later.

The *radictable* and *sparetable* were included inside the job information structure (*orte_jmap_t*). When the parallel application starts, each protector (ORTE daemon) populates its *radictable* and its *sparetable*. The *radictable* and *sparetable* are updated (on demand) when a protector notices that a process has restarted in another place.

If the application runs out of spares, the default mechanism of RADIC is used (Figure 2).

5 Experimental Results

A fault tolerant architecture, generally, introduces some kind of overhead in the system it is protecting. These overheads are generally caused by replication in some of its forms. The overheads introduced by RADIC are mostly caused by the uncoordinated checkpoints and the pessimistic log mechanism as it has been showed in [16].

Failures may cause degradation because of the loss of the computational capacity if there are no spare nodes available. The experimental evaluation that has been done tries to shows how fast is the failure detection and recovery mechanisms of our proposal, and how fast it can include automatically spare nodes into the parallel environment in order to avoid the impact on the performance of applications when resources are loosed.

We present experimental results using three different benchmarks: a static matrix multiplication benchmark, the LU benchmark that is part of the *NAS Parallel Benchmarks* (*NPB*) [17] and the SMG2000 application [18].

The matrix multiplication application is modeled as a *master/worker* application, the master sends the data to the workers only at the start, and collects the results when the application finalizes. Each application process is assigned to one core during normal execution. The matrix multiplication implemented has few communications (only at the beginning and at the end).

Experiments have been made using a *Dell PowerEdge M600* with 8 nodes, each node with 2 quad-core Intel® Xeon® E5430 running at 2.66 GHz. Each node has 16 GBytes of main memory and and a dual embedded Broadcom® NetXtreme IITM 5708 Gigabit Ethernet. RADIC have been integrated into version 1.7 of Open MPI.

Our main objective is to depict the application

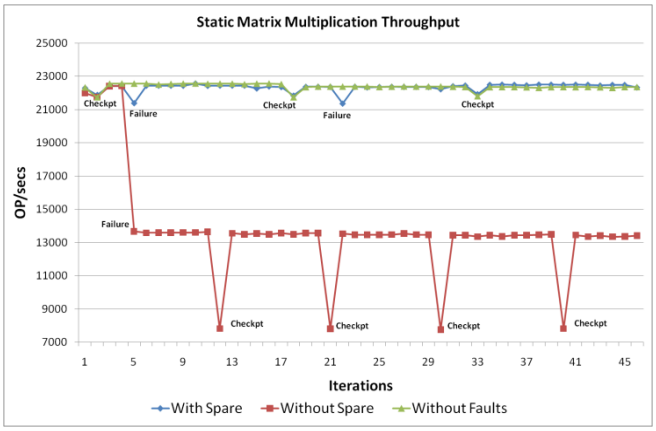

Figure 4. Throughput of the Matrix Multiplication application with and without spare nodes(32 processes – Checkpoint interval = 30 sec).

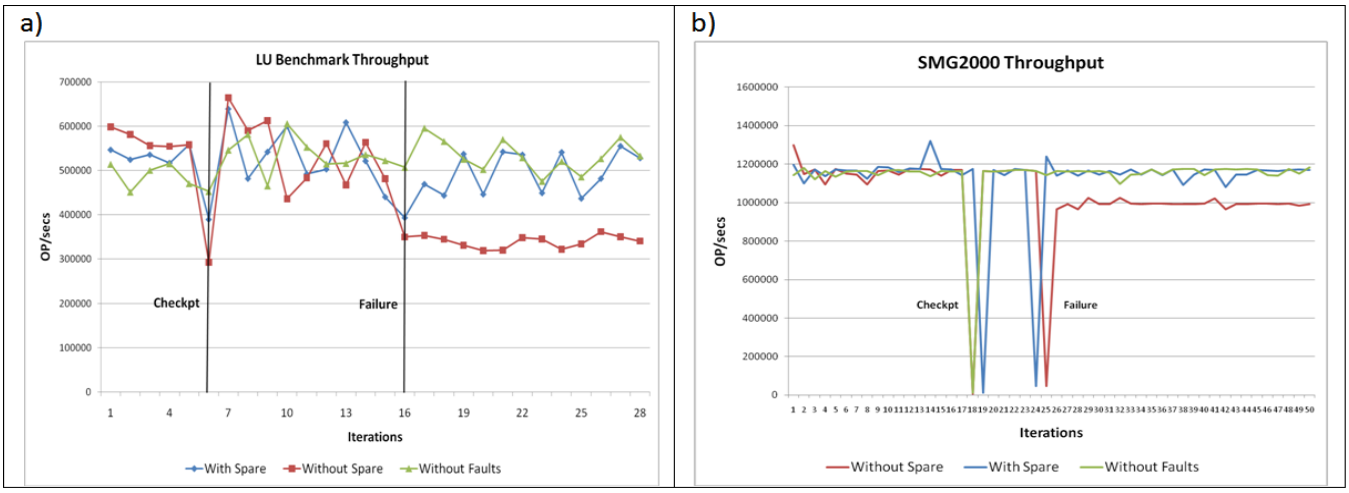

Figure 5. a) Performance of the LU Benchmark with and without Spare Nodes. b) Performance of the SMG2000 application with and without Spare Nodes.

performance degradation avoidance when failures occur in parallel computers. By using spare nodes automatically and transparently to restart failed processes into them, we can decrease the MTTR to a minimum while maintaining application performance as it was before failure.

As we mentioned before, it is crucial to deal with failures as fast as possible. If the application loses a node and we use the default approach of RADIC (Figure 2) one of the nodes become overloaded. As a consequence of this, the whole application throughput could decreases.

Replace failed nodes with spares is not trivial, because it is necessary to include the spare node into the parallel environment world and then restart the failed process or processes in it transparently and automatically. Therefore, application performance is affected only by a short period.

The experiments try to depict how performance (in terms of throughput) is affected after a failure without using spare nodes, and the benefits of using them.

To obtain the operations per second of the Matrix Multiplication application we divided the sub-matrix size that computes each process by the time spent into an internal iteration.

The checkpoint intervals that we use to make the experiments are only for test purposes. If we want to define valid checkpoint intervals we can use the model proposed in [19].

Figure 4 shows three executions of the matrix multiplication benchmark. The green line shows the fault-free execution. The blue line shows the execution of the application using RADIC with 2 spare nodes (and 2 failures). The red line shows the execution of RADIC without using spare nodes, and with one failure.

When a fault occurs and the application is not using spare nodes, the failed processes are restarted on their protectors and these nodes become overloaded. It occurs because processes compete for available resources and the application loses about 40% of its initial throughput. If we use RADIC with spare nodes, the application loses throughput only for a short period, until a spare is selected and the process is restarted in it, after that, the initial throughput is restored.

The static matrix multiplication is only a synthetic application. To evaluate the throughput changes with real applications using RADIC, we have designed a new set of experiments using the LU benchmark and the SMG2000 benchmark (Figure 5).

Figure 5a depicts the behavior of the LU benchmark using RADIC with and without spare nodes (and without faults). The application has an irregular behavior because it computes sparse matrices. If a failure occurs and the application does not have any spare node, it losses about 35% of its throughput. However, if the application uses spare nodes, the throughput is reduced in 25% during the recovery and after that, the initial throughput is recovered.

Figure 5b depicts the throughput of the SMG2000 benchmark. The checkpointing and restart operations are quite expensive for this application because the memory footprint of each process is about 2GB. If a fault occurs, and the process is restarted on its protector, the application losses about 15% of its initial throughput. However, if the process is restarted on a spare node, the initial throughput is maintained.

As is known, the execution time of an application affected by faults depends on the moment in which the failure occurs. For that reason when treating faults we focus on showing the degradation in terms of throughput not in terms of execution time.

Considering the results we can conclude that transparent and automatic management of spare nodes reduces avoids increments in the MTTR and maintains the application throughput avoiding system overload.

6 Conclusions and Future Work

The proposal presented in this paper has demonstrated that the RADIC policies are effective to automatically and transparently manage spare nodes, avoiding long recovery times while maintains initial application performance.

In this paper we have presented the design and evaluation of an alternative method to restart failed processes automatically maintaining the original computational capacity. This is an important issue because usually, applications are configured to execute with an optimal number of nodes. Loosing computational resources due to hardware failures decreases the application performance.

Having scalability as an objective, it is imperative to use a decentralized fault tolerance approach. Furthermore, when failures occur, a transparent an automatic fault treatment is desired, because the parallel application will experiment performance degradation only for a short period of time.

The use of a fault tolerance architecture with RADIC characteristics is desirable because it does not require any user intervention and it is also configurable to use available resources. When running parallel applications in computer clusters, frequently, there are free nodes that are not being used by any application, so these nodes could be used as spare nodes.

The implementation of RADIC into the Open MPI library has several advantages. The first one is that Open MPI is a widely used library used in the scientific world. It allows the utilization of RADIC with real scientific applications. The second advantage is that our implementation makes easier the processes migration without stopping the parallel application execution.

Initial analyses also show that RADIC will complement correctly with the MPI3 standard. The MPI3 standard will make easier the failure management because more information about failures will be available, so the possibilities to take corrective actions will increase.

The integration of RADIC into a stable Open MPI implementation as well as provide an interface for live migration are pending tasks. RADIC also need to start taking into account applications with I/O events (transactional applications).

A Distributed Service Architecture for Networked Automotive E/E System

Kabsu Han, Jeonghun Cho
School of E/E, Kyungpook National University, Daegu, Republic of Korea

Abstract - *Automotive Electric and Electronic systems come into wide use as requirement for more and complex functionality in vehicle is increase. Automotive E/E systems are based on networked ECUs, which each ECU is connected to each other through network, and distributed control system. As the ECUs are increase on the network, the development of automotive E/E system gets complicated. This paper considers the problems of automotive E/E system and proposes distributed service architecture, which can provide dependability and flexibility. Distributed service architecture separates service management from service processing, simplifies service layer and service node and makes development phase easy. Depend on service clustering. Proposed architecture separates services into sub-network from network and provides distributed service management.*

Keywords: In-Vehicle Network; Distributed Control Network; Fault-Tolerant Architecture; Dependable Distributed System;

1 Introduction

Electric, electronic and software are generally used in automotive system. Automotive electric/electronic system provides huge improvement of functionality, performance and product properties. But automotive industry does not have much experience in automotive E/E engineering; include software, embedded computer system and management. In fact, 49.2% of car break downs in Germany were due to E/E system failure in 2003 and also major recalls from automotive industry are based on problems of E/E system

One important point of automotive E/E system for automotive industry is the possibility to achieve competiveness through cost-efficient and dependable system. But development and modification of automotive E/E system is complicated and dangerous, even these are easier than mechanic/hydraulic system. This paper proposes distributed service architecture to solve these problems and to make automotive E/E system dependable.

Section 2 describes background for automotive E/E system. Section 3 describes the overview of distributed service architecture, section 4 presents service management, flexible implementation, fail-safety, on-line diagnosis and test. Section 5 describes experimental environment. Finally, the last section presents conclusion and future work.

2 Background

In early days, a vehicle has only a few Engine Control Units (ECU) and ECUs were not connected to each other and worked as stand-alone units, shown as fig. 1 a). It is simple enough to develop and modify, and barely need engineering efforts. Also, an ECU failure does not affect other ECUs.

As a development of electronics and embedded system technology, Electronic Control Unit (ECU) which is based on software, is used to implement automotive functionality. Automotive E/E system gets complex substantially to implement a lot of functions which demand for competitive strategy, customer requirement and law. The Mercedes S-Class included more than 50 ECUs from 1991 and the BMW 5 and 7 series have 70 networked ECUs from 2004.

In-Vehicle Network (IVN), which connects ECUs to ECUs, with point-to-point connections is the simplest topology and can make functionality easily, shown as fig. 1 b). But this topology has complex wiring which is hard to modify and extend. And as ECUs are increase, the wiring and connection points are increase exponentially. This is not good for development, production and maintenance of vehicle. The Mercedes S-class from 1991 has more than 3km of wiring.

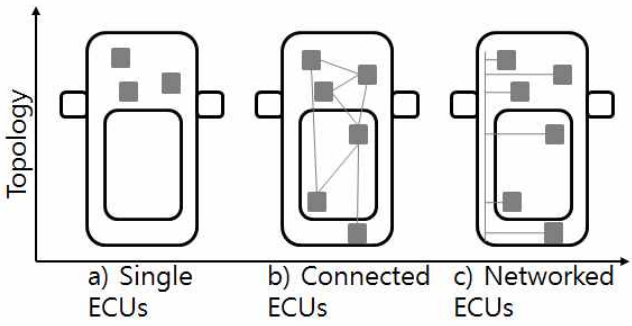

Figure 1 Automotive E/E architecture

Networked E/E system uses bus architecture for simplicity to develop, shown as Fig. 1. c), also flexibility to modify easily. ECUs, which have their own sensors and actuators, are

connected with others through network and are able to share some information from sensor. Although networked E/E system has some advantages compared to point-to-point connection, still some limitation are remaining to provide flexibility and scalability. Sensors, actuators and other properties do not have their own network interface, so they have to be a part of some kind of ECUs.

Fully networked E/E system consists of smart sensors and smart actuators which have their own network interfaces thus they can connect to IVN independently and assure high flexibility and scalability. But with the increase in number of ECUs, sensors and actuators, the development of Automotive E/E system becomes complicated. Moreover, heavy traffic on IVN causes congestion, delay and emission of data, thus safety and dependability are not sure. This paper proposes distributed service architecture to solve problems, which are described above, and provide flexibility. Distributed service management points (SMP) maintain services hierarchically and provide redundant services to assure dependability. According to the requirements, SMP can consist of various services and can modify services easily and support on-line diagnosis and test to validate services.

3 Basic System Architecture

Proposed distributed service architecture consists of a network of SMPs and Service Control Point (SCP). The functionality of SMP is a service management of system with service state messages and relays the service requests. Each SMP is connected with other SMPs through network but SMPs do not have any information over the other SMPs, shown as fig. 2. With service index table, SMP can only lookup available services and SMPs which manages services.

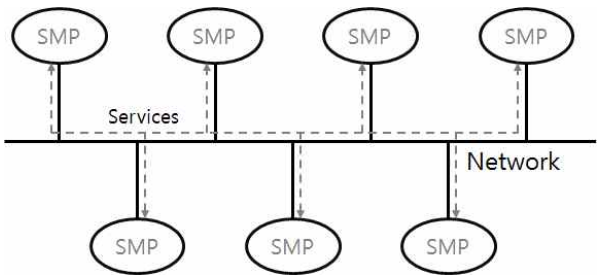

Figure 2 Simple view of SMPs

SMP manages service states of SCPs and relays service request from SCP to specific SMP which can process requested service. Each SMP checks state of other SMPs with service state message, maintains service index table which describes service information. Each SMP has its SCPs which are connected to sub-network. Depend on functional and strategic requirements of automotive E/E system, the composition of SMPs and SCPs, which called service clustering, can vary considerably. In most cases, service cluster and services are defined in system analysis documents already.

If service is processed within a SMP, it called in-bound service. If service is not processed within a SMP, SMP has to relay service request to other SMPs, it called out-bound service, shown as fig. 3. In case of in-bound service, requested services do not make any data on main network, only on sub-network which separated from main network.

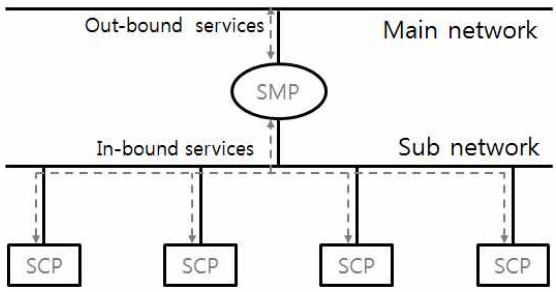

Figure 3 Basic composition of SMP and SCPs

SCP consists of ECUs, sensors, actuators and other properties. SCP processes relayed service request from SMP with its own resources. When some kind of event happened, SCP sends service request to SMP simply and processes relayed service request from SMP. If SCP needs some service it sends a service request to the SMP to which it is directly connected. If the requested service is available within the same SMP, in-bound service, it is relayed to SCP, which can process the service, on the sub network. On the other hand, if the service is unavailable, out-bound service, the SMP relays service request to another SMP on main network. In case of no SMP on the network is able to process the service, the SMP replies with a service fail message. Also, service requests and service replies are define in system analysis documents. The entire architecture is shown as fig. 4.

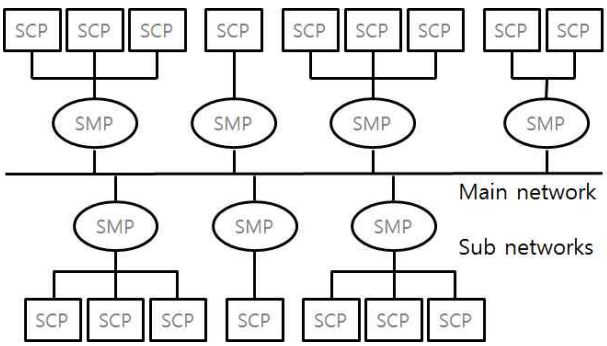

Figure 4 Overview of Distributed Service Architecture

Logging SMP can collect all of service request, service state and service failed messages. Logging SMP is connected with SCPs which are related to log services and provide on-line diagnosis with various logging data services.

Depend on service clustering, proposed distributed service architecture separates sub-network from main network. The separation of services can reduce numbers of connection points and disperse network traffic. Comparing state messages of SMPs, the proposed architecture can detect faults of SMPs and can operate in fail-operational mode with redundant SMPs. Additionally, SMPs can isolate fault of SCPs and redundant SCPs can cover faults of other SCPs.

4 Distributed Service Architecture

This section describes service management of proposed architecture and flexible configuration in implementation level. Also, describe reliability and construction of on-line diagnosis and test.

4.1 Service Management

Distributed service architecture adopts point-to-point service architecture in general distributed systems. Proposed architecture manages services and cooperates without central supervisor and central arbiter [1][9]. Because of single point failure problem, complexity and flexibility, central control supervisor is not good for distributed control system. Automotive E/E system is a kind of real-time control system which is based on a set of control units with software and interfaces interconnected on network. Depend on system requirement, allocation of control units on the network will be various as well as allocation of interfaces and software on the control units. But services have to be finished within deadline, which defined in the system requirement, although system has different design. We assume that proposed architecture just has simple layers, which consist of single SMP layer and single SCP layer, to assure service result within deadline and to provide simplicity for flexible reconfiguration. To manage services on the distributed service architecture, each SMP has 3 information tables, service index table, service page table and service list table.

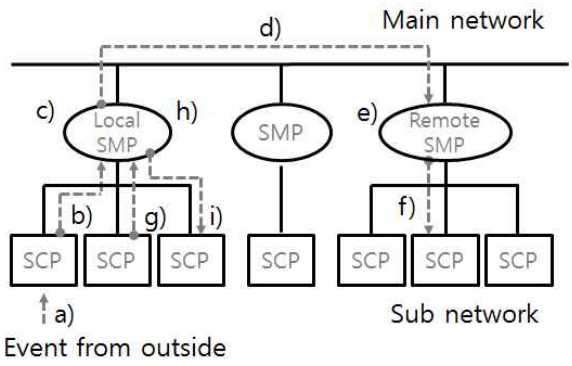

Figure 5 Basic service flow

In proposed architecture, basic service flow is shown as fig. 5. SCP detects events from outside, e.g., data from speed sensor or ACC on/off switch, and sends service request to local SMP which is connected directly with SCP. When local SMP receives service request from SCP, local SMP lookups service in service index table and relays the service to remote SMP, in case of out-bound service, or SCP, in case of in-bound service. If local SMP does not find service in service index table, local SMP replies to SCP with service fail message. When remote SMP receive the service request, remote SMP lookup the service in service index table, relays the service to SCP. Also, if SCP is not available, remote SMP has to reply with service fail message. If service is available in Local SMP, local SMP relay the service to SCP.

Service index table, which has service ID and information of SCPs and SMPs, is defined statically in system analysis documents. Each SMP maintains information of service index table dynamically with exchange of service state messages. Service index table, shown as Table 1, consists of service list ID, service page ID and service flag. SMPs have to share same information of service index table to assure service state. Service list ID identifies service uniquely. Service page ID represents a group of SMP which manages specific services. Service flag indicates service state, if service is available on a SMP at least, service flag is true. If not available on all of SMPs, service flag is False.

Table 1 Service Index Table

Service List ID	Service Page ID	Service Flag
List ID 1	Page ID 1	T
List ID 2	Page ID 1	T
List ID 3	Page ID 1	T
List ID 9	Page ID 2	T
List ID 10	Page ID 2	T
List ID 11	Page ID 9	F
…	…	…

According to service clustering and design policy, service page table is defined statically, shown as Table 2. SMPs have to share same information of service page table, also. For dependability and simplicity, service page table separate from service index table. Because service index table indicates service state only, SMP can recognize service state easily without lookup of all of SMPs. if service needs to be moved to another SMP, service page table will be modified only.

Service list table has information of SCPs which correspond to services, shown as Table 3. Each SMP has its own service list table, it is local information.

Table 2 Service Page Table

Page ID	Primary SMP	Secondary SMP
Page ID 1	SMP1	SMP4
Page ID 2	SMP2	SMP5
Page ID 9	SMP3	SMP2
…	…	…

Table 3 Service List Table

List ID	Primary SCP	Secondary
List ID 1	SCP1	SCP4
List ID 2	SCP2	SCP5
List ID 3	SCP3	SCP1
…	…	…

When local SMP receives service request from SCP, local SMP finds service list ID of service request in service index table. If local SMP finds service list ID in service index table, it retrieves service page ID. Local SMP finds information of SMP in service page table with service page ID, shown as fig. 6. In case of in-bound service, local SMP finds information of SCP in service list table with service list ID. In case of out-bound service, local SMP relays service request to remote SMP. When remote SMP receives service request from local SMP, remote SMP finds information of SCP in service list table with service list ID, also. In case of both, SMP can find SCPs in service list table and relays service request to SCP.

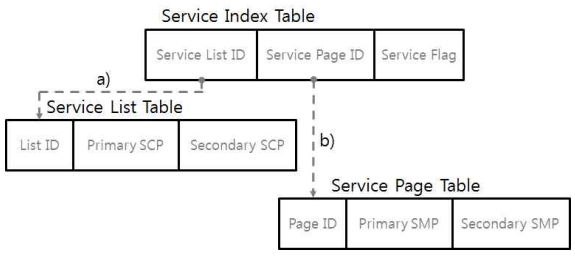

Figure 6 Relation of service tables

Table 1 is example of service index table, 6 services and 3 pages are in service index table. Service List ID 1, 2 and 3 belong to Page ID 1 and all of these services are available. Service List ID 9 and 10 belong to Page ID 2, service is available, also. Service List ID 11 belongs to Page ID 9, service is not available. When SMP receives service request with List ID 9, it retrieves Page ID 2 from service page table. Page ID 2 consists of SMP 2 and SMP 5 in service page table. From Table 2, Primary SMP is SMP 2, SMP will relay service List ID 9 to SMP 2.

Table 3 is an example of service list table of SMP1. When SMP want to relay service List ID 2 to SCP, SMP just retrieves List ID 2 in service list table. List ID 2 has two SCPs, SCP 2 for primary SCP and SCP 5 for secondary SCP in service list table. SMP will relay service list ID 2 to SCP2.

Each SMP checks service state of SCPs periodically and manages service flag in service index table. Also, if an event occurs, SMP updates service flags and notify immediately. When SMP detects that service state of SCP is changed, SMP update service state and sends service state message to other SMPs..

4.2 Flexible Implementation

Proposed distributed service architecture provides flexible implementation. Depending on system requirement, main network and sub-network can be implemented with various digital control networks [2]. Generally, CAN, FlexRay, and MOST which have high bandwidth and dependability, are used for main network. Especially, FlexRay and FT-CAN, which have redundant communication channel, are good for safety and dependability but not for flexibility. Sub network often uses CAN and LIN, which are cheap and easy to use. SMP and SCP can construct various hardware and software architecture; also, SMP and SCP can be on same hardware (like a multi-processor, SoC) in implementation level. SCP can be implemented as various combinations of ECUs and sensors, actuators, depending on system requirement and restriction.

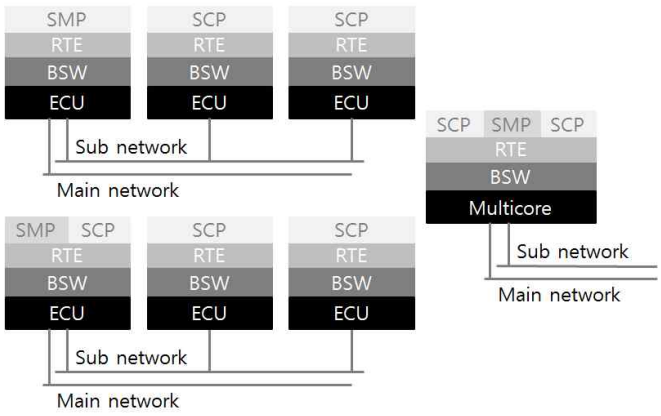

Figure 7 Flexible Implementation

Proposed architecture separates sub-network from main network. Because of this separation, numbers of ECUs, sensors and actuators are decreased on main network and network traffic is dispersed. Also, design verification and validation of automotive E/E system will be easier. Physical

restriction of network can be avoided, that's why the physical link of network can be shortened. Traditionally, IVN consists of power-train, chassis, body and entertainment domains, each domain works independently. But, they need to be connected with each other to share information, e.g., Adaptive Cruse Control needs information and control of power-train and chassis domain. Infotainment system needs information of all of domains.

Depend on system requirements, SMPs may support various network and sub-network in implementation level, shown as Table 4. For example, CAN 2.0, which generally used in automotive E/E system, for main network, CAN 1.0 and LIN for sub-network are possible. Also, FlexRay, which based on time-triggered protocol, for main network, CAN and LIN for sub-network are possible.

Table 4 Example Composition of Network

	Main Network	Sub-Network
Example 1	CAN 2.0	CAN 1.0, LIN
Example 2	FlexRay	CAN, LIN
Example 3	MOST	CAN, LIN

In case of CAN network, CAN use priority-based protocol, a kind of event-triggered, for multiple access control. To implement functions, priority assignment methods for CAN messages are needed in design phase. The design of priority assignment gets more and more complicated as the number of connection points, numbers of messages are increase. Low priority messages cannot be transferred through the network because of jitter and delay introduced after the implementation. To solve this problem, flexible priority of CAN messages are proposed [5], but this is not good for safety and reliability of the entire system. Moreover, as physical link runs long, transfer rate is going down, e.g., maximum transfer rate is up to 1Mbps at 40m but 250Kbps at 200m and 50Kbps at 1km.

In case of FlexRay, FlexRay use TTP (Time Triggered Protocol) for multiple access control, design of slot allocation of static segment is needed. According to static slot allocation, messages are transferred in each static segment. The rest of a time segment, message is transferred as a dynamic segment. Similar to CAN, as numbers of connection-points are increase, the design of slot allocation gets complicated exponentially. 74 parameters need to be configured with suitable value within predefined range. Possible configuration spans more than 10^{48} for each design. Lack of flexibility and sub-optimal resource usage problem are still remaining [13]. In worst case, messages cannot be allocated in a static segment because the numbers of slots in a static segment are limited, e.g., 16 bytes payload, 3ms static segment cycle will be 93 slots at 10Mbps, 51 slots at 5Mbps and 27 slots at 2.5Mbps [14].

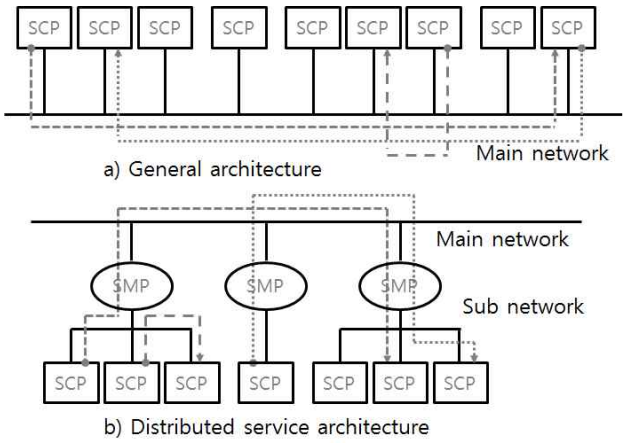

Figure 8 Comparison of service flow

The Proposed architecture separates sub-network from main network, only SMPs are connected to main network, the number of connection-points will be decrease, shown as fig.8. As only out-bound services are transferred through the main network, network traffic will be decrease and design, validation and verification will be easier. Furthermore, as physical link is shortened, loss of transfer rate can be minimized.

4.3 Fail Safety

A fault-tolerant system has redundant components to assure dependability and safety generally [3][4][8]. The proposed architecture provides distributed fault tolerant architecture. Redundant SMP in service page table and redundant SCP in service list table minimize the failure of the services. To detect software faults, at least, two version of software are needed. Also, to detect hardware faults, more than two types of hardware are needed. Use of different version of software can detect software fault and hardware transient fault, shown as Table 5. And use of different types of hardware can detect hardware permanent fault.

Table 5 Fault detection case

S/W (# of version)	H/W (# of hardware)	Fault Type		
		S/W	H/W Transient	H/W Permanent
1	1	X	O	X
1	2	X	O	O
2	1	O	O	X
2	2	O	O	O

Each SMP can manage primary SCP and secondary SCP in service list table for fault-tolerant system as well as SMP in service page table. Different software on SCP, for fault detection, is available. Depending on system requirements for safety and dependability, fault-tolerant SCP runs in dual mode. In first mode, all of SCPs can fully process services. When run in fail-operational mode, secondary SCP processes only degraded services.

4.4 On-line Diagnosis and Test

Logging SMP can collects all of state messages and service messages while logging SCPs process those messages on development phase and product phase. On-board computer, which can process simple diagnosis, can be a kind of logging SCP. Off-board interfaces, like OBD-II, for intensive diagnosis, can be a kind of logging SCP, shown as fig. 9[6].

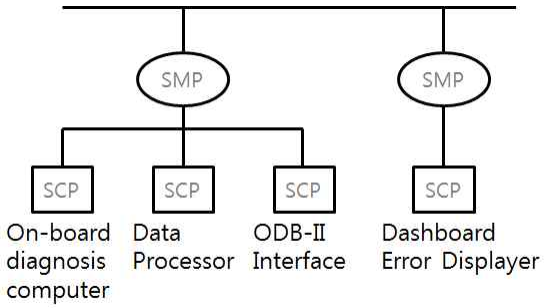

Figure 9 Example of on-line diagnosis

Collection and analysis, statistics, data-mining of messages are processed by logging SCPs. As the composition of logging services, messages can be processed efficiently and systematically for a long time during development phase. Simple logging SCPs can be used du 0.05 cming production phase for maintenance. As the increase of services, various SCPs can be used for on-line diagnosis. Flexible on-line diagnosis can be possible for domain characteristics of vehicle and requirement.

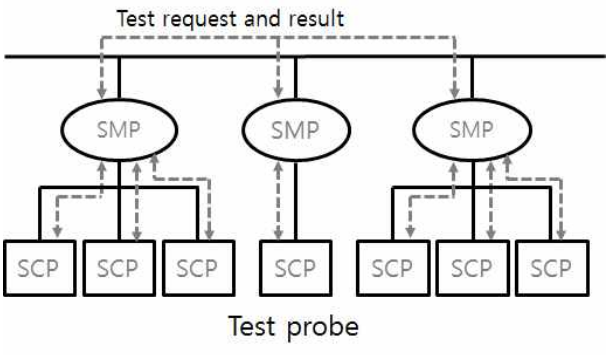

Figure 10 Example of test probe

For test automation environment, proposed architecture can configure SCPs as test probes, shown as fig. 10. To verify and validate service list and service configuration, test probe sends all of service request automatically as an acceptance test. If service list and service configuration are not correct, service fail message will be returned. Input of test cases, e.g., service ID, service table configurations, and output, e.g., expecting service result, can be generated automatically from system design documents. When service configuration is changed for optional service and variation, test automation with test probes and test case is good for verification and validation.

5 Experimental Results

5.1 Experimental environment

Experimental environment, adaptive front lamp control system, consists of three SMPs and four SCPs, shown as fig. 11. Assume that two SCPs in drive shaft cluster detect degree of steering wheel and speed of vehicle and send control request to SMP. SCP, which detects degree of steering wheel, sends control requests of yaw of the front lamps. SCP, which detects speed, sends information of control speed. As the speed of vehicle, front lamps have to move fast or slow. SMP with two SCPs use CAN for a sub-network, because of sampling rate of data. SMP with yaw SCPs use LIN as a sub-network. test SMP and test SCP is on same hardware and CAN use for main network.

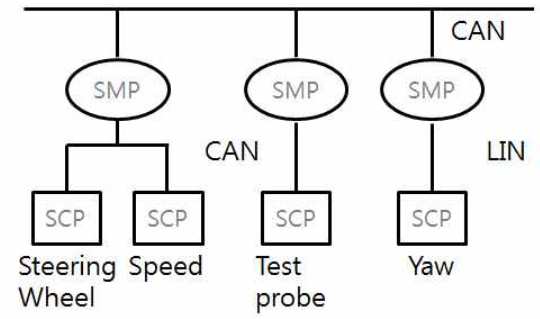

Figure 11 Experimental Environment

Freescale MC9S12XF512 board is used for SMPs which have two interfaces of each LIN, CAN, Flexray. MC9S12XF512 board is working in stand-alone mode, shown as fig. 12. Software of SMP is developed with Freescale Cordwarrior IDE and BDM interface.

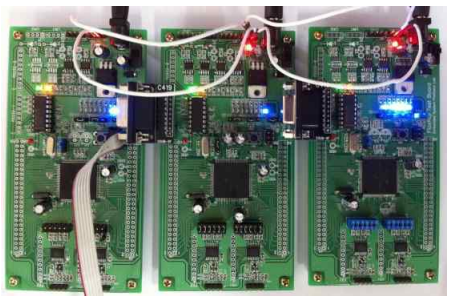

Figure 12 Implementation of SMPs

5.2 Experimental Scenarios

We design service list and service configuration of system. To manage service state, simple service flag message is developed. When SMP detects service change of SCPs, SMP sends service flag message to others. Only service flag message can change service state of service index table. If there is no corruption, all SMPs have same service state.

Service message consist of service request message and service fail message. It is possible that local SMP sends service request message to remote SMP before local SMP change service state with service flag message. In this case, remote SMP will reply with service fail message. When local SMP receives service fail message, Local SMP retrieve service state and try again. Out-bound service can be validated with CAN analyzer, shown as Fig.13.

Figure 13 CAN Messages Monitoring

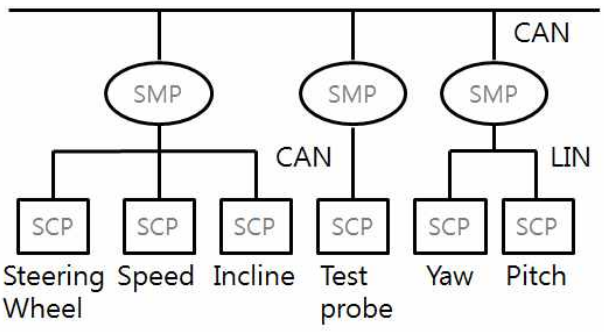

Figure 14 Reconfigured experimental environment

Now, assume that new service is added that is known as front lamp auto leveling. For this service, two SCPs, which can detect incline and control pitch of the front lamps, will be added to experimental system, shown as fig. 14. Incline SCP, pitch SCP are developed, also. SCP, which detects incline of vehicle, sends control request of pitch of front lamps.

For service reconfiguration, just add service list id to service index table, SMP to service page table and SCP to service list table. Services are verified and validated with test probe. Service list is allocated to CAN message, shown as Table 6.

Table 6 Design of messages

Message type	CAN ID

6 Conclusions

This paper proposed distributed service management to solve complexity of traditional in-vehicle network architecture and provide flexibility. The proposed architecture can use various control networks in implementation level. Because of separation of service management from processing, distributed SMPs manage their own SCPs simply and just relay service requests. As the sub-network is separated from main network, design, verification and validation of vehicle network is easier than before. Redundant SMPs and SCPs improve safety and dependability of system. Proposed architecture can be used other distributed control area. For design and implementation of automotive E/E system, EAST-ADL (Architecture Description Language) and Automotive Open system Architecture(AUTOSAR) can be used [10][11][12].

Research about the framework to define and design services and system is needed. Requirement analysis, system configuration and formalized development process, which are suitable for de-facto of the automotive industry, will be added to our future work. Moreover, research on implementation platform for SCPs and SMPs with AUTOSAR complaint is also needed. Finally, Test interfaces and test platform for verification and validation are needed for safety and dependability, also.

A File System Using GPU-Accelerated File-wise Reliability Scheme

Chien-Kai Tseng, Shang-Chieh Lin, and Yarsun Hsu
Department of Electrical Engineering, National Tsing Hua University, HsinChu, Taiwan, R.O.C

Abstract— *This work revises the original file-wise reliability scheme to cope with larger pages in storage devices nowadays, and implements it as a file system prototype: CRSFS. There are four layers in CRSFS: GPU primitive for Cauchy Reed-Solomon (CRS) coding, CrystalGPU framework, CRS coding layer and AFS FUSE layer.*

CRSFS provides GPU acceleration on the CRS encoding/ decoding operations by using the CUDA program: GPU primitive for CRS coding. Besides, it is integrated with FUSE (Filesystem in Userspace) framework and Rx (extended remote procedure call) protocol in AFS FUSE layer to provide high flexibility on storage system configurations. Hence, most programs can benefit from it without rewriting their read/ write operations.

Finally, it's shown that with the help of GPU acceleration, there are up to 24.5x performance gains compared to the CPU counterpart in AFS FUSE layer. The speed of CRS encoding/decoding operations is no longer the performance bottleneck.

Keywords: Reliability; file-wise reliability; Fault-tolerance; File System; CUDA; GPU acceleration

1. Introduction

Reliability is always a big concern for storage devices. Nearly all the storage devices have some kind of mechanism to ensure the correctness of the data stored on them.

As for large storage systems, the Redundant Arrays of Inexpensive Disks (RAID) [1] technique is commonly applied to prevent data losses caused by disks failures. However, because of the high cost and low flexibility of the RAID configuration on storage devices, the file-wise reliability scheme has been proposed to provide different level of protections based on the importance of files [2]. But the Reed-Solomon (RS) code encoding/decoding operations are time-consuming when executed on CPU. Moreover, the erasure unit size proposed at that time is no longer suitable for the storage devices nowadays. The page size in Solid-State Drives (SSDs) has increased to 4 KB or 8 KB. Even the sector size in hard disks has increased from 512 bytes to 4 KB. Therefore, it is necessary to redesign the file-wise reliability scheme and introduce the GPU acceleration to improve the encoding/decoding speed.

In this paper, the original file-wise reliability scheme is revised to deal with larger page sizes in current storage devices, and implemented in the file system prototype — CRSFS. In the revised file-wise reliability scheme, there are total four different reliability levels. All of them utilize CRS code to satisfy different file reliability requirements between ordinary user files and important system files.

Due to the low throughput of RS encoding/decoding operations on previous work, CRSFS is equipped with GPU acceleration to improve the speed of CRS encoding/decoding operations. Besides, CRSFS integrates FUSE [3] and Rx [4] to provide high flexibility on storage system configurations.

The introduced CUDA program in this work—GPU primitive for CRS coding—is optimized for the Fermi architecture of Nvidia GPUs and is integrated with CrystalGPU [5] to exploit the ability of concurrent computation and communication and eliminate the overhead of device memory allocations. In this work, it's shown that with the help of GPU acceleration, the performance gain can reach up to 24.5x compared to the CPU counterpart. Therefore, the speed of encoding/decoding operations is no longer the performance bottleneck.

The POSIX extended attribute APIs of file system are used in this work. Hence, any programs can manipulate the reliability level of a file by using setxattr(), getxattr() and removexattr() to change the *user.crsfs.rlevel* value of the file.

The rest of the paper is organized as follows: Section 2 introduces related work. Section 3 explains the design and implementation thoroughly. The performance evaluations and comparisons between GPU and CPU are presented in section 4. Finally, section 5 describes conclusions.

2. Related Work

The GPGPU computing is quite popular in recent years. Since then, researchers have exploited the GPU power to accelerate many real-world applications, including reliability mechanisms applied on storage devices. For example, a GPU-based RAID system is proposed as a user space framework to accelerate the RS code operations via table lookups [6]. Later, this system is integrated into Gibraltar RAID [7], which is executed on a server node to provide software RAID encoding/decoding services via high-speed network connections.

Other works, such as the Barracuda micro driver architecture for GPUs [8], try to leverage the GPU power in kernel space. Barracuda uses the CUDA based Peter Anvin Reed Solomon encoding (PARSE) [9] to provide the software RAID service to the file requests in kernel space. Due to the fact that the CUDA APIs are only available in user space, the data must be forwarded from kernel space to user space before processed by the CUDA program.

Gibraltar RAID provides services purely in user space, while the Barracuda provides services to the file requests in kernel space via procfs signaling forwarding. Both works are based on RS coding and use the table lookup technique to handle the complex arithmetic operations over Galois field (GF). Besides, they also provide the same software RAID service which can only handle reliability issues based on storage devices, rather than files.

In addition, the GPU accelerated storage system, which consists of MosaStore storage system, HashGPU library and CrystalGPU, is proposed as a content addressable storage system to provide hash service [10]. In that work, CrystalGPU enables up to 3x performance gains with single-GPU configuration compared with HashGPU, which is shown to have up to 5x performance gains compared with CPU.

Also, GPGPU has been shown to be a powerful off-loading engine for CRS encoding in [11]. All of these works above show that GPU has great potential of improving the parity generation performance on CPU.

3. Design and Implementation

In this section, the file-wise reliability scheme is reintroduced with some modifications. And the implemented file system prototype (*CRSFS*) is composed of four layers: GPU primitive for CRS coding, CrystalGPU framework, CRS coding layer and AFS FUSE layer.

3.1 Revised File-wise Reliability Scheme

We've proposed a file-wise reliability scheme in 2010 [2]. The idea of file-wise reliability scheme is allowing users to configure different levels of reliability on individual files according to the respective requirement, and is realized by attaching new abilities in storage subsystem of OS. These abilities are listed below:

- Record the reliability level of each file and store the checksum transparently
- Let users configure the reliability level of demanded files
- Automatically perform possible fault-tolerance when encountering I/O errors

The configuration of the revised file-wise reliability scheme is described in table 1. The CRS code for erasure coding is used to provide erasure recovery in all reliability levels. It takes 512 KB as data input of each encoding, and generates 32-KB, 64-KB, 128-KB and 256-KB redundancy in level 1, 2, 3, and 4 respectively. The larger erasure unit size(4KB) can help deal with large page size in SSDs and the Advanced Format sectors in HDDs.

Configuration or change to the reliability level of a file is performed via the POSIX extended file attribute system calls. Any change to the value of the extended file attribute named "*user.crsfs.rlevel*" invokes the encoding routine. And the recovery procedure is triggered transparently when encountering failed fetching of data pages, i.e. read errors. All these operations will be explained thoroughly in section 3.5.

Table 1: Algorithms and fault-tolerance capability (512 KB) in revised file-wise reliability scheme.

Level	1	2	3	4
Algorithm	(128,8)CRS	(128,16)CRS	(128,32)CRS	(128,64)CRS
Erasure Recovery	8 pages	16 pages	32 pages	64 pages

(k, m)CRS denotes Cauchy Reed-Solomon code with k data units and m checksum units. Packet size equals 512 bytes.

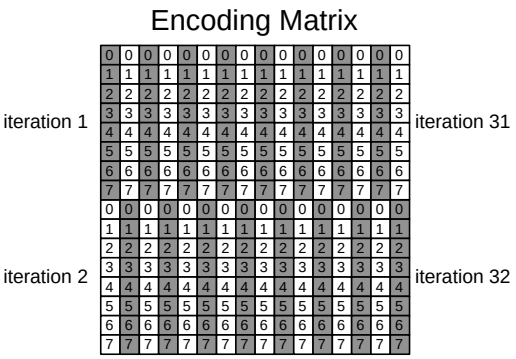

Fig. 1: Scheduling of CUDA threads according to the encoding matrix

3.2 GPU Primitive for CRS Coding

The CRS code operation for erasure coding is the matrix multiplication over $GF(2^1)$, thus converting all the operations over $GF(2^\omega)$ into bitwise *xor* and bitwise *and* operations. As a result, each column of the encoding matrix uses the same row of the data, and each row of the coding matrix contributes to the same row of the checksum.

The overall encoding computation is a $M^{m\times1024} \times N^{1024\times4096}$ matrix multiplications, and m equals 64, 128, 256 or 512. To apply the tile-based algorithm and maximize the parallelism, the workload is divided both by the rows of the encoding matrix and by the columns of the data chunk respectively. Therefore, each two-dimension block consists of $256(32 \times 8)$ threads, and is responsible for $M^{16\times1024} \times N^{1024\times1024}$ matrix multiplications.

At startup, the first warp in every block is responsible to load the encoding matrix from global memory to shared memory. Then, in each iteration, threads in the same block load one $matrix^{16\times32}$ block and one $data^{1024\times32}$ block by applying the *coalescing* technique to access continuous global address. Each element in $matrix^{16\times32}$ and $data^{1024\times32}$ is 32-bit wide. There are total $\frac{BLOCKROW}{THREADROW}(\frac{16}{8} = 2) \times BLOCKCOL(32) = 64$ iterations in the computation stage, starting from the upper-left corner of the encoding matrix along side with the same

column down to the lower-right corner as illustrated in fig. 1. In fig. 1, the elements of the encoding matrix filled with the same color are examined at the same iteration in the same CUDA block, and the number in each box represents the idy of the threads reading this value, where the idy represents the y dimension index. Every CUDA block will go through $M^{16\times1024}$ in this order to compute $C^{16\times1024}$.

In each computation iteration x_i, threads with the same idy check if the $\lfloor\frac{x_i}{2}\rfloor$-th element in the idy-th row of the the encoding matrix, denoted as matrix_val, is equal to one. If so, each of the threads does one 32-bit XOR operation, resulting in one large 1024-bit XOR operation of one $data^{1\times1024}$ block and one $cs^{1\times1024}$ block. After that, the result block is then written back to the same $cs^{1\times1024}$ block in shared memory. If matrix_val is equal to 0, then, they just skip current computation iteration. Because the threads with the same idy are in the same warp and they do the XOR operation according to the same matrix_val, there's no branch divergence.

The CRS GPU primitive is modified from an open source project - MAGMA [12] to take advantage of the Fermi architecture. The techniques used in MAGMA, such as texture cache and software pipeline, improve the matrix multiplication performance.

3.3 CrystalGPU Framework - revised

The CrystalGPU framework has been modified to better fit the need of CRS coding layer.

First, the rlevel is added to the data structure, gpufw_job_s, to record the reliability configuration of the current operation.

Second, gpufw_job_put_free() has been abandoned. Instead, the GPU master thread automatically puts the current job into the free list queue after calling the registered callback function.

Third, if there's no free streams available, gpufw_job_get_free() blocks the current program execution and waits for the MASTER_SIG_FREE_JOB signal from the GPU master thread instead of returning false directly.

Fourth, the rlevel ranges from 1 to 4 normally. But the rlevel will be added with 5 after the encoding operation to indicate that the same rlevel encoding operation has been done before. Thus, the excess encoding matrix buffer copies can be detected and avoided.

3.4 Cauchy Reed-Solomon Coding Layer

The Cauchy Reed-Solomon Coding layer is an abstraction layer upon the CrystalGPU framework, and is responsible to do CRS encoding/decoding setup and trigger the underlying encoding/decoding routines.

As illustrated in fig. 2 the Cauchy Reed-Solomon coding layer consists of 5 functions calls.

First, the *crs_init()* needs to be called before any other functions, and the number of streams need to be specified,

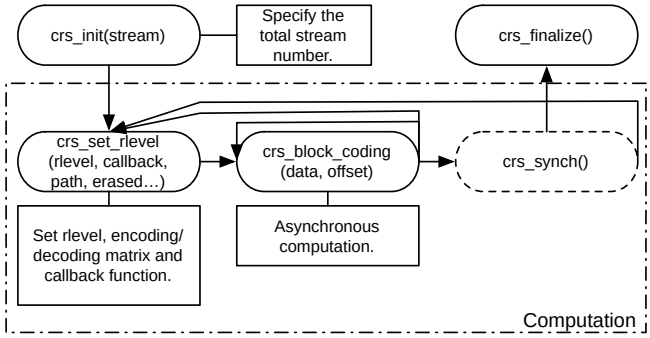

Fig. 2: Flow of CRS coding layer

or it will use the default stream number, 10. In this function, the main task is the memory allocation and GPU master thread initialization.

Second, the *crs_set_rlevel()* is called to do the reliability level configurations. If the current operation equals to CRS_DECODE, the argument erased, which is used to produce the decoding matrix, must be assigned. The erased[x] equals 1 if the x-th chunk is missing, and it equals 0 otherwise. The index of the data chunks ranges from 0 to 127, and the index of the checksum chunks ranges from 128 to 144, 160 or 192 which depends on r_level. Notice that the total number of erased units must be less or equal to the maximum erasure-tolerate number specified in the reliability level, or it will just return false to indicate failure.

Third, the *crs_block_coding()* is called to do the asynchronous computation by copying 512-KB input data to the input buffer of the CrystalGPU framework. If there's a free stream, this function call is non-blocking. Otherwise, it blocks the program execution as described in section 3.3. If the input data is larger than 512 KB, the *crs_block_coding()* can be called multiple times continuously to handle the encoding operation of different chunks in the same file.

To avoid excess data copies, the copies of the encoding matrix buffer will be skipped if the stream returned by gpufw_job_get_free() has the same r_level as the current crs_block_coding() operation.

Fourth, the *job_synch()* is used to block and wait for the last submitted job to be completed. Last, when the file server process (*afsfuse server*) is terminated, the *job_finalize()* is called to clean up the allocated memory and data structures.

3.5 AFS FUSE Layer

AFS FUSE layer is based on FUSE and Rx to implement the client-server model of CRSFS according to [13].

3.5.1 The Overview

As shown in fig. 3, a client process file request is first captured by the FUSE kernel module, *FUSEFS*, and forwarded to the /dev/fuse. Then, the user space daemon of FUSE, *afsfuse client*, reads command from /dev/fuse

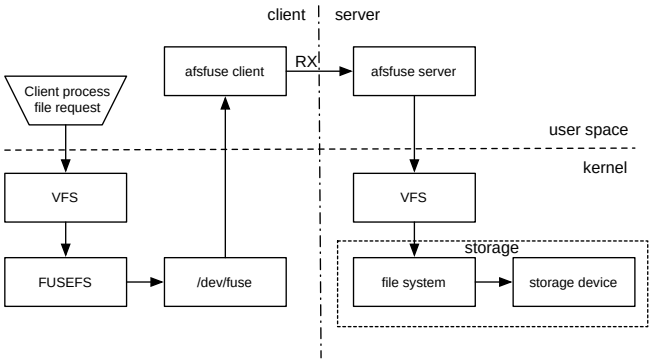

Fig. 3: Flow of AFS FUSE layer

Table 2: Hardware specifications

CPU	Intel® Xeon® CPU E5620 @ 2.4GHz 4C/8T × 2
RAM	4GB DDR3-1066MHz × 3
GPU	Nvdia® Tesla M2050 × 1
HDD	Hitachi 1.5TB 7200RPM × 2 (RAID 1)

Table 3: Software settings

OS	Ubuntu Server 10.04.3-amd64
Kernel	Linux 2.6.32-33

CPU lib	Jerasure 1.2
CUDA	4.0

and calls the corresponding xmp_xxx functions according to the fuse_operations list registered by *afsfuse client*. The xmp_xxx functions then invoke the corresponding rxc_rxc_xxx functions in *afsfuse server* via Rx to actually access the storage device and do the accompanying CRS computations if the file written to has the extended file attribute named "*user.crsfs.rlevel*" and its value is valid as listed in table 1.

The only job of the client node—with *afsfuse client* running—is to forward these file requests captured by *FUSEFS* to the server node—with *afsfuse server* running—via Rx protocol. All the CRS encoding/decoding operations are performed on the server node. There could be a storage node if the storage device is outside of the server node, such as using an external iSCSI storage node.

3.5.2 Implementations in AFSFUSE Server

The important functions that trigger the CRS coding routines in *afsfuse server* are the followings: setxattr(), write() and read().

a) Setxattr: In setxattr(), whenever there's a value change at "*user.crsfs.rlevel*" and the new value is valid, *afsfuse server* will read all the contents of the file 512-KB chunk by 512-KB chunk and skip the last one if the file size is not a multiple of 512 KB.

b) Write: As for write(), due to the limitation of the linux kernel and FUSE, the maximum write size is 4 KB. Even if this limitation dose not exist, it can't be assured that the write file request size is always 512 KB. Therefore, the write request is buffered up in a 512-KB buffer on 512-KB chunk basis Whenever 512-KB chunk is buffered up, the CRS encoding operation will be triggered asynchronously.

c) Read: As for the read(), after *afsfuse server* performing the actual file accesses, if there's an I/O error, the CRS recovering procedure is triggered. Assume that the file can tolerate up to m-page erasures according to its rlevel.

First, *afsfuse server* reads the 512-KB data chunk and $4m$-KB checksum chunk page by page. If the page is read without the *EIO* error, *afsfuse server* copys it to the 512-KB buffer. Otherwise, *afsfuse server* marks the value of the int erased[x] to 1 where x is the index number of the current page in the big chunk as described in section 3.4. All the recovering routines need are the first 512-KB survived pages and the erased[$128 + m$] with the erased page indexes set to 1. Then, *afsfuse server* calls crs_set_rlevel() to create the decoding matrix and then invokes crs_coding() to submit the job to GPU as mentioned in section 3.4. After that, crs_synch() must be called before returning the values back to xmp_read() in *afsfuse client*.

After all the missing pages in the big chunk are recovered, *afsfuse server* just re-writes these pages at the same file offset. The underlying storage devices, such as hard disks, will re-map these logic block addresses (LBAs) of the bad sectors (or pages) to the new ones in the reserved area if they encounter I/O errors with write operations.

4. Evaluation

In this section, both of the GPU primitive for CRS coding and the file operations—setxattr, write, and read—on AFS FUSE layer are evaluated.

4.1 Experiment Environment

As listed in table 2, the computer used in this evaluation is a powerful single node computer which runs all the client, server and storage nodes.

The software settings are described in table 3. Notice that, the CPU coding library used as the baseline for comparison is the Jerasure version 1.2 released by James S. Plank [14]. The Jerasure routines for CRS coding are wrapped up as the same interface as the CRS Coding layer described in section 3.4 and are inserted at the same position in the AFS FUSE layer. Therefore, the Jerasure coding routines also benefit from avoiding excess encoding operations generation if rlevel of the current job is the same as the one of the last job.

Due to the limitation of both the linux kernel and the FUSE framework, each write operation can only write up to 4-KB data per write request. Any write system call with data size larger than 4 KB is split into 4-KB write requests automatically. Similarly, the read operation is limited to 128-KB data transfer per read request.

In order to test the performance of transparent recovery with maximum erasures, the errno is set to EIO selectively and the m erasures are distributed evenly into the 128 data units. This happens only when *afsfuse client* reads the first page of each 512-KB chunk, resulting in one recovery operation for each 512-KB chunk. The read evaluation is performed by directly reading from files with preset reliability levels and excludes the time writing the recovered pages back to the files.

All the evaluated results illustrated in the following graphs are the average values of 10 identical experiments. Each experiment is tested with all reliability levels (from 1 to 4) and file sizes (from 512 KB to 16 MB or 1 GB). All the GPU parts are tested with stream_count set to 10.

4.2 GPU Primitive for CRS Coding

Fig. 4 shows the performance of GPU Primitive for CRS coding. The *htod* stands for "host to device memory copy" and the *dtoh* stands for "device to host memory copy" similarly. The m, n in each test set mean the number of checksum rows (m) and the packet size (n). There are total $\frac{m}{\omega}$ checksum units and $\frac{k}{\omega}$ data units in one big chunk, where k is 1024 and ω is 8 in this work. Moreover, both tests of 4096 bits and 8192 bits packet size are performed to examine the possibility of increasing the erasure unit size from 4 KB to 8 KB. The memory copy size of the htod and dtoh are $k \times n$ bits (data transfer) and $m \times n$ bits (checksum transfer) respectively.

For the computation part, the performance of the (64, 1024) on 8192 bits packet size is much better than the one on 4096 bits packet size, which means the workload of the latter can't fully occupy GPU. And the throughput becomes nearly half from (m, k) to $(2m, k)$ as the complexity doubles from m to $2m$. Besides these tests, (16, 64) like RAID-6, including 2 checksum units and 8 data units, is also tested and reaches up to 14GB/s with large packet size. This shows that the GPU Primitive is quite efficient.

4.3 AFS FUSE Layer

The FUSE and the AFS FUSE introduce about 3.2 ms and 24 ms overhead per 512-KB chunk write system call respectively. The former is measured by launching a write system call with 512-KB data from a user space program, and directly returned from xmp_write() in *afsfuse client*. Similarly, the latter is measured by using the same operations, but this time, it's returned from rxc_rxc_write() in *afsfuse server* after receiving the arguments of xmp_write() in *afsfuse client* via Rx.

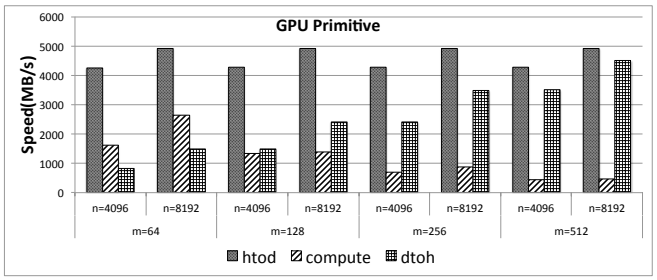

Fig. 4: Throughput of GPU primitive for CRS coding

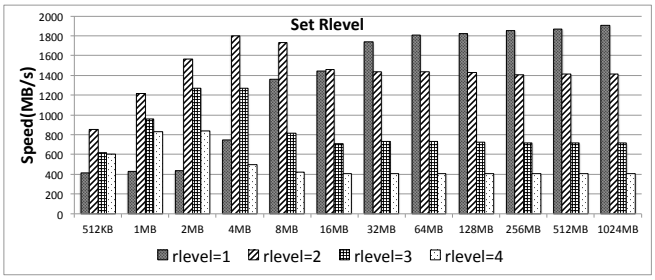
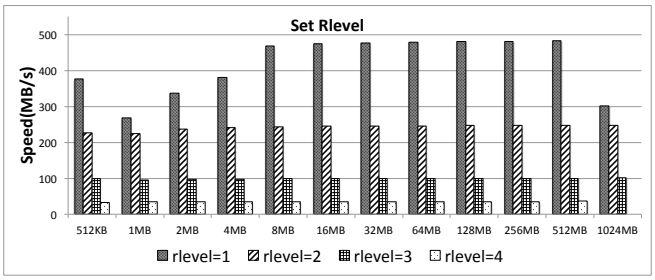


(a)



(b)

Fig. 5: Throughput of setting different rlevels on: (a) GPU. (b) CPU.

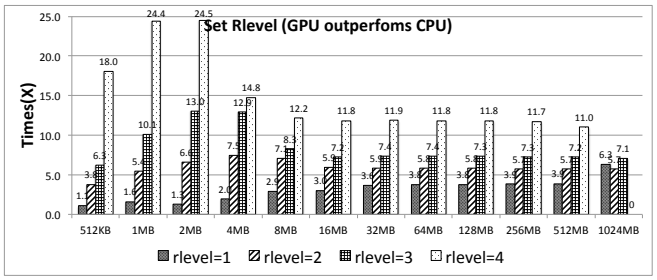


Fig. 6: Speed comparison on setting different rlevels between GPU and CPU

4.3.1 Performance of Setting Reliability Levels

As shown in fig. 5 and 6, the performance of the GPU encoding outperforms the CPU's, starting from 1.1x up to 24.5x. The results of these tests are all beyond the speed of the hard disk because all the tests are performed 10 times such that almost all files are cached in RAM.

All the performance results, except for rlevel=1, show the trend of first increasing and then decreasing to some stable value as data size increases. Some of them even outperform their counterparts in GPU primitive illustrated in fig. 4. That is the result of asynchronized operation functionality provided by CrystalGPU. By setting stream_count to 10 in this work, there are at most 10 CRS encoding/decoding jobs on the fly, which means that when the data size is less than or equal to 5 MB, *afsfuse server* at rxc_rxc_write() just reads 512-KB data from the file, copies them to the input buffer of CrystalGPU, invokes the encoding operation and then continues to encode the next 512-KB chunk *without any blocking delay*.

However, for all tests with rlevel=1, there's little benefit because the encoding task is so light such that before *afsfuse server* submits the next encoding job, the encoding job for previous chunk has already been finished.

Notice that, there's no test result in rlevel=4, 1024-MB file test on CPU because the setxattr system call has a time limit, around 14 seconds, which causes the test finished with the following error: *attr_set: Operation not permitted*.

4.3.2 Performance of Write Operations

The write performance on different size of files is also evaluated. It is tested by writing different size of data to the corresponding zero-length files with preset reliability levels. The result is shown in fig. 7. The tests with rlevel=0 are performed with no reliability levels.

As illustrated in fig. 7, the throughput of the write operations on GPU is quite stable due to asynchronized operation functionality. On the other hand, the throughput of the write operations on CPU decreases as rlevel increases because the CRS encoding operations on CPU are executed on the same thread as *afsfuse server*. Therefore, the request service time includes the encoding operation time, which hurts the performance.

All of the tests are limited by the maximum throughput in this framework. The throughput is mostly under 20 MB/s because the write system calls with data size larger than 4 KB are split into multiple 4 KB file requests as mentioned in section 4.1. Together with the round-trip overhead in the AFS FUSE framework, the throughput of the write operations becomes quite limited compared to the one of the read operations which can reach up to 120 MB/s. However, if there are multiple client nodes accessing the same server node, the total throughput can be aggregated to a larger one, reducing the impact of the low throughput for a single client node.

4.3.3 Performance of Transparent Recovery on Read Operations

The recovery throughput is quite low as shown in fig. 8 because the recovery procedure is a synchronized operation.

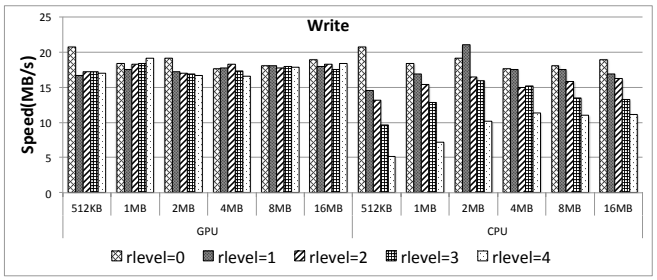

Fig. 7: Throughput of write operations.

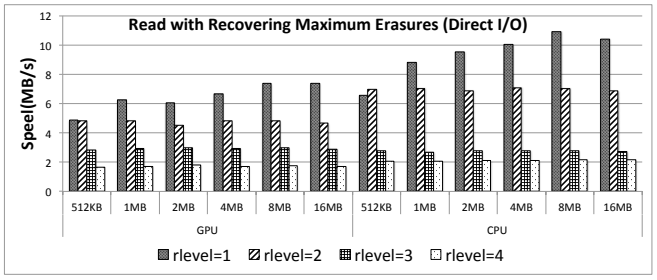

Fig. 8: Throughput of read operations with transparent recovery.

The client must block and wait until all the recovery operations finish, or this read operation fails as the data which the client requested for can't be served immediately. However, since I/O errors seldom happen, the request service time for the read operation is more important than the throughput of the recovery procedure. For a single 512-KB read operation with maximum erasures on GPU, the request service time for rlevel=1, 2, 3 and 4 are 47, 75, 126 and 233 ms respectively. When executed on CPU, these are 31, 39, 136 and 181 ms respectively.

Due to the memory transfer overhead and the synchronization of the recovery procedure, the performance of the GPU part is even worse than the one of the CPU part. However, for the tests of the rlevel=4, the performance of the GPU part is much the same as the one of the CPU part because the GPU with more computing power takes the advantage of less computation time compared to the CPU as the complexity increases.

5. Conclusion

In this work, the original file-wise reliability scheme is revised to cope with the larger page size in storage devices nowadays, and a prototype file system, *CRSFS*, is proposed to implement it with GPU acceleration and flexible design.

GPU primitive for CRS coding is a CUDA program optimized for the Fermi architecture of Nvidia GPUs. Combined with CrystalGPU, it shows up to 24.5x performance gains compared to the CPU counterpart in AFS FUSE layer. Therefore, it's clearly shown that the speed of CRS

encoding/decoding operations is no longer the performance bottleneck.

In addition to the GPU acceleration, CRSFS is also integrated with FUSE and Rx in AFS FUSE layer to provide high flexibility on storage system configurations. The client node in AFS FUSE layer provides POSIX file system APIs to client file requests via FUSE, which means that most programs can benefit from the flexible file-wise reliability scheme provided by CRSFS without rewriting their read/ write operations.

Abstract - *To implement fault detection under large-scale, high churn, strong reliability required network environments, a small proportion of members are likely to be more critical than others. The communications would be reduced significantly by removing them. We further the studies on GFDP (Grouping Fault Detection Protocol) and propose a Partitioning-avoidance GFDP (Pa-GFDP) to enhance the survivability of a detection system. Pa-GFDP could detect the critical members in the distributed system and neutralize them. Without global information, the accurate detection of critical members could be accomplished with little traffic overhead and within limited time threshold. Pa-GFDP was proven to be correct and effective by experiments.*

Keywords: Distributed System; Fault Detection; Survivability; Critical Member; Neutralization

1 Introduction

In recent years, the progress in deploying large-scale distributed systems such as Grid, Cloud, Wireless Sensor Networks (WSN) and P2P overlay networks, has been pretty fast. Related studies mainly focused on the subjects of efficient information transmission, integrity of functions, scalability and extensibility. But researches on the dependability of a system have drawn more and more attentions nowadays. David Patterson [1] has pointed out that the construction of today's computer system is to provide high-reliable network services. But the large open distributed systems suffer from threats of intrusions, attacks, component failures and so on, which make the systems undependable. How to deliver scalable and trustworthy network computing services using untrusted intermediaries becomes one of the most key tasks to build dependable distributed systems.

One of the most efficient ways to enhance the system's dependability is fault monitoring, while the fault detection is the fundamental component of fault monitoring. The traditional solutions of fault detection do not meet the requirements of modern large-scale distributed systems. The latest research achievements designed distributed approach to execute fault detection. As described in [7] and [8], the detectors formed a distributed system over the networks themselves.

For a large-scale distributed system, it is often not cost effective to protect all the nodes. Also, detectors in a distributed system are usually not equally important from the dependability point of view. Many researchers noticed the existence of critical links and critical nodes in the context of P2P overlay networks and WSNs. And in a distributed detection system, the same researches are necessary to enhance the survivability of the detection function.

An enhanced Grouping Fault Detection Protocol (GFDP [8]) called Partitioning avoidance GFDP (Pa-GFDP) is designed in this paper. And the highlights of Pa-GFDP are summarized as follows: 1) Local: Without global knowledge, a detector can identify whether it is a critical one based solely on local information; 2) Adaptive accuracy: Using limited information to estimate a critical member with high probability; 3) Traffic lightweight: No need to insert any extra traffic into the network; 4) Dynamic: As detectors could come and leave frequently, Pa-GFDP is able to run at each detector at any time to identify itself if it becomes a critical one at the given time and neutralize it.

The remainder of this paper is organized as follow. Section 2 discusses related works, the system model and definitions are introduced in section3, the protocol is discussed in section4. Experiments and conclusions are presented in section 5 and 6 respectively.

2 Related work

Highly reliable application systems which support fault detection based on fast developing Grid, P2P, and Wireless Sensor Networks systems have been brought out [9-11]. But traditional fault detection methods could not meet the requirements for modern networks. So several fault detection algorithms were brought out to satisfy these requirements such as large-scale, strong-dynamics and transmission-uncertainty [12-14]. And most of these algorithms are based on static heart-beat detection, but which could not quite meet the requirement of dynamics. A dynamic heart-beat fault detection based on grey model which efficiently reduces the

observed sample size is presented in [9], it solved the problem of dynamics in distributed systems, but it needs a large sample size, and with the problem of large network overhead.

Renesse [15] proposed a Gossip-style fault detection protocol to solve the problem of probably network congestion during messages dissemination using the fault detection based on time prediction. We furthered the theory and developed GFDP [8] and Bt-GFDP [7]. This protocol takes the advantage of the high reliability of message dissemination in the network while avoids the problem of network congestion, meanwhile the redundant messages were controlled in the system.

In our former works [7] and [8], when the detectors probabilistically leave and re-join the system, the detection structure becomes unstable. According to the observation of Saroiu et al. [3], to stabilize the detection system, cut vertexes and links should be neutralized.

3 Definitions and Limitations

A network monitoring system consists of a set of multiple members with limited size:

$$\Pi = \{m_1, m_2, \cdots, m_i\}, \text{ for } i > 2 \text{ and } i \in N$$

m_i in Π here is an abstract presentation of a module or a process, or even a node in the monitoring system. And members may be alive or failed, in other words, the member in the system may join in or leave out randomly.

The set of fault detectors in the system is defined as:

$$\Omega = \{d_1, d_2, \cdots, d_j\}, \text{ for } j > 2 \text{ and } j \in N$$

Any m_i in Π has a corresponding d_j exists in Ω, d_j is called a fault detector attached to m_i. An active member means its detector participates in the monitoring system; while a failed one means its detector may be crashed or detached. In the following description, we use "member" and its attached "detector" as the same meaning.

The following are the definitions used in this specification.

Component: A component is a maximally connected subgraph.

CM: Short for Critical Member, also refer as Cut Vertex. A CM is a vertex of a graph such that removal of it causes an increase in the number of connected components.

Bridge: A bridge, or cut edge, is an edge whose removal disconnects a graph.

K-connected: If it is always possible to establish a path from any vertex to all others even after removing any (k-1) vertices, then the graph is said to be k-connected.

Block: also called bi-connected component, a block is a maximally connected subgraph having no CM.

Three possible cases are illustrated in Fig.1, and CMs are colored in grey. In Fig.1(a), the CM is the joint of a 2-connected subgragh and a bridge; in (b), the CM is the joint of two 2-connected subgraphs; and in (c), the CM in the middle is the joint of two bridges. Indeed, all CMs fall into the three cases.

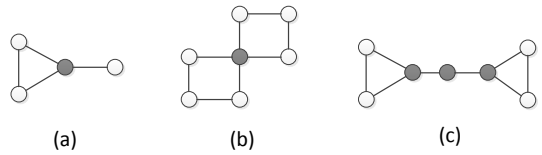

Fig.1 Three cases of CM

In this paper, we would consider the case of cut vertex. Bridges will not be considered. As removal either a vertex of a bridge would disconnect a graph.

4 Protocol specification

This section describes our distributed approach to identify the CMs under a large-scale distributed high-churn environment. The communication between members is derived from GFDP [8], mainly by gossiping. With the help of information inter-changed between members, we then design a zero-overhead passive detection method to identify CMs. The accuracy of the detection can be reinforced by an active detection method with a fairly low cost. Both passive and active detections are new functions added into Pa-GFDP, and both detections will be executed periodically to reflect the topologically changed of detection system.

4.1 Passive CM Detection

In the detection system which running Pa-GFDP, a message is propagated from one detector to others hop-by-hop using the gossiping mechanism. The forwarding message contains the path information from the starting detector to the current one. We propose to utilize such information to find CMs by sorting the neighbors of a detector into one or more blocks. According to the aforementioned definition, a detector is denoted as a CM if its neighbors belong to multiple blocks. In our scheme, we assume the following characteristics of gossiping in the monitoring system.

(1) A detector forwards the received message to part of its local view neighbors except the one where the message came from. And the number of forwarding destinations is determined by the configured gossiping fan-out, we denoted as c here.

(2) Each message is assigned a globally unique message ID. As every detector in the monitoring system only maintains a local view of its own, it does not have global

knowledge of the system. And as every detector in the system has a unique ID $d_i.id$, and it has an aforementioned *Beat Counter*, a message could be generated by combining $d_i.id$ with *Beat Counter*. Here we denote it as *Msg.id*.

(3) A detector gossips each message only once. If it receives the same message later, it simply drops the duplicates.

In the passive detection, each member keeps track of recently received messages. A list of records is cached on each member, called *MsgList*, with each entry representing a message received in the format of < *Msg.id*, list of $d_i.id$ that the message has traversed members>. A member also flags its neighbors their block information. At the beginning of a passive detection period, *MsgList* is empty and all neighbors of a member are assumed to be in different blocks. During the periodical execution of passive detection, a member randomly receives messages from its neighbors. By examining the path information of the received messages, it could discover circles formed by its neighbors. Thus a member could deduce that all neighbors on a circle belong to a block including itself. When two circles shares one or more members exclusive of itself, then it could deduce that the members on both circles are in the same block. This is how blocks merging and flags changing in a member's local view. As more messages arrive, member keeps merging the blocks and changing the block flags of its neighbors. The pseudo code of *On_Recieving*() is illustrated in Fig.2.

```
/* msg: a gossiping message;
msg.TTL: a pre-configured hops times that msg can be
     forwarded;
msg.id: the message ID of msg;
N: the detector receiving msg.*/
1.  On_Receiving( )
2.  {
3.   if( N receives msg for the 1st time )
4.     N creates a new entry in N.MsgList;
5.     if( msg.TTL > 0 )
6.       Gossip(msg); //forwarding the msg
7.   }
8.   else  //N has received the msg before
9.   {
10.    N creates a new entry in N.MsgList;
11.    FindEntry( N.MsgList, Msg.id ); //Find the entries
                                       //with same Msg.id
12.    MergeBlk( N.LocalView );  //Merge blocks and
                                 //flag Local view
13.    N drops msg;
14.  }
15. }
```

Fig.2 Pseudo code of function *On_Receiving*()

After running a determined period of passive CM detection, all the neighbors of a member will probably be merged into a few blocks. If there are only one block flag in a member's local view, it is not a CM. Otherwise; an active detection process is triggered for further determination, which is introduced in 4.2. Note that the passive detection is executed passively during the process of message dissemination. All the information is attached in the normal messages, so it would not incur any additional traffic overhead.

4.2 Active CM Detection

With the passive detection, a member knows for sure that it is not a CM if all the neighbors belong to a single block. However, having two or more blocks remaining at the end of passive detection does not mean a member is a CM. For example, a node might not be able to receive messages containing all possible paths from its neighbors because the messages are forwarded in a manner of gossip, or the message *TTL* threshold is reached. In order to identify CMs, an active detection is necessary. Compared to the passive detection, the active detection achieves shorter convergence time at the cost of additional but acceptable traffic overhead.

If a member's block flags are not consistent after a long-enough period of passive detection, which means that the neighbors of that member are sorted into two or more blocks, it regards itself as a suspect of CM and immediately starts an active detection process.

At first, it randomly selects a neighbor from each block and numbers the each neighbor with a unique *Block-index* (e.g. 1, 2, 3...). Then the node sends probe messages to these neighbors. The format of the probe message is < $d_i.id$, *Msg.id*, *TTL*, *Block-index*>, where $d_i.id$ is the suspect's member ID, *Msg.id* keeps the records the time the probe message is generated, *TTL* (time to live) is a pre-configured number of hops that the message can be forwarded, and *Block-index* denotes the index of the block to which the suspect sends the probe message. Each member keeps a probe message list. There is one entry for each suspect in the connection list with the format of <suspect's $d_i.id$, *Msg.id*, *Block-index* 1, *Block-index* 2...>.

Upon receiving a probe message, one of the following situations may arise.

(1) The member has already received the message, or the *Msg.id* of the message is smaller than that stored in the corresponding probe message list entry. The member just drops the message.

(2) There is no entry for the suspect that issues this probe message. The member creates a new entry for it.

(3) The *Msg.id* in the received message is larger than that stored in the corresponding probe message list entry. The suspect replaces the older *Msg.id* and *Block-indexes* stored in the probe message list with the new one.

(4) The *Msg.id* of the received message is the same as the one stored in the corresponding probe message list entry but the *Block-index* of the message is not the same. The node

adds the new *Block-index* to the corresponding entry and sends an arrival message back to the suspect. The arrival message therefore contains d_i.*id* of the current member, two or more *Block-indexes*, and the *Msg.id* stored in the entry. A member does not send any arrival messages until it receives at least two probe messages with different *Block-indexes*.

In this way, the neighbors of a CM suspect can be merged into fewer and fewer blocks. If only one block remains in its local view, the suspect is not a CM. Otherwise; the suspect must be a CM. In the case of being verified a CM. a progress of CM neutralization would be trigger, which is discussed below. Since the initial *TTL* value of a probe message is usually small, we are able to get the result of the active detection much sooner than the passive detection. In other words, the active detection can be applied as a useful complement to the passive detection. It can also be utilized as an independent approach to identify CMs if we value speed over cost.

4.3 CM Neutralization

The goal of CM neutralization is to enhance the system survivability with respect to topology connectivity. CM neutralization is relatively easy to achieve by building extra connections between members in different blocks. After the new connection is built, two initially independent blocks are merged into one block. Consequently, all members in the graph will get 2-connected and the CM becomes a normal node.

4.4 Traffic Overhead

We evaluate the traffic overhead by counting the messages delivered due to the CM detections. Note that gossiping is adopted in our basic GFDP as the basic mechanism for data dissemination. Even if there is no passive detection, the traffic overhead of gossiping does exist as an element of system running. Hence the passive detection does not incur any additional traffic overhead because it only utilizes the information extracted from the existing messages. For the active detection, suppose the system has n members, let ***c*** be the gossiping fan-out and let ***t*** be the initial *TTL* value.

Note that a detector will not forward the probe message if it has already sent an arrival message back to the corresponding suspect. We define the *traversal set* as the members which are traversed by the same block number of a suspect's probe message. And the traversal sets of different blocks of a suspect will not overlap. As a result, the total traffic overhead of probe messages is $O(n^2c/2)$, where $nc/2$ is the number of edges in the whole graph. On the other hand, the traffic overhead is also limited by the initial *TTL* value. It can never exceed $O(nc^t)$. Therefore the total traffic overhead of forwarding probe messages is $min(O(n^2c/2), O(nc^t))$. In the detection system, the value of c is much smaller than that of n. The inequality $c^t \leqslant n$ holds when the initial *TTL* value t is limited to save traffic cost. Thus we can conclude that the total traffic overhead of active detection is $O(nc^t)$.

5 Experiments

We make use of the test environment of [8], but we changed some configurations to modify the topology of the detection system. Altogether we have generated 10 different initial configurations with system size from 500 to 5000. 3of them are selected as representative for the subsequent experiments, their initial configurations are listed in Tab.1.

Tab.1 Information of different configurations

Round	System Size (n)	Gossip Fan-out (c)	Number of CMs	TTL (t)
1	1000	2	100	5
2	1500	4	150	5
3	3000	4	300	10

In the series of experiments we first evaluate the accuracy of CMs detection. The result is shown in Fig.3. From the result we can see that the gossiping fan-out would effect on the efficiency of CMs detection. But larger t would incur much higher traffic overhead. Moreover, larger *TTL* has less effect at last several rounds.

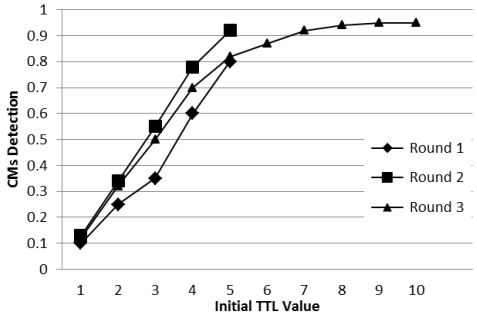

Fig.3 Accuracy of CMs Detection

We evaluate the survivability of the detection system by using GFDP and Pa-GFDP comparatively. The result is shown in Fig.4. In both experiments we deleted the CMs at a fixed rate while GFDP and Pa-GFDP were running. From the test result we can see that Pa-GFDP improves the survivability of the system remarkably.

6 Conclusions

The connectivity among members basically determines the survivability of communications in large-scale distributed systems. It is observed that a small portion of members are more critical to the system than others. Removal of the critical ones would destroy the topology of a connected graph. To further our work on GFDP, we propose a partition avoidance approach to identify critical members and neutralize them. Compare to GFDP, the proposed Pa-GFDP mainly appends three functions: passive CM detection, active CM detection

and CM neutralization. From the experimental results, we can discover that by deploying Pa-GFDP we could enhance the survivability of the system significantly.

Moreover, by little modification, the methodologies proposed in this paper could be used in many large-scale distributed systems, like WSN, P2P overlay networks, to identify the cut vertexes and cure them.

AN APPROACH FOR FAULT MANAGEMENT BASED ON AUTONOMIC COMPUTING PLUS MOBILE AGENTS

Sergio Armando Gutiérrez, Ms.Eng[1], John Willian Branch, PhD[2]
[12]Facultad de Minas, Universidad Nacional de Colombia, Sede Medellín
Email: saguti|jwbranch@unal.edu.co

Abstract - *In this paper, a new approach for Fault Management, based on the autonomic computing paradigm and mobile agents technology is introduced. The main features of this approach are discussed, its main benefits are presented and some result of its application are evaluated..*

Keywords: Autonomic computing, mobile agents, expert systems, fault management

1 Introduction

The capacity of detecting failures in a given system is a very important challenge which arises in many engineering disciplines. When dealing with expensive equipment's, large and complex systems, or an infrastructure on which critical services or processes depend, requirements of availability and reliability increase dramatically. This is a reason why fault management becomes a very important research topic in areas such as chemical, aerospatial, nuclear, and electrical engineering, among many others [1]. An emergent field in which expensive equipment and critical systems arise is telecommunications (TELCO). Today's TELCO networks are very complex systems involving hundreds and even thousands of components, every one having multiple variables and features to be evaluated in order to assess how well the services running on them are performing. Due to need of quality service, and because of the growing dependency that organizations and people have on these services, networks (and the infrastructure and platforms where services run), need to have a high degree of availability as well as the capacity to react to failures and problems which might arise during their operation. Every day, critical mission is becoming a more commonly used term for designating the infrastructure which is used to run TELCO services. Critical mission means that systems should be available 100% of the time, and must not be interrupted under any circumstance, as an interruption might mean that a critical process cannot be performed [2]. This requirement of high availability implies that any event associated to failures in any component of the system be managed in such a way that the degradation or unavailability of a system be avoided or minimized as much as possible. This is the reason why fault management has become a big issue in the field of operation and engineering. As in many cases, the ability of human operators and supervisors is not quick and efficient enough to respond in the best way to the event of a failure. This work presents an alternative to conventional fault management based on Expert Systems by using two emergent technologies as Mobile Agents and Autonomic Computing

2 Fundamentals

2.1 Autonomic Computing

Autonomic Computing is a concept inherited from bioinspired computing in its beginnings. The first work where Autonomy Oriented Computing is introduced is the work by Liu et al [3]. This work defines the fundamentals of Autonomy in computing and the four main characteristics which should be exhibited by a computing system according to this paradigm:

• **Autonomy:** The entities in the system are rational individuals, which are capable to act in an independent way; in other words, the system does not have a central component and manager.

• **Emergent:** When system entities cooperate and work together, they exhibit behaviors not available or possible to obtain by individual entities separately.

• **Adaptive:** System components are capable to modify their behavior according to changes present in the environment where system operates.

• **Self-organized:** The system components are capable to organize themselves to achieve the previous commented behaviors. This paper also presents the several types of Autonomy Oriented Computing according to how autonomy is achieved by the system.

In Jin and Liu [4], Autonomy Oriented Computing is formally defined, by employing set notation to express the concepts associated: Environment, computing entity, state, behavior, goal are some of the concepts which are expressed in a formal language. From a more applied point of view, and again from a bioinspired perspective, Horn [5] presents the approach to Autonomic Computing from perspective of a industry leader as IBM.

Following Horn, there are eight keys elements which has an Autonomic Computing System:

• **Self-Awareness:** This is, the system should know itself. It will need detailed knowledge of its components, current status, ultimate capacity, and all connections with other systems to govern itself. It will need to know the extent of its "owned" resources, those it can borrow or lend, and those that can be shared or should be isolated.

• **Self-Configuration:** System configuration or "setup" must occur automatically. Also, the system must modify itself, in such a way that its configuration be the most adequate to cope with environment conditions.

• **Self-Optimization:** This is, the system will always try to find other ways to improve its functioning. It will monitor its constituent parts and fine-tune workflow to achieve predetermined system goals.

• **Self-Healing:** System must be able to recover from events that might cause malfunctioning. The system also must be able to detect problem or potential problems, and according to this, define alternate ways to perform, applying reconfiguration to keep the system working.

• **Self-Protection**: Starting from the fact of the potentially aggressive and hostile environment where system resides, it must be able to detect, protect and identify potential attacks or vulnerabilities, so that it can protect itself and maintaining working in a secure and consistent state.

• **Self-adaptability:** This is, the system must know its environment, the context which surrounds it when operating, and the other entities cohabitating with it. It must be able to adapt to this environment, and its changing conditions, by reconfiguring itself or optimizing itself.

• **Openness:** The components in system must be open to communicate each other, and must be able to work with shared technologies. Proprietary solutions are not compatible with Autonomic Computing philosophy.

• **Self-containment:** Components within an Autonomic Computing System must be able to perform the task or tasks they have assigned, not requiring external interventions for the performing itself, and hiding the complexity to end user.

Complementing the work by Horn, Lin et al [6] review Autonomic Computing from the perspective of Software Engineering. They present a proposal of metrics which could be used to evaluate the quality of frameworks based on Autonomic Computing. In other side, the works of Sterritt [7], Magedanz et al [8], Ionescu et al [9] and Tizghadam et al [10] evidentiate how Autonomic Computing has become a very important research topic in the field of Information Technologies, both for academic communities and for industries, in solving many problems which are becoming difficult to face with traditional and conventional approaches.

2.2 Mobile Agents

Agents are enjoying a lot of popularity as a novel abstraction for structuring distributed applications. It is a technology from the field of Artificial Intelligence. Although, there is not a precise and widely adopted definition for Agents, the tendency is define it through the features they should expose [11].

Following to Yubao and Renyuan [12], an agent is an entity possessing the following characteristics:
• **Self-government:** Agents should have the ability to governate themselves, without external interference from the outside world while they are performing their tasks.
• **Smart:** Agents should implement certain functions and be able to choose the required information to complete their tasks. They also should be able to get knowledge from the performing of their tasks.
• **Lasting:** The agents should survive, according to their participation in the tasks.
• **Co-relation:** This is the social behavior defined by theoretical definitions. In real world, the cooperation is presented as messages exchange among the agents in the system.

Figure 1 presents a classification of software agents according their functions, their properties, or other relevant features which can be assigned to them. Specifically, a feature relevant in the approach to be proposed is mobility. That is, the capacity of the agent to move itself autonomously across the environment where it runs, with the goal to execute its designated task at other locations where be required.

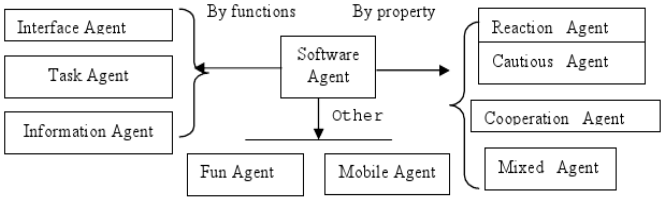

Figure 1: Software Agent Classification [12]

3 Proposed Architecture

For the goal of offering high availability and reliability on critical systems, increasing the reliability of Fault Management (FM) component or components is a very important goal to achieve. The elements detecting Faults, with the goal of detect them, isolating them or event correct them should become very smart and reliable, and should adapt to the complexity of the systems where they are meant to be used.

The approach to FM which is proposed consists in implementing Mobile Agents (MA), which exhibit the eight fundamental features of AC defined by Horn [Horn, 2001]. These agents will be designated to monitor specific resources, and will use a Knowledge Database which will store criteria defining faults for the associated resource. According to these criteria, the agents will be able to anticipate to faults on the component, by analyzing and detecting patterns on the designated assess metrics for the resource and by means of mobility feature, agents would be able to move across the system to monitor the designated resource at other locations.
The architecture for the proposed approach is composed by the following components:
• Knowledge Database (KDB): Is a database containing the criteria which are going to use by the agents to determine faults and how to react before them.
• Data Collector (DC): It is a component which will receive the data coming from the agents, and will send them information regarding changes in the criteria for fault detection.
• Mobile Agent (MA): It is an agent which will perform the actions on the resource and will traverse the network monitoring similar resources in other hosts.
• Managed Resource (MR): It is the resource in the hosts which will be supervised by the agents, for possible faults and problems in its performance. This resource can be a hardware element, a software element, or the behavior of a particular metric or behavior.

Figure 2 illustrates the architecture.

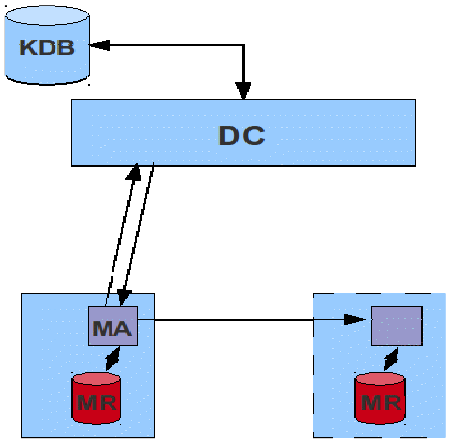

Figure 2: Proposed approach architecture.

Database as mentioned, will have two purposes. First, it will be to contain the data reported by the agents, for example, whenever it performs a correction because of a failure, or according to periodic monitoring if defined. The other purpose will be to store rules or instructions defining the criteria to act when a faulty behavior is detected. For example, if a failure is a filesystem full, the criteria could be what files to delete, or what kind of files to delete. Also, according to the functionality which performs the system component, the collected data would be useful to predict that a failure is yet to come, and so, indicate a proactive action triggered on the MA.
Data collector would be the entity which communicates with the MA. It will have two purposes. The first, collect the data from the MA, by receiving on them, or by triggering a data query to them. The other will be to perform smart analysis on data collected, and if possible, to modify the criteria of fault detection and notify these changes on criteria to MA. For example, if MR is a filesystem, the data collector could analyze the growing rate of a particular file and predict that it might cause a failure by full filesystem and notify this to MA. Also, the data collector would be useful to notify exceptions to MA, so that they could ignore the application of a criteria. The DC could be an agent itself. Mobile Agent would be the entity performing the detection and correction of failures on the hosts. It would be implemented in such a way to apply criteria to solve faults in a particular resource, and it could choose to travel or to clone itself to send a copy of itself to another host requiring supervision in the same resource. Managed Resource would be the system component under supervision and control by Mobile Agents. It might be a hardware or software element, or even a service or task.

4 Experiments and Results

The present section describes de tests performed to validate the advantages of the proposed approach for fault management. For these tests, a preliminary implementation of the proposed approach was performed, and run on a typical platform for the voice over IP Service. Two aspects were assessed. The time required to detect a failure, and the bandwidth consumed.
For the validation of the approach proposed in this work, a typical platform in the Voice over IP Services was chosen. This kind of platform was chosen, because of its criticity, and the relationships established between the components, which tend to induce failures in the other components, when a problem occurs.
The figure 3 depicts the testbed which was used for the implementation.

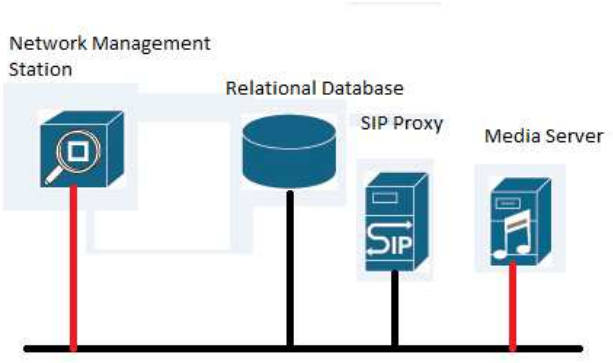

Figure 3: Testbed platform

For the implementation of the agents, the used tool was JADE, a very popular framework for implementing Mobile Agents on Java Programming Language.

For the testing, three scenarios were defined and tested. The three scenarios consist in inducing failures on a Resource node, and measuring the time used to detect (and correct) the failure.

4.1 Full filesystem event

On the first scenario, the first failure to be induced was a filesystem full on Relational Database. The failure was induced by creating an increasing size file, by means of an infinite loop script which concatenated 1MB files to an existing file until the whole filesystem was filled.

The SNMP based detection was performed by running a shell script which invocated snmpwalk system command once every second, querying the OID referencing the filesystem to be monitored. For the agent scenario, platform was started up, and a monitor agent was created on the supervised host, indicating it what filesystem to monitor. For this first test, no action was defined for the monitoring agent at startup time. At failure occurrence, DCA instructed the agent the action to perform, which in in this case was deleting the file causing the filesystem full.

Table 1 presents the results of the execution of this test scenario.

Variable	SNMP TEST	AGENT TEST
Elapsed time	3 mins, 42 sec	4 mins, 4 sec
Total packets	811	318
Average Bandwidth (Mbps/s)	0.003	0.002
Average packet size (Bytes)	87.893	155,082
Average packets per second	3,642	1,303

Table 1 : Data for the test of full filesystem fault at database

4.2 Dead system process

The second test scenario is the detection of a dead process within the SIP Proxy. The failure is induced by killing the process, making it disappears from system processes table.

The SNMP based detection was performed by running a shell script which invocated snmpwalk system command once every second, querying the OID referencing the entry of the process within the system process table exposed through SNMP. For the agent scenario, platform was started up, and a monitor agent was created on the supervised host, indicating the name of the executable associated to process. In this case, a single process was monitored, although the approach is valid for multiple instances of same process. For this test, no action was defined for the monitoring agent at start time. At failure occurrence, DCA instructed the monitoring agent to restart the process.

Table 2 presents the results of the test for a system dead process.

Variable	SNMP TEST	AGENT TEST
Elapsed time	1 min	1 min
Total packets	508	147
Average Bandwidth (Mbps/s)	0.005	0.003
Average packet size (Bytes)	87.893	155,082
Average packets per second	8,47	2.45

Table 2: Data of the test of dead system process at SIP Server

4.3 Network interface missconfiguration

The second test scenario is the detection of a missconfiguration within the Mediaserver. The failure is induced by modifying the network interface configuration, changing the duplex mode from full to half. This is a very common error on this kind of equipments, and usually causes malfunction in the service it offers.

The SNMP based detection was performed by running a shell script which invocated snmpwalk system command once every second, querying the OID referencing the duplex mode of the main network interface of the mediaserver. In this case, the monitoring script was capable, after detecting the error, to perform a correction by setting the parameter of duplex mode, by executing snmpset system command. For the agent scenario, platform was started up, and a monitor agent was created on the supervised host, indicating the name of the main network interface in the host.

For this test, no action was defined for the monitoring agent at start time. At failure occurrence, DCA instructed the monitoring agent to reconfigure the network interface.

Table 3 presents the results of the execution of this test scenario.

Variable	SNMP TEST	AGENT TEST
Elapsed time	2 min	2 min, 32 secs
Total packets	203	84
Average Bandwidth (Mbps/s)	0.001	0.0006
Average packet size (Bytes)	87.893	155,082
Average packets per second	1,69	0,55

Table 3: Data of the test of network interface missconfiguration at mediaserver.

5 Results Discussion

In this section, a discussion on the results obtained from the tests will be presented. A very important point to state is the fact that in the first two tests, besides of the fault detection, from the information that DCA returns at failure occurrence, the agent is capable to perform an action to correct the fault condition. The concept behind the implemented platform is providing the agents with logic and actions (behaviors) allowing that, from the information provided by the DCA in this case, they be capable to apply corrections.

In the standard implementation, SNMP based detection is not capable to correct complex faults as it should have external mechanisms to apply any correction. SNMP can solve very specific faults, if the correction consists in modifying a single variable, as seen on the third scenario, where the script could restore the network interface configuration. In the other cases, an autonomous correction y means of SNMP is not possible, and the intervention of a human operator is required. The fault correction is reactive, not proactive.

The agents implementation, by default is capable to provide mechanisms to apply corrections when particular types of faults are detected. Also, because of the local memory the agents have, they can try to apply corrections when faults are detected, without the need to ask for information to DCA, in an autonomous way. The agents, provided information to react to faults are capable to apply corrections in a proactive way. The traditional approaches, based on SNMP, are just based on notifications, and focused on alarm and notification triggering, leaving the action performed to correct the fault condition itself to an external entity (usually a human operator). It can be observed that the elapsed time, measured since monitoring was started until the fault condition was detected (and corrected), is a longer for agents than for SNMP. This can be explained as the agent platform (main container and satellital container) require some time for its initialization. In SNMP case, monitoring starts by just run the script executing snmpwalk. The average packet size is also greater for agents than SNMP because the network transport protocol that agent platform uses. JADE uses TCP for the communication, different to SNMP, which uses UDP. The usage of TCP as communication protocol in the agent platform increases the reliability of monitoring, as delivery of messages is guaranteed, and monitoring agents do not require to have additional logic for handling message delivery.

Another fact which can be observed is that agent approach requires less packets to be exchanged. As the agent communicates with DCA only for notifications and initialization tasks, and not for monitoring per se, less traffic is required. For SNMP, more packets are required, as the decision to detect the fault is taken at monitoring station, not in the monitored resource itself.

Briefing, from the point of view of the two variables assessed, the proposed approach, based on agents, shows to be more efficient, by exhibiting lower times to detect the fault, less traffic requirements, and besides, provides added value by the capability of executing and performing proactive corrective actions, to eliminate and avoid the fault conditions.

6 Conclusions

In this work, an approach for fault management using Autonomic Computing and Mobile Agents has been proposed. This approach ha showed to offer more advantages than conventional approaches by exhibiting the following features.

• From the architectural point of view, it is not server centric, as traditional systems, usually based on a master component which queries satelital agents to obtain information. Although the proposed approach has a master component, the monitoring agents do not require the communication with this component to perform their tasks, as they are designed to operate in autonomous way.

• It provides self-learning capacities. Traditional systems just report the fault by triggering an alarm when a threshold is reached, or when the fault itself arises, but they lack of efficient mechanisms to correct the fault. The agents in the proposed approach have the capacity to analyze causes of the detected problems, and perform further actions to avoid the fault occurrence.

• It provides a richer communication protocol among the involved entities, allowing having a detailed information regarding facts and actions to be performed. The concept of agents ontology provides a very robust mechanism for the communication protocol regarding message formats and interpretation. Traditional approaches are based on a simple request/response protocol, with very strict and limited message formats.

• It provides mobility, which allows to monitoring agents to move across the network to detect and correct faults. Traditional systems are based on static monitoring systems, which are confined to run at a single host. These features present a system which is very suitable for platforms as the ones used in Telecommunications service, which nowadays require high levels of availability because of the criticity of

the services they offer. Also, the implementation of the features previously mentioned contribute to improve the task of fault management, by providing added value to monitoring tasks, and correction for some of the limitations of traditional approaches.

Efficient data collection from Open Modeling Interface (OpenMI) components

Tom Bulatewicz, Daniel Andresen
{tombz@ksu.edu, dan@ksu.edu}

Abstract— *The management of output data from simulation models can be simplified in grid environments by automating and standardizing the way in which they are collected and stored. In the context of component-based computer models with well-defined input-output interfaces, general-purpose data collector components can be linked to model components to retrieve output data and deliver them to online repositories via web services. We have developed a distributed data collector component that adheres to the Open Modeling Interface (OpenMI). The component buffers data to minimize the impact on a simulation's runtime and shares the buffer across compute nodes for load-balancing and cooperative delivery of data to web services. The buffering capability resulted in minimal runtimes within a single simulation and reduced data delivery latencies for concurrently executing simulations across a cluster. In this paper we report on the design and performance of the component.*

Keywords: OpenMI, data, web services, modeling, simulation

1. Introduction

The output data produced by environmental computer simulations often provides a starting point for investigation into the phenomena being studied. The data may need to be archived, aggregated, processed, and analyzed statistically or geographically before they can be visualized and interpreted. These may be performed by an individual or as part of a collaborative effort between groups within or across institutions.

Model output traditionally takes the form of local data files that may be of a custom format or adhere to simple standards such has comma separated values and extensible markup language or more complex standards such as netCDF and various database formats. Managing output files can be challenging, particularly in a grid environment in which simulations execute on multiple machines across a compute cluster.

As an alternative to data files, model output data can be immediately relayed to an Internet-connected data storage service that serves as a single repository for the data. This facilitates sharing of the data over the Internet and automates common tasks such as data archiving. In the general case, this capability is added to a model program by either modifying the model source code or incorporating intermediary software (often via scripting). In the case of model components with well-defined input-output interfaces, a general-purpose data collector component can be attached to any model component to retrieve the output data. Such components can mitigate data management challenges in any linked modeling context.

The Open Modeling Interface (OpenMI) [1] defines a standard way for software components to exchange data with each other and coordinate their execution. It defines a set of capabilities that a component must possess in order for it to be linkable to other components. These capabilities are both descriptive, to support the task of specifying component interactions at the domain level, and functional, to support the execution of a set of linked components. To fulfill the descriptive requirements, a component must be capable of providing a list (via a function call) of the domain quantities that it can provide and those that it uses as input, along with the units and spatial distribution of each. These are called *output exchange items* and *input exchange items*, and in the case of model components there is typically one output item for each quantity that it simulates and one input item for each of its inputs. To fulfill the functional requirements, a component must possess a *GetValues* function through which it provides data (that correspond to the exchange items) at runtime.

The GetValues function has three parameters that collectively identify a quantity at a single point in time at one or more locations as illustrated in Figure 1. A quantity (labeled Q in the figure) is represented by an object with several properties such as a textual identifier and units information. A time T is represented by a simple date object. A list of locations E is represented by an *elementset* object that contains a collection of *element* objects that each have a textual identifier, spatial shape (point, line, or polygon) and geographic coordinates. The GetValues function returns an array of real numbers called a *valueset* V such that each number corresponds to an element (based on its index) and collectively represents the state of a quantity at a point in time.

The GetValues function not only provides a means for the exchange of data between a group of linked components (called a *composition*) but it also provides a means for their coordinated execution at runtime. A special component

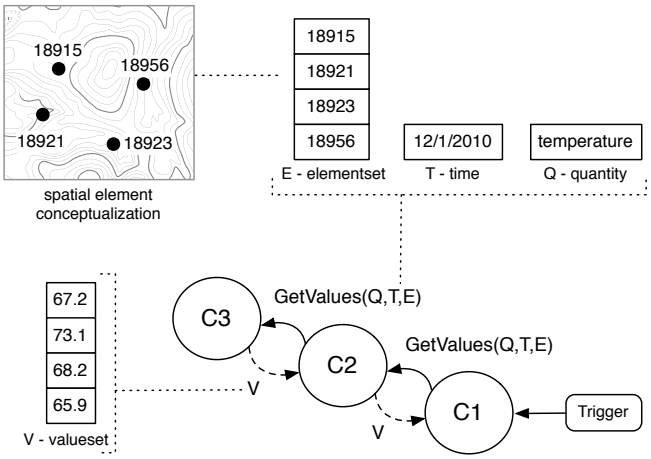

Fig. 1: OpenMI pull-based execution. Solid lines indicate function calls and dashed lines indicate the flow of data.

called a *trigger* begins by calling GetValues on one of the components. When GetValues is called on a component, it executes as many time steps as necessary to advance to the requested point in simulation time and returns a valueset corresponding to that time. Thus a component only executes time steps as-needed to respond to a GetValues call. If it needs input from another component in order to execute a time step it calls GetValues on that component and blocks until a valueset is returned. The components take turns executing synchronously and *pull* data from each other until the simulation completes.

Compositions of linked components can be created and executed using visual software tools. A scientist chooses a set of components, and for each one, assigns each output exchange item to another component's input exchange item. These assignments are called *links* and there may be multiple links between two components and may be in the same or opposite directions.

In this work we present the design and evaluation of a general-purpose Data Collector Component (DCC) that is capable of collecting data from OpenMI components and delivering them to online repositories. We describe the design and implementation of the DCC in the following section and present our experimental results in Section 3. We review related work in Section 4 and present our conclusions in Section 5.

2. Methods

Figure 2 illustrates the movement of data through a distributed data collection system for linked model components. Compositions of linked components execute on cluster nodes. Each composition includes a DCC that collects data from the components and delivers them to web services. Any web service that is capable of accepting data items consisting of a quantity identifier, date, list of location identifiers, and

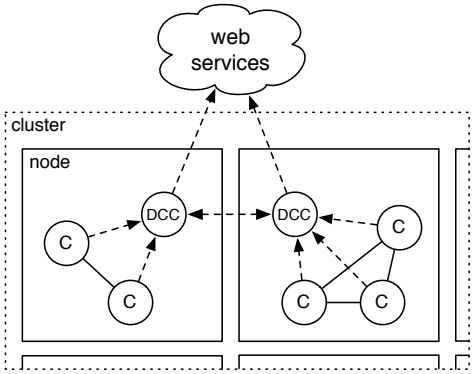

Fig. 2: System overview.

list of values, can be used.

2.1 Web Services

The Open Geospatial Consortium [2] publishes interface standards for location-based information and services to support interoperability. The Geographic Markup Language (GML) [3] standard defines XML schemas for geospatial information including observations data, which is capable of describing model output from OpenMI components. The prototype implementation of the DCC uses this XML schema to represent the data as they are sent to web services. An example of an XML document that conforms to the schema is given in Figure 3 (we used a more succinct gml:id attribute in place of a gml:location element). Additional XML schemas, such as Observations and Measurements [4] could be incorporated into the DCC as well.

```
<gml:Observation gml:id="18951">
  <gml:validTime>
    <gml:TimeInstant>
      <gml:timePosition>2010-12-01T12:00:00</gml:timePosition>
    </gml:TimeInstant>
  </gml:validTime>
  <gml:resultOf>
    <app:Temperature>67.2</app:Temperature>
  </gml:resultOf>
</gml:Observation>
```

Fig. 3: GML description of a single value.

If a DCC were to make a web service call each time it collects a valueset then the execution of the simulation would be paused for the duration of the call due to the synchronous execution of components. In addition, sending a single valueset in each web service call may result in inefficient network utilization when the network latency is comparable to the transmission time of the valueset.

In the ideal case the collection of valuesets would not increase the runtime of a simulation and a sufficient number of valuesets would be transferred in each web service call to achieve efficient network utilization. To these ends the DCC utilizes a buffer that enables the sending of valuesets to be

asynchronous with respect to their collection and allows for the coalescing of multiple valuesets into a single web service call. The buffer is shared among all DCC's across a cluster to provide a total buffer size that is greater than the local buffer size of each individual and to allow cooperation in delivering the buffered data.

The implementation of the DCC consists of a buffering module and a delivery module as illustrated in Figure 4. The buffering module collects valuesets from components and stores them in the shared buffer. The delivery module removes valuesets from the buffer and delivers them to web services. The behavior of these modules is dictated by three

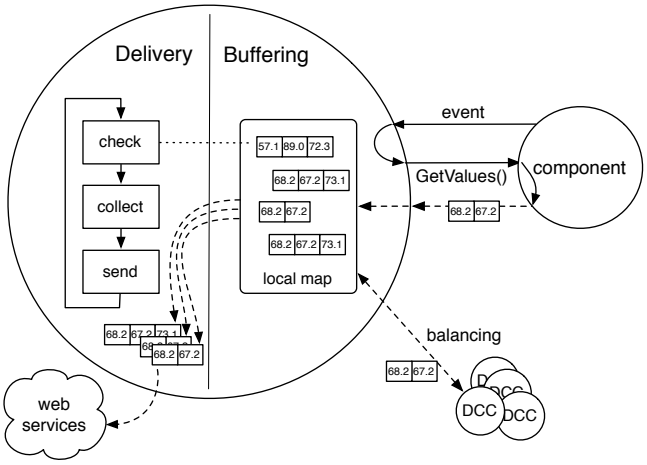

Fig. 4: Operation of the data collector component. Solid lines indicate function calls and dashed lines indicate the flow of data.

parameters: maximum local buffer size, maximum residence time, and minimum delivery size. These are described in the following sections.

2.2 Buffering

A DCC may be linked to one or more components within a composition. Components raise an event each time output data is produced, typically after each time step (the DataChanged event). The DCC listens for this event and in response calls the component's GetValues function to obtain the newly created valueset and places it into the buffer.

The shared buffer is provided by an open source data distribution platform (Hazelcast [5]) that is compiled into, and runs as a set of background threads within, each DCC. It manages a distributed map data structure, dynamically discovering peers via multicast and communicating via TCP/IP. The entries in the map are evenly distributed among all peers and each peer holds a portion of the entries in a local map. Entries are keyed by a universally unique identifier and are variably sized and include the quantity identifier (string), timestamp (long), elementset identifier (string), expiration date (long), valueset data (byte array), and valueset data size (long). The memory overhead of storing an entry in the distributed map data structure is approximately 260 bytes.

The amount of memory dedicated to the local map is dictated by the maximum local buffer size parameter, thus the total memory available to the distributed map is the sum of all peers' local maximums. If the addition of an entry into the buffer would cause the local map's size to become greater that the maximum, then the buffering module waits until there is available space, during which the execution of the simulation is blocked. The buffering module relies on the delivery module to remove entries from the buffer and send them.

2.3 Delivery

The removal of entries from the buffer by the delivery manager is dictated by two parameters: minimum delivery size and maximum residence time. The minimum delivery size provides a means to regulate network efficiency. The delivery manager attempts to remove enough valuesets from the buffer to meet the minimum delivery size before sending them in a single web service call. This may cause entries to remain in the buffer for extended periods of time. This may be acceptable in cases in which the data is being archived, but in cases where the data is consumed as the simulation is being carried out, it may be necessary to place a constraint on the duration that an entry may reside in the buffer before it is delivered. This is controlled by the maximum residence time parameter, which places a limit on the length of time an entry remains in the buffer. Each entry in the buffer has an expiration date that is calculated based on the creation date and maximum residence time. The maximum residence time has higher priority than the minimum delivery size, so in some cases a web service call may contain a small amount of data in order to enforce the time constraint.

The minimum delivery size is specified in terms of the number of values per web service call rather then the number of bytes of serialized XML because different web services may utilize different XML schemas and the latter would require *a priori* knowledge of the serialized XML size for any valueset. Identifying the serialized XML size for a valueset would require either (1) the serialized XML size per value to be known or (2) valuesets to be temporarily serialized to XML as the buffer is being inspected. The former would require calculating the serialized XML size per value for each XML schema and the latter would consume additional system resources.

The following algorithm is used by the delivery manager. The delivery thread periodically iterates over the entries in the local map and determines (1) whether there are any entries that have expired and (2) whether there are enough entries to meet the minimum delivery size. If either case is true, the delivery thread iterates over the local map to identify the entry with the lowest expiration date and removes it. It repeatedly iterates over the entries, removing

the entry with the lowest expiration date, until either (1) enough entries have been collected to meet the minimum delivery size, or (2) the local map is empty. Only the entries in the local map are iterated in order to avoid global operations and improve scalability. The valuesets within the entries are deserialized from their byte array representation, coalesced, serialized into XML, and then sent in a single web service call. The process repeats until both the simulation is completed and the number of entries delivered is equal to or greater than the number of entries inserted into the local buffer. The latter ensures that each DCC delivers a fair share of the entries and that only DCC's with excess capacity deliver more entries then they collect.

When a valueset is delivered to a web service it must include information about the location that each value represents. This information is not stored inside the buffer entries because it would be redundant as the location information is identical for all valuesets that correspond to a common elementset. Elementsets are static during a simulation run so there is typically a high ratio of valuesets to elementsets. The buffer entries only store the elementset's identifier and the actual elementset information is stored in a separate distributed map. In this way a DCC can lookup the complete elementset information for any valueset before it is delivered.

3. Experimental Results

We conducted a performance study using an onsite Linux-based Beowulf cluster. The compute nodes had 2 quad-core 2.3 GHz Opteron 2376 processors with 8 GB of memory and the server node had a quad-core 2.7 Ghz processor and 8 GB of memory. All nodes were connected via gigabit ethernet. The software components were implemented in Java using the Alterra OpenMI 1.4 SDK and the web service was SOAP-based and implemented in PHP hosted by the Apache HTTP server within a Windows virtual machine.

To represent a model component we created a *producer* component that used a fixed-length time step of 1 day and would sleep for a fixed amount of time between time steps to mimic the time spent calculating a time step. On each time step a single valueset was generated and collected by the DCC linked to it.

3.1 Minimum Delivery Size

The minimum delivery size that maximizes throughput to the web service is dependent on several factors including network latency, available bandwidth, and software performance. We conducted a series of measurements to empirically identify the ideal delivery size for our experimental configuration.

To establish a baseline of the expected performance of the DCC, we independently measured the maximum throughput from a benchmark Java application to the Apache/PHP web service and found it to be 47 MB/s. This performance was only possible when the ChunkedStreamingMode of the java.net.HttpURLConnection object was enabled, which prevents the complete POST request from being buffered in memory and streams the data directly from disk to the connection's input stream (although not all web servers support this mode).

We configured a single composition consisting of a producer component linked to a DCC and measured the throughput from the DCC to the web service in a series of simulations. In each simulation the producer generated a number of valuesets that were collected by the DCC and individually sent to the web service in separate calls. The average throughput (over all sends in each simulation) achieved in each simulation is shown in Figure 5.

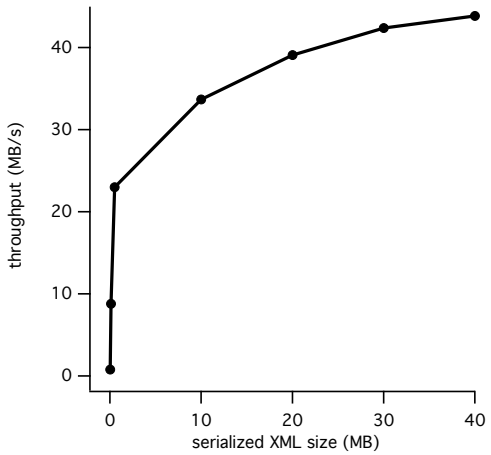

Fig. 5: Impact of minimum delivery size on throughput.

As the data size increased, the throughput increased as well until the maximum throughput was reached, at which point larger data sizes no longer improved the throughput. To achieve at least 50% of the maximum throughput it was necessary to set the minimum delivery size to 2.6×10^5 values which ensures that each web service call contains at least 11 MB of serialized XML data.

3.2 Maximum Residence Time

The maximum residence time imposes a limit on the amount of time that an entry may reside in the buffer. When expired entries are detected in the buffer, all expired entries are removed from the buffer, along with any additional entries necessary to meet the minimum delivery size, and are sent in a single web service call. Thus some entries may be removed from the buffer before they expire resulting in an average residence time that is less than the maximum residence time.

To investigate the effect of the maximum residence time, we measured the average residence time of entries that were added to the buffer at a regular interval. The testing configuration included a single producer component that generated a valueset at a regular interval that was shorter

than the maximum residence time in each case causing several entries to be added to the buffer before one of them expires. The buffer was configured such that entries were only removed as a result of an expiration (unlimited maximum buffer size) and when an expiration occurs all entries were removed from the buffer and sent in a single web service call (minimum delivery size set to maximum).

The results indicate that the average residence time was one-half the maximum residence time in all cases. The expiration of the first entry added to the buffer causes all the entries to be removed and delivered, all of which spent differing amounts of time in the buffer. In general, the sum S of the residence time rt of n entries added to the buffer at a fixed interval i is:

$$\begin{aligned} S_n &= rt_1 + (rt_1 + i) + .. + (rt_1 + (n-1)i) \\ &= n/2(rt_1 + rt_n) \end{aligned} \quad (1)$$

The first entry added to the buffer has the maximum residence time RT_{max} and the last one added has 0 residence time, thus the average residence time RT_{avg} is given by:

$$RT_{avg} = (n/2(0 + RT_{max}))/n = RT_{max}/2 \quad (2)$$

With respect to network efficiency, setting a low maximum residence time resulted in inefficient bandwidth usage because the minimum delivery size was not met. In such cases, network efficiency can be improved by increasing the maximum residence time.

3.3 Buffering

The primary purpose of the buffer is to provide a means for the asynchronous delivery of data to minimize the impact of the data collection on the simulation runtime. To evaluate the buffer's utility in this respect we measured the simulation runtime of a single composition consisting of a producer component linked to a DCC with varying buffer sizes.

The producer generated valuesets of 100 KB at a fixed interval and the DCC had an unlimited maximum residence time and a minimum delivery size equivalent to the size of the valueset so that valuesets were delivered to the web service in individual calls. We imposed a latency on the web service of twice the interval so that data was added to the buffer at exactly twice rate at which it was removed causing the amount of buffered data to increase throughout the simulation.

We measured the *simulation time* as the time spent by the producer executing time steps. In general the minimum buffer size BS_{min} to ensure no impact on runtime is given by:

$$BS_{min} = (InRate - OutRate) \times T_{sim} \quad (3)$$

where $InRate$ is the rate at which data is added to the buffer, $OutRate$ is the rate at which data is removed, and T_{sim} is the simulation time. In this experiment the expected minimum buffer size was (20.0 KB/s - 10.0 KB/s) $\times$ 2500 s = 25.0 MB.

Results are given in Figure 6. Given a sufficient buffer size the runtime remains constant with minimal overhead added by the data collection and sending (adding only the time to retrieve the valueset from the component and insert it into the buffer, both of which occur in memory). The results are consistent with the expected minimum buffer size as speedup becomes constant as the buffer size approaches 24 MB.

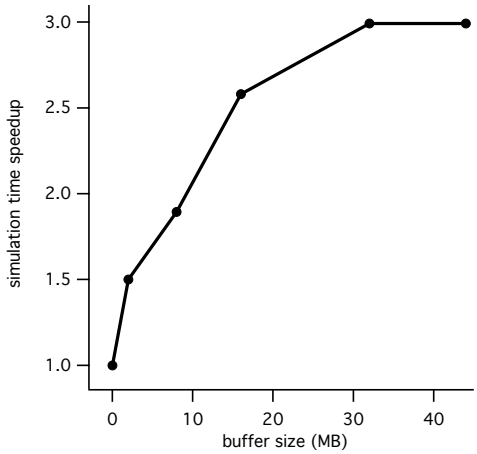

Fig. 6: Speedup for varying buffer sizes.

3.4 Distributed Cooperation

The entries in the local buffer of each DCC are evenly distributed among all the active DCC's on a cluster. This results in entries migrating away from DCC's that are collecting faster then they are delivering, and toward DCC's that are delivering faster then they are collecting, which enables cooperative sending of the data.

To evaluate the effect of cooperation among DCC's we executed concurrent simulations on multiple cluster nodes with differing rates of data collection and data delivery. A single composition consisting of a single DCC and producer executed on each compute node and we measured the *completion time* which we define as the amount of time necessary for all data to be delivered. In the ideal case the completion time is equivalent to the simulation time, but may extend past the simulation time if the simulation completes before all data is delivered.

Four *fast-production* nodes were configured such that data was produced at a faster rate than it could be delivered, and the other *slow-production* nodes were configured such that data was produced at a slower rate than it was delivered. Given a sufficient number of nodes, the runtime remains constant with minimal overhead added by the data collection and sending (adding only the time to retrieve the valueset from the component and insert it into the buffer, both of which occur in memory). The following equation describes the necessary balance of capacity across a cluster to ensure

that simulation runtimes are not affected by the data collection. For N nodes over a given simulation period:

$$0 = \sum_{i=1}^{N} InRate_i - OutRate_i \quad (4)$$

In this configuration, the 4 fast-production nodes inserted 0.5 entries per second while the remaining slow-production nodes each inserted 0.01 entries per second. All nodes removed entries at the rate of 0.1 entries per second. By Equation 4, 32 slow-production nodes would be sufficient to collectively match the rate of 1.6 entries per second inserted by the four fast-production nodes. This assumes that the slow-production nodes are actively delivering data during the complete simulation period.

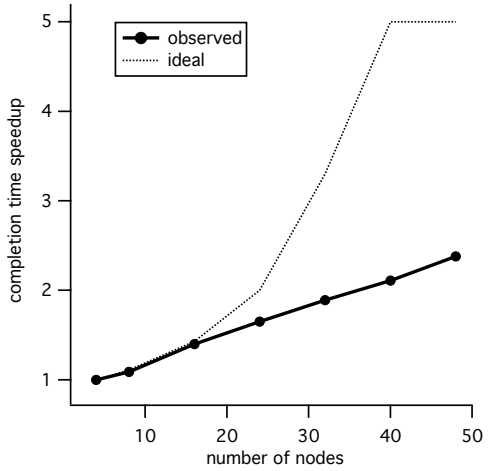

Fig. 7: Speedup for varying numbers of nodes.

We observed near-ideal speedup in the average completion time of the four fast-production nodes for up to 16 nodes as shown in Figure 7. As the number of nodes increased beyond 16, the rate at which entries were added to the distributed buffer was not sufficient to ensure each slow-production node had entries in its local buffer, resulting in the slow-production nodes not sending at all times (as in the ideal case). For example, each slow-production node spent an average of 31% less of its excess time delivering data when there were 48 nodes than when there were 16 nodes. Enabling the cooperation across nodes reduces the completion time, but achieving ideal speedup is contingent on the availability of sufficient data at each node.

4. Related Work

The DCC automates both the task of collecting model output data and transferring them to online services. These are typically performed manually or using custom software [6] that execute general-purpose tools such as GridFTP [7]. Web services have been utilized in modeling and simulation since their conception as both a means to access data and to control the execution of online models [8], [9], [10], [11]. The DCC provides a point of integration between linked models and any Internet-connected data platform that supports web services, including Workflow Management Systems such as Taverna [12] and Vistrails [13] and distributed data storage systems such as iRODS [14] and HIS [15]. It complements existing methods for input data retrieval from online services for OpenMI linked models [16], [17], [18].

5. Conclusions

We presented the design of the Data Collector Component (DCC) for OpenMI components and evaluated its performance. The DCC collects model output data from model components and efficiently delivers them to web services. It utilizes a distributed buffer optimized for the unique behavior and constraints of the OpenMI. General-purpose data collector components simplify the task of collecting model output within a grid environment and facilitate storage and post-processing by online services.

The DCC consists of a buffering module and a delivery module. The buffering module obtains output data from one or more components as they are created and stores them in a distributed buffer that is shared among all DCC's executing on a cluster. The delivery module continuously monitors the buffer and delivers data to web services in a way that balances efficiency and latency.

We evaluated the performance of the DCC and its sensitivity to its three parameters: maximum buffer size, minimum delivery size, and maximum residence time. The minimum delivery size was found to have a significant impact on the throughput and to achieve at least 50% of the maximum throughput each message must contain at least 2.6×10^5 elements in our experimental configuration. The maximum residence time resulted in an average residence time that is one-half the maximum residence time when entries are added to the buffer at a regular interval. We found that buffering resulted in maximum speedup in simulation time (a factor of 3) within a single composition, and distributed cooperation resulted in a speedup in the completion time by a factor of 2.4.

As the importance of data availability, interoperability and transparency continue to rise, so too does the need for software tools to facilitate these. General-purpose tools that intelligently and efficiently collect and deliver data will become an essential part of OpenMI linked models on workstations and grids alike and this work provides a starting point for such tools.

6. Acknowledgments

This work was supported by the National Science Foundation (grants GEO0909515, EPS0919443, EPS1006860). Access to the Beocat compute cluster at the Dept. of Computing and Information Sciences at Kansas State University was appreciated.

N-to-M Mode of IO and Data Management in Numerical Simulations

William W. Dai
Computer, Computational, and Statistical Sciences Division
Los Alamos National Laboratory
Los Alamos, New Mexico, USA

Abstract— *A library for parallel IO and data management has been developed for multi-physics simulations. The goal of the library is to provide sustainable, interoperable, efficient, scalable, and convenient tools for parallel IO and data management for high-level data structures in numerical simulations, and to provide tools for the connection between applications. The library supports the N-to-M mode, in which data on N computer processors are written into M files. The number of files is transparent to users and is chosen by users when files are open. The high-level data structures include those in particle simulations, one- and multi-dimensional arrays, structured meshes, unstructured meshes, the meshes generated through adaptive mesh refinement, and variables associated with these meshes. The IO mechanism can be collective and non-collective. The library is typically used for restarting files, visualization files, and files connecting different applications. The data objects suitable for the library could be either large or small data sets. Even for small data sets, the IO performance is close to the one of MPI-IO performance for large data sets. For resilience, the library guarantees that any parts of files that have been written be readable if computer hardware crashes during writing.*

Keywords: data structure, data management, IO.

1 Introduction

Parallel IO and scientific data management have played an important role since the beginning of large scale scientific computing, and are getting more important due to the increase of the scale of the computing. Existing products, which have partially addressed the issue, include HDF5 [1], SAF [2], CGNS [3], NetCDF [4], Silo [5], UDM [6], and others. Each of the existing products has certain advantages and disadvantages. Some of the products have good functionalities for unstructured meshes, but they either don't have capabilities for running on parallel computer environments or lack for good parallel I/O performance. Some of them are designed for parallel environments, but do not have the capabilities to deal with unstructured meshes, or they get only a fraction of MPI I/O performance. Some have good IO performance but lack the functionality to query data sets for their relationship. Some have a decent IO performance for large data sets, while they failed to deliver the similar performance for small data sets.

The HIO library is for parallel IO and data management for high-level data structures used in numerical simulations. It has been developed under Department of Energy (DoE) Advanced Simulation and Computing (ASC) program for ASC code projects. The HIO library is the further development of the UDM library [6]. The HIO library provides sustainable, interoperable, efficient, scalable, and convenient tools for parallel IO and data management for high level data structures in applications. In the DoE community, such as national laboratories, data files generated in one code project often have to be used in another code project as inputs. The HIO library provides a parallel tool for such connections.

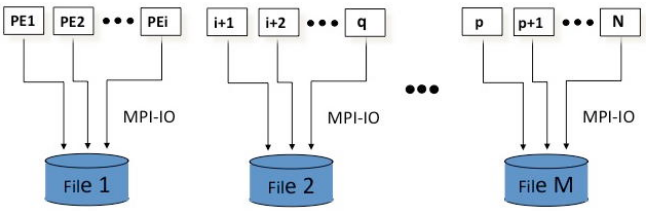

Figure 1. Data on N computer processors are written into M files.

The HIO library writes simulation data on N computer processors to M files on parallel computer environments, i.e., N to M, as shown in Fig.1. The number of files, M, is chosen by users when the files are opened, and M could be one. The library consists of functionalities for IO and data management for high-level data structures encountered in numerical simulations on parallel computer environments, such as data in particle simulations, structured meshes, unstructured meshes, meshes generated from adaptive mesh refinement (AMR), and their associated variables defined on cell centers, vertices, edges, or faces of meshes. The library is built on the top of MPI I/O, and its I/O performance is almost the same as MPI I/O. To our knowledge, the functionality and performance of the library are superior to

existing products for these data structures in numerical simulations.

In this paper, we will report the library, and its main usages. In Section II, we will present the main functionalities of the library. The usage of the library will be demonstrated in Section III. The IO performance of the library will be discussed in Section IV, and in the final section we will discuss resilience of the library and some of our future plans.

2 Functionalties

The HIO library provides IO and data management tools for data in particle simulations, single and multi-dimensional arrays, structured meshes, unstructured meshes, and the mesh generated through adaptive mesh refinement (AMR), and their associated variables defined on these meshes in numerical simulations on parallel computer environments. It also provides a hierarchical data structure within a data file. The files generated through the library are self-described.

2.1 N-to-M Mode

In the current and future computer system, the number of computer processors in a computer system is so large that writing to a single file for a writing event will not be optimal for IO performance and network communication. Therefore, the data on N computer processors, on which a simulation is run, could be written to M files, M could be one, and M could be N although the case with M equal to N is not our focus. For a given N processors, the optimal M depends on individual computer system and software on it, it also depends on the size of the data to be written into this files. For this reason, through the library, M is a file-specific parameter, and some files could be written in the N-to-M mode while others are done through the N-to-1 mode. For this library, this M is a parameter that users can choose when they create files, and by default it is one.

For writing, the library divides N processors into M groups for any M provided by users. For example, a user is to write a file with a file name foo and M = 2. The library will actually create two files with names foo.m00001 and foo.m00002. These two files are also what the user sees, and they are transparent to users. From the names of these files, foo.m00001 and foo.m00002, the user can not see each file contains the data of which group of processors, but this information could be easily queried from a function call of the library.

After the file is created, for example, foo, the library remembers the partition of M files from N processors until the file is closed. Before the file is closed, any subsequent writing into the file, foo, will be automatically partitioned into the M files. The writing call is the same as that for the case with N equal to one, without the parameter M involved.

For the convenience to query data in the M files, each of these M files contains the description of the partition of N processors among the M files and the description of data on all N processors, such as the sizes of data on each processor and the processors writing to any particular file. Each of the M files contains also the information of structure of the files and the description of all the objects in the M files, such as the information written into a single file. Therefore, from each of the M files, users can get the description of all M files.

2.2 Unstructured Meshes

One of the important and powerful functionality in the HIO library is the management of unstructured meshes and their associated variables. The library supports a broad range of unstructured meshes, which include meshes with fixed shapes, arbitrary polygons, and arbitrary polyhedrons. The mesh elements with a fixed shape may be triangles, quadrangles, pentagons, tetrahedrons, pyramids, wedges, pentagon prisms, and points in particle simulations. A mesh element may be a zone, or face, or edge, i.e., a mesh may be a zone-mesh, face-mesh, edge-mesh, and points. An edge-mesh may be one-, or two-, or three-dimensional, and a face-mesh may be either two- or three-dimensional. Mesh elements of a zone-mesh may be made directly from nodes, or the elements may be made from edges, or the elements may be made from faces and the faces are then made from either edges or nodes. The HIO library also supports ghost mesh elements, boundary faces, boundary edges, boundary nodes, slip faces, slip edges, slip nodes, etc. The variables associated with unstructured meshes may be node-variables, or edge-variables, or face-variables, or zone-variables, and variables may be scalars, or vectors, or tensors.

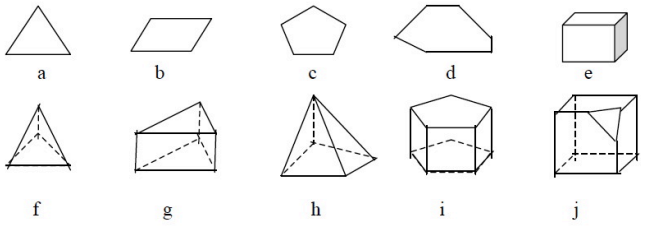

Figure 2. Examples of mesh elements supported in the HIO library for unstructured meshes.

To illustrate the meshes supported in the library, in Fig.2 we list some examples for mesh elements. They include (a) triangles, (b) quadrangles, (c) pentagons, (d) arbitrary polygons, (e) hexahedrons, (f) tetrahedrons, (g) wedges, (h)

pyramids, (i) pentagon-prisms, and (j) arbitrary polyhedrons. The mesh elements may be made from any lower level entities, such as faces, edges, and nodes. Figure 3 shows three possible ways to make up three-dimensional elements.

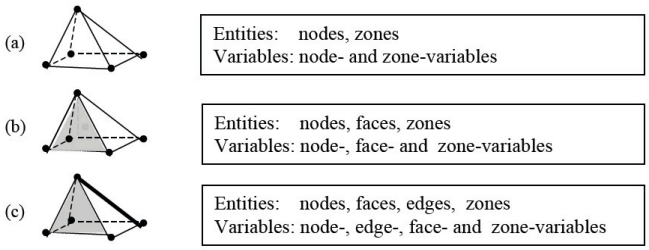

Figure 3. An element may be made from (a) nodes, or (b) faces and nodes, or (c) faces, edges, and nodes.

Although the HIO library covers a broad range of unstructured meshes, a user only has to set up his/her own mesh definition, and all other mesh definitions are hidden from the user. For example, for an unstructured zone-mesh made from nodes, only the list of nodes for each element is needed, if the elements are of a fixed shape, such as prisms. If mesh elements are arbitrary polyhedrons made from nodes, two arrays are needed, one for the numbers of nodes for elements, and the other for the list of nodes for each element. Like the capability for structured meshes, the association between a mesh and a set of variables is automatically built into the library.

2.3 Adaptive Mesh Refinement

Although a mesh generated through AMR may be considered as an unstructured mesh in IO, but it involve unnessary memory copies and additional working memory requrement. The HIO library is able to handle AMR meshs naturally without additional memory.

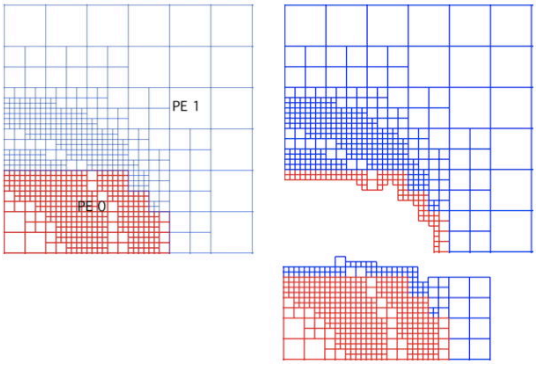

Figure 4. Illustration of ghost cells in cell-based AMR. The left image is the partition of between two processors, and the right one is the part of the mesh on each processor with ghost cells.

For element-based AMR structured meshes in the HIO library, we store the center and width of each element in each dimension. The scalar variables associated with the meshes are one-dimensional and the associated vector variables are two-dimensional arrays. The association between the variables and a mesh is automatically built and stored in the file. For block- or patch-based AMR structured meshes, each block or patch is considered as a standard structured mesh.

The library also support ghost cells in AMR meshes. Some post data anaylizers need variables on ghost cells to derive information around interfaces between processor interfaces, such as a visualization tool calculating isosurfaces. Figure 4 shows the illustration of ghost cells surrounding the part of an AMR mesh on each processor.

2.4 Writing/Reading Descriptions

Users can add any description to any object, such as a file itself, or an array, or a mesh, or a variable, as long as the description is not of the problem-size, and each processor has the same description. More importantly, writing all descriptions almost doesn't have any IO cost, since all the descriptions will be buffered together with all the meta data and are written at the end of a file when the file is closed.

The number of the descriptions and each description can be automatically queried. As writing the description, reading any description does not involve any additional IO cost since all the descriptions together with all the meta data are read into the memory when a file is open.

2.5 Small Data Sets

Writing small data sets into a file on a parallel environment will typically result in very IO performance. The HIO library provides an automatic buffering mechanism so that a large number of small data sets will automatically buffered together before they, together with their names and descriptions, are written into a file. Writing small data sets, users will get the same IO performance as they get for large data sets. But, users don't have to keep track of the locations of each individual small data set in the combined buffer and the disk file.

To read a small data set, the HIO library actually only copies small data set from a buffer to the user's memory. If the buffer is not available yet, the library will automatically read the buffer first, and then copy the data. Therefore, the library doesn't involve reading from a disk with a small set of data.

To users, all the tedious operations necessary for writing and reading the small data sets are behind the scene. Writing

small data sets is the same as writing big data sets, and even the names and arguments of the functions to be called are the same.

2.6 Querying

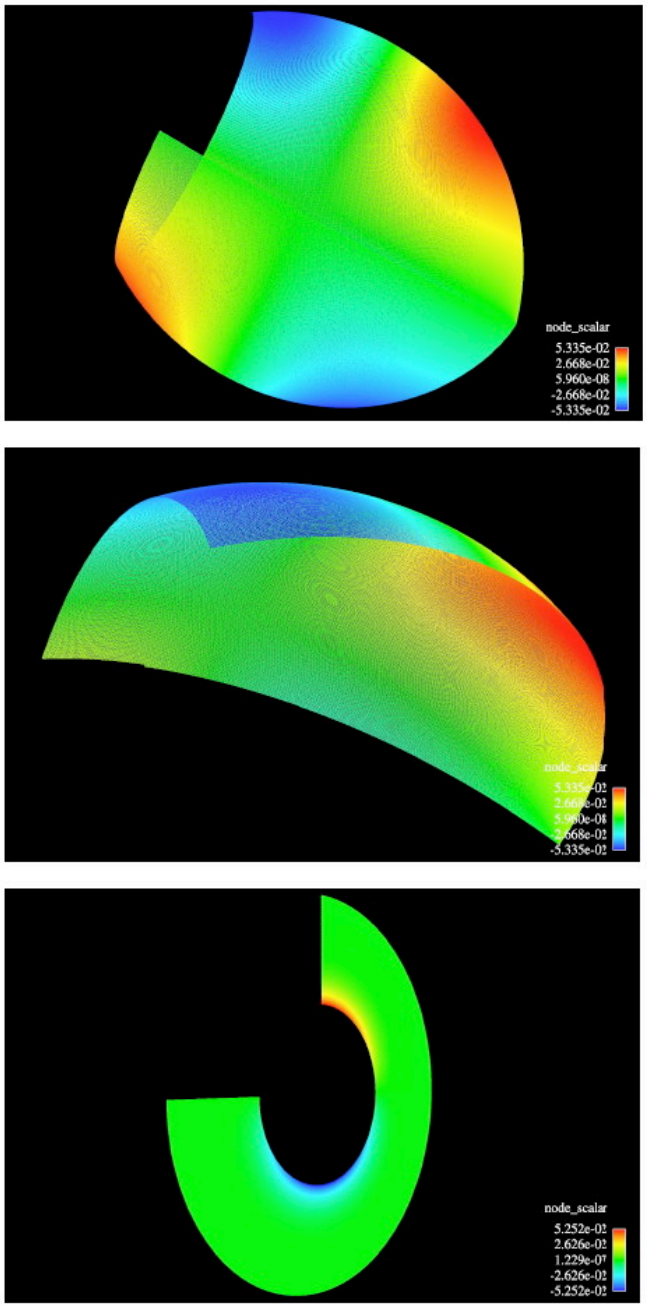

Figure 5. Three parts of an unstructured mesh with 1.6 billion elements. The left is read through an original processor rank, the middle one is read through a set of global element ids, and the right is read through a space domain.

A file written through the HIO library is self-described. All the information in the file may be queried by function calls of the library. For example, for a given file, users may find the number of arrays, meshes, and variables, the description of each array, mesh, and variable, and any association between meshes and variables. Through the querying function in the library, meshes and variables may be directly viewed through parallel graphics tools.

After a data object, such as array, mesh, and variable, is written into a file, users may read any part of the data object in terms of, for example, global ids, or a processor rank, or a space domain. Figure 5 illustrates the capability for reading three parts of an unstructured mesh with 1.6 billion elements. The top image is a part read through a processor rank, the middle one is a part identified through a set of global element ids, and the lower image is read based on a space domain.

As stated beore, one of usages of the library is to connect data files to visualization tools. All the images presented in this paper are produced through the visualization tool Ensight except the the one in Fig.6, which is produced through VisIt. Our simulations generate a set of files for visualtion, and the set of files could be read by either Ensight and VisIt without direct transformation.

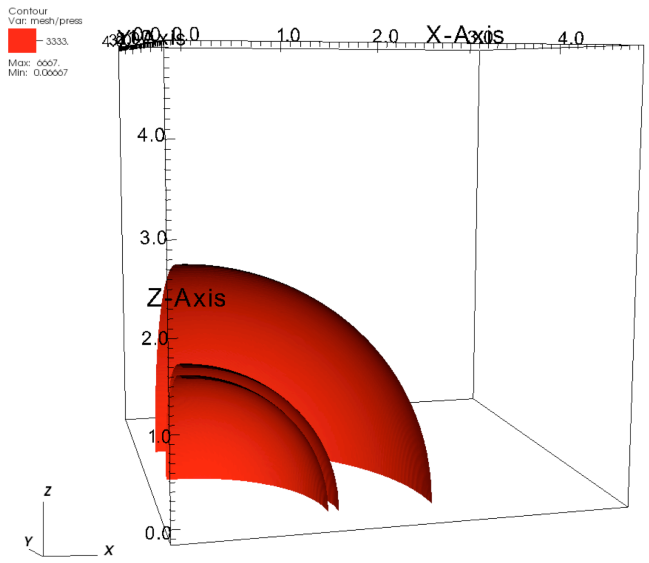

Figure 6. Iso-surfaces of pressure of a three-dimensional simulation.

2.7 Hierarchical Data Format

The HIO library supports the hierarchical data structure within each file, which is equivalent to the Unix file system, although it is not necessary for the functionalities of the library mentioned above. After a file is created, users may create any number of groups within the file. A group is a container in which other groups and data sets may be

created and written. A file is also a group. A data set is an array, or a mesh, or a variable. A number of attributes may be attached to a group or data set. An attribute is any additional description users want to store into the file for a group or data set. Due to the hierarchical data structure and the attributes, users may build their own data format that is self-described.

All the data needed for the hierarchical data structure and attributes are stored at the end of each file, which is written to a file only when the file is closed. Therefore, the cost for the hierarchical structure and attributes is very minimal.

3 Basic Functions and Uages

One of the design principles of the HIO library was a small number of functions. The following is the list of main functions of the library.

- hio_set_mcomm(mfiles)
- hio_open(filename, mode, fid)
- hio_close(fid)
- hio_init(type, fileid, obj)
- hio_write(type, fileid, obj)
- hio_query(type, fileid, filter, nobjs, objs)
- hio_clean(type, nobjs, objs)
- hio_get_size(type, domain, fileid, obj)
- hio_read(type, domain, fileid, objs, nobjs)
- hio_init_append(type, obj)
- hio_finalize_append(type, id)

The first two functions are for opening and closing files. The function hio_init is to initialize any object before it is being used, and the object includes array, structured and unstructured mesh, AMR mesh, and variable defined on a mesh. The function hio_query is for querying, which include querying files, querying variables, querying relationship between variables and meshes, querying attributes, etc. The function hio_clean is to release the memory allocated in the call of the function hio_query. The function hio_get_size to determine the sizes of grid zones, faces, edges, and nodes for a given part of a mesh, for example, a spatial domain, a part associated with a specific processor, or a number of elements. The function hio_read is to read attributes and any data for a given part of a mesh, which include coordinate, mesh, variable, etc. The functions, hio_init_append and hio_finalize_append, together with hio_write are for generating large meshes with a small number of computer processors.

The following is an example to write an unstructured mesh with general polyhedrons. To specify the mesh, each computer processor has a number of elements, nzone. The set of elements have a number of faces and nodes, nface and nnode. The arrays, num_faces_for_zone and facelist_for_zone, are to specify the elements, and the arrays, num_nodes_for_face and nodelist_for_face, are to define the faces. The arrays, x, y, and z, are the locations of these nnode nodes. All these arrays and sizes are local to the processor. Then code to write this unstructured mesh is as follows.

```
hio_unstructured_mesh m;
hio_coord *c = &m->coord;
hio_init(hio_umesh, -1, &m);
m.dims = 3;
m.type = hio_general_mesh;
m.sizes[0] = nzone;
m.sizes[1] = nface;
m.sizes[3] = nnode;
m.num_nodes_for_face = num_nodes_for_face;
m.nodelist_for_face  = nodelist_for_face;
m.num_faces_for_zone = num_faces_for_zone;
m.facelist_for_zone  = facelist_for_zone;
c->coord[0] = x; c->coord[1] = y; c->coord[2] = z;
c->datatype = hio_double;
m.datatype = hio_int;
hio_write(hio_umesh, fileid, &m);
```

After this mesh is written to a file, this mesh can be queried as described before.

The following segment of codes demonstrates the usage to write a large mesh into a file through a small number of processors.

```
hio_unstructured_mesh m;
hio_coord *c = &(m.coord);
hio_init_append(hio_umesh, -1, &m);
m.dims = 3;
m.type = hio_general_mesh;
m.datatype = hio_int;
c->datatype = hio_double;
while (more_block) {
    generate a part of mesh
    write the part to mesh
}
hio_finalize_append(hio_umesh, m.id);
```

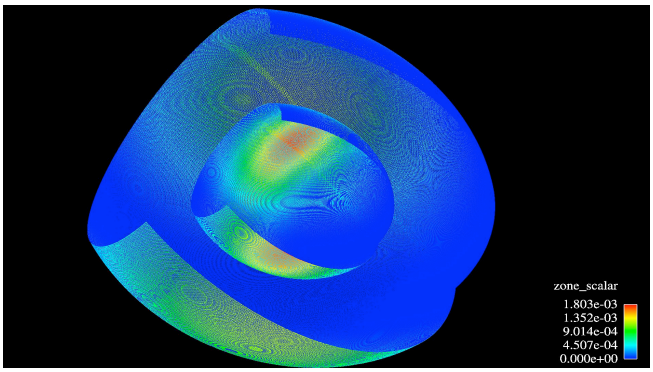

Figure 7. An unstructured mesh with 1.6 billion elements written through the "append" capability in the HIO library.

An example mesh with 1.6 billion of unstructured elements generated through 16 processors in this way is shown in Fig.6.

A cell_based AMR structured mesh is defined through arrays for the centers of elements, x, y, z, and arrays for widths of the elements, dx, dy, and dz. The following segment of codes shows the usage to write a cell_based AMR mesh. An example mesh is shown in Fig.7 that contain four materials.

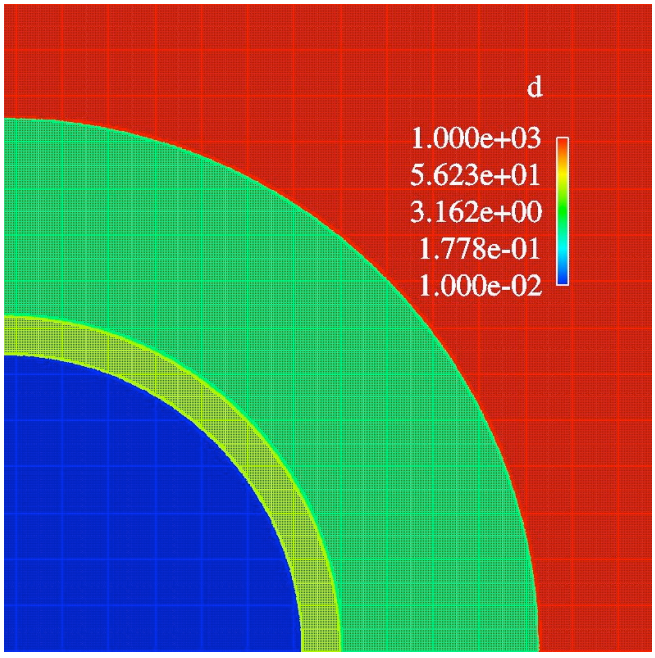

Figure 8. A cell_based AMR structured mesh with four materials and the variable of density written through the HIO library.

```
hio_Structured_Element_AMR m;
hio_init(hio_smesh_element_amr, -1, &m);
m.name = meshname;
m.dims  = 2;
m.datatype_coord = hio_double;
m.size          = nelement;
m.coord[1]   = x;
m.coord[0]   = y;
m.dcoord[1] = dx;
m.dcoord[0] = dy;
hio_write(hio_smesh_cell_amr, fileid, &m);
```

After a mesh is written into a file, a set of variables can be written into the file, and the relationship between the mesh and variables is automatically built. The following codes show the usage to write a scalar variable defined on elements, zone_density, and a vector defined on nodes, node_velocity_x and node_velcity_y.

```
hio_Mesh_Var   var;
hio_init(hio_mesh_var, -1, &var);
var.name          = varname1;
var.mesh_ids[0] = m.id;
var.type          = hio_zone;
var.datatype      = hio_double;
var.rank          = 0;
var.comps[0].buffer = zone_density;
hio_write(hio_mesh_var, fileid, &var);

hio_init(hio_mesh_var, -1, &var);
var.name          = varname2;
var.mesh_ids[0] = m.id;
var.type          = hio_node;
var.datatype      = hio_double;
var.rank          = 1;
var.comp_sizes[0]   = 2;
var.comps[0].buffer = node_velocity_x;
var.comps[1].buffer = node_velocity_y;
hio_write(hio_mesh_var, fileid, &var);
```

After a mesh and a set of variables are written into a set of files. Any part of the mesh and the variables associated with this part of the mesh may be easily read. The following segment of codes shows the usage to read a part of mesh defined through domain, and nvar variables, vars, associated with this domain.

```
int                    nvar;
hio_Domain             domain;
hio_Unstructured_Mesh  m;
hio_Mesh_Var           *vars;
specify mesh and domain
hio_get_size(type, domain, fileid, &m);
allocate space for the part of mesh, and variables
hio_read(hio_umesh, domain, fileid, &m, 1);
hio_read(hio_mesh_var, domain, fileid, &vars,
nvar);
```

The other examples include patch-based AMR structured meshes shown in Fig.8. The patches of the first and second levels of a patch-based AMR mesh in a three dimensional simulation are displayed in the figure. The rectangular with each color in Fig.8 is a patch.

4 Performance

The HIO library is built directly on the top of MPI-IO, and files generated are machine-independent. Its functionality and performance have been tested on from a couple of dozen processors to full machines, and its performance is around 97% of that of the MPI-IO.

The library depends on MPI I/O for its I/O performance, and it currently supports both collective and non-collective writes. The library doesn't explicitly move data between processors. The library itself doesn't directly interact with file systems. If it is necessary, the library have appropriate functions to set parameters of the file system through MPI

calls. If the MPI is tuned to be of high performance in a machine, the HIO library will have high IO performance too.

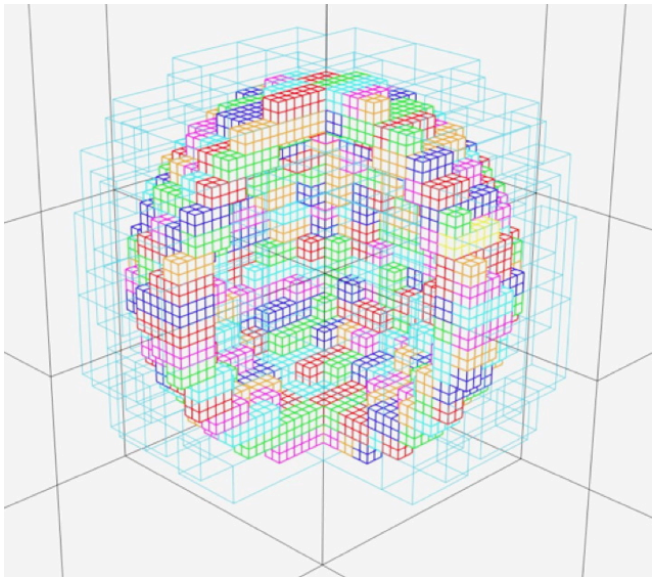

Figure 9. A patch-based AMR structured mesh written through the HIO library. The image the second level of patches on the the top of the first level patches.

To illustrate I/O performance, we used the Q, Lightning, and Lobo machines in the Los Alamos National Laboratory as examples. The Q machine has a HP proprietary parallel file system, and the Lightning and Lobo machines have global parallel file systems provided by Panasas. The MPI library, mpich, is used on the Q and Lighting machines for the tests, and OpenMPI is used on the Lobo machine. An unstructured mesh and its 50 associated variables are used in the example. The mesh is defined by three arrays for coordinates, and an array for the list of nodes for elements. We use 510 processors on the Lightning machine to write the mesh with total elements 1.6 billion and 50 associated variables. The size resulting files is about 405 Gbytes. As stated before, the files generated through the library are slightly larger than the files generated through MPI I/O. This is due to the meta data used in the HIO library. The HIO library gets 97% of writing performance of MPI I/O. On the Q machine, we use 256 processors, the size of resulting files is about 203 Gbytes, and the writing performance is also 97% of the one obtained through MPI I/O. For 1024 processors on the Lobo machine, for a data file of 813 Gbytes, the performance of the HIO library is 98% of the one of raw MPI-IO calls.

A few points about the test are worth being mentioned here. Firstly, for the pure MPI I/O test, all processors collectively write 53 large arrays, and the sizes of data on each processor are roughly equal. Secondly, the file generated through the HIO library is self-described, and may be queried and visualized, but the file generated through MPI I/O may not. Last, for the case with 510 processors, the total overhead of file size in the HIO file is 110 kbytes, or 0.00004%. Each processor contributes about 200 bytes of the 110 kbytes, and remaining 8000 bytes are the overhead for the description of file structures.

For the best possible performance, we take three main steps. We first make sure that the data on each processor are contiguously written onto a disk file, and therefore there is no movement of data during writing. Second, the library collects all the data for descriptions of arrays, meshes, variables, relationship and associations, the hierarchical file structure, etc., and writes the collection only when a file is closed. Third, when reading files, the library reads all the meta data and the file structure together and reads it only once.

5 Acknowledgments

The work presented here has been supported by Department of Energy through the Advanced Simulation and Computing program. The author is grateful to Paul Weber for his effort in readers of visualization tools for the data files written through HIO library.

Scalable Solution of Radiative Heat Transfer Problems by the Photon Monte Carlo Algorithm on Hybrid Computing Architectures

Joo Hong Lee, Mark T. Jones and Paul E. Plassmann
Department of Electrical and Computer Engineering, Virginia Tech, Blacksburg, Virginia 24061

Abstract – The simulation of Radiative Heat Transfer (RHT) effects by the Photon Monte Carlo (PMC) method is a computationally demanding problem. In this paper we present results and analysis of a new algorithm designed to solve this problem on a hybrid computing architecture. This architecture includes distributed memory, shared memory, and Graphics Processing Unit (GPU) accelerated components. In this paper we present an approach to obtain good parallel performance based on a partitioning of the application software into two parts. The first part is a multi-threaded application code that manages the ray tracing aspects of the PMC. The second part is an asynchronous, GPU-accelerated pseudo-random number generation library. An advantage of this approach is that this software framework can be easily translated to other Monte Carlo applications. We present experimental results from a large-scale hybrid computer for a standard RHT model problem and compare these results to our analytical model.

Keywords: Monte Carlo algorithms, radiative heat transfer, GPU acceleration, hybrid computing, scientific computing.

1. Introduction

Radiative Heat Transfer (RHT) plays a central role in many important engineering applications that involve combustion. The computational cost of modeling RHT effects accurately can be extremely high due to its highly nonlinear and non-local nature [1]. This nonlinearity arises because RHT rates typically depend on the fourth power of the temperature [2]. Thus, applications that involve the computation of these rates, such as with combustion, are highly sensitive to the accuracy of these temperature calculations. Omitting RHT effects from simulations in such applications can lead to inaccurately computed temperature profiles, which in turn affects the stability and the accuracy of the calculation of other variables [3].

The non-local nature of RHT comes from the fact that the photons that carry radiation (and energy) can be absorbed far from the physical position that they are emitted. Because of these non-local effects, conservation laws cannot be applied over an infinitesimal volume, but instead must be applied over the entire computational domain. The Photon Monte Carlo (PMC) method can be effectively used in the solution of thermal radiation problems [4]. This method is based on a model of radiative energy traveling in discrete packets (like photons) and the computation of the effect of these photons while traversing, scattering and interacting with matter within the computational domain. Advantages of this method include: an ability to deal with complex geometries; an ability to handle non-uniform temperature fields; the ability to include photon scattering; and the ability to employ a great variety of methods to include specialized radiative properties of the enclosure or the transport domain [5].

This paper is organized as follows. In section 2 we describe the algorithm of PMC method and our software framework. In section 3 we present an analysis of the performance of this proposed approach on a hybrid computing architecture. In section 4 we compare experimental results of the performance of a representative PMC simulation with this analytical model. We present our conclusions in section 5.

2. The Photon Monte Carlo Method

The Photon Monte Carlo (PMC) method is a sampling method based on simulating the movement and absorption of photon bundles (rays) through a discretized computational domain. The advantage of this approach, as opposed to other RHT approximation schemes, is that its overall computational cost grows slowly as a function of the complexity of the RHT problems [4]. An additional advantage is that increased accuracy can be obtained by using larger numbers of photon bundles. Hence, the PMC method is well suited to radiation calculations that include complex geometries, non-trivial absorption properties, and singular effects such as scattering. In this section we describe the basic PMC algorithm. We also review how pseudo-random numbers are used within the PMC algorithm and ultimately in the overall RHT simulation.

2.1. The PMC Algorithm

In numerical simulations that include a RHT component, the computational domain contains a participating medium (a material that both emits and absorbs photons). The PMC method traces a statistically significant sample of photon bundles from their point of emission within the medium to

a point of absorption within the medium or its boundary. When the photon bundle is absorbed, its energy is added to the local energy of the absorbing element within the discretized medium. With this approach, the PMC method is able to calculate the energy gain or loss for every element within the computational domain.

The tracking of the photon bundles through the computational domain requires that the PMC algorithm model several types of element interactions. These interaction types are illustrated in Figure 1. On the left, Figure 1 (a), we show a photon bundle entering an element and being absorbed within the element. In the middle, Figure 1 (b), we show a photon bundle entering an element and being scattered off of a particle within the element. On the right, Figure 1 (c), we show a photon entering an element, traversing the entire element, and exiting the element to enter a neighboring element. For the computational results presented in this paper we employ a software framework capable of modeling these element interactions and tracing the photon bundles through a computational mesh [6].

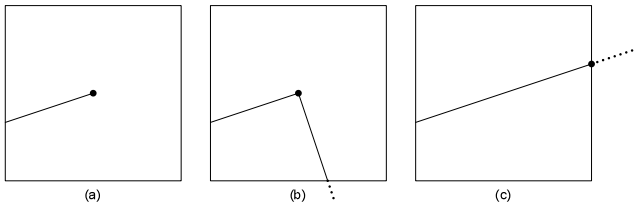

Figure 1. Possible photon interactions within an element. In (a) we show the photon bundle being absorbed within the element, in (b) the photon is scattered off a particle within the element, and in (c) the photon bundle is transmitted through the element.

The PMC algorithm can be used to solve a wide range of RHT problems. In this paper, we use the algorithm to solve a simple model problem. The model problem we use is a three-dimensional rectangular solid domain with two plates with different temperatures on opposite walls and periodic boundary conditions in the other two orthogonal dimensions [4]. The RHT problem that we solve involves computing the temperature as a function of position between the two plates. For a fixed computational mesh the overall computational work grows linearly with the number of photon bundles that we track through the domain. By increasing the number of photon bundles used in the simulation, we can examine the "scaled" speedup of the simulation when run on a hybrid parallel computer architecture. In addition, as we increase the number of photons, the accuracy of the computed solution improves and we can verify the statistical independence of sampling done by the photon bundles by looking at the convergence of the temperature from independent samples.

2.2. Pseudo-Random Numbers and PMC

For every photon bundle, the PMC algorithm must determine a point of emission, a direction of emission, a wavelength, a point of absorption, and various other properties that are independently chosen from probability distributions. Because of the large number of required pseudo-random numbers, a profile of the PMC code running a standard CPU shows that 90% or more of the computational time is spent generating these numbers. This percentage can be even higher as the complexity of the radiative properties and the accuracy required from the simulation increases. Based on this observation, a more efficient scheme for generating these pseudo-random numbers can dramatically improve the overall performance of the PMC algorithm. In the following section, we present a GPU accelerated pseudo-random number generation algorithm. In addition, we present an analysis of the running time of this algorithm and show how it achieves much of this potential efficiency gain for the PMC algorithm.

3. A Theoretical Analysis of the GPU Accelerated Algorithm

As discussed in the proceeding section, the PMC method for solving RHT problems involves the tracing of large numbers of statistically independent photon rays [4]. The statistical independence and the spatial integration of the effect of the photons as they traverse elements with non-trivial absorption properties require the use of large numbers of pseudo-random numbers [4]. The overall PMC software framework that we use for the experiment results presented in this paper was developed in [6]. The pseudo-random number generation function calls in this code are replaced with calls to the GPU accelerated software library developed in [7].

In this section we present an analysis of the running time of the PMC code on a hybrid computing architecture. This analysis consists of two parts—first an analysis of the pseudo-random number generation and, second, an analysis of the multi-threaded PMC calculation that makes use of these pseudo-random numbers.

3.1. Pseudo-Random Number Generation

The approach used to generate pseudo-random numbers for use in multi-threaded Monte Carlo applications is presented in detail in [7]. We review the analysis developed in [7] in order to be able to derive an overall analysis of the PMC simulation.

As discussed in [7], using the GPU to generate pseudo-random numbers involves three main factors: the transfer of state tables from CPU to GPU memory, the actual computation of the pseudo-random numbers on the GPU stream processors, and finally the copying back of the state tables and the pseudo-random numbers from the GPU to CPU memory.

The memory transfer time between the CPU and GPU and back again can be modeled by a linear dependence with respect to the amount of data transferred. Accordingly, if we denote the time required to copy m bytes of data from the CPU to the GPU by $T_{CPU\rightarrow GPU}(m)$ and the time required to copy m bytes of data from the GPU to the CPU by $T_{GPU\rightarrow CPU}(m)$, we have the linear relations

$$T_{CPU\rightarrow GPU}(m) = t_{CG}\, m + t_s \qquad (1)$$
$$T_{GPU\rightarrow CPU}(m) = t_{GC}\, m + t_s.$$

In these formulae t_s is a "start up" time for the copy, t_{CG} is the incremental time required to copy each addition byte of data from the CPU to the GPU, and t_{GC} is the incremental time required to copy each addition byte of data from the GPU to the CPU. These constants are architecture dependent and can easily be measured. For example, for the Athena system used for the results presented in the experimental section of this paper we obtained the data shown in Figure 2.

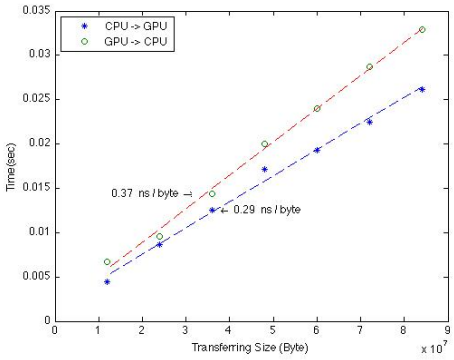

Figure 2. Experimental results from the Athena system showing the time (in seconds) required transferring data between the CPU and the GPU (and visa versa) as a function of the number of bytes transferred. Note the different incremental transfer rates to and from the GPU.

Using a linear least squares fit to the data shown in Figure 2, we obtain the values for the constants in (1) as shown in Table 1.

Table 1. The constants t_s, t_{CG} *and* t_{GC} obtained by a linear least-squares fit to the data in Figure 2. These constants are for the Athena system, the hybrid computing system used for the experimental results.

Constant	Time
t_s	*3.0ms/copy*
t_{CG}	0.29*ns/byte*
t_{GC}	0.37*ns/byte*

The second aspect of computing the pseudo-random numbers on the GPU is the time to execute the "kernel" (the OpenCL program that contains the instructions that are executed on the GPU). This time can be modeled as consisting of two parts, a "kernel start up time" T_s and a "kernel execute time" which we denote by T_e. The total time to execute the kernel, T_k, is modeled as the sum of these two terms as

$$T_k = T_e + T_s, \qquad (2)$$

The pseudo-random number generator works by generating a sequence of numbers in a loop—we denote the number of times through the loop, or the "kernel cycle," as n_k. Empirically we determine that T_s can be modeled as a function of n_k by the equation

$$T_s(n_k) = an_k + b, \qquad (3)$$

where a is an incremental rate measured to be 100*ns/kernel-cyle*, and b is a fixed setup time measured to be 1*ms*. Each kernel cycle, the GPU tries to schedule some number of threads, n_{wgs}, called the "working group size" on each compute unit in the GPU. The GPU performance is, however, limited by the number of stream processors that it has per compute unit. We denote this number by p_{wgs} (this number is 32 for the Athena system). Given that it takes some amount of time to execute the thread, say t_c^{GPU}, then the second term, the "kernel execute time," can be modeled as

$$T_e(n_k, n_{wgs}) = n_k\, t_c^{GPU} \lceil n_{wgs}/p_{wgs} \rceil, \qquad (4)$$

where t_c^{GPU} was measured to be 400*ns/number* for the Athena system. Using the equations (3) and (4) to model the overall execution time for one kernel cycle as given in (2), we obtain the black '*' points shown in Figure 3. In this figure the number of kernel cycles, n_k, is fixed at 10,000; we then measure the time it takes for the kernel to execute. The measured times are shown as the green '+' symbols in this graph. As the work group size increases beyond multiples of 32 (e.g., 32, 64, and 96), we observe discrete jumps in the measured times as predicted by equation (4).

A good way to parameterize the performance of the pseudo-random generator is in terms of the number of work items, n_{wi}, which is the product of the number of work groups, n_{wg}, and the work group size, n_{wgs}, as follows

$$n_{wi} = n_{wg}\, n_{wgs}. \qquad (5)$$

This a good way to parameterize the scaling of the parallel algorithm because the number of work items, n_{wi}, represents the number of independent "tasks" that are to be executed on the GPU. However, there are two limitations to the number of these tasks that can be executed in parallel. First, only one work group can use a compute unit at a time; hence, the number of work groups that can execute in parallel is limited by the number of compute units on the GPU. We denote the number of compute units on the GPU by n_{CU}. Second, as discussed above, the number of stream processors per compute unit, p_{wgs}, limits the number of threads that can execute at one time on a compute unit.

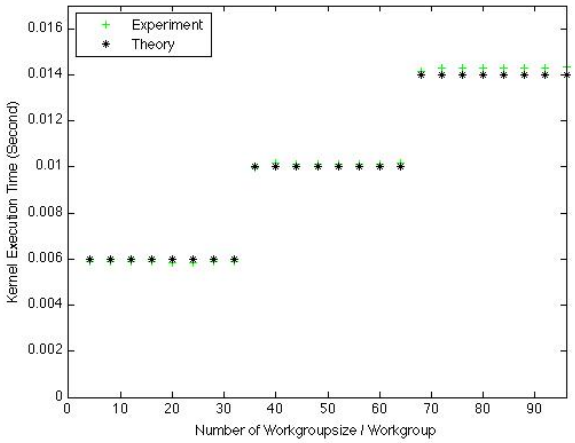

Figure 3. The time measured for the kernel to execute as a function of the work group size per work group (or compute unit). For this data we fixed the number of work groups to be one. The experimentally measured data from the Athena system is shown as the green '+' points, the modeled times, based on equation (2), are shown as the black '*' points on this graph. In this figure the number of kernel cycles is fixed at 10,000.

A complete model of the time required to generate the pseudo-random numbers requires that we also include the time necessary to copy the pseudo-random number seed tables back and forth between the CPU and GPU memory (one table for each work item) and to copy the pseudo-random numbers from the GPU to the CPU memory. To help amortize the cost of copying the seed tables between the CPU and GPU memories, we iteratively run the GPU kernel code n_i times. Each time the GPU kernel code is run we generate $n' = n_k\, n_{wi}$ pseudo-random numbers. Thus, the total number of pseudo-random numbers generated is given by $n = n_i\, n'$.

Therefore, in our model we have four separate parts to consider: (1) the time to upload the seed tables, T_{seedUp}; (2) the time to download the seed tables $T_{seedDown}$; (3) the kernel execution time, T_k; and (4) the time to download the n' pseudo-random numbers, $T_{GPU\rightarrow CPU}(n')$. Combining these factors, the time to generate n pseudo-random numbers using the GPU, $T_{RN}^{GPU}(n)$, can be expressed as:

$$\begin{aligned} T_{RN}^{GPU}(n) &= T_{seedUp} + T_{seedDown} + \\ &\quad n_i\,[T_k(n_k,n_{wgs}) + T_{GPU\rightarrow CPU}(n')] \\ &= T_{seedUp} + T_{seedDown} + \\ &\quad n_i\,[T_k(n_k,n_{wgs}) + t_{GC}\,n' + t_s]\,. \end{aligned} \tag{6}$$

The seed table size is 28 words, and we require a separate seed table for each work group. However, given that the number of work groups is at most in the thousands, and the number of pseudo-random numbers that we will be copying back from the GPU is typically in the millions, we can ignore T_{seedUp} and $T_{seedDown}$ in equation (6) and use the following approximation,

$$T_{RN}^{GPU}(n) \approx n_i\,[T_k(n_k,n_{wgs}) + t_{GC}\,n' + t_s]\,. \tag{7}$$

Also note that in our formulation of $T_k(n_k,n_{wgs})$, we tacitly assumed that there are an unlimited number of compute units available on the GPU. In practice, of course, the GPU architecture has limited number of compute units, n_{CU}. When the number of work groups is larger than the number of compute units, the extra work corresponding to these additional work groups must be scheduled sequentially on the GPU. To take this effect into account, we introduce a modified kernel execution time function, $T_k^*(n_k,\, n_{wgs},\, n_{wg})$. The modified kernel execution time can be expressed as

$$T_k^*(n_k,\, n_{wgs},\, n_{wg}) = T_k(n_k,n_{wgs})\,\lceil n_{wg} / n_{CU} \rceil\,. \tag{8}$$

To compute the speedup of the GPU accelerated algorithm, we need a model for the running time of the sequential algorithm on the CPU. As this running time should depend linearly on the number of pseudo-random numbers generated, we model the time to generate the numbers using the CPU, $T_{RN}^{CPU}(n)$, as:

$$T_{RN}^{CPU}(n) = t_c^{CPU}\, n. \tag{9}$$

The pseudo-random number generator used on the GPU is an implementation of RANLUX [8]. Thus, on the CPU we use the GNU Scientific Library (GSL) implementation of this pseudo-random number generator [9]. For the GSL implementation of RANLUX with a luxury level of 0 (gsl_rng_ranlxs0) the value measured for t_c^{CPU} for the Athena system used for our experiments is 50*ns/number*. For a luxury level of 2, this value was measured to be 120*ns/number*. Combining the two models, the speedup of generating n pseudo-random numbers using the GPU compared to CPU can be computed as

$$S_{RN}(n) = T_{RN}^{CPU}(n) \,/\, T_{RN}^{GPU}(n). \tag{10}$$

This speedup is presented below in Figure 4. In this figure we show both the experimentally measured speedup (on the Athena system) and the theoretical speedup based on the model presented above computed using the machine parameters for the Athena system. Note that we plot the theoretical speedup for two models. The first model assumes an unlimited number of compute units, and the second model is based on equation (8), where the number of compute units is limited to 14 (as for the Athena system).

How we obtain the increasing number of work items in Figure 4 requires some additional explanation. We use work group sizes, n_{wgs}, of 32, 64, and 96 and we fix the number of iterations, n_i, to 10. We adjust n_{wg} and n_k to generate the same number of pseudo-random numbers (98,304,000) for different n_{wgs} in the following manner. The number of work groups, n_{wg}, is increased from 2^0 to 2^9. When n_{wgs} is 32, 64 and 96, n_k is respectively varied from 600×2^9 to 600×2^0, from 300×2^9 to 300×2^0, and from 200×2^9 to 200×2^0.

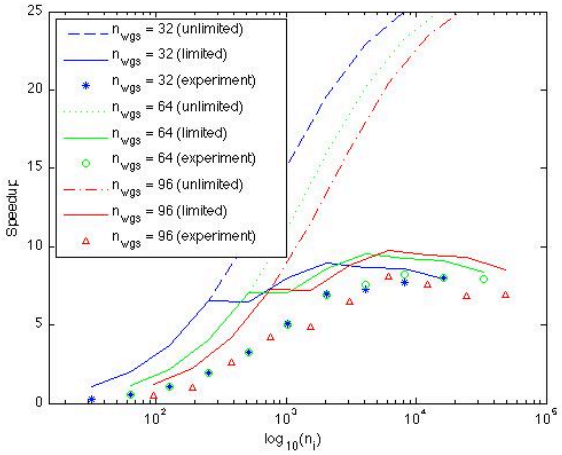

Figure 4. Speedup plots comparing the GPU execution time to the CPU execution time for the pseudo-random number generation library. Three different work group sizes (32, 64 and 96) are used. The speedup results are plotted as a function of the number of work items. As explained in the text, the number of work groups and the number of kernel cycles are both varied in order to compute the same number of pseudo-random numbers for each data point. These results are for RANLUX with luxury level 0.

Note that the experimentally measured results agree well with the modified theoretical model. We include in the plot the theoretical model for an unlimited number of compute units. As one can see, the overall speedup is limited and ultimately approaches an asymptotic value. This limit results primarily from the time required to copy back the pseudo-random numbers from the GPU to the CPU memories.

3.2. PMC Speedup Analysis

We can compute a speedup for the RHT simulation using a hybrid-computing scheme (i.e., using the GPU to compute the pseudo-random numbers) relative to using solely the CPU. First, we consider the time required on a single thread using the CPU to compute the pseudo-random numbers. Let the required number of pseudo-random numbers be denoted by n. Note that the number of pseudo-random numbers required increases linearly with the number of photons used in the RHT simulation, although the constant of proportionality depends on the specific geometry and problem parameters (e.g., the absorption coefficient as a function of position). We can express the sequential simulation time, $T_S(n)$, as

$$T_S(n)=T_{RN}^{CPU}(n)+T_{RHT}(n), \tag{11}$$

where $T_{RHT}(n)$ is a time required for the radiative heat transfer simulation (excluding the pseudo-random number generation) and $T_{RN}^{CPU}(n)$ is the time for generating pseudo-random numbers using the CPU.

An analysis of the time required for the RHT simulation running in parallel using multiple threads and a single GPU to compute the pseudo-random numbers is more complex as it involves the parallel execution of the thread managing the GPU and the GPU program itself [7]. As discussed in the preceding subsection, the time to compute a pseudo-random number on the GPU is a complex function of a number of factors specific to the GPU used and its configuration. We can, however, simplify the analysis by considering only a single parameter, the block size B. As a general rule, the efficiency of computing the numbers increases with the block size. However, the exact efficiency depends on the number of work items, n_{wi}, the number of iterations, n_i, and the number of kernel cycles, n_k (as discussed above and in detail in reference [7]). Given these parameters, the block size B is given by the formula

$$B = n_k\, n_i\, n_{wi}. \tag{12}$$

As noted earlier, the number of work items, n_{wi}, can be configured in a number of different ways by selecting different values for the number of work groups, n_{wg} and the work group size, n_{wgs} as the number of work items is the product of these two parameters. We assume that these parameters are chosen to maximize the efficiency of computation on the GPU. Given these definitions, the parallel simulation time, $T_P(p,pn,B)$, can be expressed as

$$\begin{aligned} T_P(p,np,B) = {} & pT_{RN}^{GPU}(B) + \\ & \max\{p(\lceil n/B\rceil-1)\, T_{RN}^{GPU}(B), \\ & \lfloor n/B\rfloor\, T_{RHT}(B) + T_{RHT}(n-\lfloor n/B\rfloor B)\}, \end{aligned} \tag{13}$$

where $T_{RN}^{GPU}(B)$ is a time to fill in the pseudo-random numbers using the GPU for the block size B, and p is the number of threads.

The timeline for the RHT simulation for a single thread in the above equation is illustrated in Figures 5 and 6. Figure 5 shows the simulation time when the pseudo-random number block generation time takes longer than the RHT time; note how the RHT part of the code is blocked while it waits for a new block of pseudo-random numbers is generated by the GPU.

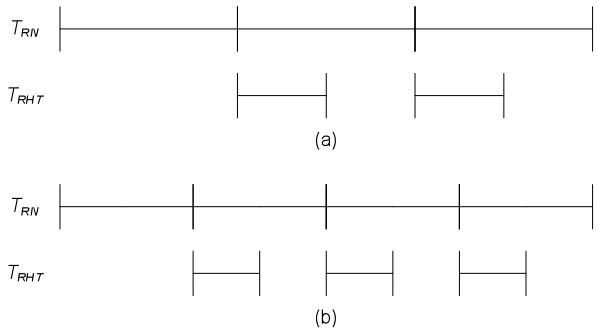

Figure 5. A timeline showing what the RHT thread and the pseudo-random number thread manager are doing relative to each other when $T_{RN}(B)$ is longer than $T_{RHT}(B)$. In (a) we show the case the block size is larger than in (b).

To illustrate where the "max" arises in equation (12), in Figure 6 we illustrate the simulation time when the $T_{RN}(B)$ (the time to generate a block of pseudo-random numbers on the GPU) is shorter than the time $T_{RHT}(B)$.

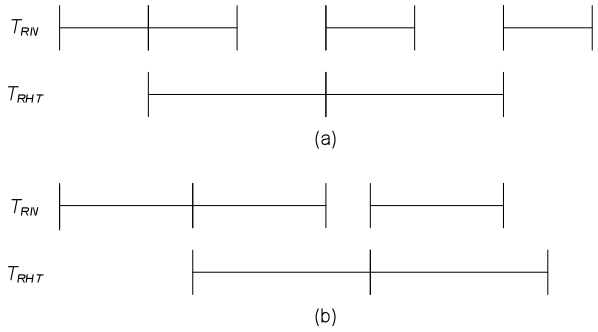

Figure 6. Illustrations of the simulation timeline showing the RHT thread and the pseudo-random number managing thread. In (a) the block size is large enough that $T_{RN}(B)$ can generate a new block before $T_{RHT}(B)$ completes. In (b) we illustrate the case when the block size is even larger than in (a).

In Figure 7 we illustrate the case when the simulation is multi-threaded with multiple threads consuming the pseudo-random numbers generated. Again, note how the "max" in equation (12) is used to describe this case.

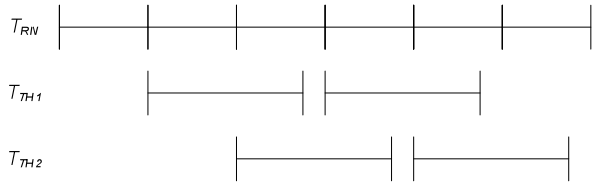

Figure 7. An example illustrating multiple threads executing the RHT part of the code using the pseudo-random numbers generated from the single thread managing the GPU.

Finally, the overall scaled speedup *SS* for the hybrid version the RHT simulation using the GPU-accelerated libraries can be expressed as:

$$SS(p,np,B) = p\ T_S(n) / T_P(p,np,B). \qquad (14)$$

4. Experimental Results

For the experimental results presented in this section, we use the Athena system in Virginia Tech [10]. Athena is a cluster system with GPUs and large RAM memory. The system is made up of 16 nodes and each node consists of 4 octa-cores. Each node also has one NVIDIA S2050 GPU. Each GPU contains 14 compute units, and each compute unit consists of 32 processing elements [11]. For all the results presented in this section, a luxury level of 2 is used for the RANLUX pseudo-random number generators.

To measure the scaled speedup on this hybrid architecture, the CPU-only version of the simulation is first run and timed on a single CPU. These measurements are compared to the running time of the simulation on the hybrid architecture for a scaled instance of the problem. In Figures 8 and 9 we show the speedup of the RHT simulation using the GPU accelerated random number generator and a single CPU as compared to the solely CPU-based version. In Figure 8, note that when the number of photons used by the simulation is small, the scaled speedup is limited by the time required to generate the first block of pseudo-random numbers (e.g., see the timelines in Figures 6). For larger numbers of photons, this initial time is amortized as many blocks are used. Note that by using a smaller block size, this transition to improved speedup occurs for a smaller number of photons. The results in Figure 8 correspond to the timelines shown in Figure 6 where the asymptotic speedup is determined by the relative amount of time spent in RHT portion of the simulation.

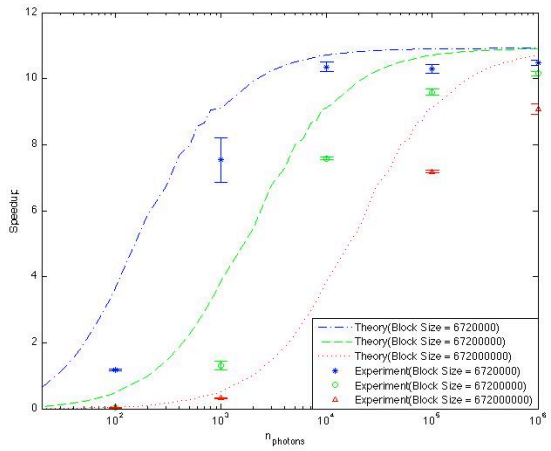

Figure 8. The speedup for the GPU-accelerated simulation run on a single CPU for large block sizes. The photon numbers are increased from 10^2 to 10^6 in order to vary the workload. The work group size is 96, the number of work groups is 14, and the number of kernel cycles is 500. To change the block size, the number of iterations is respectively set to 10, 100 and 1000.

In Figure 9 we show the speedup for the timeline case shown in Figure 5. In this case, the asymptotic speedup is limited by the speedup of pseudo-random numbers being generated on the GPU. As shown in the figure, this speedup decreases with smaller block sizes.

The scaled speedup obtained with multiple threads on a single node is in Figure 10. This plot shows that the overall performance of the simulation increases almost linearly. As with the results in Figure 8, the speedup is limited for small numbers of photons by the generation of the initial blocks of pseudo-random numbers. This fact is illustrated in the timelines shown in Figure 7. Again, as in Figure 8, this initial cost is amortized as multiple blocks are used for larger numbers of photons.

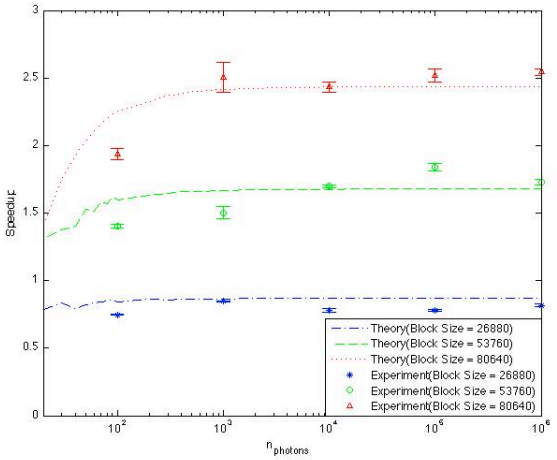

Figure 9. The speedup of the RHT simulation for on a single CPU for small block sizes. The photon numbers are increased from 10^2 to 10^6 in order to vary the workload. The work group size is 96, the number of work groups is 14 and the number of iterations is 1. To change the block size, the number of kernel cycles is set to 20, 40 and 60.

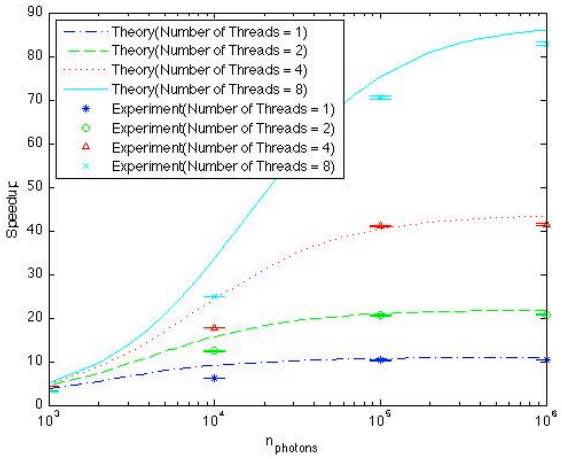

Figure 10. The measured scaled speedup for GPU-accelerated version of the RHT simulation using 1, 2, 4 and 8 threads on a single node (i.e., with one GPU). The photon numbers are increased from 10^3 to 10^6 in order to vary the workload. The work group size is 96, the number of work groups is 14, the number of iterations is 100 and the number of kernel cycles is 500.

The relative cost of the RHT portion of the simulation can be varied by increasing the computed accuracy of the energy contributed to an element during the transmission of a photon (as depicted in Figure 1(c)). This increased accuracy requires the use of more pseudo-random numbers for the Monte Carlo integration involving the absorptivity when traversing the element. The effect of this increased accuracy on the speedup is shown in Figure 11. The speedups for three different numbers of samples per element (80, 160, and 240) are shown in this figure.

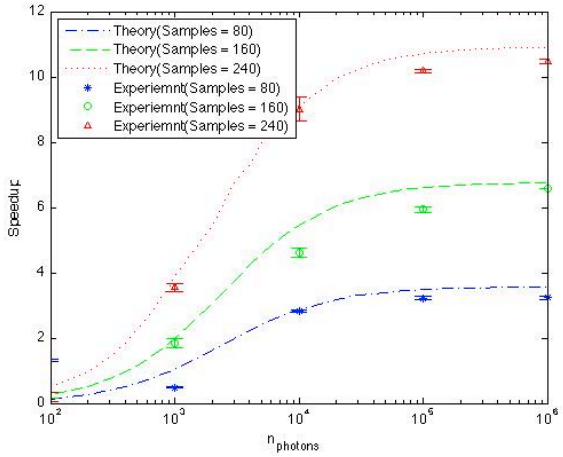

Figure 11. The speedup for the GPU-accelerated algorithm run on a single CPU for different transmission sampling strategies (as described in the text). The number of samples per element is respectively set to 80, 160 and 240. The number of photons used is increased from 10^2 to 10^6 in order to vary the workload. For these results the work group size is 96, the number of work groups is 14, the number of iterations is 100 and the number of kernel cycles is 500.

To be able to generate the theoretical curves shown in Figure 8-11, one needs to know how the RHT portion of the simulation, $T_{RHT}(B)$, scales with block size. In Figure 12 we show how this time varies with block size and with differing numbers of samples per element during the transmission calculation.

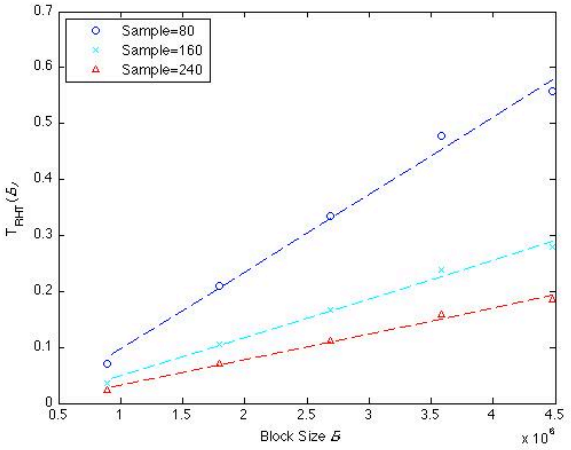

Figure 12. The change of $T_{RHT}(B)$ as a function of block size B. The block size B is increased from 896,000 to 4,480,000 for the data shown on this plot. Linear least squares fits to these data points are shown as the dashed lines in this figure. For sampling of 80, 160 and 240 points per element, the respective slopes from the least squares fit are 1.38×10^{-8}, 6.9×10^{-9} and 4.6×10^{-9}.

Finally, the RHT simulation was run on a complete hybrid architecture including distributed memory (using 10 nodes), using multiple threads on each node (8 threads per node), and using the GPU-accelerated pseudo-random number generator (using one GPU per node). The scaled speedup results obtained on this hybrid architecture are shown in Figure 13. Clearly, significant scaled speedups

can be obtained for a modestly sized hybrid architecture using this approach.

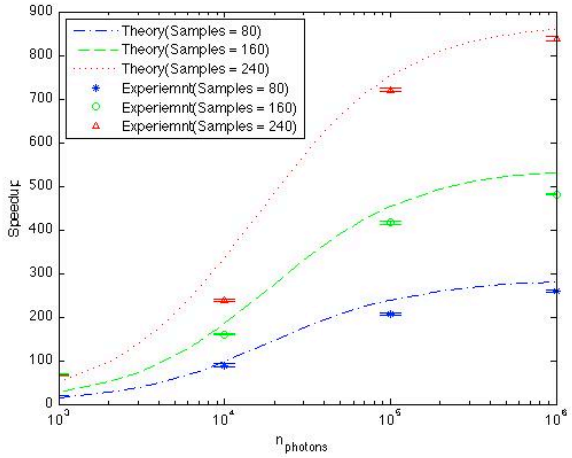

Figure 13. The scaled speedup plots for the RHT simulation using the GPU-accelerated pseudo-random number generator on a hybrid computing architecture. The number of photons used in the Monte Carlo simulation is increased from 10^3 to 10^6 in order to vary the workload. 10 compute nodes are used with 8 threads per node for the simulation. For the GPU the work group size is 96, the number of work groups is 14, the number of iterations is 100 and the number of kernel cycles is 500.

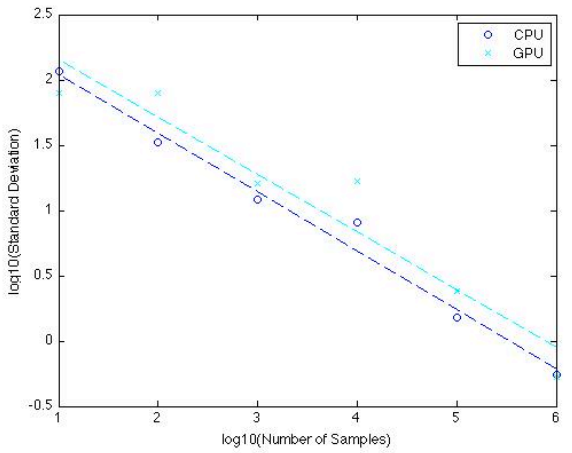

Figure 14. The standard deviation for the mean temperature obtained on different compute nodes as a function of the number of samples. Note that the slope of the best-fit line in this graph is -0.5, which is consistent with the Monte Carlo simulation data on different nodes being statistically independent.

To ensure that the simulation results obtained on this parallel system are statistically independent when using multiple nodes, we computed the mean of the temperature at one point in the interior of the domain for the multiple threads within each node. We then compute the standard deviation of these means (from the 10 nodes). This standard deviation is plotted in Figure 14 as a function of the number of photons used in the simulation. The slope of this graph is -0.5, which is what one would expect (from the central limit theorem) and is consistent with statistically independent simulation results from different nodes. Note that this result does not prove statistical independence, but it does show that the data is not statistical dependent.

5. Conclusions

In this paper, we have implemented a Monte Carlo application framework on a hybrid computer architecture where GPU acceleration is used for generating large blocks of pseudo-random numbers asynchronously. The target application is a baseline Radiative Heat Transfer (RHT) simulation; we presented experimental results that confirm our analysis about the scaled speedup of this approach. Overall, this approach can be very effective and achieve nearly a 1,000 times speedup on a modestly sized hybrid machine.

Our approach demonstrates how GPU acceleration can be used in real world applications such as RHT. We observe that transferring computation from the CPU to GPU can significantly improve the simulation efficiency. However, the overhead of memory copies to and from the CPU and GPU must be amortized through the use of large data block transfers and significant data reuse on the GPU.

March 2012

ABSTRACT
Hard-core interacting particle methods are of increasing importance for simulations and game applications as well as a tool supporting animations. We develop a high accuracy numerical integration technique for managing hard-core colliding particles of various physical properties such as differing interaction species and hard-core radii using multiple Graphical Processing Unit (m-GPU) computing techniques. We report on the performance trade-offs between communications and computations for various model parameters and for a range of individual GPU models and multiple-GPU combinations. We explore uses of the GPU Direct communications mechanisms between multiple GPUs accelerating the same CPU host and show that m-GPU multi-level parallelism is a powerful approach for complex N-Body simulations that will deploy well on commodity systems.

KEY WORDS
m-GPU; GPUDirect; N-Body; hard-core collisions; polydisperse radii; multi-species.

1 Introduction

Models based upon classical N-Body particle systems [2] are commonly used at various levels of approximation in game simulations [5,11,12] but still play an important role in understanding physical phenomena such as diffusion, phase mixing and separation [4], and other behaviours that arise from specific geometric distributions.

Considerable work has been reported in the literature on uses of molecular dynamics whereby approximate potential models are used to simulate atomic and molecular systems [14, 30, 36]. A recent review by Larsson and co-workers [26] points out that there is still considerable scope for improved algorithms and for hybrid solutions to the molecular dynamics N-Body applications problem.

Another N-Body application area of significance is in simulating astrophysical phenomena including: general relativity systems [44]; cosmological simulations [37]; simulations related to dark matter theories [25]; and other modifications to Newtonian gravity [39]. A body of recent important work is progressing in this field where simulation provides an important means of exploring the implications of various theories of dark matter.

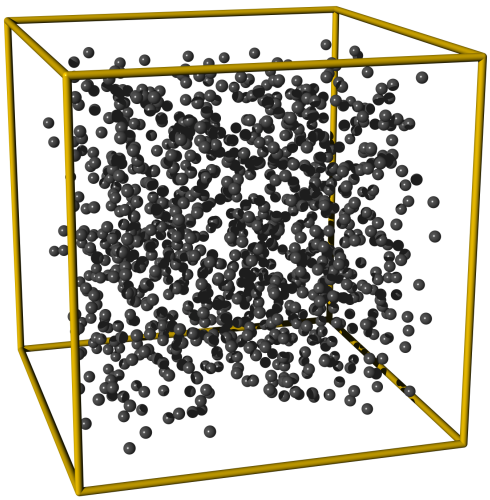

Figure 1: Three-dimensional particle system with rigid walls.

It is therefore of continuing importance to understand the computational performance for N-Body particle system simulations and indeed such simulations have found use as benchmark kernels for high-performance computing systems [8, 19, 20, 23, 29, 33, 38].

In the limit of a large number of particles and a thermodynamically equilibrated system a simple benchmark rating such as number of particle updates per second suffices, but in practice, many gaming situations in which particle models are employed the system is quite definitely not in equilibrium. Much present research into understanding growth and transient behaviour in physical, chemical and biolog-

ical systems is also concerned with models and systems that are far from equilibrium.

It is therefore interesting to add to the parametric space of a particle integration benchmark by considering how the load balance and computational organisation can be changed by varying a manageable parameter such as the temperature of a simulated system.

We consider a system of hard spherical particles that interact at long and medium range through an attractive potential with a soft repulsive core, but with a hard impenetrable core at very short range. This is a realistic model for many scenarios and allows us to experiment with a range of computational intensities in the resulting particle benchmark. The system is also usefully realistic – it can be modelled with a definite walled container and not with the unrealistic periodic boundaries often used in physics model simulations used for studying statistical mechanical properties.

Two typical paradigms for deploying N-Body simulation codes [34] are as either near teal-time interactive codes that have a built in visualisation capability, or as batch-oriented non-interactive codes, that may offer a frame dumping capability but which are not intended nor capable of rendering in real time.

There are a number of sophisticated data organisational methods that approximate the $\mathcal{O}(N^2)$ interactions with appropriate potential cut-offs which can be managed as spatial trees and neighbour lists [3, 41]. Some of these approaches can be optimised for particular architectures such as hypercubic systems [6, 15]. Collision dynamics can also be optimised using appropriate collision lists and associated techniques [10].

The size of systems that are feasible to simulate obviously depends on the desired simulated time period as well as most critically – upon the number of particles involved. At the time of writing, work has been reported on up to $N \approx 10^10$ possible particles in a gravitational simulation involving collisional and collisionless systems [7]. Articles such as that by Aarseth report work with more complex models such as post Newtonian corrections [1] with $N \approx 10^5$ particles simulated on on GRAPE [22] type computer architectures.

Various architectural approaches have been applied to this important class of application problems, including clusters and volunteer distributed computing systems [9] and conventional multi-core CPU systems modern multicore CPU systems [40]. Work by Groen and co-workers [16] indicates the typical number of cores (60-750) that have been recently feasibly employed in multicore cluster systems to tackle a single N-Body application simulation cold dark matter.

In this present paper we are interested in the capabilities of graphical processing units and systems deploying single and multiple GPU systems and several authors and research groups have reported work on N-Body calculations on GPUs – although nearly always on a very specific algorithm [14, 17, 21, 42, 43].

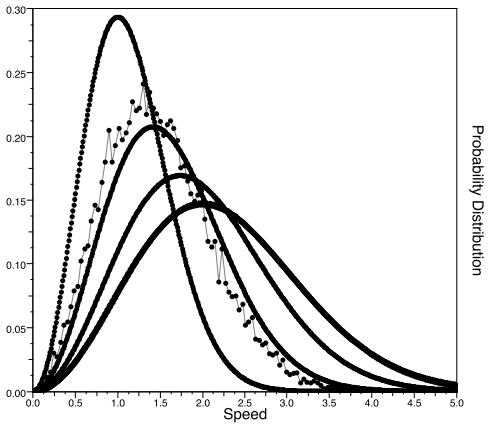

Figure 2: Theoretical Maxwell-Boltzmann distribution computed for Temperatures 1,2,3,4 with $k_B = m \equiv 1$ from equation 2 showing increasing most-probable speed and distribution width with increasing temperature. Experimental data from a sample simulation is included for reference.

A considerable range of sophisticated physics quality simulation codes for specific and special purpose N-Body applications are available and have been compared in the review by Fortin and co-workers [13].

We are interested in the computational structure of a hybrid N-Body application that involves different sorts of short or long range potentials, hard core collisions and also interactions with enclosing rigid walls of a container. This covers the principal algorithms needed for both games quality physics simulations as well as more sophisticated energy conserving statistical mechanics studies. We are also interested in being able to deploy very accurate high-order numerical integration methods such as the Hairer 10th order time stepping algorithm [18].

In this paper we explore how a sophisticated N-Body simulation can be developed for multiple GPU systems with the option of choosing collisional or collisionless systems, and parameterising the model using temperature T as well as the number of individual particles N.

2 Distribution of Speeds

It becomes feasible and realistic to ascribe a temperature to an ensemble of simulated particles once the system size N is large enough. In practice a few thousand particles yields thermal measurements that can be compared with the theoretical definition discussed below.

The scalar speed is defined in terms of the velocity com-

ponents for each particle as:

$$v = \sqrt{(v_x^2 + v_y^2 + v_z^2)} \quad (1)$$

and taking the Boltzmann probability energy factor e^{-E/k_BT} alongwith kinetic energy expression for a point particle $\frac{1}{2}mv^2$ we obtain the probability density distribution of speeds as:

$$f(v) = 4\pi \left(\frac{m}{2\pi k_B T}\right)^{3/2} v^2 \exp(-mv^2/k_B T) \quad (2)$$

which is normalised so that:

$$\int_0^\infty f(v)dv \equiv 1 \quad (3)$$

and is known as the Maxwell-Boltzmann distribution with the form as shown in Figure 2. Differentiating, we locate the most probably speed at the peak of the distribution:

$$\frac{df(v_p)}{dv} = 0 => v_p = \sqrt{(2k_B T/m)} \quad (4)$$

where v_P is the most probable occurring speed and thus temperature T can be obtained from:

$$T = \frac{mv_p^2}{2k_B} \quad (5)$$

Temperature is also related to the width of the Maxwell-Boltzmann distribution functions and can also be (more reliably) fitted to that, than from the peak position which is more prone to experimental uncertainty.

3 Molecular Dynamics

The molecular dynamics (MD) technique involves a numerical integration of the classical equations of motion for a number of particles, or molecules, given a model Hamiltonian [2, 24, 27]. The resulting numerical trajectory through phase space, can be used to make a number of useful measurements of the dynamical properties of a system [31].

There are several difficulties involved in applying this technique to the simulation of an alloy, even a purely binary one. Primarily, the first requirement is for a suitable model Hamiltonian for the system. While this is not easy to obtain exactly, it *is* possible to construct an approximate one with the basic properties, using pair-wise potentials. For example one very simple model would be to assume a system of soft spherical atoms in a box, with two atomic species present, and atoms of each species preferentially attracting atoms of its own species.

A model Hamiltonian of the Lennard-Jones form [27] can be constructed using:

$$U(R) = 4\epsilon \left[\left(\frac{\sigma}{R}\right)^{12} - x^{i,j}\left(\frac{\sigma}{R}\right)^{6}\right] \quad (6)$$

This gives the potential energy U due to the pair-wise interaction of two atoms of species i, j, separated by some radial distance $R = |\mathbf{r}_i - \mathbf{r}_j|$, given two atom specific parameters in the form of an energy ϵ and a length scale σ, and a cross term coupling fraction $x^{i,j}$ which is greater for interactions between like species i, j than for opposite species.

4 Model Implementation

This molecular dynamics simulation has been implemented for multi-GPU systems using CUDA. The simulation computes the potential between particles using the all-pairs algorithm and computes hard-sphere collisions using a posteriori method. All hard-sphere collisions are inelastic as are the collisions of particles hitting the walls of an enclosing box. A diagram of the inelastic collisions are shown in Figure 3.

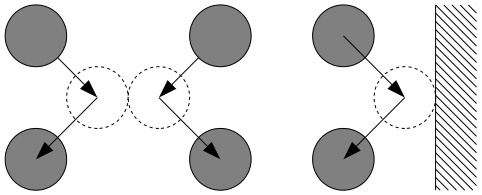

Figure 3: Inelastic Collisions

This simulation has been implemented and tested for m-GPU systems containing up to four GPU devices. The high-level algorithms are the same as the ones discussed in [19]. The particles are evenly distributed between the GPU devices and each device is responsible for updating its particles. To calculate the total force on a particle, each device will calculate the force each of it's own particles exert on each other as well as the force exerted on its particles by the particles stored in the other devices. This requires communication between the different devices, there are a number of ways this communication can be performed and they are discussed and compared in section 5. All force calculations make use of the tiling algorithm [29] as it still provides the best performance.

Various methods can be used to integrate the motion of the particles based on the laws of motion and the potential between them. The different methods have various tradeoffs in terms of memory usage, computation time, stability and accuracy. Selecting the optimal method is not always simple. It has been shown that high-order methods may be computationally more expensive per step, they are stable and accurate with larger step sizes resulting in an overall improvement in performance. The implementations in this work have been tested using the following methods - Euler, Runge-Kutta 2^{nd}, Runge-Kutta 4^{th}, Dormand-Prince 5^{th} and Hairer 10^{th}.

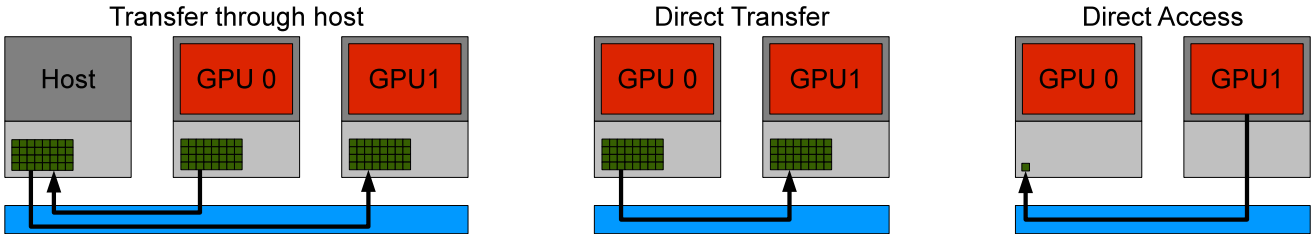

Figure 4: GPU transfer methods.

The fundamental collision model used in this research is the same as the method discussed in [19]. After each time-step, each particle is checked against every other particle to determine if a collision has occurred. The collision detection phase is similar to the all-pairs force calculation. If a collision has occurred, the device will calculate the time at which the collision occurred and record it. Once all the particles have been checked, the collision that occurred first will be corrected. Both particles are stepped backwards in time to the point of collision, an inelastic collision is computed at this point and the particles are then moved forward in time to same time as the rest of the system. This process is repeated until there are no more collisions.

5 M-GPU Communication

The focus of this research was to compare the different methods of communication CUDA provides for transferring data between devices. In [19] we evaluated the performance of PCIe extender chassis such as the Dell C410x. For that comparison the simple peer-to-peer memory copy made available by NVIDIA's GPUDirect 2.0. In this research we compare the performance of all the peer-to-peer communication methods.

Before GPUDirect, all communication in an m-GPU system had to go through the host memory. GPUDirect 2.0 allows the direct transfer of data between devices and eliminates the need for extra system memory and transfer overhead. There are two types of direct communication supported by GPUDirect 2.0 - Direct Transfer and Direct Access.

Direct Transfer is a host controlled memcpy from one device directly to another. This data transfer does not need to go through the host and thus avoids unnecessary transfer overheads. CUDA 4.0 provides two methods for Direct Transfer - `cudaMemcpyPeer` and `cudaMemcpyPeerAsync`. `cudaMemcpyPeer` is a blocking memory call that will not return until the transfer is complete. `cudaMemcpyPeerAsync` is non-blocking and the method will return immediately even though the transfer has not yet completed.

Direct Access allows a thread executing on one device to access a value stored in the memory of another device. This feature makes used of the Unified Virtual Addressing (UVA) supported by CUDA 4.0. UVA gives a single address space to the host and device memory, previously the host and each device had a separate memory address space [28]. Direct Access is designed for Non-Uniform Memory Access (NUMA) patterns. Using this method of communication the kernels on each device can simply access the values from the other devices and there is no need for any memcpy calls.

6 CUDA Implementations

To use the CUDA peer-to-peer communication methods, the devices must have Peer Access enabled. This must be set on each device for every other device peer-to-peer communication will be used. Peer-to-peer communication with device `d` can be enabled by simply calling the function `cudaDeviceEnablePeerAccess(d,0)`.

Listings 1 and 2 show the two methods of Direct Transfer. Listing 1 blocking copy method `cudaMemcpyPeer`. The thread connects two each device and uses `cudaMemcpyPeer` to copy the particle data out of another device into memory on the current device. Once all devices have performed this copy, kernels will be launched on each device to compute something with this data. This computation can either be a force calculation or a collision detection kernel.

Listing 1: Direct Transfer Method - cudaMemcpyPeer.

```
for(int t = 1; t < P; t++) {
  for(int id = 0; id < P; id++) {
    int id2 = (id + t)%P;
    cudaSetDevice(id);
    cudaMemcpyPeer(p2[id],id,p[id2], id2,size);
  }
  for(int id = 0; id < P; id++) {
    cudaSetDevice(id);
    //Compute something using p2[id]
  }
}
```

The non-blocking copy method is very similar but will use

`cudaMemcpyPeerAsync` instead. In this implementation the host will launch all the memory copy calls at once instead of waiting for each one to finish before launching the next. The kernels are also launched immediately but will not execute until the data transfer is completed. The code snippet for this data transfer method is shown in Listing 2.

Listing 2: Direct Transfer Method - cudaMemcpyPeerAsync.

```
for(int t = 1; t < P; t++) {
  for(int id = 0; id < P; id++) {
    int id2 = (id + t)%P;
    cudaSetDevice(id);
    cudaMemcpyPeerAsync(p2[id],id,p[id2], id2,
                        size, stream[id]);
  }
  for(int id = 0; id < P; id++) {
    cudaSetDevice(id);
    //Compute something using p2[id]
  }
}
```

The Direct Access method shown in Listing 3 does not use any copy functions. Instead the computation kernels can simply access the particles in the other devices. Each device simply calculates the device id of all the other devices and get the address of their particle data. The computation kernels can then access the particles at these addresses. This requires Unified Virtual Addressing otherwise each device would access its own memory and not the memory on other devices.

Listing 3: Direct Access Method.

```
for(int id = 0; id < P; id++) {
  cudaSetDevice(id);
  id1 = (id + 1)%P;
  id2 = (id + 2)%P;
  ...
  //Compute something using p[id1], p[id2]...
}
```

These three implementations can all be used to transfer data between multiple devices for molecular dynamics simulations on m-GPU systems. The performance of these three methods are compared in Section 7.

7 Performance Results

The implementations discussed in this work have been evaluated using two different experiments. The first shows the time required to compute a molecular dynamics simulation with potentials and hard-sphere collisions at different system densities. The second compares the performance of the different m-GPU implementations. Both of these experiments have been computed with four NVIDIA C2070 compute cards connected to a Dell C410x PCIe extender chassis and use the Runge-Kutta 4^{th} order integration method. The performance of this system is compared to other GeForce and Tesla card configurations in [19].

The first experiment was to compare the three peer-to-peer transfer methods - Synchronous Direct Transfer (DT-S), Asynchronous Direct Transfer (DT-A) and Direct Access (DA). These three methods have been tested on the Dell C410x and the results for a range of transfer sizes are shown in Figure 5. This shows that the Asynchronous Direct Transfer method provides the best performance and Direct Access outperforms Synchronous Direct Transfer for small transfers but is slightly slower for larger transfers ($>$ 256 KB). It is important to note that the Direct Transfer methods communicate the information between devices but it must still be read by the kernels from global memory, whereas the kernels using Direct Access will have already read the required values.

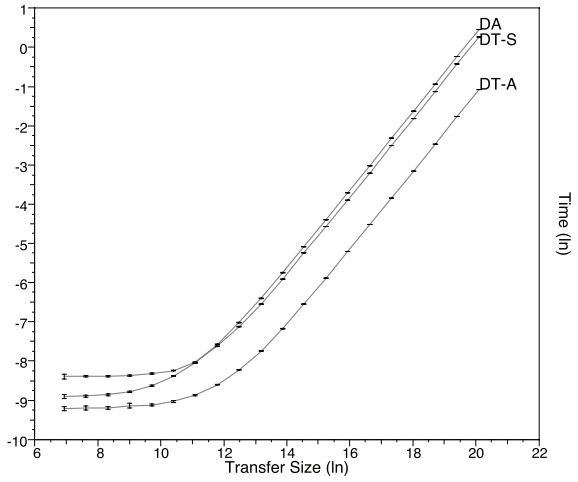

Figure 5: Transfer time for three peer-to-peer communication methods for 4KB-2GB shown in ln-ln scale.

The second experiment is designed to compare the performance of the three m-GPU implementations in the actual simulation. The methods have been compared across a range of system sizes and densities. The performance results (in milliseconds per time step) are presented for one fixed density. These results are shown in Table 1.

8 Discussion

The almost indistinguishable performance results of the three implementations presented in Section 7 are surprising to say the least. The close performance of the two Direct Transfer methods is not entirely unusual as the data is transferred as a block in by both implementations. In previous work [35], with asynchronous data transfer through host showed a significant performance improvement over

Table 1: Performance comparision of GPUDirect simulation implementations. Times acurate to ± 0.005 millisecs per timestep.)

Size N	Direct Transfer	Direct Transfer (Async)	Direct Access
1024	3.46	2.66	3.52
2048	5.55	4.76	5.58
4096	9.81	9.03	9.80
8192	18.78	18.12	18.73
16384	53.38	52.26	53.18
32768	194.56	193.50	193.78
65536	729.27	727.75	727.01

synchronous. However, this work focused on lattice models where only the borders had to be transferred and thus all communication could be completely hidden.

However, it was highly unexpected that the Direct Access method would provide almost the same performance as the other two implementations. It was expected that the NUMA style of access to another device's memory would significantly reduce performance. However, all performance benchmarks and tests for both all-pairs force calculation and collision detection show almost no difference in performance. The high performance of Direct Access represents a significant step forward for m-GPU programming. Previous m-GPU research [32,35] which used communication through the host found the performance of m-GPU programs to be extremely sensitive to communication methods used. Getting the best performance out of such applications required a great deal of fine-tuning.

For this reason, the high-performance of the Direct Access functionality of GPUDirect 2.0 was unexpected. However, it has performed well in every test and significantly reduces programmer effort. Kernels can simply access data from other devices without the need for explicit data transfer and extra memory to store duplicated data. For this reason we believe the Direct Access functionality of GPUDirect 2.0 to be extremely valuable for m-GPU systems.

9 Conclusions

The molecular dynamics simulation discussed in this work is capable of collisional and collision less simulations, with or without elastic wall collisions and a range of possible force/potential models including simple gravitational attraction and multiple species Lennard Jones style systems. These simulations have been implemented for m-GPU systems with multiple GPUs to accelerate a single CPU. Such systems are becoming an increasingly important node architecture for future supercomputers and clusters.

These implementations make use of the GPUDirect 2.0 device-device communication methods that allow data to be directly transferred from one device to another without going through the host. The three implementations show almost no difference in performance despite the fact that the Direct Access method uses a Non-Uniform Memory Access pattern. This surprising result makes it significantly easier to develop efficient m-GPU applications and represent a major step forward in m-GPU technology.

In-Situ Data Compression for Flow Simulation in Porous Media

Henry Lehmann[1], **Bernhard Jung**[1]
[1]Virtual Reality and Multimedia Group, TU Bergakademie Freiberg, Freiberg (Saxony), Germany

Abstract— *Supercomputing simulations easily generate datasets in the range of tera or even peta bytes. However, writing datasets during simulation and reading them for post-processing implies a high I/O load and thus imposes a major bottleneck. In the computation phase, compute nodes stall at writing large amounts of data and the simulation slows down - scientists have to capture data less frequently losing important information. In the post-processing phase, the data has to be read into memory and visualization becomes a time consuming batch process. These problems can be addressed with in-situ data reduction techniques which reduce the I/O load significantly. Recently a novel in-situ data compression method, ISABELA, has been proposed [6]. It provides high compression rates at negligible run time overhead while being local, communication-free, and scalable. This contribution describes a variant of the ISABELA method and its application to a fluid simulation in porous media. Modifications to the original algorithm concern the specific properties of porous media as well as a general new method for exploiting temporal coherence in time-dependent fluid simulation data. Evaluation results concern the optimal choice of curve fitting parameters for data compression and give insight into the trade-off between desired error bounds and compression rates. Overall, the very high compression rate of the ISABELA method is confirmed by our experiments.*

Keywords: in-situ processing, lossy compression, high performance computing, b-spline, data-intensive application, temporal pattern

1. Introduction

As high performance computing resources and algorithms become generally available to scientists, the simulation of physical phenomena plays an increasingly important role in prototyping and knowledge discovery. However the growing computational power raises new problems and challenges to existing hard- and software [2]. With numerical simulations producing amounts of data in the order of tera or even peta bytes, storage devices are driven to peak performance on file systems not optimized for parallel operation [14]. Similarly, for later post-processing, large amounts of data have to be read into memory. This makes post-processing a time consuming batch process which hardly can be influenced by the user once being started [8].

In-situ data reduction is a promising approach to deal with the heavy I/O load of high-resolution supercomputing simulations. In in-situ processing, data compression techniques are directly integrated into the computation phase of the simulation run. Instead of forcing scientists to write out only a subset of the computed simulation data, in-situ processing offers the potential of storing simulation data in their full resolution [8], [6].

The work in this paper is specifically motivated by the need for in-situ data reduction in large-scale Lattice Boltzmann simulations [13] of flow in porous media. Porous media are characterized by highly complex geometries, which present special challenges to numerical simulations. In the Collaborative Research Center (CRC) 920 [1] at Technical University Bergakademie Freiberg (Germany), multifunctional filters for metal melt filtration are researched. The aim is to contribute towards the development of zero-defect materials improving safety of road and railway vehicles as well as aircrafts and other applications requiring highly stressable metal based components.

A further goal is to provide a basis for the design of a new real-time visualization framework using immersive Virtual Reality, replacing offline batch processing by interactive data exploration experiences. With interactive data visualization playing an increasingly important role in data analysis, in-situ data reduction is seen a key feature in CRC 920's evolving simulation and visualization frameworks.

Recently, a novel in-situ data reduction technique called ISABELA (for "In-situ Sort-And-B-spline Error-bounded Lossy Abatement") has been proposed [6]. It outperforms existing lossy and lossless compression techniques for scientific data and offers surprisingly high compression rates while introducing only a minor overhead in computation time into the simulation.

This paper reports on a variant of the ISABELA method (as no implementation details are given in [6]) and its application to fluid simulation data of flow within porous media. In Section 2, we review related work on lossless and lossy compression of scientific data. Section 3 presents our variant of the ISABELA compression method. Our ISABELA-variant takes advantage of differentiating between geometry and fluid cells when applied to voxel grids of porous media. We further describe an error quantization scheme and investigate a novel general method for exploiting temporal coherence in fluid simulation data to enhance com-

pression ratio. In Section 4, we present compression results and analyze different parameterizations of the compression algorithm. Finally, we conclude that ISABELA-like methods provide very good compression results for flow simulation in porous media as well. However, the optimal parameterization and implementation details for our melt simulation dataset varies from the suggested parameterization in the original ISABELA description.

2. Related Work

The complex internal structure of scientific data makes compression a challenge for existing compression methods. Lossless techniques for fast online compression of floating point data are presented e.g. in [10] and [3]. These techniques function by predicting data values and storing small differences between predicted and original data values. They also offer options to omit precision bits supporting lossy compression. However, at high compression rates the relative error increases significantly [6]. Moreover, the compression is not block-based making them unsuitable for random read/write applications.

In the context of compression of medical images, [11] introduces a lossless method based on wavelets improved by detection of global and local symmetries. However, this method induces significant computational effort to enable high compression rates and is thus not suited for in-situ data reduction.

Generally, scientific floating point data is commonly known to be inherently noisy and random-like, high-entropy data without repeating bit or byte patterns, thus commonly considered to be hardly compressible [15]. As argued in [6], standard lossless compression methods do not reach satisfying compression rates or otherwise introduce significant computational overhead.

Due to approximations and discretizations, simulation data is already flawed. Thus, lossy compression with a user-defined error bound is a reasonable choice for achieving high compression rates.

A lossy data reduction technique for "In-situ Sort-And-B-spline Error-bounded Lossy Abatement" (ISABELA) was recently proposed [6]. It outperforms existing lossy compression techniques, like Wavelets [5], and lossless compression techniques, like FPC [3], LZMA and Bzip. ISABELA offers surprisingly high compression rates of up to $\sim$85% while introducing only a minor overhead in computation time and ensuring a user-defined error bound. It is designed for local encoding and decoding of scientific data.

The main idea of ISABELA is to apply a pre-conditioner, which sets up a very strong signal-to-noise ratio by sorting data values. Due to monotonic and smooth behavior of the sorted data, a regression model approximates the data with significantly fewer coefficients compared to the overall amount of data [6], [4].

Relatively few studies have been conducted on the application of B-splines for compression of scientific data. In [4] and [7] B-splines are used to fit scattered data by optimizing positions of control points. ISABELA extends this concept and transforms the data to guarantee an accurate fitting model.

3. Compression Algorithm

In this section, a variant of the ISABELA-algorithm for in-situ data reduction is presented. As in the original proposal, a first pre-processing step is to subdivide, linearize and sort the data; in our variant, the algorithm further accounts for special properties of porous media, by differentiating between geometry and fluid cells. Then, the sorted data is fitted through cubic B-splines. A new variable width error quantization scheme is applied, which bounds the maximum relative error on a per-point basis. Finally a new method for exploiting the temporal coherence of fluid simulation data is integrated into the compression algorithm.

3.1 Subdividing, Linearizing and Sorting

As first pre-processing step, the data is subdivided into smaller contiguous blocks that can be compressed and decompressed independently from each other, thus supporting random access of data blocks. By linearizing the data, the three-dimensional compression problem is transformed into a one-dimensional one. Sorting of the linearized data results in smooth curves, that can be approximated much better through B-splines [6].

In figure 1 the procedure of subdividing, linearizing and sorting the data is sketched. In step 1 the entire data grid is subdivided into smaller blocks, which contain N data values. In step 2 the blocks are linearized in a fixed serialization order. This gives a scattered sequence $\alpha = (a_1, \ldots, a_N)$ of N data values for each block, which is shown in step 3. In step 4 the data is sorted in ascending order to get a monotonic sequence $\alpha' = (a'_1, \ldots, a'_N)$. In general, the method is independent of a particular block size N.

In simulations of porous media, the data grid contains geometry cells, which are represented by a constant data value $\bar{a}$ in α'. This offers a further opportunity for compression. Discarding data values belonging to geometry cells in the sorted sequence α' yields a new sequence of $n \leq N$ data values, which is denoted as $\beta = (b_1, \ldots, b_n)$. This enhances the performance of the compression, but keeps the possibility to reconstruct the data on per-block basis without decompressing the entire dataset. The sequence β then is applied to a regression model, which is able to represent the data accurately.

To be able to revert the sorting process and reconstruct α during decompression, one has to keep track of the indices, when sorting and shortening α to obtain β. The shortened sequence of indices of elements of β in α is denoted as $\tau = (t_1, \ldots, t_n)$. Remaining values with indices not being

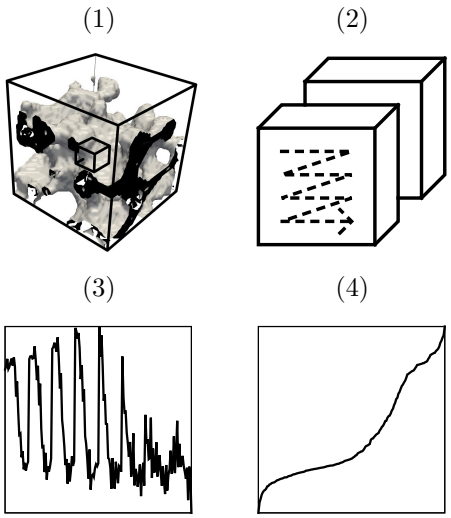

Fig. 1: Illustration of pre-processing the data for compression: *(1)* subdividing voxel grid containing porous media into smaller blocks, *(2) + (3)* linearizing data in blocks into scattered sequence, *(4)* sorting scattered sequence yields monotonic smooth data.

in τ, are set to the constant $\bar{a}$ in order to reconstruct the geometry cells omitted in β. In following an example of a particular instantiation of α, α', β and τ, with geometry cells having $\bar{a} = 0$ is given:

$$\begin{array}{lcccccccc} \alpha & : & 0.3 & 0.1 & 0.0 & 0.2 & 0.4 & 0.5 & 0.3 & 0.0 \\ \alpha' & : & 0.0 & 0.0 & 0.1 & 0.2 & 0.3 & 0.3 & 0.4 & 0.5 \\ \beta & : & 0.1 & 0.2 & 0.3 & 0.3 & 0.4 & 0.5 & & \\ \tau & : & 2 & 4 & 1 & 7 & 5 & 6 & & \end{array} \quad (1)$$

3.2 Cubic B-Spline Fit

The sequence β has a high signal-to-noise ratio and can be fitted by a cubic B-spline with few control points accurately [6].

Originally developed in the CAD and computer graphics fields, B-splines provide a flexible framework for representing complex shapes [9]. Cubic B-splines are constructed from a set of control points and a knot vector. The control points are used to specify the shape of the resulting curve, whereas the knot vector defines the influence of the control points on piecewise polynomial curve segments.

Cubic B-splines are denoted as a sum of M control points p_j, weighted by B-spline basis functions N_j^3 of degree 3:

$$S(u) = \sum_{j=1}^{M} N_j^3(u) \cdot p_j \quad (2)$$

The knot vector is chosen to have equally spaced knots, which means each control point has the same influence on the curve. B-splines are able to locally adapt the shape of a monotonic point cloud accurately, which makes them a very flexible and efficient tool in the present case of data compression [6], [4].

In order to fit the sequence β using the above setup, the n data values b_i are mapped to uniformly distributed values $x_i \in [0, 1]$. For each point a linear equation $S(x_i) = b_i$ according to eqn. (2) is set up, which gives a linear system

$$\mathcal{N}_n \cdot \mathcal{P} = \beta \quad (3)$$

$\mathcal{N}_n$ holds B-spline basis functions $N_j^3(x_i)$ for n equations and $\mathcal{P}$ holds control points p_j. The system is solved using the least squares method. This involves computing the Moore-Penrose Pseudoinverse $\mathcal{N}_n^+$. The control points, which minimize least square distances are given by $\mathcal{P} = \mathcal{N}_n^+ \cdot \beta$.

In the case of $n \leq M$, the observed block has a high amount of geometry cells. Then the system is underdetermined and the data will be stored directly, since the number of data values is less or equal to the number of control points.

Since the number n of data values per block is varying, the number of equations in the linear system 3 also varies. To address this problem, the matrices $\mathcal{N}_n$ and $\mathcal{N}_n^+$ are precomputed for $n = M+1, \ldots, N$ and the corresponding case is selected at compressing and decompressing respectively.

Once the data has been fitted, eqn. 2 is used to reconstruct the data from control points $\mathcal{P}$ and x_i values, which yields an approximation of β. The approximate sequence is denoted as $\beta' = (b'_1, \ldots, b'_n)$ and is obtained by $\beta' = \mathcal{N}_n \cdot \mathcal{P}$. In the next step the approximation error $b_i - b'_i$ is handled by applying error correction.

3.3 Error Quantization

Cubic B-spline regression ensures an accurate fitting model for the data. However, the approximation β' does not meet the precision needed for scientific data analysis. Thus an (unspecified) additional error quantization step is applied in ISABELA [6]. In the following, we describe the error quantization method developed for our ISABELA variant.

A user-defined error criterion is met by setting an upper bound p for the relative error ϵ_i on a per-point basis. The relative error is measured between sequence β and $\gamma = (c_1, \ldots, c_n)$:

$$\epsilon_i = \frac{(b_i - c_i)^2}{b_i^2 + \bar{\epsilon}} \leq p \quad (4)$$

γ denotes the sequence of data, reconstructed from the approximate sequence β' by applying an error correction step. Since the relative error can grow without limit for values near zero, the maximum relative error is bounded by introducing $\bar{\epsilon}$ into eqn. 4 [12]. The error correction step is given by the following quantization scheme

$$c_i = b'_i + \delta_i \cdot \bar{c} \cdot \Delta(b'_i) \quad (5)$$

where δ_i denotes integer quantization steps and $\bar{c} \cdot \Delta(b'_i)$ denotes the real valued width of the quantized value grid.

The quantization scheme in eqn. 5 uses a variable quantization width depending on b'_i, since a global width guaranteeing $\epsilon_i \leq p$ can become very small having δ_i to grow very high.

$\Delta(b'_i)$ describes the maximum tolerance, so that the relative error between b'_i and $b'_i \pm \Delta(b'_i)$ is less or equal to p. The variable quantization width follows from eqn. 4 and is given by

$$\Delta(b'_i) = p \cdot \sqrt{b'^2_i + \bar{\epsilon}} \tag{6}$$

Since original data values b_i from β are not known at decompressing, B-spline approximations b'_i near b_i are used to predict the quantization width. Since $\Delta(b'_i)$ does not bound the relative error with respect to b_i, a scaling factor $\bar{c}$ is applied to ensure, that

$$\bar{c} \cdot \Delta(b'_i) \leq \Delta(b_i) \tag{7}$$

holds, which guarantees eqn. 4 to hold for c_i computed from eqn. 5. The scaling factor is obtained by

$$\bar{c} = \min_i \frac{\Delta(b_i)}{\Delta(b'_i)} \tag{8}$$

Given β, β' and $\bar{c}$, the integer quantization steps are computed by

$$\delta_i = \left\lfloor \frac{b_i - b'_i}{\bar{c} \cdot \Delta(b'_i)} + \frac{1}{2} \right\rfloor \tag{9}$$

To store δ_i efficiently a stream of B_δ bit numbers is used. The number of bits needed to store δ_i is determined by

$$B_\delta = \left\lceil \mathrm{ld}\left(\max_i \delta_i\right) \right\rceil \tag{10}$$

Using τ the values c_i of γ are reordered into $\gamma' = (c'_1, \ldots, c'_N)$, which denotes an approximation of α meeting bounded relative error criterion. The reconstruction is accomplished for $i = 1, \ldots, n$ by setting $c'_{t_i} = c_i$. Remaining values with indices i not being in τ are set to $c'_i = \bar{a}$ to reconstruct geometry cells.

3.4 Exploiting Temporal Coherence

In ISABELA, temporal data patterns are exploited to enhance compression ratio. The improvement results from similarities in the index sequence τ, which changes only slightly over consecutive timesteps on a per block-basis. The pattern is applied by introducing a reference sequence τ^0 and delta sequences $\tau^1, \tau^2, \ldots$. Instead of storing the indices of delta sequences directly, the differences $\tau^1 - \tau^0, \tau^2 - \tau^0, \ldots$ are stored. This yields mainly small integer numbers, which are compressed using a lossless compression technique. Using this procedure the compression performance of ISABELA is improved by $\sim 3\%$.

In our implementation, we exploit another temporal pattern, which relies on the continuous nature of the data in time dimension. Since linearized sequences α of consecutive timesteps change smoothly, difference encoding of data values can be applied. For this, α^0 is considered a reference sequence and following sequences $\alpha^1, \alpha^2, \ldots$ are considered delta sequences. Temporal smoothness is sketched in figure 2.

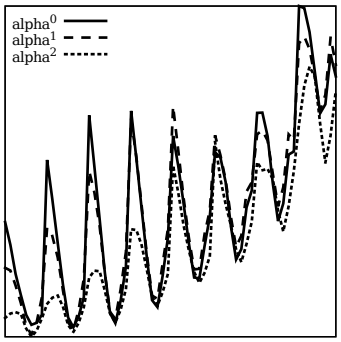

Fig. 2: Illustration of temporal smoothness of consecutive sequences α^0, α^1 and α^2 of u data for one block.

Instead of compressing the data values of delta sequences directly, differences of data values to decompressed reference sequence $\bar{\alpha}^1 = \alpha^1 - \gamma'^0, \bar{\alpha}^2 = \alpha^2 - \gamma'^0, \ldots$ are taken into account. The resulting values $\bar{\alpha}^k = (\bar{a}^k_1, \ldots, \bar{a}^k_N)$ of a delta sequence with index $k > 0$ are small. Applying sorting, linearizing and B-spline regression yields shortened sequences $\bar{\beta}$, $\bar{\beta}'^k$ and τ^k belonging to $\bar{\alpha}^k$.

Now, the relative error between $\bar{b}^k_i$ and $\bar{c}^k_i$ has to be bounded by p on a per-point basis. The error quantization is accomplished by

$$\begin{array}{rcl} c^k_i & = & c'^0_{t^k_i} + \bar{b}'^k_i \quad + \quad \delta_i \cdot \bar{c} \cdot \Delta(c'^0_{t^k_i} + \bar{b}'^k_i) \\ \underbrace{\bar{c}^k_i}_{c^k_i - c'^0_{t^k_i}} & = & \bar{b}'^k_i \quad + \quad \delta_i \cdot \bar{c} \cdot \Delta(c'^0_{t^k_i} + \bar{b}'^k_i) \end{array} \tag{11}$$

to meet the criterion. As $\Delta(c'^0_{t^k_i} + \bar{b}'^k_i) \approx \Delta(b'^k_i)$ and $\bar{b}^k_i - \bar{b}'^k_i < b^k_i - b'^k_i$, the integer quantization steps

$$\delta_i = \left\lfloor \frac{\bar{b}^k_i - \bar{b}'^k_i}{\bar{c} \cdot \Delta(c'^0_{t^k_i} + \bar{b}'^k_i)} + \frac{1}{2} \right\rfloor \tag{12}$$

become smaller. Thus, B_δ also decreases which reduces the amount of memory needed to reconstruct delta timestep k.

4. Results

The algorithm described in 3 has three parameters: block size N, number of B-spline control points M, and user-defined error threshold p. The parameters influence the compression ratio CR. Assuming 64 bit double precision floating point values, the compression ratio of one block is given by

$$\begin{array}{rcl} CR & = & 1 - \quad [64 \cdot (M+1) + \lceil \mathrm{ld}(N) \rceil \cdot \\ & & \quad (n+2) + B_\delta \cdot n] \cdot {}^1\!/_{(64 \cdot N)} \end{array} \tag{13}$$

Compression ratio is calculated by taking into account $M \cdot 64$ bits for B-spline control points, 64 bits for the scaling factor $\bar{c}$, $\lceil \mathrm{ld}(N) \rceil \cdot (n+2)$ bits for storing τ as well as n and B_δ and $B_\delta \cdot n$ bits for storing error quantization steps.

In order to estimate performance parameters, the algorithm is applied to subgrids of 26 timesteps of simulation data extracted from a Lattice Boltzmann simulation of melt in porous media. The data contains velocity (u, v, w) and density (ρ) values in a $64 \times 64 \times 64$ grid. The entire dataset has a size of $212,992KB$, where each feature has a total size of $53,248KB$.

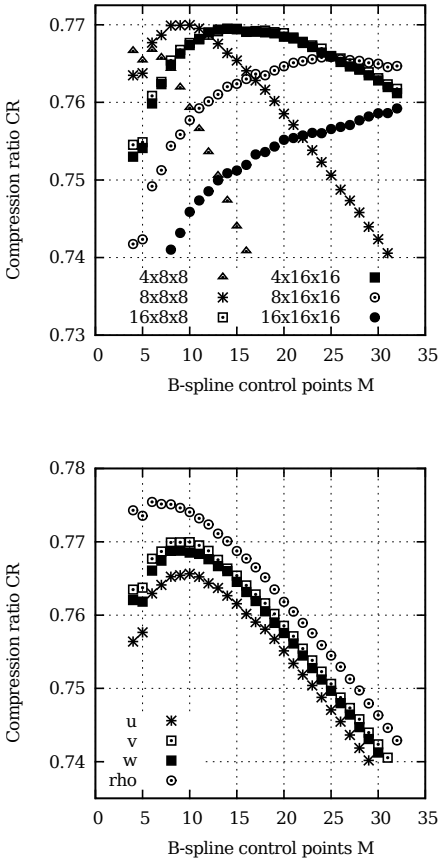

Fig. 3: *Top:* Mean compression rate achieved at compressing u plotted against number of B-spline control points for different block sizes. The optimal compression rate of about 77% was achieved with block size $N = 8 \times 8 \times 8$. *Bottom:* Performance of compressing u, v, w and ρ using block size $N = 8 \times 8 \times 8$. Best compression results over all attributes were achieved for $M = 10$.

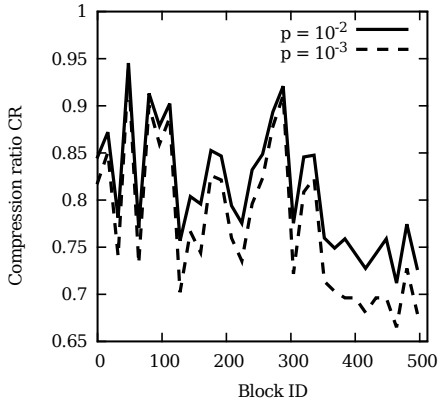
4.1 Parameter Analysis

In the compression algorithm as described, the accuracy of cubic B-spline regression primarily depends on the parameters N and M. To resolve the impact of the parameters on the compression ratio, the algorithm was run with varying block sizes and varying number of control points. In figure 3 the results are depicted. We found that $N = 512$ and $M = 10$ yield the best overall compression ratio in our case. We also found that the use of non-cubic block shapes did not improve the compression ratio and we decided to use cubic $8 \times 8 \times 8$ blocks.

On one hand, $N = 512$ is a power of two, which allows to use all $\lceil \mathrm{ld}(N) \rceil$ bits to store the indices in τ optimally. On the other hand, there exists a trade-off between B_δ bits needed to encode the error and the number of control points M. If the data is fitted more accurately by the B-spline, less storage is needed to encode the error quantization steps.

In figure 4, the compression ratio for $N = 512$ and $M = 10$ is given for different user-defined relative error bounds $p = 10^{-2}, 10^{-3}, 10^{-4}$. In parentheses CR for setting $N := n$ is given, which corresponds to not considering geometry cells in the compression rate. In the whole data set 26.9% of the cells are geometry cells. Our experiments show that the algorithm yields high compression ratio ensuring the user-defined error bound. In particular, the algorithm clearly outperforms lossless methods like *gzip* (50.6%), *bzip2* (52.7%) and *lzma* (57.5%), ISABELA-variant algorithms achieve higher compression rates while being local,



p	u	v	w	ρ
10^{-2}	80.2 (71.2)	80.6 (71.7)	80.5 (71.6)	80.9 (70.1)
10^{-3}	76.5 (66.2)	76.9 (66.7)	76.8 (66.5)	77.4 (65.2)
10^{-4}	72.7 (61.0)	73.1 (61.5)	73.0 (61.3)	73.6 (60.1)

Fig. 4: *Top:* Variation of CR per block, implied by changing number of geometry cells and changing number of bits B_δ needed to encode error quantization steps. *Bottom:* Mean compression ratio CR achieved at compressing u, v, w and ρ using $M = 10$ and $N = 8 \times 8 \times 8$ (using variable amount n of data values per block) for different user-defined relative error bounds p. Numbers in parentheses indicate compression rates for non-geometry cells only.

scalable, communication-free and in-situ applicable [6].

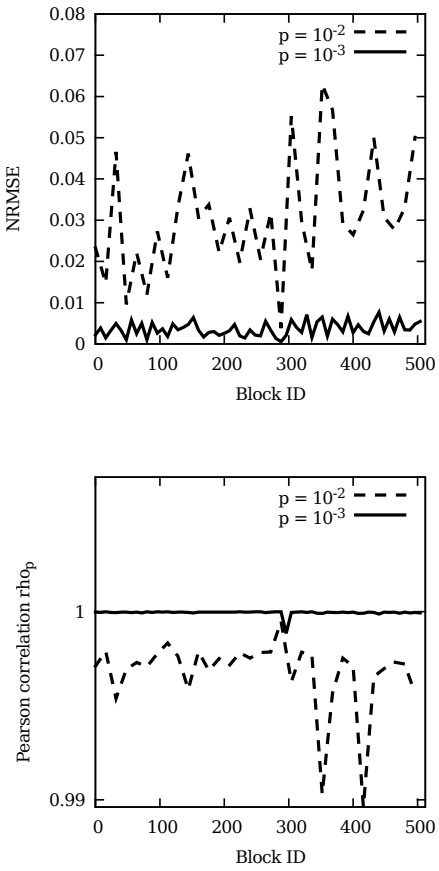


Fig. 5: Performance of the compression algorithm on per-block basis for user-defined relative error bound $p = 10^{-2}, 10^{-3}$. *Top:* normalized root mean square error $NRMSE(\alpha, \gamma')$. *Bottom:* Pearson Correlation $\rho_p(\alpha, \gamma')$.

4.2 Error Analysis

As in [6], normalized root mean square error $NRMSE(\alpha, \gamma')$ and Pearson correlation $\rho_p(\alpha, \gamma')$ are taken into account to observe the performance of the compression algorithm. $NRMSE(\alpha, \gamma')$ and $\rho_p(\alpha, \gamma')$ are given on per-block basis by

$$NRMSE(\alpha, \gamma') = \frac{\sum_{i=1}^{N} \sqrt{(a_i - c'_i)^2}}{\max_j a_j - \min_j a_j} \quad (14)$$

$$\rho(\alpha, \gamma') = \frac{\mathrm{Cov}(\alpha, \gamma')}{\sqrt{\mathrm{Var}(\alpha) \cdot \mathrm{Var}(\gamma')}} \quad (15)$$

Error quantization and regression using the least squares method excellently reconstruct the data and yield high compression ratios even for low error threshold $p = 10^{-2}$. In figure 5, the performance is shown in terms of $NRMSE$ and Pearson Correlation ρ_p. $NRMSE$ shows low values, whereas ρ_p shows values being nearly one, which indicates excellent data reconstruction.

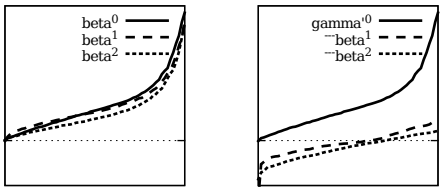

Fig. 6: Impact of difference encoding on the sorted shortened data to be compressed. *Left:* sequences β^0, β^1 and β^2 without difference encoding. *Right:* decompressed reference sequence γ'^0 and difference encoded delta sequences $\bar{\beta}^1, \bar{\beta}^2$. As can be seen, delta sequences are flatter and therefore need less error correction bits.

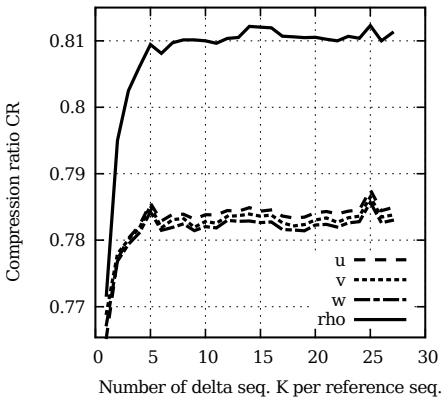
4.3 Analysis of Time Difference Encoding

The pre-conditioning step exploits the continuous nature of the data in spatial dimensions and produces smooth monotonic curves. Applying cubic B-spline regression with few control points accurately fits the data allowing high compression rates. By also taking advantage of the continuous nature of the flow data in temporal dimension, it is possible to further enhance compression ratio. Considering differences between reference sequences and delta sequences allows to reduce the amount of storage needed to encode error quantization steps. The impact of difference encoding data sequences is depicted in figure 6. For consecutive timesteps' sequences, differences are small and therefore, when being compressed with the same relative error bound as the original data, the amount of error correction data is reduced.

The performance of difference encoding K delta sequences $\alpha_1, \ldots, \alpha_K$ per reference sequence α_0 is shown at compressing 26 timesteps of simulation data. The mean compression ratio and the reduction of the number of bits B_δ needed to encode error quantization steps is shown in figure 7. Compression gain ranges from $\sim 2\%$ to $\sim 3\%$ which compares to the gain of the ISABELA method proposed in [6] exploiting temporal pattern in index sequences.

5. Conclusion

We presented a variant of the ISABELA method for in-situ compression of scientific data. One of our modifications to ISABELA addresses specific properties of flow in porous media. Another modification concerns the exploitation of temporal coherence of time-continuous datasets by compressing differences between reference and delta timesteps. For continuous smooth data, compressing differences yields a significant reduction of error correction data. As a (minor) drawback, difference encoding requires decompressing



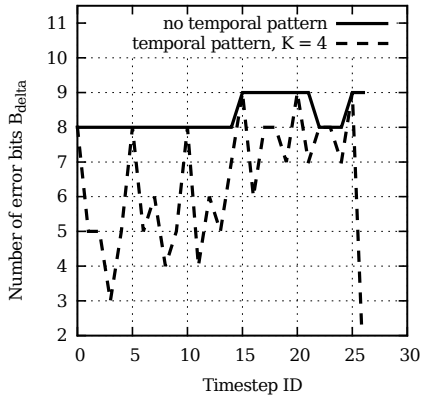


Fig. 7: *Top:* Compressing difference data in temporal dimension enhances mean compression ratio (CR). Plot shows the mean compression ratio achieved at compressing 26 timesteps with varying number of delta sequences K per reference sequence. *Bottom:* Showing reduction of number of bits B_δ needed to encode error quantization steps for one block of u data using difference encoding of $K = 4$ delta sequences.

blocks of reference timesteps. However, the underlying data structures involve B-splines which can be evaluated locally. Thus, local decompression is still possible without significant overhead. Improvements of the overall compression ratio compare to the delta-encoding in the original ISABELA method. Through the combination of both methods, the overall compression rate may be improved even more.

Our results on a melt simulation dataset confirm that high compression rates can be achieved with ISABELA-like algorithms also in the case of porous media. Further, compression lossiness can be controlled comfortably by providing the algorithm with a user-defined error bound. Results were presented that relate several error bound choices to achieved compression rates.

The analysis of our ISABELA variant applied to flow in porous media suggests an optimal block size of $8 \times 8 \times 8 = 512$ data cells. Further, our results indicate that the optimal number of B-spline control points is 10. These results differ from the original ISABELA publication [6] where a block size of 1024 and 30 control points are suggested as optimal. Future work is needed to clarify the optimal parametrizations of ISABELA-like compression methods on different types of datasets.

Abstract— *Certain simulations are characterized by alternating periods of "expansion" and "contraction." For example, simulated populations of migratory birds may congregate in a central geographic location for overwintering, handled by a single processor, then fan out to dispersed locations for local ecological interactions during the rest of the year, handled by one processor per location. In another application, the difficult problem of fitting parameters to large-scale stochastic simulation models may fan out to numerous processors computing independent stochastic trajectories from the same initial conditions, then "contract" to allow a new, more likely set of parameters to be estimated from the computed distribution of independent trajectories. The contraction is commonly handled by a designated "master processor." In this paper, we point out a simpler, completely symmetric algorithm in which all processors act identically and no processor is designated master. We have used it for applications in simulated annealing and exhibit it here in a standard MPI (Message Passing Interface) environment.*

Keywords: parallel processing, symmetric multiprocessing, parallel–serial simulation, parameter fitting, individual-based modeling

1. Introduction

The goal of this paper is to demonstrate a symmetric technique for coordinating multiple processors and contrast that technique with a more usual master–subordinate technique. We consider the case where multiple processors calculate results independently of one another for an extended length of time, from seconds to minutes or more. The processors then pool their results before partitioning the calculations and expanding to multiple independent processors again. This repeats through multiple expansion–contraction phases until the computation converges to some result. We exhibit the algorithms in detail and illustrate them within an application of parameter fitting.

2. Algorithms

We assume each processor accepts a data structure as input and returns the results of its calculations in the same or another data structure. For simplicity here, we represent this data structure as an array of double-precision floating-point numbers, $local[j]$, though it could take any form. In addition, an array of these data structures, $global[i][j]$, has one row per processor. In the symmetric algorithm, all processors use this array, but in the master–subordinate algorithm, only the master uses it. Any processor can be the master, but here we make it the one numbered 0. The processor number is placed in an integer variable named *cproc* by Function 1 of the appendix. Algorithms in the appendix encapsulate the MPI environment [1] and provide a degree of system independence.

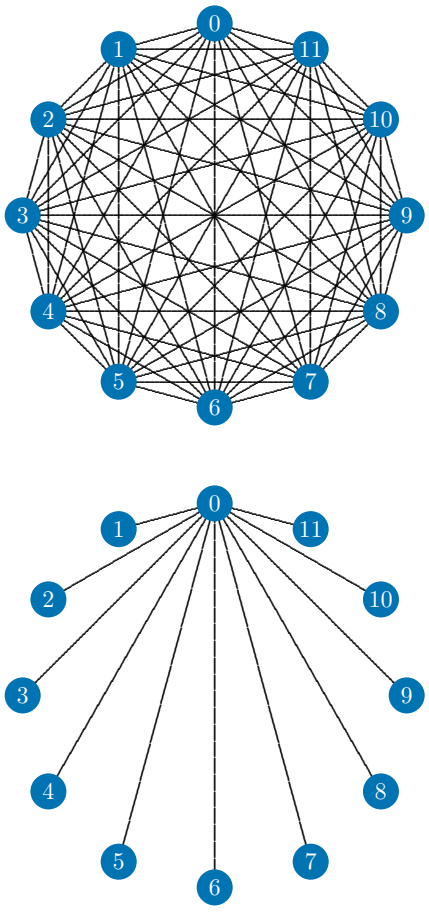

Figure 1. *Communications among a dozen processors in the symmetric technique, top, and the master–subordinate technique, bottom. The standard technique on the bottom might seem simpler, because of fewer interconnections, but asymmetries actually make it more complex.*

We present the algorithms in a stylized form of the language C, as an alternative to pseudocode, so that they define the interface precisely, and so they can be compiled, run, and modified. In the displayed algorithms, flow control and reserved words are bolded, variables and function names are italicized, and certain operations such as '<=', '>=', '!=', and '==' are displayed in a mathematical form as '$\leq$', '$\geq$', '$\neq$', and '$\equiv$', respectively.

2.1 Symmetric technique

In applications of parameter fitting, computing a new set of parameters is a global step, needing input from all the processors together. Therefore, it seems natural to assign that step to a master processor. However, such assignment is unnecessary. If all processors share information equally, then every processor can compute the new parameters for itself, using the same algorithm that would be used by the master processor. No time is lost, for all subordinate processors would be waiting for the master processor anyway. No chance of error arises, for all processors are executing the same code. And a notable simplification results, cutting the number of lines of code needed almost four-fold (see discussion below).

For the symmetric case, the program begins by invoking function *MPBegin* and ends by invoking *MPEnd*, defined in the appendix (steps 1 and 4, respectively, in the algorithm below). Variables t and *tmax* are integers recording the current and the maximum times, respectively. The main loop has five lines.

[1] *MPBegin*();

[2] **for** ($t = 0$; $t \leq tmax$; $t{+}{+}$)
{ *converge* = *NewParameters*(*global*);
if (*converge*) **break**;

[3] *Simulate*(*local*);
MPCommon(*global*, *local*, *W*); }

[4] *MPEnd*();

Steps 1 and 4 above merely begin and end multiprocessing operations. Step 2 loops through the procedure, with each processor invoking function *NewParameters* to handle data from all the processors (array *global*), for example computing a new set of parameters by whatever technique is desired—gradient descent, simulated annealing, genetic search, and so forth. That function returns an indication of whether the process has converged, and if convergence is detected, the program terminates the main loop.

Step 3 invokes function *Simulate*, which carries out the current processor's simulation task, getting its parameters from array *local* and returning its results in the same array. Finally each processor communicates its results to all other processors and symmetrically receives all results back by invoking function *MPCommon* before repeating. W in the example is the width of arrays $global$ and $local$.

In addition to the code for *MPBegin* and *MPEnd* (Functions 1 and 2 in the appendix), this process uses only the five lines of code of Function 3 in the appendix. The amount of data communicated is $WN(N-1)$ elements, where W is the number of elements per processor and N is the number of processors. Processors pass messages only once per iteration.

2.2 Master–subordinate technique

When the global process is assigned to a master processor, the program also begins by invoking function *MPBegin* and ends by invoking *MPEnd*, defined in the appendix (steps 1 and 8, respectively, in the algorithm below). The variable *cproc* defines the processor number, which was not needed in the symmetric case. As before, t and *tmax* are integers recording the current and the maximum times, respectively. The main loop has nine lines.

[1] *MPBegin*();

[2] **for** ($t = 0$; $t \leq tmax$; $t{+}{+}$)

[3] { **if** (*cproc* $\equiv 0$)
{ *converge* = *NewParameters*(*global*);
if (*converge*) **break**;
MPMasterSend(*global*, *W*); }

[4] **else** *MPSubordinateReceive*(*local*, *W*);

[5] *Simulate*(*local*);

[6] **if** (*cproc* $\equiv 0$) *MPMasterReceive*(*global*, *W*);
[7] **else** *MPSubordinateSend*(*local*, *W*); }

[8] *MPEnd*();

At the beginning of the loop, *cproc* is tested to determine whether the master processor is running (processor number 0). If so, then the master processor computes the new parameters, checks for convergence, and if convergence has not been achieved, sends the parameters out to all subordinates for additional computation (step 3 in the algorithm). If, on the other hand, a subordinate processor is running, it merely waits for the master processor to send it the parameters (step 4 in the algorithm).

After that, all processors, master and subordinate alike, run one simulation task by invoking function *Simulate* (step 5), as in the symmetric technique. Next the master processor receives the simulation results from all subordinates (step 6) while subordinates send them (step 7). Then the loop repeats. As before, W is the width of arrays $global$ and $local$.

In addition to the code for *MPBegin* and *MPEnd* (Functions 1 and 2 in the appendix) this process uses the twenty-eight lines of code of Functions 4a, 4b, 5a, and 5b in the appendix. The amount of data communicated is $2W(N-1)$ elements, where W is the number of elements per processor and N is the number of processors. Both master and subordinate processors pass messages twice per iteration.

3. Discussion

The symmetric version needs no conditional if–else statements to determine which processor is running. It makes half the number of calls to the message passing interface per iteration, which simplifies the communications. It is somewhat less error prone, not only because of its greater simplicity, but also because multiple processors can be automatically checking each others work, detecting such mistakes as uninitialized variables that may behave differently under different conditions. It is shorter. The symmetric version uses 5 lines within its loop in the algorithm above and calls upon the 5 lines of Function 3 in the appendix, for a total of 10 lines in the loop. Functions 4a, 4b, 5a, and 5b in the appendix do not exist in the symmetric version. The master–subordinate version, in contrast, uses 9 lines within its loop and calls upon the additional 28 lines of Functions 4a, 4b, 5a, and 5b in the appendix, for a total of 37 lines in the loop.

The code to support symmetric multiprocessing is thus almost four times as compact. This savings can become compounded in the application code, because that code does not have to differentiate between master and subordinate communications. In parts of the code not connected with inter-processor communication, such as printing, one processor may still have to act as master. Yet since each level of reduction in complexity can be significant in a large program, this technique is preferred, all other things being equal.

One thing not equal is energy consumption. With all processors computing during the contraction phase, more heat will be generated and more energy consumed. Computations performed during the contraction phase will typically be short and simple compared with long and complicated simulations in the expansion phase, so this will be negligible. But if it is not, then a master–subordinate approach might be preferred.

Another thing not equal is the amount of information communicated among processors. The master–subordinate technique has only $N-1$ communication paths, where N is the number of processors, whereas the symmetric technique has $\frac{1}{2}N(N-1)$ paths (Figure 1). Though this can be a large difference, it can also be insignificant in many applications. If the computation step is seconds or minutes or more, as it often will be, the microseconds or milliseconds dedicated to communications will vanish into the rest of the computation.

4. Conclusions

The symmetric version is simple. It is a viable way of communicating among multiple processors that can be incorporated into any expansion–contraction simulation programs, or related kinds of simulations. We have used it successfully in a large-scale simulation model developed by one of us (A.K.) for human tuberculosis in the UK. Compilable copies of the code described here and related simulation algorithms are available free from the authors upon request.

5. Acknowledgements

We are grateful to Shuxia Zhang and David Porter for helpful discussions of the message passing interface, to Mark Nelson for generous guidance to make things work, to Todd Lehman for reading the manuscript and helping with presentation of the code, and for Richard Barnes for help of many kinds.

6. Contributions

C.L. and A.K. worked together on various techniques for controlling the multiprocessors on a large-scale simulation carried out by A.K. C.L. conceived and coded the symmetric technique and A.K. built it into the simulation program and tested it in actual use. Both authors reviewed the code and contributed to the manuscript.

7. Funding

This project was supported in part by grants of computer time from the Minnesota Supercomputer Institute, Minneapolis, Minnesota, and by doctoral research funding to A.K. from the Modelling and Economics Unit at the Health Protection Agency, London.

8. Appendix

This appendix defines the precise connections with the "Message Passing Interface," MPI [1]. Prototypes for functions and constants are defined in a file "mpi.h", which must be included at the top of the code. Then each process must call Function 1 before beginning. That function initializes communications, determines the number of processors that are participating, and assigns a number to the current processor. Furthermore, each process calls Function 2 after its work is complete, just before ceasing operations.

Function 3 is used in both symmetric and master–subordinate techniques. In this example it assembles an *nproc* by *w* array of data from all processors, where *nproc* is the number of processors and *w* is the number of data elements shared by each processor. It is typically called at the end of each processing step to synchronize all processors and put them all in a common data state. Processing is delayed until all processors have called this function. Therefore, note that all processors must call at corresponding points in the cycle or operations could deadlock.

Functions 4a, 4b, 5a, and 5b are additional algorithms needed for master–subordinate processing. Function 4a sends data from the master processor, numbered 0, to all processors allocated, including itself. Data to be sent reside in the *nproc* by w array of data. Function 4a is typically called at the beginning of each processing step to synchronize all processors and give each processor the data it needs to carry out the next step. The master process must call this function and all others must call the companion function *MPSubordinateReceive*, Function 4b, at corresponding points in the cycle. Function 4b receives data from the master processor, resulting from that processor's call to 4a.

Function 5a receives data from subordinate processors, whose numbers are greater than 0. Data are assembled in the *nproc* by w array. Function 5a is typically called by the master processor at the end of each processing step to receive results back from all processors and compute the data to begin the next step. The master process must call this function and all others must call the companion function *MPSubordinateSend*, 5b, at corresponding points in the cycle. Function 5b sends data back to the master processor, numbered 0, to satisfy its call to *MPMasterReceive*, Function 5a.

Function 1.

Upon entry to the algorithm, no conditions are significant. **At exit, (1)** multiprocessing operations have commenced. **(2)** $nproc$ contains the total number of processors allocated. **(3)** $cproc$ contains the number of the current processor, in the range 0 to $nproc - 1$.

```
int MPBegin()
{ static int argc; static char **argv; int n;
  MPI_Init(&argc, &argv);                          1. Initialize message processing.
  MPI_Comm_rank(MPI_COMM_WORLD, &cproc);           2. Determine this processor's number.
  MPI_Comm_size(MPI_COMM_WORLD, &nproc);           3. Determine the number of processors.
  return 0; }                                      4. Return to caller.
```

Function 2.

Upon entry to the algorithm, multiprocessing operations have closed. **At exit,** the main program may itself exit.

```
int MPEnd() { MPI_Finalize(); return 0; }
```

Function 3.

Upon entry to the algorithm, (1) $local$ is a vector of w data elements (double precision floating point) that are this processor's contribution to the global data set. **(2)** $global$ is a $nproc$ by w matrix to receive the values of $local$ from all processors. **(3)** w contains the width of $local$ and $global$. **At exit,** $global[n]$ contains a copy of the contents of $local$ from each processor n, where n ranges from 0 to $nproc - 1$. In particular, the $local$ of this processsor passed on entry is in row $global[cproc]$.

```
int MPCommon(double global[][], double local[], int w)
{ MPI_Allgather(local, w, MPI_DOUBLE,
                global, w, MPI_DOUBLE,
                MPI_COMM_WORLD);
  return 0; }
```

Function 4a.

Upon entry to the algorithm, (1) $cproc$ is 0. **(2)** $global$ is a $nproc$ by w matrix containing values to be sent to each processor n in row $global[n]$. **(3)** w contains the width of $global[i]$. **At exit,** $global[n]$ has been sent to each processor n.

```
int MPMasterSend(double *global, int w)
{ double *temp =
    (double*)malloc(w*sizeof(double));
  MPI_Scatter(global, w, MPI_DOUBLE,
              temp, w, MPI_DOUBLE,
              0, MPI_COMM_WORLD);
  free(temp);
  return 0; }
```

1. Allocate a temporary area to receive the master's data back from itself.
2. Send data from $global[n]$ to each processor n.
3. Release the temporary area.
4. return to caller.

Function 4b.

Upon entry to the algorithm, (1) $cproc$ is not 0. **(2)** $local$ is vector of w elements to receive data from the master processor. **At exit,** $local$ contains the data received.

```
int MPSubordinateReceive(double local[], int w)
{ MPI_Scatter((double*)0, 0, MPI_DOUBLE,
              local, w, MPI_DOUBLE,
              0, MPI_COMM_WORLD);
  return 0; }
```

Function 5a.

Upon entry to the algorithm, (1) $cproc$ is 0. **(2)** $global[nproc][w]$ is an area to receive values for each processor n in row $global[n]$. **(3)** $global[0]$ contains any results from the master processor, to be sent back to itself. **(4)** w contains the width of $global[i]$. **At exit,** $global[n]$ contains the results from each processor n, except that $global[0]$ is unchanged.

```
int MPMasterReceive(double global[][], int w)
{ int i;
  double *temp =
    (double*)malloc(w*sizeof(double));
  for (i = 0; i < w; i++) temp[i] = global[i];
  MPI_Gather(temp, w, MPI_DOUBLE,
             global, w, MPI_DOUBLE,
             0, MPI_COMM_WORLD);
  free(temp);
  return 0; }
```

1. Allocate a temporary area to receive the master's data back from itself.
2. Send data from $global[n]$ to each processor n.
3. Release the temporary area and return to caller.

Function 5b.

Upon entry to the algorithm, (1) $cproc$ is not 0. **(2)** $local$ is vector of w elements to send to the master processor. **At exit,** the data have been sent.

```
int MPSubordinateSend(double local[][], int w)
{ MPI_Gather(local, w, MPI_DOUBLE,
             (double*)0, 0, MPI_DOUBLE,
             0, MPI_COMM_WORLD);
  return 0; }
```

1. Send data to processor 0.
2. Return to caller.

Halo Gathering Scalability for Large Scale Multi-dimensional Sznajd Opinion Models Using Data Parallelism with GPUs

March 2012

ABSTRACT
The Sznajd model of opinion formation exhibits complex phase transitional and growth behaviour and can be studied with numerical simulations on a number of different network structures. Large system sizes and detailed statistical sampling of the model both require data-parallel computing to accelerate simulation performance. Data structures and computational performance issues are reported for simulations on single and multi-core processing devices. A discussion of optimal data structures for performance on Graphical Processing Units using NVIDIA's Compute Unified Device Architecture (CUDA) is also given. System size and memory layout tradeoffs for different processing devices are also presented.

KEY WORDS
Sznajd opinion formation model; complex system; simulation; data-parallelism; GPU; CUDA; memory halo

1 Introduction

Opinion formation models [21] such as the Sznajd model [40] display some interesting phase transitional and complex behaviours that rely upon computer simulation for their study. Opinion formation models can capture individual behaviour at a microscopic level that manifests itself as a macroscopic or system-wide outcome when implemented with system of many participating agents. The Sznajd model of opinion formation exhibits complex phase transitional and growth behaviour and can be studied with numerical simulations on a number of different network structures [18, 35].

One of the main points of interest in simulating this sort of model is to study the dynamics [29, 43] and kinetics [5, 11] of the system both from the perspective of a well-defined model of phase transitional behaviour but also for to study the spread of influence of opinions [13,22,44] for comparison with real sociological phenomena.

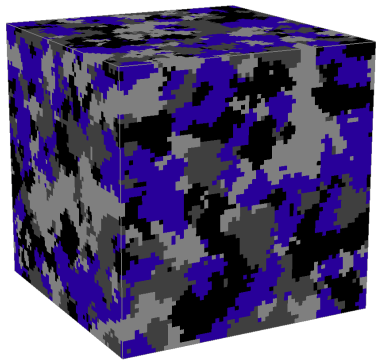

Figure 1: Multi-opinion Sznajd Model simulated on a 40^3 periodic lattice with 4 opinions in the population.

Sznajd models can be simulated on a range of network structures with varying number of neighbouring opinion sites [33]. Results have been reported for one dimensional systems [32]; triangular lattices [23] and generalised heterogeneous graphs and small-world [1] and Watts-Strogatz graph structures [42]. In this present paper we focus on square lattices but our simulation system can also manage arbitrary dimensional hyper-cubic structures in 3 dimensions and higher. Figure 1 is a system snapshot from our simulation, and shows the ongoing formation of spatial groups of like-minded opinion holding agents arranged on a cubic symmetry lattice.

This class of model can capture important sociological behaviours such as conformity [36]; crowd dynamics [25]; political extremism and relative agreements [9]; and voter herding and the role of independents [20]. Sznajd models can be usefully compared with real sociological systems such as political elections [34]; proportional and majority elections [41]; and other sociological and knowledge exchange scenarios [28].

The Sznajd model and its variants are also of interest as abstract models for the study of dynamics and criticality. Nu-

merical experiments and data obtained from simulations allow comparisons with theoretical predictions. An area of theoretical comparison is with non-equilibrium [10] and growth theories including Fokker-Planck theory, fluctuation dissipation theory [12] and other relaxation modelling equations [26].

Comparisons are drawn in the literature between the Sznajd model and related systems like the Ising model [37]. The Sznajd system has been described as a "push" model as influence is pushed outwards from an updated cell, whereas the Ising model is a "pull" model since it changes a cell's value based upon the value of its immediate neighbours [4, 39]. Other areas of comparison are based on the use of externally applied opinion or magnetic field biases [3, 7]. Active areas of development include incorporation of bulk parameters such as an effective temperature into Sznajd-like models [24, 38].

In summary, the Sznajd model and related models are an important class of complex system to study numerically. Large and fast simulations are necessary to support useful comparisons with realistic real systems and with theoretical predictions. We can achieve large fast simulations using data-parallel computing techniques.

Graphical Processing Units (GPUs) are finding many important uses as engines for data parallelism, over and above their original purpose for accelerating graphics systems. Opinion formation models such as the Sznajd system are relatively well suited to this form of parallel simulation and GPUs enable a rapid exploration of the parameter space of such models is possible interactively and with good statistical sampling on relatively large model systems.

Compute Unified Device Architecture (CUDA) [30] is NVIDIA's proprietary programming language that is widely used in programming computational model simulations including Ising systems. In this present paper we show how the Sznajd model can be implemented on GPU systems but that there are some unexpected complications due to the particular nature of the Sznajd model neighbourhoods. We also show that there is an interesting tradeoff between achieving realistically large system sizes the scalability requirements of simulating a system long enough to reach a well defined consensus opinion point.

Our paper is structured as follows: In Section 2 we summarise the Sznajd model and describe how we implemented it in Section 3. We include details on memory utilisation issues and a simple and more memory efficient implementation. We present some performance benchmark data on multiple GPU systems in Section 4. We offer some areas for further work in Section 5 and some conclusions in Section 6.

2 Sznajd Model Formulation

The Sznajd model formulation used in this research is formulated in the same manner as described in [18]. The simulation consists of some very simple microscopic rules that result in complex macroscopic behavior. Each update consists of selecting a cell and a random neighbor. If the two cells have the same opinion they convince their direct neighbors. This particular variation of the Sznajd model update can be applied for Sznajd systems of any dimensionality and is therefore useful for the parallel algorithmic and scalability analysis presented in this present work.

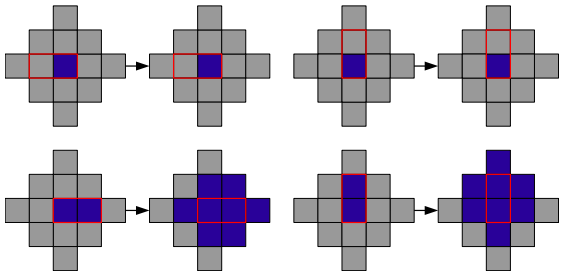

Figure 2: The update rules for the Sznajd Model, if both selected cells agree, they convince their neighbors. If they disagree the neighbors are unchanged.

The Sznajd model is constructed as follows:

1. each of the N lattice cells represents a voter agent holding a single opinion
2. starting conditions are chosen for a random mixture of Q different opinion states.
3. each voter is updated at each time step
4. upon choosing a voter, we randomly look at one of its neighbours.
5. if the voter and the chosen neighbour hold the same opinion they "persuade" all their immediate neighbours to this opinion
6. this process repeats until consensus is reached (whereby all voters hold the same final opinion state)

There are a number of properties that can be measured to study the changes in the population of opinion agents: the time to achieve consensus t_c; the time t_q to eliminate a species and yield only $q < Q - 1$ states present in the system; and the mean fluctuation sizes in these. These can be studied for different sizes of system N and also for different dimensionalities and indeed differing neighbour influence regions.

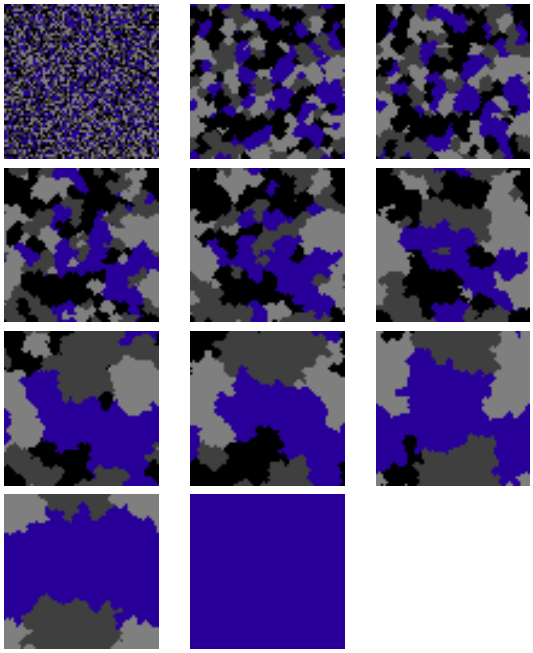

Figure 3: Sznajd Model on 64×64 periodic lattice at times: 0,1,2,4,8,16,32,64,128,256 and final configuration after random 25/25/25/25 start.

The Sznajd model and models like it can be run to full consensus under many dynamical conditions [29]. The meshes we study do lead (eventually) to a consensus outcome. The consensus state is a stable state since there are no thermal or spontaneous changes of opinion in the model we study. However although the consensus state will be arrived at eventually in finite time for a finite system, these completion times do grow with system size. We explore this effect and the implications for the maximum feasible system sizes that we can study.

Figure 2 shows the transition rules for the Sznajd model. The model behaviour is best understood from examination of a time series of model configurations. Figure 3 shows a two dimensional lattice of Sznajd opinion-holding agents evolving over logarithmic times from a random initial mix of opinions to a single consensus.

3 Data-Parallel Implementation

Sznajd model simulations present an challenge for Graphical Processing Units. In previous investigation of lattice-based simulations [15, 17, 19, 27, 31] GPUs generally exhibit the best performance for large system sizes as small simulations struggle to fully utilize the computational throughput of GPU architectures.

The nature of the Sznajd model means that the number of steps required for a system to reach consensus grows rapidly with system size. Because of this relationship, simulations of large system sizes that are well-suited to the GPU architectures require a very large number of steps to reach consensus. Even on powerful GPU architectures these large system sizes take an in feasibly long time to compute the thousands of runs required for statistical analysis.

This means an implementation must be developed that can perform effectively for small system sizes $N = 128^2$ to $N = 256^2$.

3.1 Sznajd Model Memory Access

The Sznajd model has a relatively large memory access pattern or memory halo. Each cell update has the potential to change the values of twelve different neighbouring cells. To perform parallel updates, it is important that these updates do not overlap or else the behavior of the model will be affected.

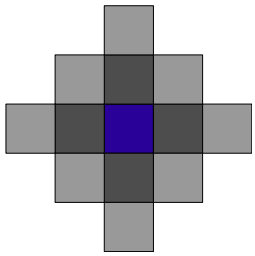

Figure 4: The potential memory halo of a Sznajd model update. The blue cell is the cell selected for update, the dark grey cells represent the immediate neighbors and the light grey cells represent cells whose values could potentially be affected.

3.2 Naive GPU Implementation

The initial idea of implementing the Sznajd model was to implement a checkerboard style update commonly used to simulate the Ising model [19]. The checkerboard update or red/black update performs a parallel update on every cell belonging to one half of the checkerboard. This update method is applicable to the Ising model because it reads from it's nearest neighbors and only changes the value of the cell being updated. Because the Sznajd model has quite a different memory halo, a different checkerboard pattern is required.

To ensure that no two parallel update ever write to the same cell, the memory halos of the updated cells must not overlap. One possible checkerboard design is to split the lattice into 5×5 (2D) or 5^3 (3D) sections. Each update selects the same cell out of this section and updates it. Each update will randomly select one neighbor but this is already accounted for in the memory halo. Importantly the

memory halos of the updates never overlap, this can be seen in Figure 5.

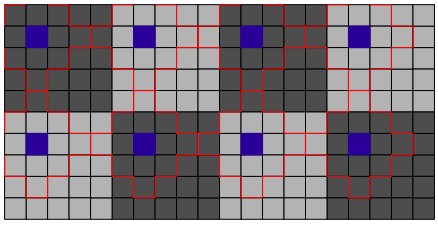

Figure 5: Update pattern of the naive GPU implementation, the update pattern ensures no cell value is changed by two different updates.

This implementation has regular memory access patterns and would be a perfect candidate for lattice crinkling which rearranges data in a lattice for better memory access [16]. However, during initial testing a problem was discovered with this implementation. When two neighboring cells are updated one after another, there is a tendency for an opinion to propagate in that direction. Because the cells are updated in a regular pattern, any neighboring updates will occur across the entire lattice. This means opinions propagate in one direction across the entire lattice and causes the lattice to 'jitter' during the course of the simulation.

Any correlation between updates such as this have the potential to affect the behavior of the model and skew any results. For this reason the Sznajd checkerboard update has not been used for any results gathering and instead an alternative implementation was developed to remove the correlation.

3.3 Improved GPU Implementation

The improved Sznajd update method is similar to the checkerboard update but with a few important differences. Instead of splitting the lattice into 5×5 sections, the improved method splits the lattice into 8×8 sections. These 8×8 sections are further split into 4×4 quadrants. Instead of the same cell in each section being updated at the same time, each quadrant of each section is updated at the same time. This update will randomly select a cell from the quadrant and update that cell. This breaks the correlation seen in the previous implementation while still insuring that the memory halos from two update never overlap. This update method is shown in Figure 6.

While this update method can be used to simulate the Sznajd model, it does severely restrict the computational load of each update. Each parallel update only processes one cell out of an entire 8x8 cell. This means for an N^2 system only $\frac{N^2}{8^2}$ cells can be updated in parallel. To perform an entire system update, 8^2 parallel updates are required.

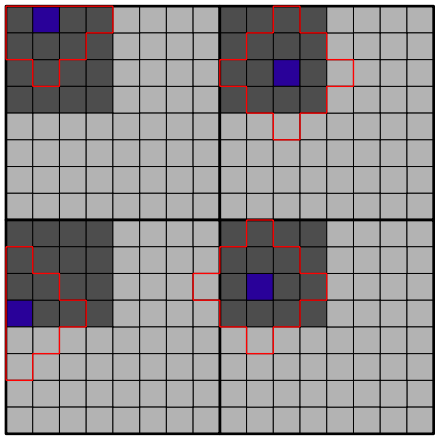

Figure 6: The update pattern of the improved GPU implementation. One random cell in each quadrant is updated

This severely restricts the performance of the simulation which is already limited to small system sizes due to the nature of the model but is necessary to break correlation between sequential updates.

3.4 Optimising the Implementation

Unfortunately due to the semi-random access pattern of this update method, previously successful optimization techniques such as data crinkling are not applicable [14, 19]. However, some optimization strategies such as bit-packing can be used. We are investigating Sznajd systems with $Q = \{2..16\}$, this means only 4 bits of storage are required for each cell. This allows the values of 8 cells to be packed into a single 32-bit integer. This conveniently allows each row of the 8x8 sections to be stored in a single integer.

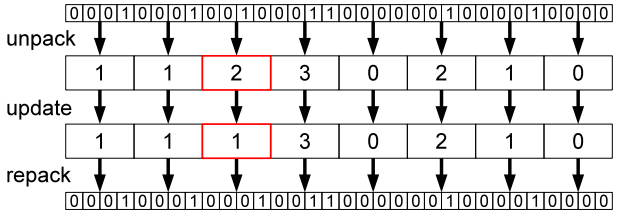

Figure 7: The process of unpacking integers, updating the simulation and re-packing them into the integers for storage.

This not only helps reduce the storage requirements for a Sznajd system but also helps memory access. Because each line of every 8x8 section will be stored in sequential memory addresses, they can be read in a single coalesced memory read. Once these values are read, they will be unpacked into a shared memory array which will be used to compute the simulation. The threads computing the up-

date will change the values in this shared memory array and then re-pack them into integers which will be written back to GPU memory. This process is illustrated in Figure 7.

4 Performance and Results

Due to the highly restricted and sparse update method coupled with very limited system sizes, the GPU implementation struggles to provide the kind of speed-ups seen in many simulations. For the system sizes appropriate for Sznajd simulations (64^2 - 256^2) the computational power of the GPU cannot be fully utilized. However, the GPU implementation can still performance faster than the CPU version for system sizes $N >= 160^2$.

As the system size increases, more of the computational power of the GPU can be used and the speedup it provides will increase. This performance improvement becomes increasingly important as the behavior of larger systems is investigated.

The performance of the GPU implementation has been compared to the un-optimised version and a CPU version for a range of system sizes and number of opinions. Varying the number of opinions had little impact on the performance of any simulation and only the results for $Q = 2$ are presented.

The CPU implementation has been written in C, compiled with gcc 4.5 and executed on a 2.67GHz Intel Core i7 920. Both the un-optimised (GPU1) and optimised (GPU2) implementations have been compiled using CUDA 4.0 and executed on a GTX580. The performance results of these three Sznajd model simulations are shown in Figure 8.

The improved performance of the GPU2 implementation allows larger system sizes to be investigated. The number of steps to consensus of the Sznajd model has been investigated for system sizes of $N = \{64^2...256^2\}$ and $Q = \{2...10\}$. The results of this experiment are presented in Figure 9 and appear to shown some unexpected results.

Previous work with system sizes of $N <= 96^2$ has shown that the number of steps required to reach consensus increases as the number of opinions increases [18]. However, the findings from the previous experiment shows that for Sznajd systems of $N >= 192^2$ and $Q = 2$ require more steps to reach consensus than systems with higher values of Q.

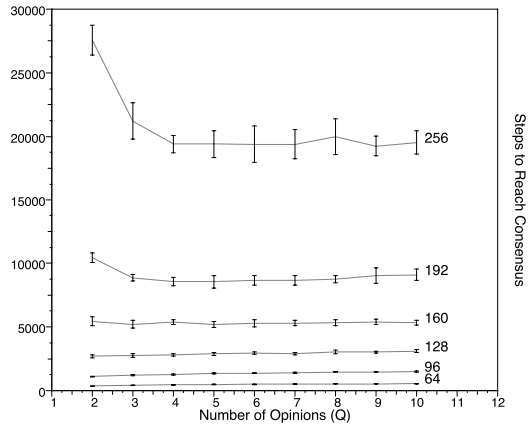

Figure 9: The number of simulation steps required for the Sznajd system to reach consensus.

5 Discussion

There are a number of variations to the simple Sznajd model that have been explored in the literature. The notion that two voters with the same opinion will have a strong influence on their immediate neighbours is not unreasonable, although it is possible to vary the number of agreeing voters required to cause a local sway of opinion. Triples and plaquettes of four have been tried. It appears that a pair is enough to capture the essential model behaviour however, and we have used the simplest "voter pairs" in this paper.

A simple regular mesh is not particularly realistic and a number of other meshes and graph networks including preferential and scale free network structures have also been studied and reported in the literature. Again, it appears that the square mesh captures the essence of the model behaviour and we use a simple square mesh in the work reported here. However we do consider the neighbourhood of influence of the agreeing pair of voters.

There are various ways the Sznajd model could be extended. One interesting possibility is modelling opinions that are continuous rather than discrete [2]. This sort of simulation would require use of floating point capabilities, which present a different set of performance tradeoffs on GPUs, which typically share floating point units across the their cores.

Another area for development is the study of agent reputations and how the reputation - or long term behaviour of an agent - affects its power of influence on its neighbouring agents [6, 8]. Temporal memory effects like reputation will require storage of agent histories and will considerably change the memory requirements. This will lower the feasibility of containing the simulation state within cache.

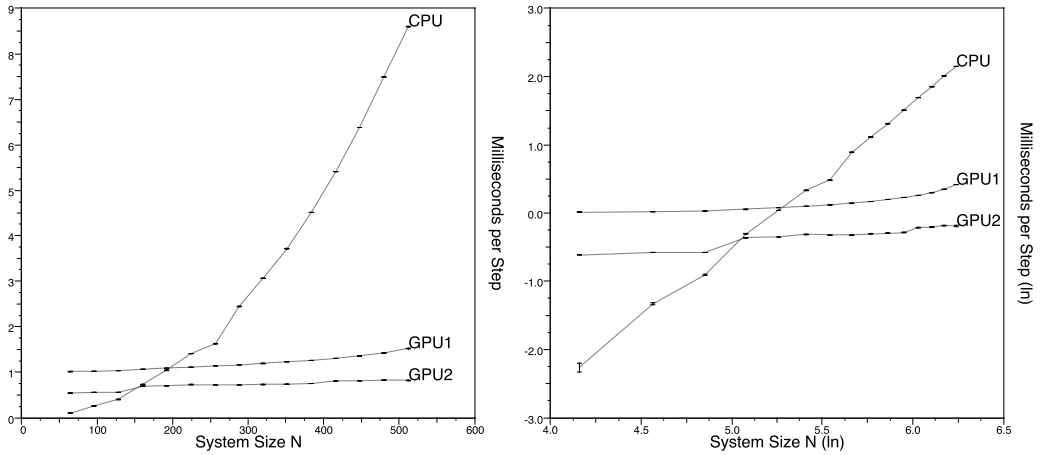

Figure 8: The milliseconds per time-step of three Sznajd model simulations - the CPU, GPU1 (un-optimised) and GPU2 (optimised) implementations. The results are shown in normal scale (left) and log-log scale (right).

6 Conclusion

We have discussed the importance of Sznajd opinion models and their role in simulation studies of real sociological systems and as models of phase transitional and complex emergent behaviour. We have described the need for large simulations that must be run to the point of single opinion consensus.

We have experimented with various data and multi parallel implementations and have identified a tradeoff that makes good use for multiple GPU devices attached to a CPU. The computational performance tradeoff space is not trivial and is dominated by the halo gathering scalability effects.

The Sznajd model neighbour-hood and the push nature of the information propagation means that the simulated system has to be arranged with a relatively large crinkle length, to safely delegate compute responsibility across the data parallel cores of a GPU. While this supports good scalability for large simulated system sizes, we are constrained to having systems sizes that are not so large as to make it infeasible to achieve single opinion consensus. Numerical experiments require us to run the simulations to this point for sensible comparisons with theory. The multi-GPU approach addresses this by achieving good job throughput.

Some areas for further development of Sznajd-like models have also been identified. These include the use of continuous opinion dynamics and historical reputation effects that would further exercise the floating point and memory management properties of GPUs.

Abstract— *Climate simulations have significant role in analyzing changes that have occurred in the Earth, give us better understanding of the recently happened processes. Most of the existing models perform approximate results and fundamental improvements of the software models are necessary to increase accuracy. We present an efficient implementation of ultra-high resolution atmospheric global circulation model on graphics processing units(GPUs). The model based on the nonhydrostatic system with the icosahedral grid and called "NICAM". We ported computationally intensive part of the NICAM code to GPU by using CUDA FORTRAN, then validated and compared its GPU performance to that for the parallel CPU version of the code. This approach shows a good performance results together with reducing memory consumption compared to a fully GPU approaches. Our results show 5x speedup for a computationally intensive part of shallow water simulation model on a single GPU in comparison with a parallel CPU implementation (5 cores).*

Keywords: GPU computations, CUDA Fortran, climate simulations, nonhydrostatic system

1. Introduction

One of the main goals of climate simulations is a prediction of future climate changes and their impact on the Earth and society. It is essential to get a reliable results from the simulations to plan our future ecological, financial and human strategy. For this purpose we need significantly increase scales of the current climate simulations. Thus, it is important to adapt current climate applications to take advantage of the performance capabilities of novel hybrid architectures.

Performance rise of the climate and weather simulation software was based on increasing processor speed rather than increasing parallelism for last years[1]. Nowadays, to sustain such an increase towards the exascale era, we need some significant changes in the software models. GPUs are a very high performance alternative to conventional microprocessor. The massive parallelism of GPUs offers tremendous performance in many high-performance computing applications. GPUs were designed to exploit fine-grained parallelism, which gives us an ability to create weather and climate models with much finer parallelism.

In order to increase performance of the existing climate simulation, we ported and optimized a high resolution climate model to GPU. We aimed to get significant acceleration from applying heterogeneous computing with both conventional CPUs and vector-oriented GPU accelerators.

In this work we use single GPU to run a new type of ultra-high resolution atmospheric global circulation model NICAM (Nonhydrostatic ICosahedral Atmospheric Model) [2] being developed at Advanced Institute for Computational Science, RIKEN (see section II). Initial NICAM code uses 2-dimensional MPI-parallelization and shows good scalability results.

We propose to localize and port the most computation-intensive part of the climate model to GPU. For this purpose, we first study the original NICAM code and isolate the most time-consuming modules. Then, we ported those modules to GPU and evaluated the performance of our implementation.

The main difference of our strategy from some of existing GPU-based approaches [3], [4] is that we do not port to the GPU entire climate model application. Our method allows to reduce the memory to be allocated on GPU by performing on CPU some low-cost computations and porting to the GPU only the most time-consuming computations.

The results of our evaluation show that we reach an almost optimal performance for most of the ported kernels and we see an important speedup. We have got 5x speedup for a computationally intensive part of shallow water simulation model on a single GPU, in comparison with a parallel CPU implementation. Our GPU kernels give us performance, close to the maximum one, which indicate the efficient hardware utilization.

This paper is organized as follows. We describe some important background in the "NICAMmodel" section. Section III outlines our GPU NICAM implementation approach, presents step-by-step algorithm of the "mapping to GPU" process. In section IV we give some information about environment we used, describe performance results for both CPU and GPU versions of the code and present GPU performance model. We give some conclusions and outline our plans for future work in section V.

2. NICAM model

NICAM is a Nonhydrostatic ICosahedral Atmospheric Model, used as a Global Cloud Resolving Model (GCRM). It was designed to perform "cloud resolving simulations" by directly calculating deep convection and meso-scale

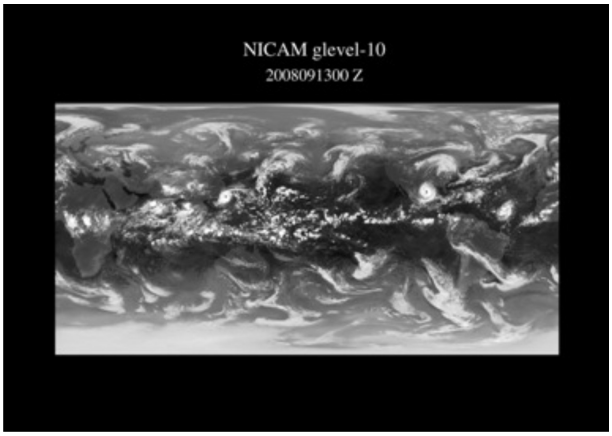

Fig. 1: Tropical cyclones SINLAKU and IKE reproduced by NICAM 7km simulation [6] (00UTC 13 Sep. 2008) (by H.L. Tanaka).

circulations, which play key roles not only in the tropical circulations but in the global circulations of the atmosphere[2]. NICAM - is a unified model in the sense that it can be used for both short term numerical predictions for weather systems such as a week, and long term simulations to obtain quasi-equilibrium climate states (see Figure 1).

The model uses fully compressible (elastic) nonhydrostatic system to obtain thermodynamically quasi-equilibrium states by long time simulations. For this purpose a nonhydrostatic numerical scheme which guarantees conservation of mass and energy was devised and implemented to the global model using the icosahedral grid configuration. The formulation and numerical scheme of NICAM along with numerical results of some test cases are thoroughly presented in [5].

The finite volume method is used for numerical discretization, so that total mass and energy over the domain is conserved; thus this model is suitable for long term climate simulation.

2.1 Numerical methods

For the horizontal discretization, icosahedral grid system on the sphere is used. Figure 2 shows an example of series of consecutive icosahedral grids.

The icosahedral grids are constructed by a recursive division of geodesic arches on the sphere. Starting from the original icosahedron, one-level finer grids are generated by bisecting the geodesic arches of the former coarser grids. We call the n-th bisection of the icosahedron glevel n (glevel: grid division level). The average grid interval of glevel 11 is about 3.5 km, for example. The total number of grid points is Ng = $10(2^n)^2 + 2$.

Numerical models with this grid system are first investigated by Sadourny et al. [7] and Williamson [8], and are recently revisited as a candidate for next-generation high-resolution global models.

In the [9] Tomita et al. describe the modifications, which was applied to the original icosahedral grids by using the

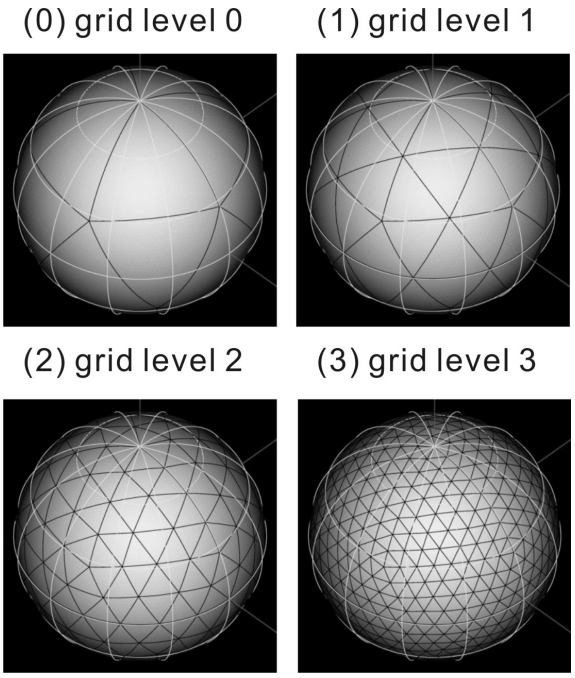

Fig. 2: Horizontal discretization scheme of NICAM model, based on icosahedral grid system on the sphere. Grid level 0 - original icosahedron, 2 grid points. The number of grid points for grid level n can be calculated by $Ng = 10(2^n)^2 + 2$

spring dynamics. With this modifications, the fractal structure of the original icosahedral grid is relaxed and more uniform grid structure with a smaller ratio of minimum to maximum grid intervals is obtained by smoothing the grid arrangement. It was found that the numerical errors can be reduced using the modified grid[10].

The governing equations of the global model are a newly developed nonhydrostatic schemes that guarantees conservation of mass and energy. The finite volume method is used for the flux form equations. The Arakawa-A type grid is used where all the variables are allocated at the vertices of triangles. The shape of the control volume is either hexagon or pentagon.

Further details about numerical scheme, used in NICAM are described in [2], [9], [10].

2.2 MPI parallelization

In this paper we present our single GPU implementation of NICAM model, but we plan to use current NICAM MPI-parallelization method to create a multi-GPU implementation for a following work.

Initial NICAM code use 2-d domain decomposition with FLAT-MPI parallel programming model (see Figure 3, Figure 4).

MPI parallelization strategy is based on discretization grid by regions, which then managed by the different MPI processes.

Region discretization algorithm is shown at the Figure 3. First, we create region level 0 by connecting two neighboring icosahedral triangles. In this case we have

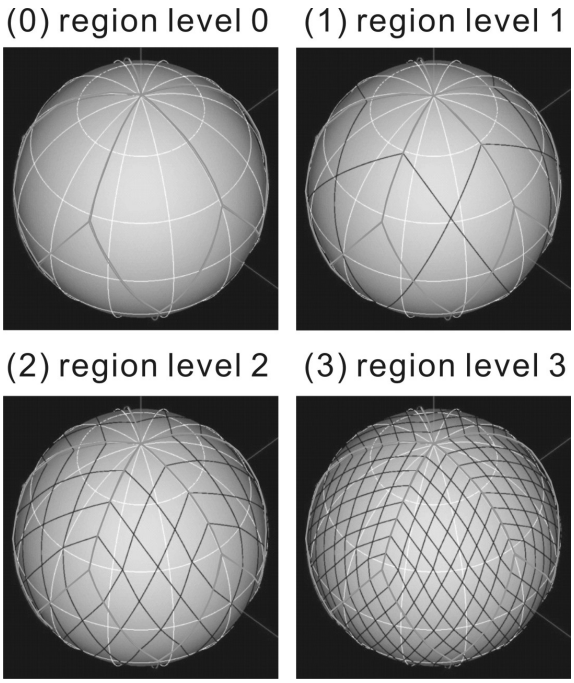

Fig. 3: NICAM region decomposition, used for FLAT MPI parallelization scheme. Region level 0 has 10 rectangles. The number of rectangles for the region level n can be calculated by $Nr = 10(4^n)$

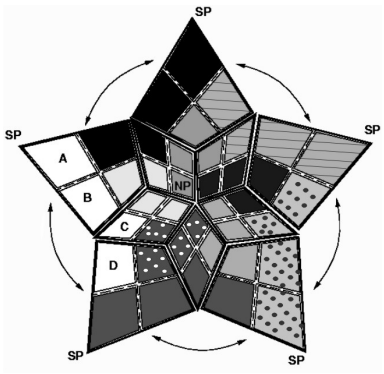

Fig. 4: MPI distribution strategy: region level 1, 40 regions and 10 MPI processes. Each process manage 4 regions with the same color

only 10 rectangles for the level 0 region. To increase region level to 1, we divide each of rectangles into 4 sub-rectangles by connecting the diagonal mid-points (revel-1). Continuing this process recursively we can get region level-n.

MPI distribution strategy is presented on Figure 4. One process manages rectangle regions with the same color. Figure 4 shows an example case for the region level 1, 40 regions and 10 MPI processes. Each process manages 4 regions with the same color.

Assuming one process manages one rectangle region, increasing r-level computational intensity on 1 process is reducing.

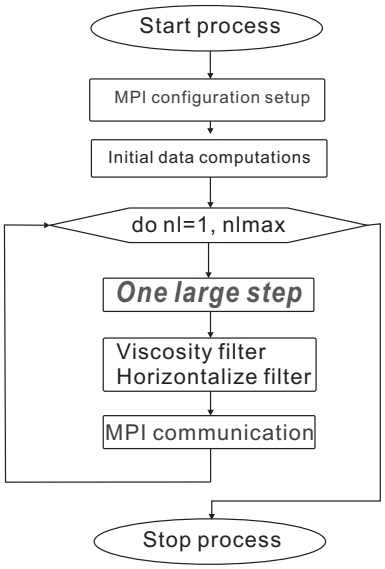

Fig. 5: Simplified flow-graph of the original NICAM Shallow Water model code.

3. GPU implementation

Our GPU implementation approach is based on porting the most computationally intensive part of the initial NICAM code to GPU. In this work we investigate 2-dimensional (Shallow water) case of NICAM model [11], which plan to implement for the 3- dimensional case in future work.

First, we selected a computationally intensive module of NICAM, then modified this Fortran model to run on NVIDIA GPU using PGI CUDA Fortran[12], [13], validated and compared its GPU performance to that of the original MPI parallel module.

In purpose to analyze runtime behavior of the given code we used the Scalasca performance toolset [14]. We have got profiling results for different configurations of the grid and region level numbers.

In the Figure 5 we present a simplified flow-graph of the original NICAM Shallow Water model code. The main computations performs in the cycle by the time steps (nl). Before starting the main cycle computations we need to setup MPI configuration and compute the initial data. At the end of each time step we collect the data from each MPI process and go to the next time iteration.

According to the profiling results "one large step" is the most time consuming module of the code. It takes more then 50% of the whole time to compute this module. Therefore, in purpose to accelerate computations, we decided to port this module to GPU.

In the Figure 6 we present our GPU implementation approach scheme.

After we computed an initial data on CPU we send the ones, necessary for "One large step" computations, to GPU and store them in GPU global memory. Some of this initial data are constant and by porting them once in the beginning of the NICAM computations we reduce CPU-GPU communicational overheads.

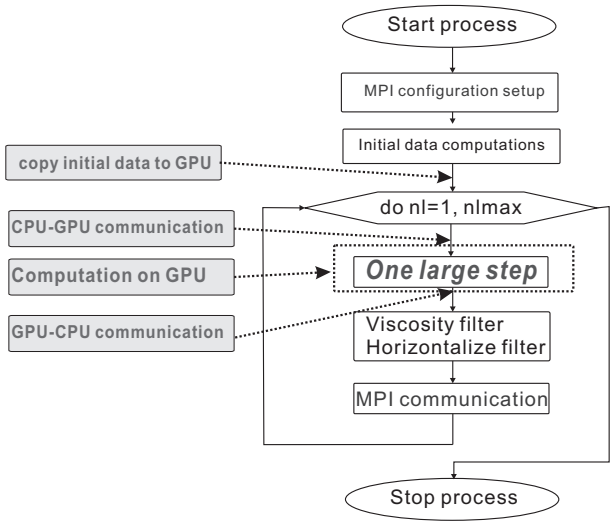

Fig. 6: NICAM GPU implementation approach. Porting the most computationally intensive module "One large step" to the GPU

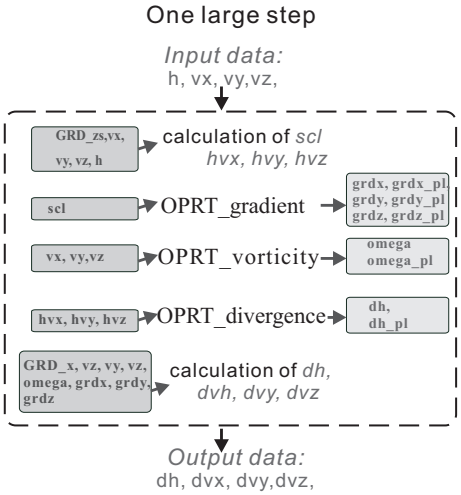

Fig. 7: "One large step" module. Left side blocks - input data, right side blocks - output data.

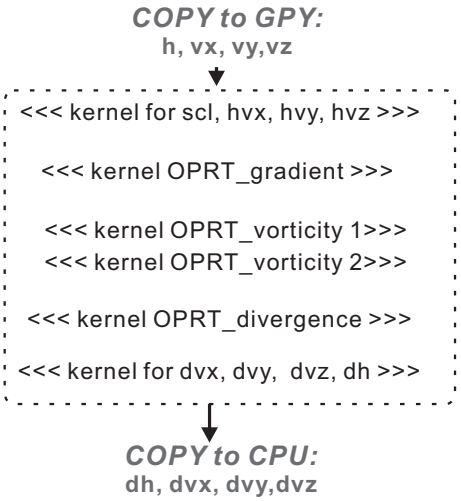

Fig. 8: "One large step" on GPU.

The data, which are variable inside the cycle and necessary for the GPU computations, are transferring to GPU before the "One large step" module on each time step. Then, data, computed on GPU and needed for farther computations on CPU, copying to the CPU at the end of the "One large step".

In the Figure 7 we present "One large step" module in detail. This module performs one full time step of the second-order Runge-Kutta scheme, which uses for the approximation of solutions of ordinary differential equations. "One large step" module consist of 3 main subroutines: OPRT_gradient, OPRT_vorticity and OPRT_divergence. If we port only this subroutines to GPU the communication overheads will be significant and affect to the performance. Therefore we also port initial data and output data computation modules to GPU and keep all temporary data in the GPU global memory. Initial CPU code for this module was slightly modified in purpose to reduce the amount of memory to be allocated on GPU.

We created one kernel for OPRT_gradient and one for OPRT_divergence. For OPRT_vorticity module it was necessary to create 2 kernels for the data synchronization issue. Figure 8 shows how our numerical scheme is computed by executing 6 CUDA kernels in order.

Each module, ported to the kernels, based on a nested loop calculation. Each loop iteration computes 1 element of 2-dimensional array. Each thread of our GPU kernels calculates 1 element of the array.

The CUDA programming model requires the programmer to organize parallel kernels into a grid blocks, which divided into thread blocks with at most 512 threads each. The NVIDIA GPU architecture executes the threads of a block in SIMT (single instruction, multiple thread) groups of 32 called warps.

We use 2-dimensional grid, which size depends on the of grid level and region level sizes. We use a block configuration of 256 threads where we have one thread per element. Our block size is a multiple of 32 which fits with the warp size and, therefore, allow us to achieve maximum efficiency.

We have h, vx, vy and vz arrays as an input data for the GPU computations, and dh, dvx, dvy, dvz as an output data. All the data, used for GPU computations, are stored in GPU Global memory during the entire NICAM model computation process. This allows different kernels access to the common data.

4. Evaluation

In this section we present results of implementation NICAM code on 1 node and single GPU.

4.1 Evaluation environment

Described approach was implemented on the TSUBAME 2.0 supercomputer, established at Tokyo Institute of Technology.

TSUBAME 2.0 consists of 1408 compute nodes (thin nodes) of two Intel Xeon Westreme-EP 2.9 GHz CPUs and tree NVIDIA M2050 GPUs with 52Gb and 3Gb of system

and GPU memory, running SUSE Linux Enterprise Server II SP1.

1 node has 2 sockets, 12 cores/node. Each node is interconnected by dual QDR Infinitband network with a full bisection- bandwidth fat-tree topology.

NICAM code consists of both FORTRAN and C++ modules. We use PGI CUDA FORTRAN $pgfortran$ version 2011 compiler for the GPU and FORTRAN code and $mpicc$ compiler for the C++ code.

4.2 Performance results

In purpose to compare NICAM CPU version performance with one for the GPU version we investigated initial CPU version for the code performance on TSUBAME 2.0 supercomputer. After performing the CPU code analysis we modified the code, porting the most time-consuming module to the single GPU, verified and validated our implementation. Then we compared MPI-parallel code performance with the single GPU code performance.

4.2.1 CPU performance

As it was described in section II, NICAM CPU code is based on 2d-domain decomposition with FLAT-MPI parallel programming model. Initial grid is divided by regions, managed by different MPI processes. The number of cores is restricted by the region division level, which can has limited number of the regions, that is $10*(2^n)^2$, where n - the region level order. Therefore, the total number of processes can be only the divisor of the total number of regions.

Figure 9 shows strong scalability results for the initial CPU version on TSUBAME 2.0 supercomputer. Problem size is grid level 11 with region level 5, which corresponds to 41943042 grid points. Strong scalability results demonstrate good speed up resulting on the number of cores up to 2560.

Figure 10 and Figure 11 present CPU performance results for the most time-consuming modules, ported to GPU.

From the CPU performance graph we can see that increasing grid level the scalability is rising due to increasing of the computational intensity per one process.

We assume 5 processes is a saturation point of the MPI parallelization and further compare CPU performance results on 5 processes with the GPU performance results on single GPU (see Figure 12)

4.2.2 GPU numerical performance

We compared single GPU version performance result with the performance for parallel MPI-parallel version (saturation point). We assume that the saturation point for performance of the MPI-parallel version achieves when the number of cores equal 5. Due to the fact that we have 6 cores in one socket on Intel Xeon X5670, we compare 1 CPU socket results versus 1 GPU socket.

This comparison results for the 3 main subroutines of the NICAM Shallow Water model are shown on the Figure 12. We can see that for the grid level 6 (gl06)

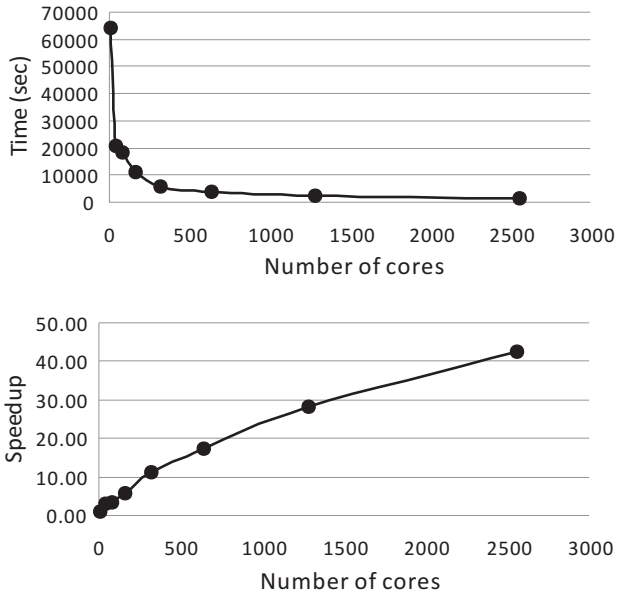

Fig. 9: Strong scalability of the CPU version. Average running time and speedup as a function of the number of cores for the grid level 11 and region level 5, which is correspond to horizontal size of grid cell around 3.5 km, 41943042 grid points

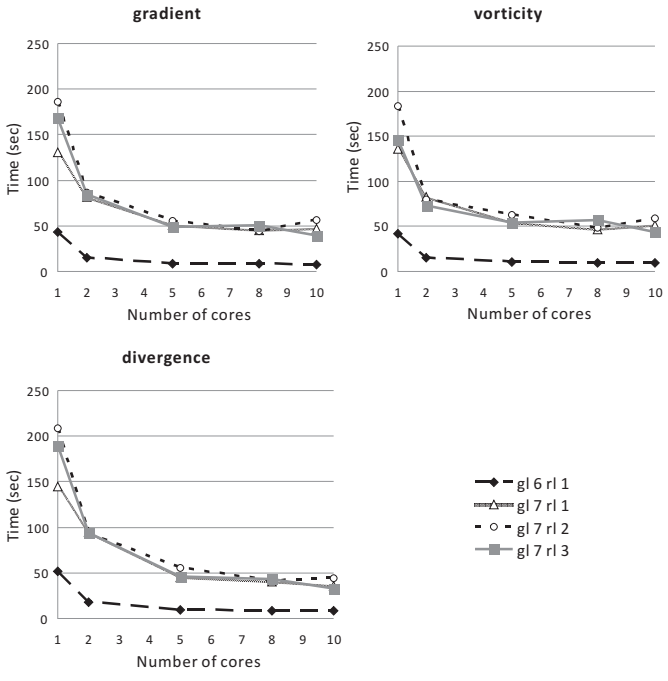

Fig. 10: CPU performance graph. Average running time as a function of the number of cores for the different configurations of the grid and region levels

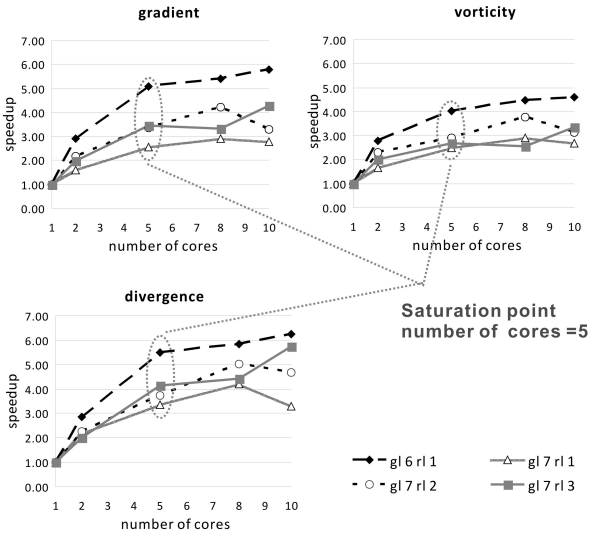

Fig. 11: CPU performance graph. Average speedup as a function of the number of cores for the different configurations of the grid and region levels

GPU versions performs 3 times faster then multi-CPU one. Increasing grid level to gl07 GPU version performs about 5 times faster then parallel-CPU one. It can be explained by the increasing computational intensity per kernel. We get 5x acceleration also for the grid level 8.

Due to limitations in GPU global memory, we were unable to scale NICAM code to a grid level higher then 8. The NVIDIA M2050 GPU only provides 3 GByte of Global memory. This limitation can be relaxed by using GPUs with higher amount of global memory. Also, as a future work, we are going to reduce amount of memory to be allocated per one GPU by splitting kernels between multiple GPUs, sharing 1 node.

4.2.3 GPU performance model

In purpose to measure the performance of our GPU NICAM implementation, we used "roofline" model of Samuel Willams [15]. This model compares achieved performance to a "roofline" graph of peak data streaming bandwidth and peak FLOP/s capacity.

We calculated performance by the next formula (1):

$$Performance = \frac{FLOP}{\frac{FLOP}{Fpeak} + \frac{Byte}{Bpeak} + \alpha} = \\ = \frac{FLOP/Byte}{\frac{FLOP}{Byte} + \frac{Fpeak}{Bpeak} + \alpha\frac{Fpeak}{Byte}} Fpeak \qquad (1)$$

Here $FLOP$ - number of floating-point operations for applications, $Byte$ - byte number of memory access for applications, $Fpeak$ - peak performance of floating-point operation, $Bpeak$ - peak memory bandwidth, α - time taken by other OPs except both FP and memory access.

For TSUBAME 2.0 supercomputer $Fpeak = 515GFlops$, $Bpeak = 148GByte/sec$ in double precision, we assume $\alpha = 0$.

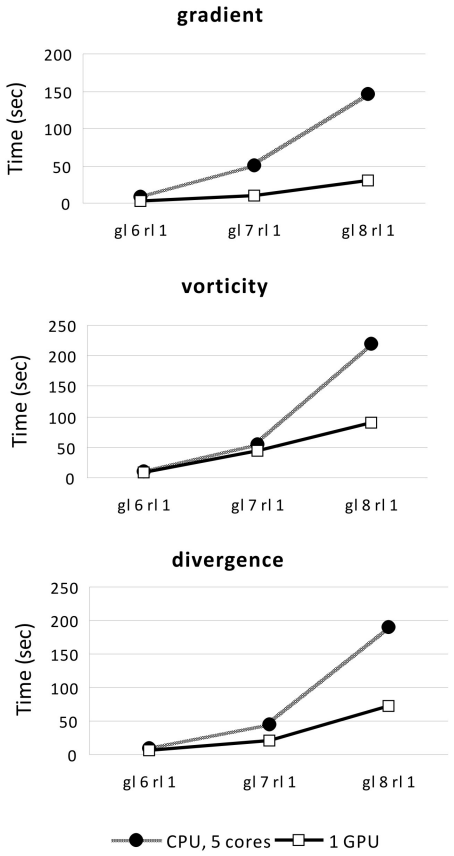

Fig. 12: Average running time for MPI-parallel CPU module versus time for GPU kernel as a function of the problem configuration for 3 main modules of the NICAM code.

Arithmetic intensity was calculated as $FLOP/Byte$.

Figure 13 shows "roofline" performance model for all GPU kernels of the GPU NICAM implementation. It is shown that output data calculations kernel, both vorticity kernels and gradient kernel give performance, close to theoretical one. This results indicate that we get maximum performance from the kernels. Performance of the input calculation kernel and divergence kernel we get is not the maximum one, but we will try to increase it by applying some additional optimization in the following work.

5. Conclusion

In this paper we have described our strategy of mapping to GPU a ultra-high resolution atmospheric model NICAM. We outlined the main steps of the mapping process and reported about results we got on TSUBAME 2.0 supercomputer.

We ported the most time-consuming modules of the initial NICAM Fortran code to a single GPU by using PGI CUDA Fortran. In this work we investigated 2-dimensional (Shallow water) case of NICAM model, and we plan to implement our GPU algorithm to the 3- dimensional case in a future work.

The results of our evaluation show a 5x speedup for a

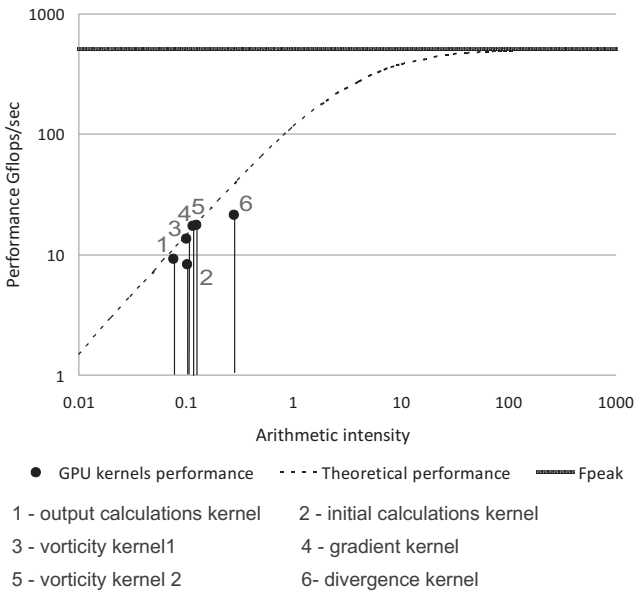

Fig. 13: Roofline graph: Visual GPU kernels performance model.

computationally intensive part of shallow water simulation model on a single GPU in comparison with a parallel CPU implementation.

In purpose to investigate performance of our GPU NICAM implementation, we created a "roofline" performance model for the GPU kernels. It was shown, that 4 of our 6 kernels give us performance close to the maximum one and, therefore, do not need any optimization. Two kernels still can be optimized to get better performance.

As our work progresses we will optimize current GPU implementation to get better performance. Then, we plan to apply our strategy to the multiple GPUs on one node, in order to reduce the amount of memory to be stored on one GPU. After that we plan to finish our MPI-CUDA implementation and run on multiple GPU nodes. We hope to see additional significant performance gains.

We also plan to investigate behavior of the NICAM code with OpenACC and the 3 compilers: PGI, CAPS/OMPP and Cray. Then it might be interesting to look at the NICAM code at the Cray XK6, which has been installed at Tokyo Tech this spring.

Acknowledgment

This work is done under the G8 ECS (Enabling Climate Simulation at Extreme Scale) project[16], focus on investigating ways to run efficiently climate simulations on future Exascale systems and get correct results.

***Abstract*—Nowadays, a heat and mass transfer simulation plays an important role in various engineering and industrial fields. To analyze physical behaviors of a thermal environment, we have to simulate heat and mass transfer phenomena. However to obtain numerical solutions to heat and mass transfer equations is much time-consuming. In this paper, therefore, one of acceleration techniques developed in the graphics community that exploits a graphics processing unit (GPU) is applied to the numerical solutions of heat and mass transfer equations. Implementation of the simulation on GPU makes GPU computing power available for the most time-consuming part of the simulation and calculation. The nVidia CUDA programming model provides a straightforward means of describing inherently parallel computations. This paper improves the computational performance of solving heat and mass transfer equations with the second boundary and initial conditions numerically running on GPU. We implemented simulation of heat and mass transfer using the novel CUDA platform on nVidia Quadro FX 4800 and compared its performance with an optimized CPU implementation on a high-end Intel Xeon CPU. The experimental results clearly show that GPU can perform heat and mass transfer simulation accurately and significantly accelerate the numerical calculation with the maximum observed speedups 10 times. Therefore, the GPU implementation is a promising approach to acceleration of the heat and mass transfer simulation.**

I. INTRODUCTION

During the last 4-5 decades, many scientists and engineers working in Heat and Mass Transfer processes have focused their attention to finding solutions both analytically/numerically, and experimentally. To precisely analyze physical behaviors of thermal environments, we need to simulate several heat and mass transfer phenomena such as heat conduction, convection, and radiation. A heat transfer simulation is accomplished by combining multiple computer simulations of such heat and mass transfer phenomena. With the advent of computer, initially the sequential solutions were found, and later when super-computers became available, fast solutions were obtained to above mentioned problems. However, the simulation of heat and mass transfer requires much longer execution time than the other simulations. Therefore, acceleration of the heat and mass transfer simulation is essential to realize a practical large-scale heat and mass transfer simulation.

This paper exploits the computing power of graphics processing units (GPUs) to accelerate the heat and mass transfer simulation. GPUs are cost-effective in terms of theoretical peak floating-point operation rates [1]. Therefore, comparing with expensive cluster, GPUs is a powerful co-processor on a common desktop PC that is ready to achieve a large-scale heat and mass transfer simulation at a low cost. The GPU has several key advantages over CPU architectures for highly parallel, compute intensive workloads, including higher memory bandwidth, significantly higher floating-point throughput. The GPU can be an attractive alternative to CPU clusters in high performance computing environments.

Recent announcement like CUDA [2] by nVidia proved their effort to extend both programming and memory models. CUDA (Compute Unified Device Architecture) is a new data-parallel, C-language programming API that bypasses the rendering interface and avoids the difficulties of classic GPGPU. Parallel computations are instead expressed as general-purpose, C-language kernels operating in parallel over all the points in a domain.

This paper investigates the numerical solutions to Two-point Initial-Boundary Value Problems (TIBVP) of Heat and Mass with the second boundary and initial conditions arising in capillary porous media. These problems find applications in drying processes, under-ground contaminants transport, absorption of nutrients in human bodies, transpiration cooling of space vehicles at re-entry into atmosphere, and many other science and engineering problems. Although traditional approaches of parallel-distributed processing have been applied with advantage to the solutions of some of these problems, no more seem to have explored the high performance solutions to these problems with compact multi-processing capabilities of GPU, which is multi-processors technology on a chip. With the power of this compact technology and develop relevant algorithms to find the solution of TIBVP with the second boundary and initial conditions and compare with some of the existing solutions to simple known problems. All of our experimental results show satisfactory speedups. The maximum observed speedups are about 10 times.

The rest of the paper is organized as follow: Section II introduces some previous related work; Section III describes the background on GPU and CUDA briefly; Section IV presents the mathematical model of heat and mass transfer and numerical solutions to heat and mass transfer equations;

Our experimental results are presented in Section V; Finally Section VI concludes this paper with our future direction.

II. Related Work

The simulation of heat and mass transfer has received much attention for years. And there is much work related to this field, such as modeling and dynamic simulation. Here we just refer to some recent work closely related.

Soviet Union was in the fore-front for exploring the coupled Heat and Mass Transfer in Porous media was researched as a part of chemical engineering discipline, and major advances were made at Heat and Mss Transfer Institute at Minsk, BSSR. Later England and India took the lead and made further advances in terms of analytical and numerical solutions to certain problems. Later Narang and Rajiv [4] explored the wavelet solutions and Ambethkar [5] explored the numerical solutions to some of these problems.

With the programmability of fragments on GPU, Krüger et al. [6] computed the basic linear algebra problems, and further computed the 2D wave equations and NSEs on GPU. Bolz et al. [7] rearranged the sparse matrix into textures, and utilized them multigrid method to solve the fluid problem. Similarly, Goodnight et al. [8] used the multigrid method to solve the boundary value problems on GPU. Harris [9, 10] solved the PDEs of fluid motion to get cloud animation.

GPU is also used to solve other kinds of PDEs. For example, Kim et al. [11] solved the crystal formation equations on GPU. Lefohn et al. [12] packed the level-set isosurface data into a dynamic sparse texture format, which was used to solve the PDEs. Another creative usage was to pack the information of the next active tiles into a vector message, which was used to control the vertices and texture coordinates needed to send from CPU to GPU. To learn more applications about GPU for general-purpose computations, readers can refer to [13].

III. An Overview of CUDA Architecture

The GPU that we have used in our implementations is nVidia's Quadro FX 4800, which is DirectX 10 compliant. It is one of nVidia's fastest processors that support the CUDA API and as such all implementations using this API are forward compatible with newer CUDA compliant devices. All CUDA compatible devices support 32-bit integer processing. An important consideration for GPU performance is its level of occupancy. Occupancy refers to the number of threads available for execution at any one time. It is normally desirable to have a high level of occupancy as it facilitates the hiding of memory latency.

The GPU memory architecture is shown in figure 1.

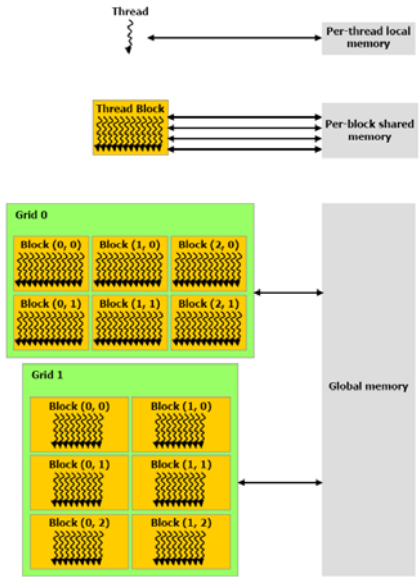

Figure 1: GPU Memory Architecture [2]

IV. Mathematical Model and Numerical Solutions of Heat and Mass Transfer

A. Mathematical Model

Consider the Heat and Mass Transfer through a porous slab with boundary conditions of the second kind. Let the x-axis be directed upward along the slab and the y-axis normal to the slab. Let u and v be the velocity components along the x- and y- axes respectively. Let us assume that the slab is accelerating with a velocity $u = Ut$ in its own plane at time $t \geq 0$. Then the heat and mass transfer equations in the Boussinesq's approximation, are:

$$\frac{\partial v_1}{\partial x_1} = 0 \tag{1}$$

$$\frac{\partial u_1}{\partial t_1} + v_1 \frac{\partial u_1}{\partial x_1} = g\beta(T_1 - T_\infty) + \frac{v\partial^2 u_1}{\partial x_1^2} - \frac{\sigma B_0^2 u_1}{\rho} \tag{2}$$

$$\frac{\partial T_1}{\partial t_1} + v_1 \frac{\partial C_1}{\partial x_1} = \frac{k\partial^2 T_1}{\partial x_1^2} \tag{3}$$

$$\frac{\partial C_1}{\partial t_1} + v_1 \frac{\partial C_1}{\partial x_1} = \frac{D'\partial^2 C_1}{\partial x_1^2} \tag{4}$$

A prescribed constant heat flux q supplied by the hot plate at the left end $X=0$ of the slab, the initial and boundary conditions of the problem are:

$$t_1 \leq 0, u_1(x_1, t_1) = 0$$
$$T_1(x_1, t_1) = T_\infty \text{ , } C_1(x_1, t_1) = C_\infty \tag{5}$$

$$t_1 > 0, u_1(0, t_1) = V_0 \tag{6}$$

$$k\frac{\partial T(0,t_1)}{\partial x_1} = -q$$
$$\frac{\partial C(0,t_1)}{\partial x_1} + k\frac{\partial T(0,t_1)}{\partial x_1} = 0$$
$$t_1 > 0 \qquad (7)$$
$$u_1(\infty,t_1) \to 0,\ T_1(\infty,t_1) \to T_\infty$$
$$C_1(\infty,t_1) \to C_\infty \text{ as } x_1 \to \infty$$

Since the slab is assumed to be porous, Equation (1) integrates to $v_1 = -v_0$ is the constant velocity. Here, μ_1 is the velocity of the fluid, T_p the temperature of the fluid near the slab, T_∞ the temperature of the fluid far away from the slab, C_p the concentration near the slab, C_∞ the concentration far away from the slab, g the acceleration due to gravity, β the coefficient of volume expansion for heat transfer, β' the coefficient of volume expansion for concentration, ν the kinematic viscosity, σ the scalar electrical conductivity, ω the frequency of oscillation, k the thermal conductivity, q is the heat flux and t_1 is the time.

From Equation (1) we observe that v_1 is independent of space co-ordinates and may be taken as constant. We define the following non-dimensional variables and parameters.

$$t = \frac{t_1 V_0^2}{4\nu}, x = \frac{V_0 x_1}{4\nu} \qquad (8)$$
$$u = \frac{u_1}{V_0}, T = \frac{T_1 - T_\infty}{T_P - T_\infty}, C = \frac{C_1 - C_\infty}{C_P - C_\infty}, P_r = \frac{\nu}{k}, S_c = \frac{\nu}{D'}$$

$$M = \frac{\sigma B_0^2 \nu}{\rho V_0^2}, G_r = \frac{\nu g\beta(T_P - T_\infty)}{V_0^3}$$
$$G_m = \frac{\nu g\beta'(C_P - C_\infty)}{V_0^3}, \omega = \frac{4\nu\omega_i}{V_0^2}$$

Now taking into account Equations (5), (6), (7), and (8), equations (2), (3) and (4) reduce to the following form:

$$\frac{\partial u}{\partial t} - 4\frac{\partial u}{\partial x} = 4\frac{\partial^2 u}{\partial x^2} + 4G_r T - 4Mu + 4G_m C \qquad (9)$$

$$\frac{\partial T}{\partial t} - 4\frac{\partial T}{\partial x} = \frac{4}{P_r}\frac{\partial^2 T}{\partial x^2} \qquad (10)$$

$$\frac{\partial C}{\partial t} - 4\frac{\partial C}{\partial x} = \frac{4}{S_c}\frac{\partial^2 T}{\partial x^2} \qquad (11)$$

with

$$t \le 0 \qquad (12)$$
$$u(x,t) = 0,\ T(x,t) = 0$$

$$t > 0 \qquad (13)$$
$$u(0,t) = 0,\ k\frac{\partial T(0,t_1)}{\partial x_1} = -q$$
$$\frac{\partial C(0,t_1)}{\partial x_1} + k\frac{\partial T(0,t_1)}{\partial x_1} = 0$$

$$t > 0 \qquad (14)$$
$$u(\infty,t) = 0,\ T(\infty,t) = 0$$
$$C(\infty,t) = 0, \text{ as } x_1 \to \infty$$

B. Numerical Solutions

Here we sought a solution by finite difference technique of implicit type namely Crank- Nicolson implicit finite difference method which is always convergent and stable. This method has been used to solve Equations (9), (10), and (11) subject to the conditions given by (12), (13) and (14). To obtain the difference equations, the region of the heat is divided into a gird or mesh of lines parallel to x and t axes. Solutions of difference equations are obtained at the intersection of these mesh lines called nodes. The values of the dependent variables T, u and C at the nodal points along the plane $x = 0$ are given by $T(0,t)$, $u(0,t)$ and $C(0,t)$ hence are known from the boundary conditions.

In the figure 2, Δx, Δt are constant mesh sizes along x and t directions respectively. We need an algorithm to find single values at next time level in terms of known values at an earlier time level. A forward difference approximation for the first order partial derivatives of u, T and C. And a central difference approximation for the second order partial derivative of u, T and C are used. On introducing finite difference approximations for:

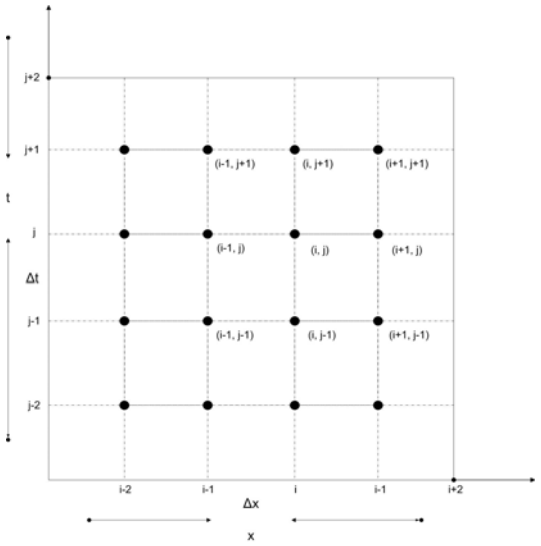

Figure 2: Finite Difference Grid

$$\left(\frac{\partial T}{\partial x}\right)_{i,j}=\frac{T_{i+1,j}-T_{i-1,j}+T_{i+1,j+1}-T_{i-1,j+1}}{4(\Delta x)}$$

$$\left(\frac{\partial C}{\partial x}\right)_{i,j}=\frac{C_{i+1,j}-C_{i-1,j}+C_{i+1,j+1}-C_{i-1,j+1}}{4(\Delta x)} \tag{15}$$

$$\left(\frac{\partial u}{\partial x}\right)_{i,j}=\frac{u_{i+1,j}-u_{i-1,j}+u_{i+1,j+1}-u_{i-1,j+1}}{4(\Delta x)}$$

$$\left(\frac{\partial T}{\partial t}\right)_{i,j}=\frac{T_{i,j+1}-T_{i,j}}{\Delta t},\left(\frac{\partial C}{\partial t}\right)_{i,j}=\frac{C_{i,j+1}-C_{i,j}}{\Delta t},\left(\frac{\partial u}{\partial t}\right)_{i,j}=\frac{u_{i,j+1}-u_{i,j}}{\Delta t}$$

$$\left(\frac{\partial^2 T}{\partial x^2}\right)_{i,j}=\frac{T_{i+1,j}+T_{i-1,j}-2T_{i,j}+T_{i+1,j+1}+T_{i-1,j+1}-2T_{i,j+1}}{2(\Delta x)^2}$$

$$\left(\frac{\partial^2 C}{\partial x^2}\right)_{i,j}=\frac{C_{i+1,j}+C_{i-1,j}-2C_{i,j}+C_{i+1,j+1}+C_{i-1,j+1}-2C_{i,j+1}}{2(\Delta x)^2}$$

$$\left(\frac{\partial^2 u}{\partial x^2}\right)_{i,j}=\frac{u_{i+1,j}+u_{i-1,j}-2u_{i,j}+u_{i+1,j+1}+u_{i-1,j+1}-2u_{i,j+1}}{2(\Delta x)^2}$$

The finite difference approximation of Equations (9), (10) and (11) are obtained with substituting Equation (15) into Equations (9), (10) and (11) and multiplying both sides by Δt and after simplifying, we let $\frac{\Delta t}{(\Delta x)^2}=r'=1$ (method is always stable and convergent), under this condition the above equations can be written as:

$$\begin{aligned}&2u_{i,j+1}\left(\frac{1}{2}+\frac{\Delta t}{\Delta x}\right)u_{i+1,j+1}+\left(\frac{\Delta t}{\Delta x}-\frac{1}{2}\right)u_{i-1,j+1}\\&=\left(\frac{1}{2}+\frac{\Delta t}{\Delta x}\right)u_{i+1,j}+\left(\frac{1}{2}+\frac{\Delta t}{\Delta x}\right)u_{i-1,j+1}+\\&+4G_r\Delta tT_{i,j}+4G_m\Delta tC_{i,j}-4M\Delta tu_{i,j}\end{aligned} \tag{16}$$

$$\begin{aligned}&\left(1+\frac{4}{P_r}\right)T_{i,j+1}+\left(\frac{\Delta t}{\Delta x}-\frac{2}{P_r}\right)T_{i-1,j+1}-\left(\frac{\Delta t}{\Delta x}-\frac{2}{P_r}\right)T_{i+1,j+1}\\&=\left(\frac{\Delta t}{\Delta x}-\frac{2}{P_r}\right)T_{i+1,j}+\left(\frac{2}{P_r}-\frac{\Delta t}{\Delta x}\right)T_{i-1,j}+\left(1-\frac{4}{P_r}\right)T_{i,j}\end{aligned} \tag{17}$$

$$\begin{aligned}&\left(1+\frac{4}{S_c}\right)C_{i,j+1}+\left(\frac{\Delta t}{\Delta x}-\frac{2}{S_c}\right)C_{i-1,j+1}-\left(\frac{\Delta t}{\Delta x}-\frac{2}{S_c}\right)C_{i+1,j+1}\\&=\left(\frac{2}{S_c}+\frac{\Delta t}{\Delta x}\right)C_{i+1,j}+\left(\frac{2}{S_c}-\frac{\Delta t}{\Delta x}\right)C_{i-1,j}+\left(1-\frac{4}{S_c}\right)C_{i,j}\end{aligned} \tag{18}$$

V. EXPERIMENTAL RESULTS AND DISCUSSION

A. Setup and Device Configuration

The experiment was executed using the CUDA Runtime Library, Quadro FX 4800 graphics card, Intel Core 2 Duo. The programming interface used was Visual Studio.

The experiments were performed using a 64-bit Lenovo ThinkStation D20 with an Intel Xeon CPU E5520 with processor speed of 2.27 GHZ and physical RAM of 4.00GB. The Graphics Processing Unit (GPU) used was an NVIDIA Quadro FX 4800 with the following specifications:

CUDA Driver Version:	3.0
Total amount of global memory:	1.59 Gbytes
Number of multiprocessors:	24
Number of cores:	92
Total amount of constant memory:	65536 bytes
Total amount of shared memory per block:	16384 bytes
Total number of registers available per block:	16384
Maximum number of threads per block:	512

Banwitdh:

Host to Device Bandwith: 3412.1 (MB/s)
Device to Host Bandwith: 3189.4 (MB/s)
Device to Device Bandwitdh: 57509.6 (MB/s)

In the experiments, we considered solving heat and mass transfer differential equations in an infinite slab with boundary conditions of the second kind using numerical methods. Our main purpose here was to obtain numerical solutions for Temperature *T*, and concentration *C* distributions across the various points in a slab as heat and mass are transferred from one end of the slab to the other. For our experiment, we compared the similarity of the CPU

and GPU results. We also compared the performance of the CPU and GPU in terms of processing times of these results.

In the experimental setup, we are given the initial temperature T_0 and concentration C_0 at point $x = 0$ on the slab. Also, there is a constant heat flux q_0 and mass flux N_0 constantly working the surface of the slab. The temperature at the other end of the slab where $x = \infty$ is assumed to be ambient temperature (assumed to be zero). Also, the concentration at the other end of the slab where $x = \infty$ is assumed to be negligible (≈ 0) and so are the heat and mass fluxes. Our initial problem was to derive the temperature T_1 and concentration C_1 associated with the heat and mass fluxes respectively. This we did by employing the finite difference technique. Hence, we obtained total initial temperature of $(T_0 + T_1)$ and total initial concentration of $(C_0 + C_1)$ at $x = 0$. These total initial conditions were then used to perform calculations.

For the purpose of implementation, we assumed a fixed length of the slab and varied the number of nodal points N to be determined in the slab. Since N is inversely proportional to the step size Δx, increasing N decreases Δx and therefore more accurate results are obtained with larger values of N. For easy implementation in Visual Studio, we employed the Forward Euler Method (FEM) for forward calculation of the temperature and concentration distributions at each nodal point in both the CPU and GPU. For a given array of size N, the nodal points are calculated iteratively until the values of temperature and concentration become stable. In this experiment, we performed the iteration for 10 different time steps. After the tenth step, the values of the temperature and concentration became stable and are recorded. We run the tests for several different values of N and Δx and the error between the GPU and CPU calculated results was increasingly smaller as N increased. Finally, our results were normalized in both the GPU and CPU.

B. *Experimental Results*

The normalized temperature and concentration distributions at various points in the slab are depicted in Table 1 and Table 2 respectively. We can immediately see that, at each point in the slab, the CPU and GPU computed results are similar. In addition, the values of temperature and concentration are highest at the point on the slab where the heat flux and mass flux are constantly applied. As we move away from this point, the values of the temperature and concentration decrease. At a point near the designated end of the slab, the values of the temperature and concentration approach zero. This is depicted clearly in the graphs of Figure 1 and Figure 2.

Furthermore, we also evaluated the performance of the GPU (NVIDIA Quadro FX 4800) in terms of solving heat and mass transfer equations by comparing its execution time to that of the CPU (Intel Xeon E5520).

For the purpose of measuring the execution time, the same functions were implemented in both the device (GPU) and the host (CPU), to initialize the temperature and concentration and to compute the numerical solutions. In this case, we measured the processing time for different values of N. The graph in Figure 3 depicts the performance of the GPU versus the CPU in terms of the processing time. We run the test for N running from 15 to 1005 with increments of 30 and generally, the GPU performed the calculations a lot faster than the CPU.

- When N was smaller than 75, the CPU performed the calculations faster than the GPU.
- When N was between 75 and 135 both CPU and GPU performed around the same speed.

- For N larger than 135 the GPU performance began to increase considerably

Figure 3 and figure 4 show some of our experimental results.

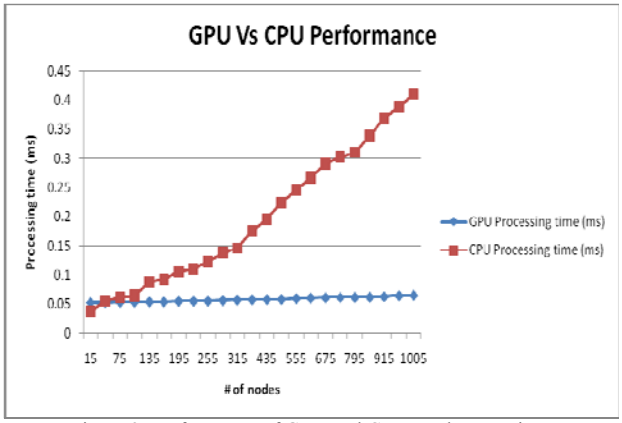

Figure 3: Performance of GPU and CPU Implementations

Finally, the accuracy of our numerical solution was dependent on the number of iterations we performed in calculating each nodal point, where more iteration mean more accurate results. In our experiment, we observed that after 9 or 10 iterations, the solution to the heat and mass equation at a given point became stable. For optimal performance, and to keep the number of iterations the same for both CPU and GPU, we used 10 iterations.

VI. Conclusion and Future Work

We have presented our numerical approximations to the solution of the heat and mass transfer equation with the second kind of boundary and initial conditions using finite difference method on GPGPUs. Our conclusion shows that finite difference method is well suited for parallel programming. We implemented numerical solutions utilizing highly parallel computations capability of GPGPU on nVidia CUDA. We have demonstrated GPU can perform significantly faster than CPU in the field of numerical solution to heat and mass transfer. Our experimental results indicate that our GPU-based implementation shows a significant performance improvement over CPU-based implementation and the maximum observed speedups are about 10 times.

There are several avenues for future work. We would like to test our algorithm on different GPUs and explore the new performance opportunities offered by newer generations of GPUs. It would also be interesting to explore more tests with large scale data set. Finally, further attempts will be made to explore more complicated problems both in terms of boundary conditions as well as geometry.

Abstract— *The arrangement graph $A_{n,k}$ has been used as the underlying topology for many practical multicomputers, and has been extensively studied in the past. The construction scheme of mutually independent hamiltonian cycle, abbreviated as MIHCs, on $A_{n,k}$ has not been done except for two special cases with $n-k=1$ and $n-k=2$. In this paper, we will prove that any $A_{n,k}$, where $n-k \geq 3$ and $k \geq 2$, contains $k(n-k)$ MIHCs. More specifically, let $N = \mid V(A_{n,k}) \mid$, $v(i) \in V(A_{n,k})$ for $1 \leq i \leq N$ and $\langle v(1), v(2), \cdots, v(N), v(1)\rangle$ be a hamiltonian cycle of $A_{n,k}$. We prove that $A_{n,k}$ contains $k(n-k)$ hamiltonian cycles, denoted by $C_l = \langle v(1), v_l(2), \cdots, v_l(N), v(1)\rangle$ for $1 \leq l \leq k(n-k)$, such that $v_l(i) \neq v_{l'}(i)$ for $2 \leq i \leq N$ whenever $l \neq l'$. The result is optimal since each vertex of $A_{n,k}$ has exactly $k(n-k)$ neighbors.*

Keywords: Arrangement graph, hamiltonian cycle, mutually independent.

1. Introduction

The architecture of an interconnection network is usually represented by a graph, in which vertices and edges correspond to processors and communication links, respectively. Thus, we use the terms "graph" and "network" interchangeably. Mutually independent hamiltonian cycles, abbreviated as MIHCs, and its related issues have attracted numerous studies on graphs and interconnection networks due to its many applications. (See [6], [10]–[16].) For example, in communications and in signal processing. When information has to be processed along all communication nodes, using the existence of MIHCs on an interconnection network, one can divide the information into groups and let each group be processed along different hamiltonian cycles in parallel. Obviously, it provides a more efficient way for information processing. The arrangement graph, denoted by $A_{n,k}$, is a well-studied interconnection network since it has many pleasant properties. In [2], $A_{n,k}$ was shown to be vertex symmetric and edge symmetric, $(k(n-k))$-regular with $\frac{n!}{(n-k)!}$ vertices, and contain a hamiltonian cycle. It was further shown that $A_{n,k}$ can embed multidimensional grids, hypercubes, and spanning trees all with constant dilations [4]. Readers can refer to [2]–[5], [7], [9], [17] for more results. The construction scheme of MIHCs on any arrangement graph is certainly an important task, but so far only special cases are done. Researchers have derived MIHCs on $A_{n,n-1}$ and $A_{n,n-2}$, which are called *star graphs and alternating group graphs*, respectively. (See [11] and [14].) However, a general construction scheme for MIHCs on $A_{n,k}$ with any given pair of n and k is still unknown. In this paper, we will prove that any arrangement graph $A_{n,k}$ contains $k(n-k)$ MIHCs for given integers n and k with $n-k \geq 3$ and $k \geq 2$. The result is optimal in the sense that each node of $A_{n,k}$ has exactly $k(n-k)$ neighbors and cannot have more cycles emerging from it.

2. Preliminary

For the graph definitions and notations, we follow [1]. Given a graph $G = (V, E)$, the meanings of path, cycle, hamiltonian path, hamiltonian cycle, hamiltonian graph, and hamiltonian connected graph are as usual. A path P between two vertices $v(0)$ and $v(k)$ is represented by P=$\langle v(0), v(1), ..., v(k)\rangle$, where each pair of consecutive vertices are adjacent. We also write path P=$\langle v(0), v(1), ..., v(k)\rangle$ as $\langle v(0), v(1), ..., v(i), Q, v(j), v(j+1), ..., v(k)\rangle$, where Q denotes the path $\langle v(i), v(i+1), ..., v(j)\rangle$. Let $F \subseteq V(G)$ and $G-F$ be the graph obtained by deleting v and all edges adjacent to v for all $v \in F$. If $G-F$ remains hamiltonian (resp. hamiltonian connected) for any $F \subseteq V(G)$ with $|F| \leq k$, then G is a *k-vertex-fault-tolerant hamiltonian* (resp. *k-vertex-fault-tolerant hamiltonian connected*) graph. If $G-F$ remains hamiltonian (resp. hamiltonian connected) for any $F \subseteq E(G)$ with $|F| \leq k$, then G is a *k-edge-fault-tolerant hamiltonian* (resp. *k-edge-fault-tolerant hamiltonian connected*) graph. Let $F \subseteq V(G) \cup E(G)$. If $G-F$ remains hamiltonian (resp. hamiltonian connected) for any F with $|F| \leq k$, then G is a *k-fault-tolerant hamiltonian* (resp. *k-fault-tolerant hamiltonian connected*) graph.

Two *cycles* C_1=$\langle u(1), u(2), ..., u(m), u(1)\rangle$ and C_2=$\langle v(1), v(2), ..., v(m), v(1)\rangle$ beginning at s in a graph G are *independent* if $u(1) = v(1) = s$

and $u(i) \neq v(i)$ for $2 \leq i \leq m$. Cycles beginning at s with the same length are *mutually independent* if every two different cycles are independent. A graph G is said to contain n *mutually independent hamiltonian cycles* if there exist n hamiltonian cycles in G beginning at any vertex s such that the n cycles are mutually independent.

Let $\langle n \rangle = \{1, 2, 3, ..., n\}$ and $p = p_1 p_2 ... p_k$ be a permutation of k elements in $\langle n \rangle$, where $n \geq k$. The n-dimensional arrangement graph, denoted by $A_{n,k}$, is the graph with the vertex set $V(A_{n,k})$={$p | p_i \in \langle n \rangle$ for $1 \leq i \leq k$ and $p_i \neq p_j$ if $i \neq j$}, and the edge set $E(A_{n,k})$={$(p,q) | p, q \in V(A_{n,k})$ such that $p_i \neq q_i$ and $p_j = q_j$ for all $j \neq i$ for some $i \in \langle k \rangle$}. Thus (p, q) is an edge if and only if there exists some $i \in \langle k \rangle$ such that $p_i \neq q_i$ and $p_j = q_j$ for all $j \neq i$. The k-bit label, $p_1 p_2 ... p_k$, of each vertex of $A_{n,k}$ is called the *vertex id*. See Figure 1 for an illustration.

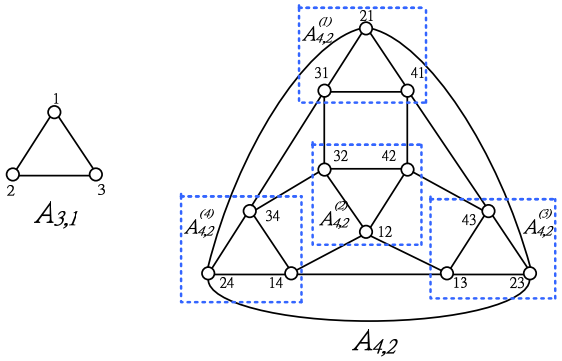

Fig. 1: The arrangement graph $A_{3,1}$ and $A_{4,2}$.

Note that each vertex of $A_{n,k}$ is represented by a k-bit sequence. In [9], it is known that $A_{n,k}$ can be decomposed into n subgraphs $A_{n-1,k-1}$ by fixing each different vertex id on one particular position among $\{1, 2..., k\}$. Without loss of generality, we partition $A_{n,k}$ into n subgraphs $A_{n-1,k-1}$, denoted by $A^{(1)}_{n,k}, A^{(2)}_{n,k}, ..., A^{(n)}_{n,k}$, by letting all vertices of $A^{(i)}_{n,k}$ with the rightmost bit being i. For example, $A_{4,2}$ consists of four copies of $A_{3,1}$. An illustration is given in Figure 1. Repeating the partitioning process, it is obvious that $A_{n,k}$ consists of $n!/(n-k+1)!$ copies of $A_{n-k+1,1}$.

Let $p = p_1 p_2 ... p_k \in V(A_{n,k})$. Note that $A^{(n)}_{n,k}$ is isomorphic to $A_{n-1,k-1}$. Moreover, it is easy to see that the k-bit id's of all vertices of $A^{(n)}_{n,k}$ can be obtained by adding one bit, the number n, to the rightmost of the $(k-1)$-bit id's of all vertices in $A_{n-1,k-1}$. That is, $\mathbf{p}n = p_1 p_2 \cdots p_{k-1} n$ is a vertex in $A^{(n)}_{n,k}$ if $\mathbf{p} = p_1 p_2 \cdots p_{k-1} \in V(A_{n-1,k-1})$.

The following proposition is an immediate consequence of the above.

Proposition 1: Let $\mathbf{u_i} \in V(A_{n-1,k-1})$ for $1 \leq \mathbf{i} \leq m$. If $\langle \mathbf{u_1}, \mathbf{u_2}, \cdots, \mathbf{u_t}, \mathbf{u_{t+1}}, \cdots, \mathbf{u_m} \rangle$ is a path of $A_{n-1,k-1}$ that passes the edge $(\mathbf{u_t}, \mathbf{u_{t+1}})$, then $\langle \mathbf{u_1}n, \mathbf{u_2}n, \cdots, \mathbf{u_t}n, \mathbf{u_{t+1}}n, \cdots, \mathbf{u_m}n \rangle$ is a path of $A^{(n)}_{n,k}$ that passes the edge $(\mathbf{u_t}n, \mathbf{u_{t+1}}n)$.

The following two propositions will be useful in our derivation.

Proposition 2: [7] Let n≥5. For $1 \leq i, j \leq n$ and $i \neq j$, the number of edges between $A^{(i)}_{n,k}$ and $A^{(j)}_{n,k}$, denoted by $|E^{i,j}_n|$, is $(n-2)!/(n-k-1)!$.

Proposition 3: [7] For positive integers n, k with $n - k \geq 2$, $A_{n,k}$ is $(k(n-k)-3)$-fault-tolerant hamiltonian connected.

3. Main Result

We will construct the $k(n-k)$ MIHCs for $A_{n,k}$ using mathematical induction. Based on the fact that $A_{n,k}$ consists of n copies of $A_{n-1,k-1}$, we must ensure that $A_{n-k+1,1}$ contains $(n-k)$ MIHCs for $n-k+1 \geq 3$. It is obvious since $A_{n-k+1,1}$ is the complete graph K_{n-k+1}. For the base case in our induction, we shall show that $A_{n,2}$ contains $2(n-2)$ MIHCs, each of which passes a common edge, in Lemma 1 and Lemma 2. Since MIHCs for $A_{n,n-1}$ and $A_{n,n-2}$ were already derived [11], [14], we concentrate on MIHCs for $A_{n,k}$ with $n - k \geq 3$ and $k \geq 2$ in Theorem 2, which is our main theorem. Figure 2 is the flowchart of the outline of our derivation.

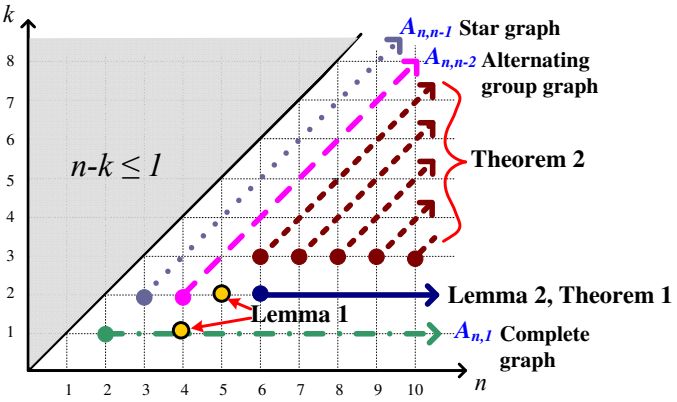

Fig. 2: Outline of the structure of lemmas and theorems in this paper.

To distinguish numbers and consecutive bits in a vertex id, we underline each bit in the vertex id should there be a possible confusion. Let $s \in V(A^{(n)}_{n,k})$ with the vertex id $s = \underline{n-k+1} \ldots \underline{n-1}\ \underline{n}$. We will show that $A_{n,k}$ contains $k(n-k)$ MIHCs. This is the maximum number of MIHCs that can be constructed on $A_{n,k}$ since any vertex in $A_{n,k}$ has exactly $k(n-k)$ neighbors. To show that $A_{n,k}$ contains $k(n-k)$ MIHCs, we construct these MIHCs beginning at any vertex u in $A_{n,k}$. Without loss of generality, let $u = s$.

Lemma 1: (1)There exist three MIHCs in $A_{4,1}$. (2)There exist six MIHCs in $A_{5,2}$, denoted by C_i, $for\ 1 \le i \le 6$, such that the edge $(21, 31)$ belongs to C_i for all $1 \le i \le 6$.

Proof: Since $A_{4,1}$ is isomorphic to the complete graph K_4, it contains three MIHCs. To prove this lemma for $A_{5,2}$, we construct six MIHCs of $A_{5,2}$ that include the edge $(21, 31)$ below. Let

$C_1 = \langle 45, 15, 14, 24, 34, 54, 51, (21, 31), 41, 42, 12, 32, 52, 53, 13, 43, 23, 25, 35, 45\rangle$;

$C_2 = \langle 45, 25, 24, 34, 54, 14, 12, 32, 42, 52, 53, 13, 23, 43, 41, 51, (21, 31), 35, 15, 45\rangle$;

$C_3 = \langle 45, 35, 34, 54, 14, 24, 23, 53, 13, 43, 41, (21, 31), 51, 52, 32, 42, 12, 15, 25, 45\rangle$;

$C_4 = \langle 45, 41, 51, (21, 31), 34, 24, 14, 54, 52, 42, 32, 12, 15, 35, 25, 23, 53, 13, 43, 45\rangle$;

$C_5 = \langle 45, 42, 52, 32, 12, 13, 53, 43, 23, 25, 15, 35, 34, 14, 24, 54, 51, (21, 31), 41, 45\rangle$;

$C_6 = \langle 45, 43, 53, 23, 13, 15, 35, 25, 24, 34, 14, 54, 51, 41, (21, 31), 32, 52, 12, 42, 45\rangle$.

Note that we add a parentheses on the required edge in C_i $for\ 1 \le i \le 6$. $\{C_i | 1 \le i \le 6\}$ are the six MIHCs in $A_{5,2}$ required by the lemma. ■

We know that $A^{(i_1)}_{n,k}$ is a subgraph of $A_{n,k}$ in which the rightmost bit of the vertex id of any vertex of $A^{(i_1)}_{n,k}$ is i_1. $A^{(i_2 i_1)}_{n,k}$ denotes a subgraph of $A^{(i_1)}_{n,k}$ in which the rightmost two bits of the vertex id of any vertex of $A^{(i_2 i_1)}_{n,k}$ is $i_2 i_1$. In fact, any vertex $i_k i_{k-1} ... i_2 i_1$ in $A_{n,k}$ can be identified as a vertex in the smallest subgraph $A^{(i_{k-1} ... i_2 i_1)}_{n,k}$. For example, 321 is a vertex in $A_{6,3}$ and it belongs to the smallest subgraph $A^{(21)}_{6,3}$. Note that $A^{(21)}_{6,3}$ is isomorphic to $A_{4,1} = K_4$.

Note that $s = \underline{n-k+1} \ldots \underline{n-1}\ \underline{n}$. In the following lemmas and theorems, s is the first (and the last) vertex of all hamiltonian cycles. For $1 \le i \le (k-1)(n-k)$, we define C^I_i as the ith hamiltonian cycle whose second vertex belongs to $A^{(n)}_{n,k}$. For $1 \le i \le (n-k)$, we define $C^O_{i+(k-1)(n-k)}$ as the $(i + (k-1)(n-k))$-th hamiltonian cycle whose second vertex is in $A^{(i)}_{n,k}$, where $i \ne n$.

In the following, we define a new symbol $[r]_n \equiv (r\ mod\ n) + 1$, where $(r \bmod n)$ denotes the remainder of n dividing r.

Lemma 2: For $n \ge 6$, there are $2(n-2)$ MIHCs in $A_{n,2}$, denoted by C_i $for\ 1 \le i \le\ 2(n-2)$, such that the edge $(21, 31)$ belongs to C_i, for all i.

Proof: Note that any vertex $u \in A_{n,2}$ is labeled by $u = u_1 u_2$. Let $n \ge 6$, we construct $2(n-2)$ MIHCs beginning at $\underline{n-1}\ \underline{n}$, denoted by $\{C_i | 1 \le i \le 2(n-2)\}$, which consists of $\{C^I_i |\ 1 \le i \le (n-2)\}$ and $\{C^O_{i+(n-2)} |\ 1 \le i \le n-2\}$.

Let $\overrightarrow{c} = (1, 2, ..., n-2)$ be a $(n-2)$-dimensional vector, $\overrightarrow{d} = (1, 2, ..., n-2, n)$ be a $(n-1)$-dimensional vector, and $c(i)$(resp. $d(i)$) denote the ith element of $\overrightarrow{c}$ (resp. $\overrightarrow{d}$). Let $P^{n-1}_i = \langle \underline{d([1+(i-2)]_{n-1})}\ \underline{n-1}, \underline{d([2+(i-2)]_{n-1})}\ \underline{n-1}, \cdots, \underline{d([(n-1)+(i-2)]_{n-1})}\ \underline{n-1}\rangle$, where P^{n-1}_i is the ith path in the subgraph $A^{(n-1)}_{n,2}$. By Proposition 2, for distinct integers i and j with $1 \le i, j \le n$, $|E^{i,j}_n| = n-2$. We choose distinct vertices $a^i, b^i \in A^{(i)}_{n,2}$, such that $\{(b^i, a^j) | 1 \le i, j \le n,\ i \ne j\} \subseteq E(A_{n,2})$ and $|\{a^1, b^1\} \cap \{21, 31\}| \le 1$. By Proposition 3, $A^{(i)}_{n,2}$, is $(2n-7)$-fault-tolerant hamiltonian connected for any $1 \le i \le n$. Thus for $1 \le i \le n-1$, there exists a hamiltonian path P^i of $A^{(i)}_{n,2}$ between a^i and b^i. Since $A^{(1)}_{n,2}$ is isomorphic to K_{n-1}, there exists a hamiltonian path P^1 between a^1 and b^1 on $A^{(1)}_{n,2}$, such that the edge $(21, 31)$ lies on P^1. For $i = 1, 2, ..., (n-2)$, we construct $(n-2)$ MIHCs as follow:

$$
\begin{aligned}
C^I_i = \langle & \underline{n-1}\ \underline{n},\ \underline{c([1+(i-2)]_{n-2})}\ \underline{n}, \\
& \underline{d([1+(i-2)]_{n-2})}\ \underline{n-1},\ P^{n-1}_i, \\
& \underline{d([(n-1)+(i-2)]_{n-1})}\ \underline{n-1}, \\
& \underline{d([(n-1)+(i-2)]_{n-1})}\ \underline{c([1+(i-2)]_{n-2})}, \\
& P^{c([1+(i-2)]_{n-2})}, b^{c([1+(i-2)]_{n-2})}, a^{c([2+(i-2)]_{n-2})}, \\
& P^{c([2+(i-2)]_{n-2})}, b^{c([2+(i-2)]_{n-2})}, \cdots, \\
& a^{c([(n-2)+(i-2)]_{n-2})}, P^{c([(n-2)+(i-2)]_{n-2})}, \\
& \underline{c([2+(i-2)]_{n-2})}\ \underline{c([(n-2)+(i-2)]_{n-2})}, \\
& \underline{c([2+(i-2)]_{n-2})}\ \underline{n}, \underline{c([3+(i-2)]_{n-2})}\ \underline{n}, \cdots, \\
& \underline{c([(n-2)+(i-2)]_{n-2})}\ \underline{n}, \underline{n-1}\ \underline{n}\rangle.
\end{aligned}
$$

Then we construct the other $(n-2)$ MIHCs as follows. By Proposition 2, for distinct integers i and j with $1 \le i, j \le n$, $|E^{i,j}_n| = n-2$. We choose $v^{c(1)} = \underline{d(n-2)}\ \underline{c(1)}$ so that the $(n+1)$th vertex $\underline{d(n-2)}\ \underline{n-1}$ of $C^O_{1+(n-2)}$ never collides with C^I_i, and distinct vertices $u^i, v^i \in A^{(i)}_{n,2}$ such that $\{(v^i, u^j) | 1 \le i, j \le n,\ i \ne j\} \subseteq E(A_{n,2})$ and $|\{u^1, v^1\} \cap \{21, 31\}| \le 1$. By Proposition 3, $A^{(i)}_{n,2}$, is $(2n-7)$-fault-tolerant hamiltonian connected for any $1 \le i \le n$. Thus there exists a hamiltonian path Q^i of $A^{(i)}_{n,2}$ between u^i and v^i for $1 \le i \le n-1$, and a hamiltonian path Q^n of $A^{(n)}_{n,2} - \{s\}$ between u^n and v^n. Since $A^{(1)}_{n,2}$ is isomorphic to K_{n-1}, there exists a hamiltonian path Q^1 between u^1 and v^1 on $A^{(1)}_{n,2}$ such that the edge $e = (21, 31)$ lies on Q^1. For $1 \le i \le (n-2)$, we define

$$C^O_{1+(n-2)} = \langle \underline{n-1}\ \underline{n}, \underline{n-1}\ \underline{c(1)}, Q^{c(1)}, \underline{d(n-2)}\ \underline{c(1)},$$
$$\underline{d(n-2)}\ \underline{n-1}, Q^{n-1}, v^{n-1}, u^{c(2)}, Q^{c(2)}, v^{c(2)},$$
$$\cdots, v^{c(n-3)}, u^n, Q^n, v^n, u^{c(n-2)}, Q^{c(n-2)},$$
$$\underline{n-1}\ \underline{c(n-2)}, \underline{n-1}\ \underline{n}\rangle.$$

For $i = 2, ..., (n-2)$, we set:

$$C^O_{i+(n-2)} = \langle \underline{n-1}\ \underline{n}, \underline{n-1}\ \underline{c([1+(i-2)]_{n-2})},$$
$$Q^{c([1+(i-2)]_{n-2})}, v^{c([1+(i-2)]_{n-2})}, \cdots,$$
$$u^{c([(n-i-1)+(i-2)]_{n-2})}, Q^{c([(n-i-1)+(i-2)]_{n-2})},$$
$$v^{c([(n-i-1)+(i-2)]_{n-2})}, u^n, Q^n, v^n, u^{n-1}, Q^{n-1},$$
$$v^{n-1}, u^{c([(n-i)+(i-2)]_{n-2})}, Q^{c([(n-i)+(i-2)]_{n-2})},$$
$$v^{c([(n-i)+(i-2)]_{n-2})}, \cdots, u^{c([(n-2)+(i-2)]_{n-2})},$$
$$Q^{c([(n-2)+(i-2)]_{n-2})},$$
$$\underline{n-1}\ \underline{c([(n-2)+(i-1)]_{n-2})}, \underline{n-1}\ \underline{n}\rangle.$$

In the construction of $C^O_{i+(n-2)}$ above, Q^j denotes a hamiltonian path between u^j and v^j in $A^{(j)}_{n,k}$, where j is a function of i. Thus even in the same $A^{(j)}_{n,k}$, we pick different u^j and v^j for $C^O_{i+(n-2)}$ as i is different. The lemma has been proved. ■

For instance, we construct the eight MIHCs of $A_{6,2}$ with the above algorithm. Let $\overrightarrow{c} = (1,2,3,4)$, $\overrightarrow{d} = (1,2,3,4,6)$, and $c(i)$(resp. $d(i)$) denote the ith element of $\overrightarrow{c}$ (resp. $\overrightarrow{d}$). Let P^5_i=$\langle d([i-1]_5)\ \underline{5}, d([i]_5)\ \underline{5}, \cdots, \underline{d([i+3]_5)}\ \underline{5}\rangle$ for $1 \le i \le 4$. For $i = 1,2,3,4$, C^I_i and C^O_{i+4} are illustrated in Figure 3 and Figure 4, respectively.

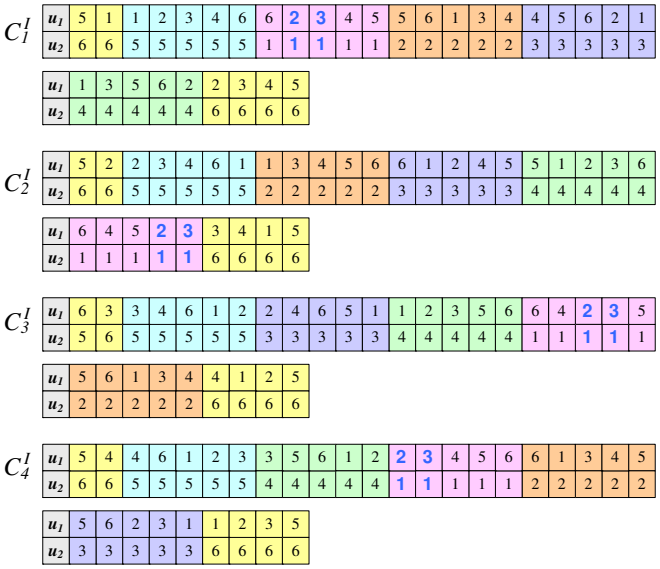

Fig. 3: An illustration of C^I_i in $A_{6,2}$.

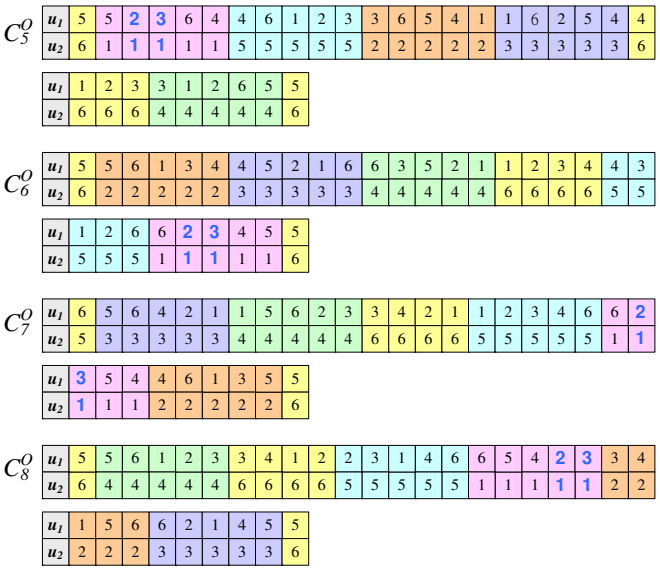

Fig. 4: An illustration of C^O_i in $A_{6,2}$.

With Lemma 1 and Lemma 2, we have the following theorem.

Theorem 1: For $n \ge 5$, there are $2(n-2)$ MIHCs in the arrangement graphs $A_{n,2}$.

Lemma 3: Let $n \ge 6$, $n-k \ge 2$ and $k \ge 3$. Given four vertices $\mathbf{u}i_2i_1$, $\mathbf{v}i_ni_1$, $\mathbf{a}i_3i_1$ and $\mathbf{b}i_3i_1$ of $A^{(i_1)}_{n,k}$, where i_2, i_3 and i_n are three distinct integers such that $\mathbf{u}i_2i_1 \in V(A^{(i_2i_1)}_{n,k})$ $\mathbf{v}i_ni_1 \in V(A^{(i_ni_1)}_{n,k})$ and ($\mathbf{a}i_3i_1$,$\mathbf{b}i_3i_1$)$\in E(A^{(i_3i_1)}_{n,k})$. Then the following two statements are true. (1) In $A^{(i_1)}_{n,k} \backslash A^{(i_2i_1)}_{n,k} \backslash A^{(i_3i_1)}_{n,k}$, there exists a hamiltonian path between $\mathbf{v}i_ni_1$ and any vertex $\mathbf{d}i_4i_1 \in V(A^{(i_4i_1)}_{n,k})$, $i_4 \notin \{i_2, i_3, i_n\}$. (2) There exists a hamiltonian path between $\mathbf{u}i_2i_1$ and $\mathbf{v}i_ni_1$ on $A^{(i_1)}_{n,k}$ passing through the assigned edge ($\mathbf{a}i_3i_1$,$\mathbf{b}i_3i_1$).

Proof: (1) By Proposition 2, for distinct integers i and j with $i, j \in \langle n\rangle \backslash \{i_1\}$, there exist $(n-3)!/(n-k-1)!$ edges between $A^{(ii_1)}_{n,k}$ and $A^{(ji_1)}_{n,k}$. By Proposition 3, $A^{(ii_1)}_{n,k}$ is hamiltonian connected for any $i \in \langle n\rangle \backslash \{i_1\}$. Let $\{i_4, i_5, ..., i_n\} = \langle n\rangle \backslash \{i_1, i_2, i_3\}$, $u^{i_4i_1}$=$\mathbf{d}i_4i_1$ and $v^{i_ni_1}$=$\mathbf{v}i_ni_1$. We choose distinct vertices $u^{i_ji_1} \in A^{(i_1)}_{n,k}$ for $5 \le j \le n$ and $v^{i_ji_1} \in A^{(i_1)}_{n,k}$ for $4 \le j \le n-1$, such that $\{(v^{i_ji_1}, u^{i_{j+1}i_1}) | 4 \le j \le n-1\} \subseteq E(A^{(i_1)}_{n,k})$. There exists a hamiltonian path $P^{i_ji_1}$ on $A^{(i_ji_1)}_{n,k}$ between $u^{i_ji_1}$ and $v^{i_ji_1}$ for any $4 \le j \le n$. We can construct a hamiltonian path on $A^{(i_1)}_{n,k} \backslash A^{(i_2i_1)}_{n,k} \backslash A^{(i_3i_1)}_{n,k}$ between $u^{i_4i_1}$ and $v^{i_ni_1}$ as $P^{i_1}_2 = \langle u^{i_4i_1}, P^{i_4i_1}, v^{i_4i_1}, u^{i_5i_1}, P^{i_5i_1}, v^{i_5i_1}, \cdots, u^{i_ni_1}, P^{i_ni_1}, v^{i_ni_1}, \rangle$. Thus there exists a hamiltonian path between $\mathbf{d}i_4i_1$ and $\mathbf{v}i_ni_1$ on $A^{(i_1)}_{n,k} \backslash A^{(i_2i_1)}_{n,k} \backslash A^{(i_3i_1)}_{n,k}$. See Figure 5 for an illustration.

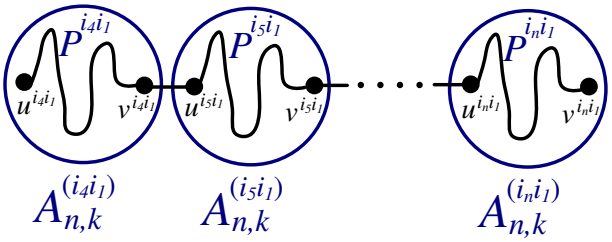

Fig. 5: An illustration of Lemma 3 (1).

(2) By Proposition 3, there exists a hamiltonian path between $\mathbf{a}i_3i_1$, $\mathbf{b}i_3i_1$ on $A^{(i_3i_1)}_{n,k}$. We set $P^{i_3i_1} = \langle \mathbf{a}i_3i_1, Q_1^{i_3i_1}, \mathbf{c}i_3i_1, \mathbf{d}i_3i_1, Q_2^{i_3i_1}, \mathbf{b}i_3i_1 \rangle$, where $(\mathbf{c}i_3i_1, \mathbf{c}i_2i_1)$, $(\mathbf{d}i_3i_1, \mathbf{d}i_4i_1) \in E(A^{(i_1)}_{n,k})$ and $\mathbf{c}i_2i_1 \neq \mathbf{u}i_2i_1$. There exists a hamiltonian path $\langle \mathbf{u}i_2i_1, P^{i_2i_1}, \mathbf{c}i_2i_1 \rangle$ on $A^{(i_2i_1)}_{n,k}$. By (1), there exists a hamiltonian path $\langle \mathbf{d}i_4i_1, P_2^{i_1}, \mathbf{v}i_ni_1 \rangle$ on $A^{(i_1)}_{n,k} \backslash A^{(i_2i_1)}_{n,k} \backslash A^{(i_3i_1)}_{n,k}$ also. So there exists a hamiltonian path $\langle \mathbf{u}i_2i_1, P^{i_2i_1}, \mathbf{c}i_2i_1, \mathbf{c}i_3i_1, (Q_1^{i_3i_1})^{-1}, \underline{\mathbf{a}i_3i_1}, \underline{\mathbf{b}i_3i_1}, (Q_2^{i_3i_1})^{-1}, \mathbf{d}i_3i_1, \mathbf{d}i_4i_1, P_2^{i_1}, \mathbf{v}i_ni_1 \rangle$ on $A^{(i_1)}_{n,k}$. See Figure 6 for an illustration. ■

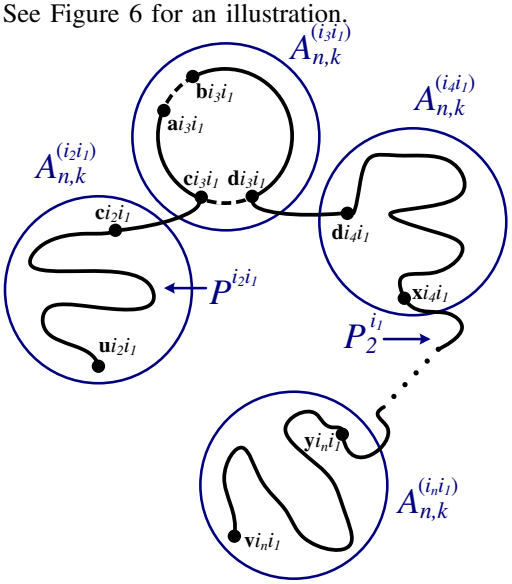

Fig. 6: An illustration of Lemma 3 (2).

Theorem 2: For $n \geq 5$, $k \geq 2$, $n - k \geq 3$, there exist $k(n-k)$ MIHCs in $A_{n,k}$, denoted by $C_1, C_2, ..., C_{k(n-k)}$, such that the edge $(\ \underline{k}\ \underline{k-1}\ \underline{k-2}\ \cdots\ \underline{1},\ \underline{k+1}\ \underline{k-1}\ \underline{k-2}\ \cdots\ \underline{1}\ )$ lies on each cycle C_i for $1 \leq i \leq k(n-k)$.

Proof: We prove this theorem by mathematical induction. By Theorem 1, the statement holds when $k = 2$. With the induction hypothesis, we assume that this theorem is true for $A_{n-1,k-1}$, where n is an integer and k is an integer with $3 \leq k \leq n-3$. It suffices to show that the statement holds for $A_{n,k}$. We first construct $(k-1)(n-k)$ MIHCs in $A_{n,k}$, denoted by $C_1^I, C_2^I, ..., C_{(k-1)(n-k)}^I$, such that the edge $(\ \underline{k}\ \underline{k-1}\ \underline{k-2}\ \cdots\ \underline{1},\ \underline{k+1}\ \underline{k-1}\ \underline{k-2}\ \cdots\ \underline{1}\ )$ is on each cycle C_i^I for $1 \leq i \leq (k-1)(n-k)$ for $n \geq 6,\ 3 \leq k \leq n-2$.

By the induction hypothesis, this theorem holds for $A_{n-1,k-1}$. There exist $(k-1)(n-k)$ MIHCs in $A^{(n)}_{n,k}$, denoted by $C_1^{'}, C_2^{'}, \cdots, C_{(k-1)(n-k)}^{'}$, such that the edge $(\ \underline{k-1}\ \underline{k-2} \cdots \underline{1}\ \ \underline{n}, \underline{k}\ \ \underline{k-2}\ \cdots \underline{1}\ \ \underline{n}\ )$ belongs to $C_i^{'}$ for all $1 \leq i \leq (k-1)(n-k)$. Assume that $a^n = \underline{k-1}\ \underline{k-2} \cdots \underline{1}\ \underline{n}$ and $b^n = \underline{k}\ \underline{k-2}\ \cdots \underline{1}\ \underline{n}$. Obviously, (a^n, b^n) appears on the $(k-1)(n-k)$ MIHCs $C_1^{'}, C_2^{'}, \cdots, C_{(k-1)(n-k)}^{'}$ at different time-steps. Let $C_i^{'} = \langle s, D^n_{i,1}, a^n, b^n, D^n_{i,2}, s \rangle$ for $1 \leq i \leq (k-1)(n-k)$, where $D^n_{i,1}$ is a path of $A^{(n)}_{n,k}$ between s and a^n, $D^n_{i,2}$ is a path of $A^{(n)}_{n,k}$ between b^n and s, and $D^n_{i,1} \bigcup D^n_{i,2}$ covers $V(A^{(n)}_{n,k})$. By Proposition 2, for distinct integers i and j with $1 \leq i, j \leq n$, $|E^{i,j}_n| = (n-2)!/(n-k-1)!$. We choose distinct vertices $a^i, b^i \in A^{(i)}_{n,k}$ for $1 \leq i \leq n$, such that $(a^n, a^{n-1}), (b^{n-1}, a^1), (b^1, a^2), \cdots, (b^{n-3}, a^{n-2}), (b^{n-2}, b^n) \in E(A_{n,k})$. By Proposition 3, $A^{(i)}_{n,k}$, which is isomorphic to $A_{n-1,k-1}$, is $((k-1)(n-k)-3)$-fault-tolerant hamiltonian connected for any $1 \leq i \leq n$, and hence is hamiltonian connected. Thus for $2 \leq i \leq n-1$, there exists a hamiltonian path P^i of $A^{(i)}_{n,k}$ between a^i and b^i. With Lemma 3, there exists a hamiltonian path P^1 between a^1 and b^1 on $A^{(1)}_{n,k}$ such that the edge $(\ \underline{k}\ \underline{k-1}\ \underline{k-2}\ \cdots\ \underline{1},\ \underline{k+1}\ \underline{k-1}\ \underline{k-2}\ \cdots\ \underline{1}\ )$ lies on P^1. For $1 \leq i \leq (k-1)(n-k)$, let

$$C_i^I = \langle s, D^n_{i,1}, a^n, a^{n-1}, P^{n-1}, b^{n-1}, a^1, P^1, b^1, a^2, P^2, b^2, ..., a^{n-3}, P^{n-3}, b^{n-3}, a^{n-2}, P^{n-2}, b^{n-2}, b^n, D^n_{i,2}, s \rangle.$$

Now we construct the rest $(n-k)$ MIHCs, which we denote by $C^O_{i+(k-1)(n-k)}$ for $1 \leq i \leq n-k$. Our method for $C^O_{i+(k-1)(n-k)}$ works successfully for all n, k except for $n \equiv 1 (\mathrm{mod}\ k)$ and $n \equiv 2 (\mathrm{mod}\ k)$. When $n \equiv 1 (\mathrm{mod}\ k)$, if we follow the same rule for $C^O_{k(n-k)}$, then the vertex next to s (the starting vertex) will be in $A^{(n-1)}_{n,k}$, which is impossible. Besides, when $n \equiv 2 (\mathrm{mod}\ k)$, it is possible that $C^O_{k(n-k)-1}$ collides with any C_i^I. Thus we will construct $C^O_{k(n-k)-1}$ and $C^O_{k(n-k)}$ with a different rule. Let $\overrightarrow{e} = (1, 2, ..., n-1, n)$. Define $\overrightarrow{c} = (1, 2, ..., n-2, n, n-1)$ as a n-dimensional vector, which is constructed by switching the $(n-1)$th element and the nth element of $\overrightarrow{e}$; $\overrightarrow{d} = (1, 2, ..., n-k-1, n-1, n-k+1, ..., n-2, n, n-k)$ as a n-dimensional vector, which is constructed by switching the $(n-k)th$ element and nth element of $\overrightarrow{c}$. Let $c(i)$ (resp. $d(i)$) denote the ith element of $\overrightarrow{c}$ (resp. $\overrightarrow{d}$). By Proposition 2, for distinct integers i and j with $1 \leq i, j \leq n$, $|E^{i,j}_n| = (n-2)!/(n-k-1)!$. We choose distinct vertices $u^i, v^i \in A^{(i)}_{n,k}$, such that $\{(v^i, u^j) | 1 \leq i, j \leq n,\ i \neq j\} \subseteq E(A_{n,k})$ and $|\{u^1, v^1\} \cap \{\underline{k}\ \underline{k-1}\ \underline{k-2}\ \cdots\ \underline{1},\ \underline{k+1}\ \underline{k-1}\ \underline{k-2}\ \cdots\ \underline{1}\}| \leq 1$. By

Proposition 3, $A^{(i)}_{n,k}$, which is isomorphic to $A_{n-1,k-1}$, is $((k-1)(n-k)-3)$-fault-tolerant hamiltonian connected for any $1 \le i \le n$, and hence is hamiltonian connected. Thus there exists a hamiltonian path Q^i of $A^{(i)}_{n,k}$ between u^i and v^i for $1 \le i \le n-1$, and a hamiltonian path Q^n of $A^{(n)}_{n,k} - \{s\}$ between u^n and v^n. With Lemma 3, there exists a hamiltonian path Q^1 between u^1 and v^1 on $A^{(1)}_{n,k}$ such that the edge $(\ \underline{k}\ \underline{k-1}\ \underline{k-2}\ \cdots\ \underline{1},\ \underline{k+1}\ \underline{k-1}\ \underline{k-2}\ \cdots\ \underline{1}\ )$ lies on Q^1. For all n with $n \ge 6$ and for $1 \le i \le (n-k-2)$, let

$$\begin{aligned} C^O_{i+(k-1)(n-k)} = \langle s, & u^{c([1+i-2]_n)}, Q^{c([1+i-2]_n)}, v^{c([1+i-2]_n)}, \\ & u^{c([2+i-2]_n)}, Q^{c([2+i-2]_n)}, v^{c([2+i-2]_n)}, \cdots, \\ & u^{c([n+i-2]_n)}, Q^{c([n+i-2]_n)}, v^{c([n+i-2]_n)}, s\rangle \\ & \text{for } i \not\equiv 1 (\text{mod } k), \end{aligned}$$

or

$$\begin{aligned} C^O_{i+(k-1)(n-k)} = \langle s, & u^{d([1+i-2]_n)}, Q^{d([1+i-2]_n)}, v^{d([1+i-2]_n)}, \\ & u^{d([2+i-2]_n)}, Q^{d([2+i-2]_n)}, v^{d([2+i-2]_n)}, \cdots, \\ & u^{d([n+i-2]_n)}, Q^{d([n+i-2]_n)}, v^{d([n+i-2]_n)}, s\rangle, \\ & \text{for } i \equiv 1 (\text{mod } k). \end{aligned}$$

For $i = n-k-1$ and $i = n-k$, we have the following three cases.

Case 1. $n \not\equiv 1(\text{mod } k)$ *and* $n \not\equiv 2(\text{mod } k)$.
If $i = n-k-1$,

$$\begin{aligned} C^O_{k(n-k)-1} = \langle s, & u^{n-k-1}, Q^{n-k-1}, v^{n-k-1}, \cdots, u^{n-3}, \\ & Q^{n-3}, v^{n-3}, u^{n-2}, Q^{n-2}, v^{n-2}, u^n, Q^n, v^n, \\ & u^{n-1}, Q^{n-1}, v^{n-1}, u^1, Q^1, v^1, \cdots, u^{n-k-2}, \\ & Q^{n-k-2}, v^{n-k-2}, s\rangle. \end{aligned}$$

If $i = n-k$,

$$\begin{aligned} C^O_{k(n-k)} = \langle s, & u^{n-k}, Q^{n-k}, v^{n-k}, \cdots, u^{n-2}, Q^{n-2}, v^{n-2}, \\ & u^n, Q^n, v^n, u^{n-1}, Q^{n-1}, v^{n-1}, u^1, Q^1, v^1, u^2, \\ & Q^2, v^2, \cdots, u^{n-k-1}, Q^{n-k-1}, v^{n-k-1}, s\rangle. \end{aligned}$$

Case 2. $n \equiv 1(\text{mod } k)$.
If $i = n-k-1$,

$$\begin{aligned} C^O_{k(n-k)-1} = \langle s, & u^{n-k-1}, Q^{n-k-1}, v^{n-k-1}, u^n, Q^n, v^n, \\ & u^{n-k+1}, Q^{n-k+1}, v^{n-k+1}, u^{n-k+2}, Q^{n-k+2}, \\ & v^{n-k+2}, \cdots, u^{n-2}, Q^{n-2}, v^{n-2}, u^{n-k}, Q^{n-k}, \\ & v^{n-k}, u^{n-1}, Q^{n-1}, v^{n-1}, u^1, Q^1, v^1, u^2, Q^2, \\ & v^2, \cdots, u^{n-k-2}, Q^{n-k-2}, v^{n-k-2}, s\rangle. \end{aligned}$$

If $i = n-k$,

$$\begin{aligned} C^O_{k(n-k)} = \langle s, & u^{n-k}, Q^{n-k}, v^{n-k}, \cdots, u^n, Q^n, v^n, u^1, Q^1, \\ & v^1, \cdots, u^{n-k-1}, Q^{n-k-1}, v^{n-k-1}, s\rangle. \end{aligned}$$

Case 3. $n \equiv 2(\text{mod } k)$.
If $i = n-k-1$,

$$\begin{aligned} C^O_{k(n-k)-1} = \langle s, & u^{n-k-1}, Q^{n-k-1}, v^{n-k-1}, u^n, Q^n, v^n, \\ & u^{n-k+1}, Q^{n-k+1}, v^{n-k+1}, Q^{n-1}, v^{n-1}, \\ & u^{n-k+2}, Q^{n-k+2}, v^{n-k+2}, \cdots, u^{n-1}, u^{n-k}, \\ & Q^{n-k}, v^{n-k}, u^1, Q^1, v^1, u^2, Q^2, v^2, \cdots, \\ & u^{n-k-2}, Q^{n-k-2}, v^{n-k-2}, s\rangle. \end{aligned}$$

If $i = n-k$,

$$\begin{aligned} C^O_{k(n-k)} = \langle s, & u^{n-k}, Q^{n-k}, v^{n-k}, \cdots, u^n, Q^n, v^n, u^1, Q^1, \\ & v^1, \cdots, u^{n-k-1}, Q^{n-k-1}, v^{n-k-1}, s\rangle. \end{aligned}$$

By Case 1, Case 2, and Case 3, the proof is finished. ■

Readers can refer to [8] for concrete examples where the desired MIHCs are constructed using the algorithm in Theorem 2.

4. Conclusion

In this work, we showed that any $A_{n,k}$ contains $k(n-k)$ mutually independent hamiltonian cycles, where and $n-k \ge 3$, $k \ge 2$. The cycles are specifically constructed using the recursive structure of $A_{n,k}$ based on the fact that $A_{n,k}$ consists of n subgraphs, $A_{n-1,k-1}$. For the same topics on special arrangement graphs with $n-k=1$, $n-k=2$, the corresponding results are presented in [11] and [14], repectively. It is natural to explore the existence of mutually independent hamiltonian cycles on a given arrangement graph when any fault occurs. That is, given a set of faulty vertices/edges on an arrangement graph, how can we construct mutually independent hamiltonian cycles that include the most non-faulty vertices in any $A_{n,k}$? The answer to the question is interesting and a thorough study for such a problem on the alternating group graphs $(A_{n,n-2})$ or the star graphs $(A_{n,n-1})$ is surely a good start.

Acknowledgement

This paper adapted the thesis of C.-D. Lin [8] by rewriting the major lemma of the main theorem and correcting the redundancies.

Parallel LEACH Algorithm for Wireless Sensor Networks

Yi Zhu[1], Qingmei Yao[1], Glover George[2], Shaoen Wu[2], and Chaoyang Zhang[2]
School of Computing, University of Southern Mississippi, Hattiesburg, MS, U.S.A

Abstract - *Hierarchical-based protocols are some of the most popular routing schemes used in wireless sensor networks due to their favorable, energy-saving properties. However, when it comes to large-scale wireless sensor network applications, these algorithms suffer from an increase in computational complexity and latency. In this paper, a parallel algorithm for the hierarchical-based protocol has been designed based on the Low-Energy Adaptive Clustering Hierarchy (LEACH) algorithm in order to improve the routing efficiency of wireless sensor networks. This algorithm was implemented in parallel using the C programming language and mpich2, an implementation of the Message Passing Interface (MPI) specification. The routing algorithm was evaluated for large-scale sensor networks on both a shared memory supercomputer and two Linux Beowulf clusters. The results show that the parallel implementation of the hierarchical-based protocol improves the overall performance of the routing computations, while still maintaining high energy efficiency levels compared to previous hierarchical-based methods.*

Keywords: LEACH, parallel algorithm, wireless sensor networks, routing protocol

1 Introduction

In recent years, wireless sensor networks (WSNs) have been widely used in a variety of applications ranging from home and industry to civilian and military. Technological advances in electronics have enabled the development of small, low-cost wireless sensors with signal processing and communication capabilities that are used to sense various types of information among adjacent regions. These properties have made large-scale deployments of WSNs much more possible. Large-scale WSNs consist of base stations and hundreds or thousands of small sensors with sensing, computing and wireless communications capabilities. A greater number of sensors allow for monitoring physical and environmental conditions, such as temperature, barometric pressure, presences of smoke, etc., over much larger geographical regions with both finer accuracy and an increase in resiliency through better fault-tolerance. However, sensor nodes are powered by batteries, which are constrained by their limited energy supply. Therefore, an energy-efficient approach is highly desirable in order to extend the lifetime of the sensors in the WSN.

A variety of network routing protocols for WSNs have been proposed in the literature [1], such as the direct communication protocol, the minimum-transmission-energy multi-hop routing, and the clustering-based routing protocols. In the direct communication protocol, each sensor node sends collected data directly to the base station. If the base station is very far away from the sensor nodes this kind of communication will drain the power of sensor nodes quickly, significantly reducing the system lifetime. In minimum-transmission-energy (MTE) routing, sensor nodes route data to the base station in a multi-hop routing fashion via intermediate nodes. In this case, the intermediate nodes act as routers for other nodes, in addition to sensing the environment. The drawback of MTE routing is that the nodes nearest the base station will act as routers for the majority of data sent to the base station. Thus, the power of these nodes will be drained quickly, resulting in a cascading effect on the entire network and shortening the lifetime of the WSN.

LEACH [2] is one of the first clustering based protocols for sensor networks, and it has inspired many other hierarchical routing protocols [3, 4, 5, and 7]. Even now, it is still one of the most popular hierarchical routing algorithms for WSNs. It is a self-organizing, adaptive clustering protocol that forms clusters of sensor nodes based on the received signal strength and uses local cluster heads as routers to the base station. Since clusters and routing cluster heads are adaptive (cluster heads change in each round), and only the head of the cluster transmits data to the base station, this kind of approach can balance the energy usage among all of the sensors and save significant amounts of energy across the entire WSN, increasing the lifetime of the network.

However, in the case of large-scale sensor networks which consist of hundreds or thousands of nodes, the computational and communication costs of dynamic routing protocols such as LEACH are increased significantly, and it quickly becomes a significant obstacle to energy efficiency. The less time and energy spent on routing decisions, the more time we have available for data transmissions. This necessitates high-performance, parallel algorithms and techniques applied to routing protocols. Unfortunately, little work has been done in the design and development of parallel routing schemes for sensor networks. In this work, we develop a novel, parallel hierarchical-based routing protocol based on the LEACH algorithm for sensor networks to achieve high routing efficiency. This approach has been developed using the C programming language and mpich2. The routing algorithm was evaluated for large-scale sensor

networks on both a shared memory supercomputer and two Linux Beowulf clusters. The performance of our approach has been analysed and evaluated based on simulations of a radio propagation model and a circuit energy cost model. The simulations show that the parallel hierarchical-based routing protocol, as compared to previous-work in this field, can significantly improve the performance of routing without a loss of energy-efficient properties.

In this paper, we first give an introduction to the serial LEACH algorithm in Section 2. Parallel hierarchical-based routing design is given in Section 3. Section 4 mainly describes the implementation environment. Section 5 describes the simulation model. Performance Evaluations and Analysis are done in Section 6. Finally, we conclude our work in Section 7.

2 Serial Hierarchical-Based Routing Protocol

Hierarchical-based routing protocols cluster the nodes so that cluster heads with relatively high energy can collect data from other low energy nodes and transmit data to the base station. In this way, hierarchical-based routing is able to achieve the goals of energy savings and lifetime extension. LEACH is one of the first and the most popular hierarchical routing approaches for sensor networks. We choose it as our basic serial program. To better describe the parallel algorithm, we first briefly introduce the LEACH algorithm and then elaborate on the decomposition and task scheduling involved with designing parallel hierarchical-based routing.

The following description is the main idea behind the LEACH algorithm. Cluster heads change randomly over time in order to balance the energy consumption of the sensor nodes. The optimal percentage of nodes to be chosen as cluster heads is 5%. Each node will randomly choose a number between 0.0 and 1.0. If the number is less than some predefined threshold, the node is chosen to be a cluster head for the current round. The equation is as follows:

$$R(n) = \begin{cases} \frac{p}{1-p*(r \bmod \frac{1}{p})} & \text{if } n \in F \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

where p is the desired percentage of cluster heads, r is the current round, and F is the set of nodes which have not been chosen as cluster heads in the last 20 rounds. Each elected cluster head then broadcasts a message to the rest of the nodes in the network to notify them that they are the new cluster heads. After receiving the message, all non-cluster head nodes will chose the cluster with the closest cluster head and join the cluster. When the setup phase is stable, the sensor nodes can begin sensing and forwarding data to the cluster heads. The cluster heads receive data from each of the nodes in the cluster, aggregate this data, and subsequently send it to the base station. After a certain period of time, the network will go back into the setup phase, performing another round of choosing cluster heads, and then returning to the stable phase in which data transmission can occur. This process continues, until all of the nodes in the network have exhausted their energy supply.

There are three steps in one round of the serial LEACH algorithm.

STEP 1: Select heads

The head node selections are based on two requirements. If the node meets the two requirements, it will be selected as a head node.

The two requirements are:

1. Generate a random number uniformly from 0.0 to 1.0. If the random number is less than $R(n)$ as in formula (1), where p is the desired percentage of heads then we designate it as a head node. We set p as 0.05, and r is the current round.

2. The node has not been selected as a head node in the past 20 rounds.

STEP 2: Clustering

Check the distance from each node to each head node (based on received signal strength). Then choose the nearest head node as its cluster head. The number of clusters equals the number of head nodes.

STEP 3: Transmission

Every node in the cluster transmits data to its respective cluster head. Each cluster head then gathers and compresses all of the information and sends it to the base station.

3 Parallel Hierarchical-Based Routing

In the routing of large-scale sensor networks, which have hundreds or thousands of sensor nodes, the serial LEACH algorithm will have to go through every sensor node to select the heads of clusters and solve a large clustering problem. This can have a severe impact on the performance of a time sensitive routing procedure such as LEACH. Therefore, it is desirable to decompose the head selection and clustering tasks onto multiple processors, and have each processor perform a sub-task to improve the performance.

3.1 Data Decomposition

The initial data of every sensor node consists of four parts:

1. The location_coordinate.

2. The flag_head that indicates whether it is the head of the cluster.

3. The flag_head_log which indicates whether it is chosen to be a head in the last 20 rounds.

4. The flag_cluster indicating which cluster it belongs to.

These data are gathered in an array, where each element has four attributes as described above. The input data array is partitioned into equal-size sub-arrays, which are sent to each processor. Figure 1 shows the data decomposition scheme.

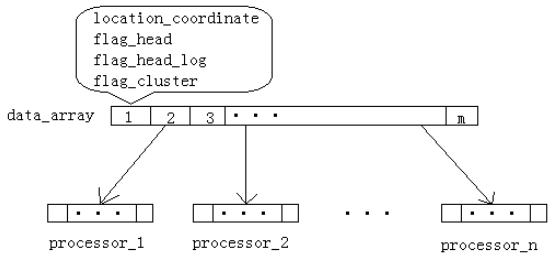

Figure 1. Data decomposition scheme

3.2 Task Dependency

The two main tasks in each round are head selection and clustering. Head selection is an independent task but clustering highly depends on the results of head selection, which can be illustrated by the analysis of the requirements and results of the two tasks. The head selection procedure requires the data array, but not necessarily the entire data array, because it does not depend on other sensors whether a sensor will be selected to be a head or not. In other words, it does not depend on other elements of the data array. Results of head selection are stored in the flag_head attribute of the data array. The clustering procedure requires all the results of head selection, since it has to check the distance from each sensor node to each head in order to determine which head is the closest one. The results of clustering are stored in flag_ cluster in the data array. The two main tasks are summarized as follows:

Head Selection Task:

Requirements: Partial data array, not necessarily the entire data array
Results: The decisions about which sensors are heads
Task dependency: Selection is an independent task

Clustering Task:

Requirements: All the results of head selection task
Results: The decisions about which head or cluster it belongs to.
Task dependency: Clustering highly depends on the results of head selection.

3.3 Parallel LEACH Algorithm Design

STEP 1: Data Decomposition

Assume there are *n* sensor nodes, data array (*data_array (i), i = 1, 2… n*) and p processors. The data array with length n is partitioned into *p* sub_arrays with equal length *n/p (sub_array(j,i), j = 1,2,...,p i = 1,2,..., n/p)*. The sub-arrays are scattered to each of the *p* processors.

STEP 2: Head Selection

Each processor selects head nodes from its own local sub-array according to the same selection process as defined in the serial implementation of LEACH, and save the result in the flag_head attribute of the local sub-array. We must also record the history of whether it has been chosen as a head node in the flag_head_log.

For each processor
If every element in flag_head_log is 0
Generate a random number r from [0.0, 1.0] uniformly.
R：= 0.05/ (1-0.05(r mod 20))
If R<threshold
flag_head = 1
flag_head_log for current round = 1
Else
flag_head = 0

STEP 3: Gather and Update data_array

Gather all the local sub-arrays from each processor into the data_array. Then scatter the data_array to every processor. At this step, each parallel task holds the information of all head nodes.

STEP 4: Clustering

Each processor completes the clustering task on their own local sub-arrays based on the information of all head nodes. The results are stored in flag_cluster.

For each node in sub-arrays
Calculate the distance between itself and every head node
Choose the head node with minimum distance
This node belongs to the cluster of this head
flag_cluster = cluster_index

STEP 5: Gather All Results and Go to the Next Round

Gather all the local sub-arrays from each processor into the global data array. Then go to STEP 1 to repeat the above steps.

4 Parallel Implementation Environment

LEACH was first simulated in serial by Wendi, et al using Matlab. Our parallel approach was implemented using the C programming language and the mpich2 implementation of MPI. The Simulations were conducted on two platforms available to students of the University of Southern Mississippi (USM). One is the Albacore cluster which is the primary HPC cluster in the School of Computing at USM [6]. The cluster consists of 256 processor cores, 300GB of RAM and 1Gbit Ethernet interconnects. Albacore is a hybrid, distributed-shared memory cluster, consisting primarily of Intel Xeon 56xx processors, Intel Xeon 55xx processors. The second platform available to our research group was Sequoia, an HPC Linux cluster at the University of Mississippi's Center for

Super Computing Research (MCSR) [8]. Sequoia is a hybrid, distributed-shared memory system, consisting of. 84 compute nodes, 22 Altix XE 310, 24 Altix 320 and 38 Rackable computing nodes. The overall memory of Sequoia is 2.1 TB.

5 Simulation Model

In this section, we describe the simulation model used for performance analysis of our parallel implementation. In order to maintain a similar comparison, the same simulation model is used for both the serial and parallel implementations. The environment configuration and energy cost model for the sensor networks are described.

5.1 Environment Configuration

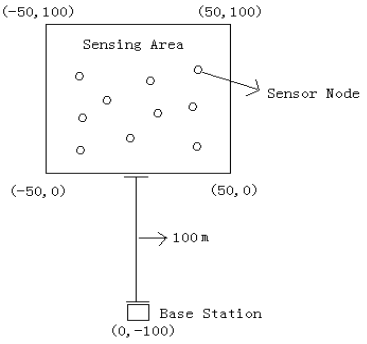

Figure 2 The coordinates of sensor areas and base station

The sensors are deployed uniformly in a 100-by-100 meter area. Figure 2 shows an example of a sensor area, along with its corresponding base station, along with coordinates. The base station is allocated 100 meters away from the sensing area, which is specifically at the location of (0, -100) in Figure2.

5.2 Energy Cost Model

The initial energy of each sensor node is 50J. In each round, every sensor node sends 2000 bits data. The energy cost of transmission consists of two parts:

1. The energy cost of transmitter and receiver circuit

$$E_{elec} = 50nJ / bit \qquad (2)$$

Every bit the circuit transmits and receives will cost 50nJ energy.

2. The energy loss of radio propagation

$$\varepsilon_{amp} = \frac{100\,pJ}{bit} / m^2 \qquad (3)$$

The energy loss of radio propagation is inversely proportional to the square of the distance it travels. In addition to this loss, the total energy consumed is also proportional to the number of bits transmitted.

The formulas of energy cost at both transmitter and receiver side are given below.

$$E_{Tx}(k,d) = E_{elec} * k + \varepsilon_{amp} * k * d^2 \qquad (4)$$

$$E_{Rx}(k) = E_{elec} * k \qquad (5)$$

E_{Tx} and E_{Rx} denote the energy cost at transmitter and receiver respectively. k is the number of bits transmitted.

6 Performance Evaluations and Analysis

6.1 System life time

The hierarchical-based routing protocol's main advantage is its high energy-efficiency, which supports a much longer system lifetime than other routing protocols. Therefore, the parallel hierarchical-based routing solution should reflect the same energy saving advantages as the serial algorithm. There are two important attributes that indicate the system stability and lifetime. One attribute is the number of head nodes in the sensor network at each round, as the energy cost of the network is highly dependent on the number and length, both distance and bit-wise, of the data transmissions. Since only the head nodes of the system do the majority of transmissions, it is important to keep track of how many of these are active at any time in the system. Although the nodes have data compression capability, the head nodes still have to transmit a relatively large amount of data, which is usually a long distance, energy consuming transmission. The other attribute is the number of sensor nodes at each round which have not exhausted their energy supply. The definition of system lifetime is the period of time that there is at least one live sensor node.

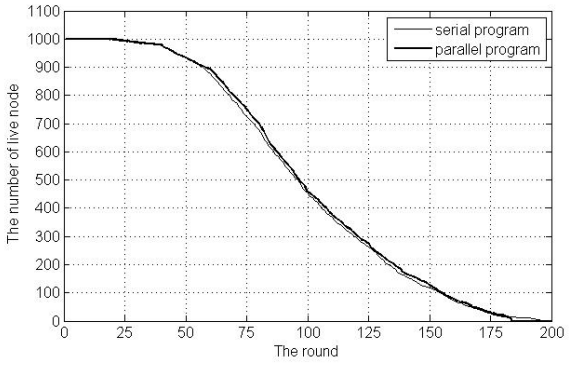

Figure 3 Number of live nodes in every round of both serial and parallel programs

Both the parallel and serial programs use the same header selection strategy, which involved a random procedure. Therefore the number of head nodes in each round can be slightly different, but the trend should be similar. In Figure 3, the number of live nodes decreases over time as the overall number of nodes decreases due to drained batteries. The variations in the number of live nodes between the serial and parallel plots are due

to the random selection of head nodes. However, the general trends of the two plots match well. In addition, the initial total energies of both the sensor networks are the same so that the lifetimes of system are the same, i.e. 200.

6.2 Performance Analysis

To evaluate the performance of our parallel hierarchical-based routing algorithm, the simulation method presented in Section 5 is employed. The parallel program was executed on Albacore and Sequoia separately using four different initial node counts (320, 640, 960 and 1280). The location and environmental conditions, including the initial energies of the sensors, were consistent across all simulation runs. The serial and parallel run times, denoted as T_p and T_s, are recorded from the experiment and shown in Tables 1 and 2, as well as in Figure 4 and 5. Derived variables used to analyse the performance are the speedup and efficiency [9, 10]. The speedup is defined as $S = T_s / T_p$; the efficiency is defined as S / p, where p is the number of processors. The reasons why the speedup and efficiency are chosen are that, for speedup, it delineates how much performance gain is achieved via parallel design over serial design; and for efficiency, it describes how much time spent on the computation, not on idle time or communication, for each processor.

Table 1: The execution times with different number of processors on Sequoia (*p* is the number of processors and column *N* is the data size)

	P=1	P=2	P=4	P=8	P=12
N=320	2.672	1.514	1.140	1.204	0.809

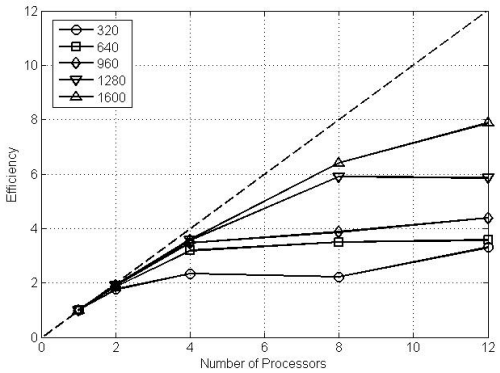

Figure 6 The speedup with different number of processors on Sequoia

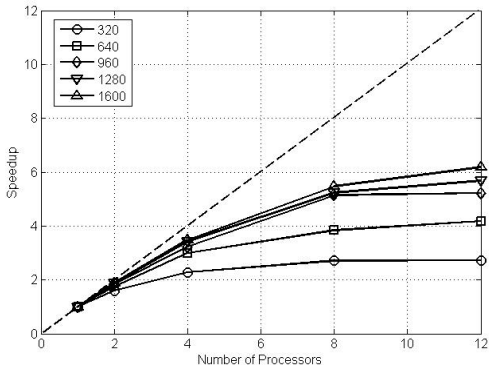

Figure 7 The speedup with different number of processors on Albacore

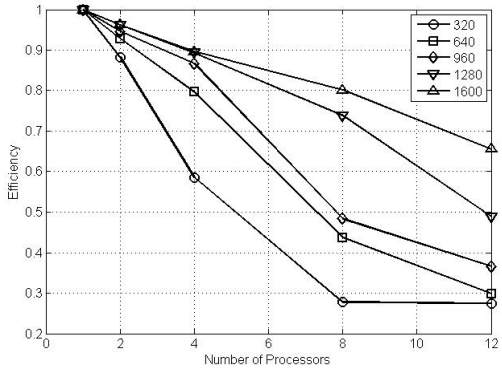

Figure 8. The efficiency with different number of processors Sequoia

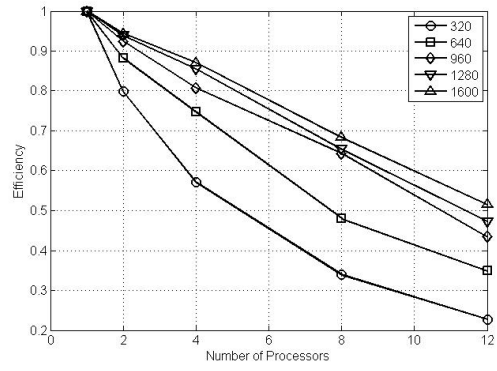

Figure 9 The efficiency with different number of processors Albacore

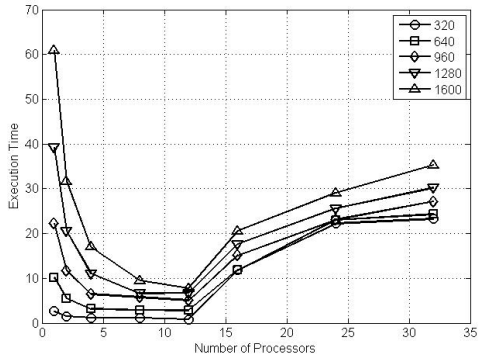

Figure 10 The execution with different number of processors on Sequoia (up to 32 processors)

From Figures 4 and 5, we can see that the execution time drops very fast for large problem size, for instance, 1280 and 1600. Nevertheless, when the number of processors is above 8, the decreasing of the execution time is less significant than that below 8. This is consistent with the speedup. Figures 6 and 7 show that, for different numbers of nodes, the speedup increases as the number of processors increases. However, the slope decreases, when the number of processor is over 8. The reason is that the communication time increases as the number of processors increases. Figures 8 and 9 show that the parallel LEACH algorithm have almost the same efficiency [11] on both Albacore and Sequoia systems. This is because these two systems have nearly identical specifications in memory and processors. Figure 10 shows that the execution time increases when the number of processors is greater than 12. This is due to the fact that both Sequoia and Albacore are hybrid, distributed-shared memory systems. Each node in the cluster consists of a single motherboard with dual-six core Intel Xeon 56xx class processors. Therefore, when executing this algorithm, the communication costs are negligible within a single node (where memory is shared), but cross-node communication costs, which occurs over 1Gbit Ethernet, is much higher than that within a single node.

7 Conclusion

The parallel hierarchical-based routing algorithm was designed and implemented in MPI based on the serial LEACH algorithm to achieve high performance routing. The task is partitioned and scheduled among all the available processors to improve the performance. The simulation results show that the high-performance computing techniques and parallel implementation can achieve a significant speedup while maintaining the energy-efficient properties of hierarchical-based routing protocols.

Koganei-shi, Tokyo, JAPAN

Abstract ***In this paper, we propose a new fault-tolerant routing algorithm for hypercube networks based on directed probabilities. The directed probabilities are obtained by improving the probabilities proposed by Al-Sadi et al. The probability represents ability of routing to any node at a specific distance. Each node selects one of its neighbor nodes to send a message by taking the probabilities into consideration. We also conducted a computer experiment to verify the effectiveness of our algorithms.***

Keywords: multicomputer, interconnection network, parallel processing, fault-tolerant routing, hypercube, performance evaluation

1 Introduction

Recently, large-scaled computation is required in many fields, and interests in researches on parallel processing are increasing. Among them, studies on massively parallel systems where many processors are connected to execute computation are eagerly conducted. With a progressive increase in the number of processors in the system, probability of existence of faulty processors increases. Hence, it is necessary for massively parallel systems to establish a fault-free routing path. Such path construction is formulated to be a fault-tolerant routing problem in graph theory mapping processors and links between them to nodes and edges, respectively.

In this study, we focused on hypercubes [8, 9], which have simple and recursive structure and low diameter, and provide interconnection networks suitable for massively parallel systems. Figure 1 shows an example of a 4-dimensional hypercube Q_4. In an interconnection network, if each node can collect information of all the faulty nodes, shortest-path routing between any pair of nodes is possible. However, this method asks each node to store information of all the faulty nodes, and it requires too much memory space. In addition, collection of such information takes too much time complexity for communication.

To solve the problem, there are many routing approaches based on restricted global information where each node stores some restricted information of faulty nodes and executes quasi-optimal routing [1, 2, 3, 4, 5, 6, 7, 10, 11]. The approach by Al-Sadi et al. [1] is one such approach. In their approach, each node calculates probability of unreachability by minimal paths to destination nodes with each Hamming distance, exchanges these probabilities with its neighbors, and routes based on these probabilities. Although, their approach attains high reachability in a hypercube with faulty nodes, we believe that there remains some room for improvement. Therefore, in this study, we introduce a notion of directed routing probability, and try to improve the approach by Al-Sadi et al.

The rest of this paper is structured as follows. First, we survey related works in Section

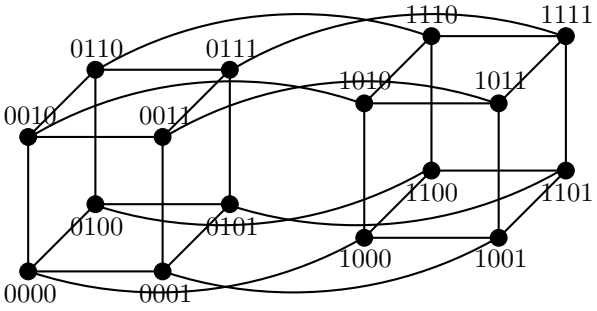

Figure 1: An example of 4-dimensional hypercube Q_4.

2. Next, requisite terminology and notations are defined in Section 3. Then, in Section 4, we introduce the algorithm proposed by Al-Sadi et al. We proposed a fault-tolerant routing algorithm that is obtained by improving the algorithm by Al-Sadi et al. in Section 5. The algorithm is evaluated by a computer experiment in Section 6. Finally, we give a conclusion and future works in Section 7.

2 Related Works

For these two decades, there are many attempts in research for fault-tolerant routing in hypercube networks. Chiu and Wu have proposed an efficient fault-tolerant routing algorithm by recursively classifying non-faulty nodes into safe, ordinary unsafe, and strongly unsafe nodes depending on the classification of neighbor nodes [5]. Chiu and Chen have improved the algorithm by introducing the routing capabilities that are obtained by classifying the safety nodes with respect to the Hamming distance to the destination nodes [6]. Wu has also proposed a similar fault-tolerant routing algorithm independently by introducing the safety vectors [10]. Moreover, Kaneko and Ito have proposed a fault-tolerant routing algorithm based on classification of ordinary and strongly unsafe nodes with respect to the Hamming distance as well as an efficient method to obtain classification of them [7].

All of the above attempts are based on information if a message is surely routed to the destination node or not. On the other hand, Al-Sadi et al. have proposed a fault-tolerant routing algorithm that is based on probabilities that a message is sent from the source node to the destination node with a path of length of Hamming distance between them [1, 2]. In the algorithm, each non-faulty node exchanges information at most $O(n^2)$ times with its neighbor nodes to calculate the probabilities with respect to the Hamming distances to destinations. However, there are several cases where the algorithm fails to find a fault-free path even if there is a such path.

3 Preliminaries

In this section, we define a hypercube network and introduce requisite notations.

Definition 1 An n-dimensional hypercube Q_n is an undirected graph, and Q_n consists of 2^n nodes. Each node $\boldsymbol{a}$ in Q_n is an n-bit sequence $(a_1, a_2, \ldots, a_n)$ where $a_i \in \{0, 1\}$ $(1 \leq i \leq n)$, and a_i is called the bit of i-th dimension. For two nodes $\boldsymbol{a}$ and $\boldsymbol{b}$ in Q_n, there is an edge $(\boldsymbol{a}, \boldsymbol{b})$ between them if and only if the Hamming distance between them $H(\boldsymbol{a}, \boldsymbol{b})$ is equal to 1. □

In general, a path in a graph is represented by an alternate sequence of nodes and edges $\boldsymbol{a}_1$, $(\boldsymbol{a}_1, \boldsymbol{a}_2)$, $\boldsymbol{a}_2$, …, $\boldsymbol{a}_{k-1}$, $(\boldsymbol{a}_{k-1}, \boldsymbol{a}_k)$, $\boldsymbol{a}_k$. The length of the path P is the number of edges included in the path, and it is denoted by $L(P)$. If Q_n is fault-free, the length of the shortest path between $\boldsymbol{a}$ and $\boldsymbol{b}$ is equal to $H(\boldsymbol{a}, \boldsymbol{b})$.

Definition 2 For a node $\boldsymbol{a}$ in Q_n, a set of nodes $N(\boldsymbol{a})$ defined by

$$N(\boldsymbol{a}) = \{\boldsymbol{n} \mid H(\boldsymbol{a}, \boldsymbol{n}) = 1\}.$$

is called a set of neighbor nodes of $\boldsymbol{a}$. □

The neighbor node of $\boldsymbol{a}$ that is obtained by changing the i-th bit $(1 \leq i \leq n)$ is denoted by $\boldsymbol{a}^{(i)}$ in the rest of paper.

In a hypercube Q_n with a set of faulty nodes F, for a source node $\boldsymbol{s}$ and a destination node $\boldsymbol{d}$

that are both non-faulty, a fault-tolerant routing algorithm finds a fault-free path between $\boldsymbol{s}$ and $\boldsymbol{d}$.

Definition 3 For two nodes $\boldsymbol{a}$ and $\boldsymbol{b}$ in Q_n, the set of preferred neighbor nodes of $\boldsymbol{a}$ for $\boldsymbol{b}$ is denoted by $N_0(\boldsymbol{a},\boldsymbol{b})$, and is defined by $N_0(\boldsymbol{a},\boldsymbol{b}) = \{\boldsymbol{n} \mid \boldsymbol{n} \in N(\boldsymbol{a}), H(\boldsymbol{n},\boldsymbol{b}) = H(\boldsymbol{a},\boldsymbol{b}) - 1\}$. In addition, the set of spare neighbor nodes of $\boldsymbol{a}$ for $\boldsymbol{b}$ is denoted by $N_1(\boldsymbol{a},\boldsymbol{b})$, and is defined by $N_1(\boldsymbol{a},\boldsymbol{b}) = \{\boldsymbol{n} \mid \boldsymbol{n} \in N(\boldsymbol{a}), H(\boldsymbol{n},\boldsymbol{b}) = H(\boldsymbol{a},\boldsymbol{b}) + 1\}$. □

Note that, in Q_n, the number of nodes that are apart from a node $\boldsymbol{a}$ by Hamming distance h is equal to ${}_nC_h$. Note also that, for two nodes $\boldsymbol{a}$ and $\boldsymbol{b}$ in Q_n, if $H(\boldsymbol{a},\boldsymbol{b}) = h$, then $|N_0(\boldsymbol{a},\boldsymbol{b})| = h$ holds.

4 Algorithm by Al-Sadi et al.

In this section, we give the idea of the algorithm by Al-Sadi et al. In their algorithm, for an arbitrary non faulty node $\boldsymbol{a}$ in an n-dimensional hypercube Q_n with a faulty node set F, an estimate value of the probability that there is not any fault-free minimal path from $\boldsymbol{a}$ to an arbitrary node $\boldsymbol{b}$ such that $H(\boldsymbol{a},\boldsymbol{b}) = h$ is calculated, and routing is executed based on the estimated values.

For simplicity of explanation, we use an estimate value of the probability that there is some fault-free path instead of the probability that there is not any fault-free path in our paper. In addition, we assume that F represents a faulty node set in Q_n in the rest of the paper.

$P_h(\boldsymbol{a})$ represents an estimate value of probability of existence of a fault-free minimal path from a fault-free node $\boldsymbol{a}$ to an arbitrary node at Hamming distance h from $\boldsymbol{a}$. $P_h(\boldsymbol{a})$ is defined recursively:

$$P_h(\boldsymbol{a}) = \begin{cases} |N(\boldsymbol{a}) \setminus F|/n & (h = 1) \\ 1 - \prod_{i=1}^{n}(1 - R_h(\boldsymbol{a}^{(i)})) & \\ \qquad (2 \le h \le n, \boldsymbol{a} \notin F) & \end{cases}$$

$$R_h(\boldsymbol{b}) = \begin{cases} 0 & (\boldsymbol{b} \in F) \\ hP_{h-1}(\boldsymbol{b})/n & (\boldsymbol{b} \notin F) \end{cases}$$

The estimate values of probabilities can be calculated by the algorithm shown in Figure 2.

```
function EVP(a, h, F)
begin
  if h = 1 then P_h(a) := |N(a) \ F| / n
  else begin
    P := 1;
    for i := 1 to n do begin
      if a^(i) ∈ F then R_h(a^(i)) := 0
      else R_h(a^(i)) := h × P_{h-1}(a^(i)) / n;
      P := P × (1 - R_h(a^(i)))
    end;
    P_h(a) := 1 - P
  end;
  return P_h(a)
end
```

Figure 2: Function to calculate estimate values of probabilities

Their routing algorithm `route` based on the estimate values of probabilities is shown in Figure 3. When a node $\boldsymbol{a}$ has to forward a message to its destination $\boldsymbol{d}$, the algorithm is used.

The algorithm first checks whether the current node $\boldsymbol{a}$ is the destination node $\boldsymbol{d}$ itself or not. If $\boldsymbol{a} = \boldsymbol{d}$, the message is delivered to $\boldsymbol{d}$ immediately. Otherwise, if $\boldsymbol{d}$ is a neighbor node of $\boldsymbol{a}$ ($\boldsymbol{d} \in N(\boldsymbol{a})$), the message is also delivered to $\boldsymbol{d}$ immediately. If $H(\boldsymbol{a},\boldsymbol{d}) \ge 2$, the algorithm tries to find the preferred neighbor node of $\boldsymbol{a}$ that has the largest estimate value of probability. If the value is positive, then the message is forwarded to the node. Otherwise, if it is 0, then the spare neighbor nodes are checked to find one with the largest estimate value. If the value is not 0, the message is sent to the node while if it is 0, the delivery fails.

Their algorithm attains high reachability in Q_n with faulty nodes. However, there remains some room for improvement. That is, the value $P_{h-1}(\boldsymbol{a})$ may has an effect on $P_h(\boldsymbol{a}^{(i)})$. Hence, $\boldsymbol{a}$ may send a message to its neighbor $\boldsymbol{a}^{(i)}$ even if $P_h(\boldsymbol{a}^{(i)}) = 0$ without $P_{h-1}(\boldsymbol{a})$. Figure 4

```
function route(a, d, F)
begin
  h := H(a, d);
  if h = 0 then begin
    deliver the message to a; exit
  end;
  if h = 1 then begin
    send the message to d; exit
  end;
  i0 := argmax_i{P_{h-1}(a^(i)) | a^(i) ∈ N0(a, d)};
  if a^(i0) ∉ F then begin
    deliver the message to a^(i0); exit
  end;
  i1 := argmax_i{P_{h+1}(a^(i)) | a^(i) ∈ N1(a, d)};
  if a^(i1) ∉ F then begin
    deliver the message to a^(i1); exit
  end;
  error('message delivery failed')
end
```

Figure 3: Routing algorithm based on estimate values of probabilities

shows an example of this case. In the figure, $P_h(\boldsymbol{a}^{(i)})$ may be positive if $P_{h-1}(\boldsymbol{a})$ is also positive though there is no way out from $\boldsymbol{a}^{(i)}$. Therefore, in the next section, we introduce a notion of directed routing probability, and try to improve the algorithm by Al-Sadi et al.

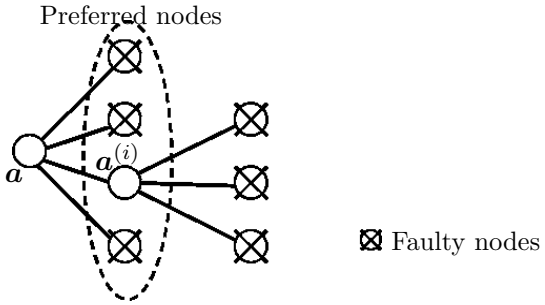

Figure 4: An example of an unreachable case

5 Proposed Algorithm

To address the problem mentioned at the end of the previous section, we have excluded an effect by $P_{h-1}(\boldsymbol{a})$ from calculation of $P_h(\boldsymbol{a}^{(k)})$. The new probability is called directed probability, and we calculate estimate values of directed probabilities $\vec{P}_h^k(\boldsymbol{a})$ where k represents the direction to which the estimate value is transmitted.

$$\vec{P}_h^k(\boldsymbol{a}) = \begin{cases} |(N(\boldsymbol{a}) \setminus \{\boldsymbol{a}^{(k)}\}) \setminus F|/(n-1) & (h=1) \\ 1 - \prod_{\substack{i=1 \\ i \neq k}}^{n} (1 - \vec{R}_h^i(\boldsymbol{a}^{(i)})) & (2 \leq h \leq n, \boldsymbol{a} \notin F) \end{cases}$$

$$\vec{R}_h^i(\boldsymbol{b}) = \begin{cases} 0 & (\boldsymbol{b} \in F) \\ h\vec{P}_{h-1}^i(\boldsymbol{b})/(n-1) & (\boldsymbol{b} \notin F) \end{cases}$$

The estimate values of directed probabilities can be calculated by the algorithm shown in Figure 5.

```
function EVDP(a, h, k, F)
begin
  if h = 1 then
    P⃗_h^k(a) := |(N(a)\{a^(k)})\F| / (n - 1)
  else begin
    P⃗ := 1;
    for i := 1 to n do begin
      if i = k then continue;
      if a^(i) ∈ F then R⃗_h^i(a^(i)) := 0
      else R⃗_h^i(a^(i)) := h × P⃗_{h-1}^i(a^(i)) / (n - 1);
      P := P × (1 - R⃗_h^i(a^(i)))
    end;
    P⃗_h^k(a) := 1 - P
  end;
  return P⃗_h^k(a)
end
```

Figure 5: Function to calculate estimate values of directed probabilities

Our routing algorithm `route2` based on the estimate values of directed probabilities is shown in Figure 6. It is similar to the algorithm by Al-Sadi et al., and it is used when a node $\boldsymbol{a}$ has to forward a message to its destination $\boldsymbol{d}$.

The time complexity to calculate estimate values of directed probabilities $\vec{P}_1^k(\boldsymbol{a})$, $\vec{P}_2^k(\boldsymbol{a})$,

```
function route2(a, d, F)
begin
  h := H(a, d);
  if h = 0 then begin
    deliver the message to a; exit
  end;
  if h = 1 then begin
    send the message to d; exit
  end;
  i_0 := argmax_i{P^i_{h-1}(a^(i)) | a^(i) ∈ N_0(a, d)};
  if a^(i_0) ∉ F then begin
    deliver the message to a^(i_0); exit
  end;
  i_1 := argmax_i{P^i_{h+1}(a^(i)) | a^(i) ∈ N_1(a, d)};
  if a^(i_1) ∉ F then begin
    deliver the message to a^(i_1); exit
  end;
  error('message delivery failed')
end
```

Figure 6: Routing algorithm based on estimate values of directed probabilities

..., $\vec{P}^k_n(\boldsymbol{a})$ $(k = 1, 2, \ldots, n)$ is $O(n^3)$, which is larger than the time complexity of the approach by Al-Sadi et al. The number of times that a node exchanges these values with its neighbor nodes is $O(n^2)$. It is same as that by Al-Sadi et al.

6 Evaluation

To evaluate performance of our algorithm, we carried out an computer experiment to compare it with the algorithm by Al-Sadi et al. The experiment is conducted based on the following procedure:

1. In Q_n, for the ratio of faulty nodes $\alpha = 0, 0.1, \ldots, 1.0$, repeat Steps 2 to 4 for 10,000 times.

2. Set $\lfloor \alpha 2^n \rfloor$ faulty nodes in Q_n.

3. Select two nodes $\boldsymbol{s}$ and $\boldsymbol{d}$ randomly such that there exists a fault-free path between them.

4. Apply the algorithms `route` and `route2`, and check if the message is delivered to the destination or not.

Figure 7 shows the result of the experiment with Q_{10}. According to the figure, we can see that our algorithm is superior to the algorithm by Al-Sadi et al. for $\alpha = 0.6, 0.7, 0.8$ and 0.9. The reason that the ratios of successful routings increased for $\alpha = 0.9$ is that the ratio of faulty nodes is so high that the pairs of $\boldsymbol{s}$ and $\boldsymbol{d}$ could be found with short Hamming distance only.

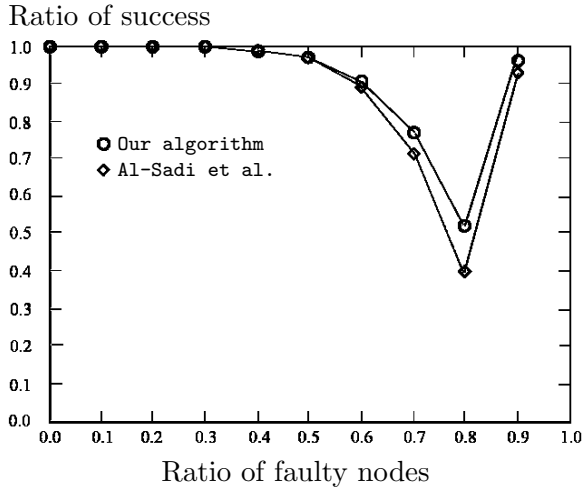

Figure 7: Ratio of successful routings by algorithms `route` and `route2` in Q_{10}

7 Conclusion

In this paper, we have proposed a new fault-tolerant routing algorithm for hypercube networks based on directed probabilities, which are obtained by improving the probabilities proposed by Al-Sadi et al. The time complexity to calculate all of the estimate values of directed probabilities is $O(n^3)$. The number of times for each node to exchange these values with its neighbors is $O(n^2)$. We also conducted a computer experiment to verify the effectiveness of our algorithm, and we showed that our algorithm is superior to that by Al-Sadi et al. when the ratio of faulty nodes α is relatively high ($\alpha = 0.6, 0.7, 0.8$, and 0.9).

Future works include reduction of the time complexity of the algorithm. Applying similar approach to other topologies is also included in future works.

Stabilizing Information Dissemination in Wireless Sensor Networks

Sain Saginbekov and Arshad Jhumka
Department of Computer Science, University of Warwick, Coventry, CV4 7AL, UK

Abstract— *One important component of network reprogramming is code dissemination, when the new program code is distributed to the relevant nodes. Very few information dissemination protocols, if any, tolerate transient data faults, i.e., faults that corrupt the memory state of nodes. We address this limitation by proposing a novel protocol, called* Repair*, that transforms any fault-intolerant information dissemination protocol into a stabilizing protocol where, eventually, all nodes obtain the updated code. We conduct simulations to show the performance of Repair, and we integrate Repair with Varuna, and our results show that Repair induces low overhead on Varuna, and causes all nodes to receive the new code. Our main contribution is the first corrector protocol that stabilizes information dissemination in the presence of transient faults.*

Keywords: Information dissemination; Transient faults; Stabilization; Wireless sensor networks; Composition

1. Introduction

Wireless sensor networks (WSNs) have enabled the deployment of several novel classes of applications, such as monitoring and tracking. However, to be useful, they need to operate unattended for long periods of time. However, this operational mode places several requirements on the network applications, but mainly that the applications are able to adapt to changing conditions. Given that WSNs are often deployed in hostile environments, human intervention is impossible. Thus, over-the-air reprogramming becomes a fundamental activity.

A network reprogramming protocol consists of several specific components: (i) a component that decides whether a complete code needs to be sent or only an update, (ii) information dissemination component, and (iii) reliability components [1]. The reliability component is to ensure that nodes receive all the parts of the code update that may be lost due to collisions. In this paper, we focus on the information dissemination aspect of network reprogramming.

Several information dissemination protocols have been proposed as part of network reprogramming protocols [2], [3], [4], [5]. However, to the best of our knowledge, none of them is *fault-tolerant*, i.e., none of them tolerate transient faults that corrupt the memory state of the nodes, which are known to occur in WSNs [6], [7], [8]. Such transient faults are also called soft errors. Given that several information dissemination protocols work by advertising the metadata of the new code, e.g., [2], [3], [9], any corruption of the metadata can, in the worst case, lead to the network nodes having stale code. Thus, it is important to have make these information dissemination protocols fault-tolerant. One trivial way of addressing this problem is to have the base station to periodically initiate the dissemination of the new code. However, this is a very expensive process, not suitable for WSNs.

In this work, instead of proposing a new fault-tolerant information dissemination protocol for WSNs, we propose a *corrector* protocol, called *Repair*, that, when integrated with a fault-intolerant information dissemination protocol, transforms the protocol into a stabilizing [10] fault-tolerant dissemination protocol, i.e, a protocol that guarantees that, eventually, all nodes will download the correct code. The novelty of our approach is that Repair enables the deployment of several stabilizing fault-tolerant information dissemination protocols. The corrector protocol, Repair, is triggered only when an erroneous state exists in the network, thus no overhead is incurred when no transient failures occur.

Contributions: In this context, we make the following contributions:

- We present a corrector protocol called *Repair* that, when integrated with any fault-intolerant information dissemination protocol, generates a corresponding stabilising fault-tolerant information dissemination protocol, and we prove its correctness.
- We run simulation experiments on *Repair* using TOSSIM [11], and show the performance of Repair, especially its locality property.
- We present a case study where we compose *Repair* with an existing dissemination algorithm, namely Varuna [3]. We show that our protocol (Repair) induces very little overhead over the Varuna in presence of transient faults. Further, Varuna, when executed in presence of even a single transient fault resulted in all the nodes downloading the wrong code. In contrast, when running Varuna with *Repair*, all the nodes eventually obtained the new code.

The paper is structured as follows: In Section 2, we present an overview of related work. In Section3, we present the system and fault models assumed in the paper. In Section 4, we present a corrector algorithm that stabilises the information dissemination of code updates. We present the simulation setup to evaluate the performance of the proposed algorithm in Section 5. The simulation results are presented in Section 6. In Section 7, we present a case

study where we integrate the algorithm with an existing information dissemination protocol to show the viability of our approach. We conclude the paper in Section 8, and present some avenues for future work.

2. Related Work

Information Dissemination There exist several dissemination protocols which update nodes'codes to new ones. While some of the protocols deliver complete binary image of the code like [12], [13], [9], [4], some deliver only the difference between the new code and the old code [14], [15]. Also there exist protocols which deliver tasks [16], network parameters [17], and queries [18].

In XNP[12], the base station broadcasts the code image to the nodes which are in its coverage range. The nodes outside of the range cannot receive the code image. The protocol proposed in MOAP[13] is a multihop dissemination protocol that can deliver code images to nodes that are several hops away from the base station. Each node forwards the code image further after receiving the complete code image. Deluge [9], allows large data transmission by fragmenting data into fixed-size pages. It also supports pipelining page transmission to make dissemination faster. Unlike MOAP, nodes in Deluge should not wait for complete code image before forwarding it. Authors of MNP [4] proposes another protocol like Deluge, which fragments the code image and uses pipelining mechanism. However, unlike Deluge, MNP selects the sender of the code such that there is only one sender at a time in a neighbourhood. Sender selection reduces collision and hidden terminal problem. Also, in MNP, some of the nodes can go to sleep mode to save energy whenever there is no data to receive and transmit.

Because of the feature of a wireless sensor network, such as transient link failures and node mobility, not all nodes update their code to the newest one during dissemination phase. The Trickle algorithm [2] addresses this problem by using a "polite gossip"policy. In Trickle, every node broadcasts advertisement messages, a metadata that includes version number of the code, at most once per period given between [τ/2, τ]. If a node hears more than k identical metadata before it transmits, it suppresses its broadcast and doubles the value of τ up to τ_h, which is upper bound for τ. If it hears different metadata, τ becomes τ_l, which is lower bound for τ. Varuna [3] is another protocol which supports code update maintenance. This protocol saves energy in steady phase, the phase where no dissemination is being done. Unlike Trickle, where there is a linear increase of energy consumption, energy consumption in Varuna is constant in steady phase. To achieve constant energy consumption in steady phase, nodes in Varuna send advertisement messages only when there is a change in neighbourhood topology or metadata since its last advertisement transmission. In Varuna, a node detects a fault when its version is less than that of the sender. These protocols do not consider transient memory faults, which may lead to a protocol to work incorrectly. For example, a node with new code may download old code if such a fault occurs. To the best of our knowledge, the work presented in this paper is the first to address fault-tolerant information dissemination. **Fault Tolerance** In [19], it has been shown that a class of components, known as correctors, is sufficient to design non-masking fault tolerance. Thus, stabilisation, which is a special type of non-masking fault tolerance, is achieved by adding corrector mechanisms to a program, thereby transforming the program into a non-masking fault-tolerant one. Correctors are components that enforce a given predicate on program executions, whenever the predicate has been violated. The area of self-stabilization is mature, and several stabilizing algorithms exist [10].

3. Models: System and Faults

Graphs and networks: We define a wireless sensor node, or node, as a computing device equipped with a wireless interface and associated with a unique identifier. A node can communicate with a set of other nodes that lie at a certain distance from it. Generally, communication in wireless networks is typically modelled with a circular communication range centred on the node. However, we do not assume that all nodes have the same communication range and we do not assume that the range is circular. In this model, a node is thought as able to exchange data with all devices within its communication range.

A wireless sensor network is a collection of wireless sensor nodes and is modelled as an directed graph $G = (V, E)$ where V is a set of $N = |V|$ wireless sensor nodes and E is a set of edges or links, each link being a pair of distinct nodes. A node $n \in V$ is said to be a 1-hop neighbour of a node $m \in V$ iff $(m, n) \in E$, i.e., m can send a message to n. Observe that communication need not be symmetric, i.e., if m can send a message to n, n may not be able to do so. We denote by M, the set of m's 1-hop neighbours (or neighbours, for short). We say that two nodes m and n can collide at node p if $(p \in M) \wedge (p \in N)$ [1].

Faults: A fault model stipulates the way programs may fail. We consider *transient data faults* that corrupt the state of the program by artificially corrupting the values held by variables. These faults are also known as soft errors.

Definition 1 (d-local algorithm): Given a network $G = (V, E)$, a problem specification ¶ for G, and an algorithm A that solves ¶. Algorithm A is said to be d-local if a node $n \in V$ executes a transition that requires the state of its d-hop neighbourhood to be queried.

4. Repair: A Corrector Protocol for Stabilizing Information Dissemination

In this section, we present a *corrector* protocol, called *Repair*. When *Repair* is composed with a fault-intolerant

[1] We will say two nodes m and n can collide if such a node p exists

dissemination protocol Σ, the resulting protocol (*Repair*$||\Sigma$) (pronounced Repair composed with Σ) is a stabilizing dissemination protocol, which guarantees that all nodes eventually download the correct code.

4.1 The *Repair* Protocol

Repair, shown in Figure 1, works with all reprogramming dissemination protocols that enable the detection of a fault. Specifically, Repair is triggered only when an erroneous state is detected due to a transient fault. Thus, any dissemination protocol that can interface with Repair must have enough state information to determine when a state is erroneous and, to the best of our knowledge, all current information dissemination protocols enable this. When a dissemination protocol detects a fault, then *Repair* is executed. In *Repair*, only corrupted nodes upgrade their code, avoiding unnecessary code updates.

Repair uses six special types of data packets (we call them *Repair* packets), in addition to dissemination packets used in the dissemination protocol:

- **Prob**: It contains code metadata and it is used to ask a neighbouring node to correct a fault.
- **Check**: It is used to request neighbouring nodes' code metadata.
- **Rep**: It contains a node's metadata and is used to reply to *Check* packet.
- **OK**: It is used to release some nodes from the correction process.
- **Cor**: It contains the correct metadata and is used to inform nodes about the correct metadata.
- **Hello**: It contains the correct metadata and is used to inform nodes that it has correct code.

Informally, *Repair* works as follows (The detailed algorithm is in Figure 3): When a node n_1 detects a fault after communicating with node n_2, it attempts to correct the fault. A *Prob* packet is sent to indicate a problem. If the fault cannot be corrected with n_2, then *Check* packets are broadcast, creating a *correction tree*, rooted at the node (n_1) that detected the fault. The leaf nodes of the tree responds to *Check* packets by sending *Rep* packets. If any of the leaf nodes detects a fault, it will spawn a subtree, within the main correction tree. Once a region in the network is reached where there is no fault, then no more subtree is spawned. This means that a node's neighbourhood have the same code version, with the version being presumed correct, since the probability of identical corruption of the metadata is very low. Then, this node responds through a *Rep* packet, and its subtree "disappears". Any node sending a *Rep* packet will cause its subtree to "disappear". Ultimately, *Cor* or *Hello* packet will be issued, with node n_1 getting the correct code. Notice that, since *Repair* ensures f-locality, the correction tree will be on depth f.

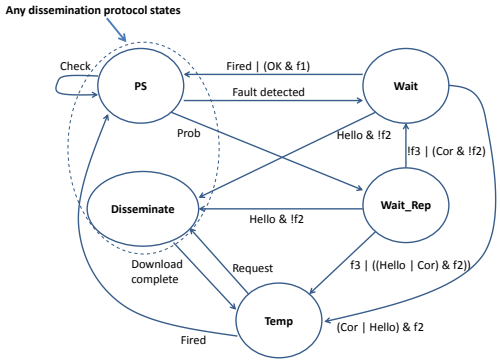

Fig. 1: The state machine. Two states in dashed area are the states of any dissemination protocol. f1=TRUE if sender of *OK* packet is the node which sent P, f2=TRUE if Sender.Vers=Receiver.Vers, f3=TRUE if all received metadata are the same.

4.2 Proof of Correctness of Repair

Lemma 1 (f-local stabilization): Given a network $G = (V, E)$, fault model F, and a set S of corrupted nodes, with the diameter of the corrupted area being f. Then, *Repair* guarantees that, eventually, all nodes in S will have the correct code.

Proof: Assume that a node n_f has detected a fault and wants to correct it. Given the diameter of the corrupted area is f, i.e., the maximum distance between two corrupted nodes in an area is f hops, we assume that all nodes on the path between n_{f-1} and n_0, namely n_{f-2}, n_{f-3},...,n_0 are corrupted. Node n_0 has neighbours with correct versions since corrupted area is of diameter f. We will prove by induction that node n_f will eventually get the correct code.
Base case: Since all neighbouring nodes of n_0 have correct metadata, according to *Repair*, n_0 will receive *Rep* packets with all equal metadata. Then n_0 requests the correct code from one of the neighbours and goes to *Disseminate* state to download the correct code.
Inductive hypothesis: Assume that a node n_i, where $0 < i < f - 1$, eventually receives *Hello* packet and updates its code from node n_{i-1}.
Inductive step: We need to prove that a node n_{i+1}, a neighbour node of n_i, eventually receives *Hello* packet and updates its code.

We know that in our protocol every node broadcasts *Hello* packet periodically upto h times after receiving *Hello* packet or updating its code. Now there are two cases that can happen after n_i receives *Hello* packet and updates its code.

- Case 1: n_{i+1} receives a *Hello* packet and updates its code from n_i, which proves the inductive step.
- Case 2: Because of message losses, n_{i+1} will not receive *Hello* packet from n_i. In this case, n_{i+1} waits *Wait_Time* and goes to PS state and starts to receive and send P packets. Eventually, n_{i+1} or a neighbour

Fig. 3: Repair Algorithm.

node of n_{i+1} will detect the fault, and executes *Repair* again, this time the affected area will be of size $(f - i)$, assuming no further fault has occurred. Assuming that the number of message losses is finite, eventually, n_{i+1} will get a *Hello* packet. The first case will be eventually true.

□

Theorem 1 (Correctness of Repair*):* Given a network $G = (V, E)$, transient fault model F, a F-intolerant information dissemination protocol Σ for a specification σ. Then, *Repair* is a *corrector component* of Σ for σ.

Proof: The proof follows from Lemma 1, and from the fact that Repair is only triggered when a fault is detected. □

Observe also that *Repair* is *self-correcting*, i.e., if a transient fault occurs in *Repair* when *Repair* is executing, leading to a node downloading the wrong code. This fault will eventually be detected, and *Repair* will be executed again to correct the fault. Put otherwise, *Repair* is a corrector component for *Repair* itself.

5. Experimental Setup

We perform TOSSIM[11] simulations on a 20x20 grid network to evaluate *Repair*. We set the distance between neighbouring nodes to 10 feet. Each node has a communication radius of around 30 feet. Network topology with asymmetric links is constructed by a tool given on tinyos.net. Each node is given a noise model from a heavy-meyer noise trace file.

Parameter values used in our simulation are given in Table 1. Some of the parameter values depend on other

parameters. For example, *WaitRep_Time* is the time for waiting for *Rep* packets after broadcasting *Check* packet. So, *WaitRep_Time* $\geq$ *SendCheck+SendRep*. *Wait_Time* should be set according to the code size and the size of the network. If the network and code size is large, this time should be large enough to allow neighbouring nodes to correct their code and forward it. Usually nodes enter *Temp* state from *Wait* state where it waits less time. The only case when a node waits *Wait_Time* is when there is a packet loss. *Temp_Time* time does not depend on other parameters. The value of t should be small because a node waits a maximum *SendProb* time to receive all possible *Prob* packets. The values of h and p can be set to any values.

In our simulations, each node periodically broadcasts P packet, with period randomly selected between $[0, U]$ at the start. We simulated two scenarios: (i) we incremented the number of corrupted nodes per circular area, which has diameter of 60 feet, and (ii) we kept the number of corrupted nodes to 5 and increased the size of a given (square) area, i.e., decrease the fault density. In both scenarios, the corrupted nodes were selected randomly in the given area. We then counted (i) the number of packets, (ii) the number of involved nodes, i.e., nodes that sent a *Repair* packet, and (iii) the number of nodes which changed their states to *Wait* and/or *WaitRep* states. For each given number of corrupted nodes in the first scenario and for each length of square area in the second scenario, we ran simulations 5 times and computed the min, average and max values.

6. Simulation Results

In this section, we present two metrics to show the *locality property* of *Repair*, namely (i) number of nodes executing *Repair*, and (ii) number of packets sent.

Number of nodes: From Figure 4(a), we observe that, on average, the number of nodes executing the protocol varies linearly with the number of corrupted nodes. Given that the number of nodes involved is much less than the size of the network, it indicates that the number of nodes involved is proportional to the size of the corrupted area. Further, in Figure 4(b), we observe that, when 5 transient faults were injected, the number of nodes executing the protocol becomes almost constant, on the average. This is because, with decreasing fault density, the transient faults appear as single independent faults, with each of them involving a similar number of nodes, i.e., since the area increases, the chance of the 5 faulty nodes being neighbours is very low. These two observations support the fact that *Repair* in f-local, where f is the diameter of the fault-affected area.

Number of packets: We observe a similar trend as in Figure 5, further supporting the f-locality property of *Repair*.

7. Composition of *Repair* with Varuna

In this section, we discuss the composition of Repair with an existing information dissemination protocol, namely Varuna [3]. The reason for choosing Varuna is that it is one of the latest information dissemination protocol that have been proposed.

As mentioned before, Repair is triggered by the detection of a fault. In Varuna, such a detection is enabled by one of the following conditions: (i) two nodes' metadata (i.e., version number) are corrupted in such a way that the difference in versions is greater than 1, and (ii) the receiver of an advertisement message finds that its version is bigger than the advertised one and, at the same time, the sender exists in its neighbourhood table.

We simulated the composite protocol of Varuna and Repair in TOSSIM. All nodes, except faulty nodes, are booted in the first minute. Faulty nodes are located at the center of the network. A packet with new version number is injected at 2 minutes. We simulated three faulty scenarios: (i) with 1 fault, (ii) with 4 faults and (iii) with 7 faults. For each scenario, we booted the faulty nodes (i) 30 seconds, (ii) 45 seconds and (iii) 60 seconds after injecting the new code, so that only a proportion of nodes had the new code version. We are specifically interested in (i) the overhead induced by *Repair* on the performance of Varuna and (ii) the number of nodes with correct code at a given time. We simulated Varuna in conditions similar to those detailed in Section 5. Further, the values for Varuna-specific parameters are: DISS-RAND=2 sec, ADV-RAND=2 sec, τ=8 sec, T_{MOODY}=1 min. For reasons of space, we only present a sample of the results obtained.

Performance of Repair: As can be observed in Figures 7 and 8, in all cases, injecting transient faults in the network during Varuna only execution causes the whole network to disseminate stale code. On the other hand, when Varuna is composed with Repair, every node downloads the correct code.

Packet Overhead: In Figure 6(a), it can be seen that the packets overhead induced by Repair on Varuna is low. Specifically, with 7 faulty nodes, the packet overhead is less than 3%. From Figure 5, it can be observed that the number of packets will increase linearly with increasing number of corrupted nodes. The reason for the linear increase (as opposed to a constant value) is that the fault density increases when more corrupted appear at the centre of the network (condition under which we simulated the composite protocol).

Temporal Overhead: In Figure 6(b), it can be observed that the whole network receives the new code in approximately 80 seconds, after the new code has been injected into the network. Further, it can be observed that, when there are faulty nodes in the network, the time for the whole network to receive the correct code is approximately 80 seconds. Thus, *there is almost no temporal overhead induced by Repair on Varuna*, highlighting the composable nature of Repair. This is so because Repair executes in parallel with Varuna, and also corrects only corrupted nodes.

Table 1: Parameters for the simulation

Wait_Time	50 sec	*SendRep*	2 sec	*SendHello*	1.5 sec	*Temp_Time*	30 sec

8. Conclusion and Further Work

We have presented *Repair*, which when integrated with a fault-intolerant information dissemination protocol, transforms it into a stabilizing fault-tolerant one. We have shown the performance of Repair, and also when it was integrated with Varuna, one of the most recent information dissemination protocol. In presence of faults, Varuna causes all nodes to download the wrong code, while the composite protocol of Varuna and Repair ensured that all nodes eventually download the new code, while incurring minimal overhead.

Whitewash-Aware Reputation Management in Peer-to-Peer File Sharing Systems

Xiao YU[1] **and Satoshi FUJITA**[1]
[1]Department of Information Engineering, Hiroshima University
Higashi-Hiroshima, 739-8527, Japan

Abstract— *In this paper, we propose new schemes for the reputation management in P2P applications which discourage whitewash while encouraging good behaviors. The basic idea of the schemes is to design update rules for the reputation scores to satisfy the following requirements: 1) the score of a peer is strictly greater than the initial score at any point in time if it conducted at least one good behavior, 2) the score gradually increases if it conducted a good behavior while it rapidly decreases if it conducted a bad behavior, and 3) the strength of penalty is refined by allowing the system to give a penalty for several consecutive rounds.*

1. Introduction

Peer-to-Peer systems (P2Ps, for short) are autonomous distribute systems which have been used in many applications such as file sharing, video streaming, IP phone, and others. Different from traditional Client/Server (C/S) systems which rely on few dedicated servers, services in P2Ps are provided by each computer participating in the system in a "peer-to-peer" manner. In other words, each computer in P2Ps, called **peer** hereafter, plays the role of a client and a service provider at the same time. Such a remarkable property of P2Ps enables the designer of distributed systems to increase the scalability and the fault-tolerance of the constructed system, because it effectively removes the single point of failure existing in C/S systems as well as the service bottleneck.

However, such a distributed nature of P2Ps would cause several critical issues, such that a malicious peer can provide wrong, devastating services to the client peers, the quality of the services is not guaranteed by any authority, and the security of transactions could not be retained. In this paper, we focus on P2P reputation systems as a way of resolving such issues. In typical reputation management systems, each recipient of a service can *evaluate* the quality of the service and a collection of such evaluations will be disclosed to all participants so that it could be used to select safe and appropriate services in the next time. Examples of reputation systems include [2], [3], [4], [12], [13], [14]. A key idea of such reputation systems is to share information on past transactions among all participants to the system, i.e., if a transaction conducted by peer i is observed by peer j and another transaction conducted by i is observed by peer k ($\neq j$), by merging those two observations, we will have a more reliable evaluation concerned with the transactions conducted by peer i than the case in which each peer individually keeps such an evaluation.

In many P2P applications, a peer to have a high reputation will be granted to access high quality services such as the broader communication bandwidth and the video streaming in HD quality. On the other hand, the reputation of a peer rapidly becomes worse if it conducted malicious actions, such as an intentional provision of low quality services and the distribution of malwares such as spyware and computer viruses. In other words, the reputation system works as an incentive mechanism for the participants to conduct good behaviors. However, such an effect of reputation systems can be significantly reduced if a peer with a bad reputation could become a new participant by changing its identifier (ID) after leaving the system. Such a malicious behavior of peers is known as **whitewash**, and it has been recognized as a crucial issue in many distributed applications with reputation management [6], [5], [9].

In this paper, we propose new schemes for the reputation management in P2P applications *which discourage whitewash while encouraging good behaviors*. The basic idea of the schemes is to design update rules for the reputation scores to satisfy the following three requirements: 1) the score of a peer is strictly greater than the initial score at any point in time if it conducted at least one good behavior, 2) the score gradually increases if it conducted a good behavior while it rapidly decreases if it conducted a bad behavior, and 3) the strength of penalty is refined by allowing the system to give a penalty during several consecutive rounds.

The remainder of this paper is organized as follows. After overviewing related works in Section 2, Section 3 describes the model of P2P reputation systems. Section 4 proposes basic update rules for reputation scores, which is extended in Section 5. Section 6 proposes several reputation management schemes based on the extended update rules. Finally, Section 7 concludes the paper with future work.

2. Related Work

There are few proposals on whitewash-aware reputation management in spite of the importance of the problem. Pinninck *et al.* proposed a scheme which increases the

resistance of trust assessment schemes against whitewash attacks with the aid of social networks [7]. This scheme assumes that all interactions among peers are conducted according to the following simple protocol: 1) the initiator peer p chooses a set of potential partner peers S_p and evaluates the trust of all members in S_p; 2) p selects a peer q in S_p and sends an invitation message to q, 3) if q accepts the invitation, it starts an interaction with p, 4) after completing the interaction, q sends a feedback about the interaction to p. The key idea of the scheme is to use a social network in which each peer must be adjacent with a set of contact peers. Invitation messages are routed to the receivers through such contact peers, so that any peer wishing to interact with other peers must know at least one contact peer in the social network. Such a restriction makes a simple whitewashing meaningless, since if it changes ID, contact peers do not recognize the peer any more, so that the invitation message will not be routed to any receiver (note that the scheme could not completely prohibit whitewash if each peer can have several temporary IDs and tries to connect the network through a permanent ID among them).

Chen *et al.* proposed a scheme to identify whitewashers in P2P file sharing systems using the notion of observation preordering [1]. This scheme is based on an assumption such that actions conducted in our daily life are *habitual* so that it is hard to change even under different situations. Whitewashers are no exceptions. Namely, even after re-entering the system with a different ID, a whitewasher should contact similar peers to download files in a similar category. Observation preordering is a data structure to record the history of actions concerned with a peer, which is observed and recorded by another peer during the interaction with the target peer. Thus, for example, after interacting with peer j, peer i stores (or updates) the observation preordering concerned with j in its local storage. Suppose that j is malicious and conducts a whitewash to acquire new ID k ($\neq j$). By the assumption described above, peer k should contact peer i again to download files, and such an action is observed by i which will be stored as an observation preordering concerned with k. Thus, peer i could identify that k is likely to be j by comparing observation preorderings concerned with j and k, and if it concludes that k is j, it recognizes k as a malicious peer and degrades the reputation score of k accordingly.

How to encourage peers to conduct collaborative actions is another important issue in realizing practical incentive systems. Tseng and Chen proposed a free-rider aware reputation scheme for P2P file-sharing systems [11]. In this scheme, peers and files are divided into five levels depending on the reputation score, and the incentive mechanism is designed in such a way that a peer which does not share its files with the other peers can not access files at a higher level; i.e., in order to access files at a higher level, it needs to share its files with the other participants. This scheme also provides a penalty mechanism such that: 1) if a peer tried to share harmful files with the other peers including malwares and inauthentic files, and if such a malicious behavior is reported by the other peers, the reputation of the peer is reduced according to the penalty function (hence the level of the peer would also degrade accordingly), and 2) if a peer shares no files with the other peers, the reputation score gradually decreases as the elapsed time increases.

3. Model

In this section, we describe the model of P2P systems considered in this paper. The model of malicious actions of peers and the basic framework of reputation management will also be described.

3.1 System Model

In this paper, we consider P2P file sharing systems consisting of a number of peers which play the role of a client and a service provider at the same time. Each peer holds several files which can be shared with the other peers. Each peer, which wishes to acquire a copy of a file, firstly sends an inquiry message to the system so that the inquiry message will be delivered to peers holding the requested file [8], [10], [15]. The requesting peer will receive a response from several peers holding the requested file, and the receiver conducts the selection of a peer from the set of candidate peers according to the *reputation* of the candidates; e.g., high reputation peers are likely to be selected as an uploader compared with low reputation peers. Download of the requested file is conducted merely from the selected peer.

After completing the download, the downloader evaluates the transaction and gives a score to the uploader so that it reflects the *degree of satisfaction* of the downloader concerned with the transaction. In other words, the score is given for each transaction even if such transactions are provided by the same uploader. Such scores are aggregated to a central manager which keeps the reputation scores of all peers in the system, and if a peer conducts an evaluation of another peer, the outcome of the evaluation is immediately notified to the central manager.

3.2 Reputation Score

The **reputation score** of a peer is a sum of scores given by the downloaders. In this paper, we assume the existence of an appropriate incentive mechanism so that a peer with high reputation score will be granted a right to access high quality services, such as the higher priority while conducting a download from service providers and a wider bandwidth when it uses shared communication channels. Thus, it is natural to assume that *every rational peer should try to increase its reputation score*. If it is an honest peer, such an increase of the score will be attained by providing satisfactory transactions to the downloaders, but if it is dishonest, it tries to cheat by conducting malicious actions,

such as the issue of incorrect report to decrease the score of other peers, refusal of given requests, and provision of low quality services instead of providing requested services.

In general, to encourage honest actions of the peers, reputation scores should be managed in such a way that: 1) the score of a peer increases if it conducted collaborative actions to increase the satisfaction of downloaders (e.g., to increase the score by Δ^+), and 2) the score decreases if it conducted adversarial actions to decrease the satisfaction of downloaders (e.g., to decrease the score by Δ^-). As the strength of the penalty increases, i.e., as the value of Δ^- increases, each peer would likely to conduct collaborative actions without conducting adversarial actions, i.e., an incentive to encourage collaborative actions works well. However, if it was too strong, a peer which conducted an adversarial action would select a (malicious) way such that it quits the system once and re-enters the system as a new participant. Such a malicious behavior of a peer is called **whitewash** which is known to degrade the effectiveness of the underlying incentive mechanisms. In fact, to discourage whitewash, Δ^- must not be too large, but if it is not too large, the force to encourage honest actions should become weak.

4. Basic Update Rule

In this section, we propose a collection of update rules of the reputation scores which discourage whitewashes but encourage honest actions. The proposed rules are designed to satisfy the following requiremenrs:

1) The reputation score of a peer increases if it conducts a collaborative action, while it decreases if it conducts an adversarial action.
2) The reputation score is strictly larger than the initial score at any point in time, if it conducted at least one collaborative action.

The second requirement intends that a peer conducted collaborative actions becomes harder to be penalized even if it occasionally conducts adversarial actions.

4.1 Update Rules

Let $R_i \in (0,1)$ denote the reputation score of peer i. R_i is initialized to R_0 at the time of participation. Suppose that peer j downloaded a file from peer i, and j is satisfied with the transaction. Then, peer j notifies the result of such a positive evaluation to the central manager, and after receiving it, the central manager updates the reputation score of i as follows:

$$R_i \;:=\; \alpha R_i + (1-\alpha) \tag{1}$$

where α is a parameter in range $(0,1)$. The above update rule indicates that as the value of R_i increases, the "amount of increase" gradually decreases even if it repeatedly conducts collaborative actions, e.g., if $R_0 = 0$, a sequence of collaborative actions monotonically increases the score as

$$0 \to (1-\alpha) \to (1-\alpha^2) \to (1-\alpha^3) \to \cdots .$$

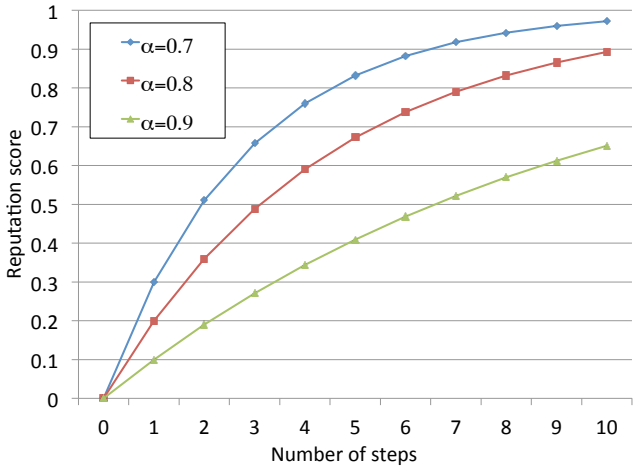

Figure 1: Increase of the reputation score along with collaborative actions ($R_0 = 0$).

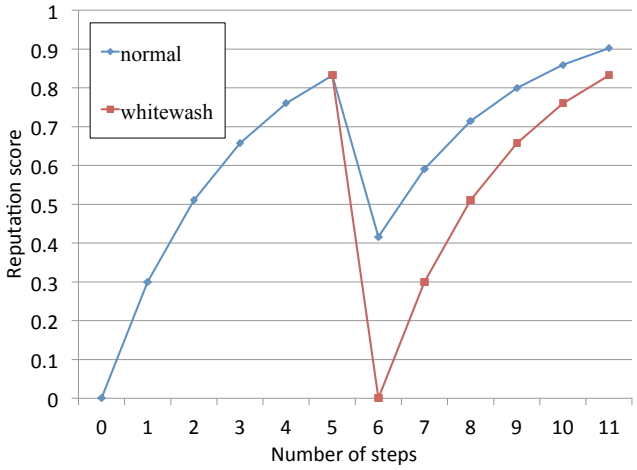

Figure 2: Badness of the reputation score under whitewash.

Figure 1 illustrates the increase of the reputation score along with collaborative actions, for different α's. On the other hand, if j is not satisfied with the transaction, j sends a negative notification to the central manager, and after receiving it, the central manager updates the reputation score of i as follows:

$$R_i \;:=\; \frac{R_i - R_0}{\beta} + R_0 \tag{2}$$

where β is a parameter greater than 1. The reader can easily verify that the second condition described above is certainly satisfied for any selection of $\beta > 1$. In fact, once $R_i > R_0$ holds, this inequality remains to hold even after any number of applications of the second update rule.

4.2 Analysis

In the last section, we observed that by conducting a whitewash, the reputation score becomes worse than the score *immediately before* the whitewash. In this section, we extend this simple argument. More concretely, we prove that by conducting a whitewash, the reputation score always becomes worse than the case without whitewash for any sequence of collaborative and adversarial actions. Let S be a ternary string representing a sequence of actions, where 0 and 1 indicate collaborative and adversarial actions respectively, and 2 indicates whitewash. Let $R(S)$ denote the reputation score of a peer after conducting an action sequence S.

We can prove the following claim.

Remark 1: Let $S = a_1, a_2, \ldots, a_n$ be a sequence of actions conducted by a user starting with a collaborative action, and S' be a sequence of actions which is obtained from S by inserting a whitewash after the i^{th} action for some $1 \leq i \leq n$. Then, $R(S) > R(S')$.

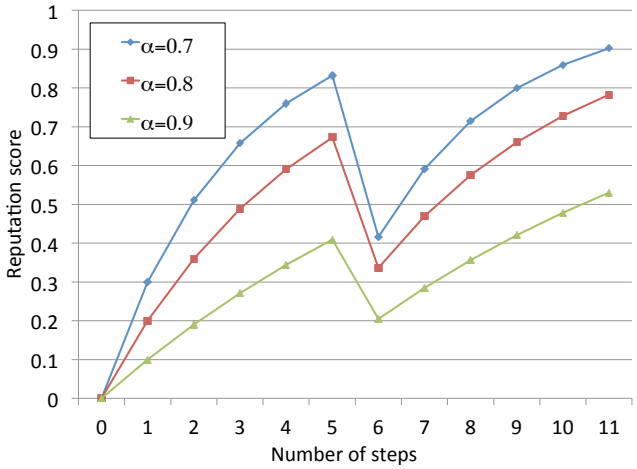
Proof: Suppose that a whitewash is inserted after the i^{th} action, i.e., it divides S into two parts $S_1 = a_1, a_2, \ldots, a_i$ and $S_2 = a_{i+1}, \ldots, a_n$. Since a whitewash initializes the reputation score, $R(S') = R(S_2)$. By the second condition described above, since it is assumed that S_1 contains at least one collaborative action, $R(S_1) > R_0$. By the definition of update rules, as the initial score R_0 increases, the resultant score monotonically glows. Hence the claim follows. ■

The badness of whitewash with respect to the reputation score is illustrated in Figure 2.

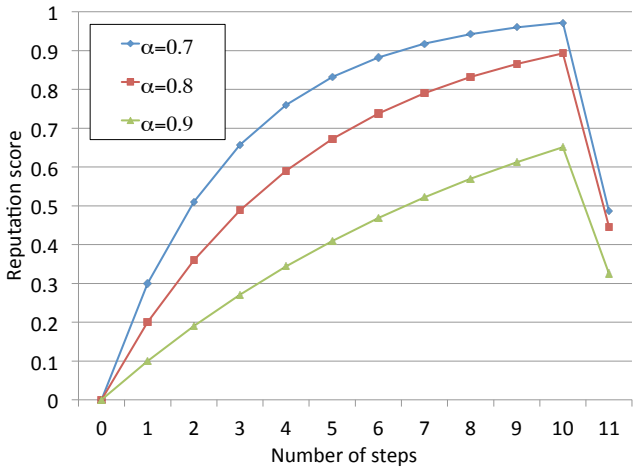
5. Extension

5.1 Motivation

In the above scheme, each peer who conducted an adversarial action is penalized by "uniformly" reducing the reputation score to $1/\beta$. Although it certainly penalizes adversarial actions of malicious peers, those rules give a penalty exactly once. In other words, after reducing the reputation score, the system "allows" the peer and treats him as an honest peer in the succeeding rounds. Thus, it could not effectively work as a *deterrent for addicts* of adversarial actions of malicious peers particularly when they repeat a sequence of actions consisting of an adversarial action and few collaborative actions. For example, if $\alpha = 0.5$, $1/\beta = 0.6$, and $R_0 = 0$, by repeating three collaborative actions after the participation, the score of the peer becomes $1 - 0.5^3 = 0.875$, and by conducting an adversarial action at that time, the score reduces to $0.6 \times (1 - 0.5^3) = 0.525$, but it is slightly larger than the score after the first collaborative action. In other words, one penalty is weaker than two collaborative actions in this case. On the other hand, the penalty seems to be too strong for the peers which have repeated many collaborative actions. For example, if it repeats 1000 collaborative actions in the above example,



(a) Adversarial action at the sixth step.



(b) Adversarial action at the 11th step.

Figure 3: Difference of the impact of adversarial actions to the reputation score.

the penalty for (only) one adversarial action is heavier than 998 collaborative actions. Figure 3 shows the change of the reputation score according to the difference of the position of an adversarial action in a sequence of collaborative actions, assuming $R_0 = 0$ and $1/\beta = 0.5$. When an adversarial action occurs at the sixth step, it "cancels" three or four collaborative actions conducted before it (Figure 3 (a)). However, if it occurs at the 11th step, it cancels 6 steps for $\alpha = 0.9$ and 8 steps for $\alpha = 0.7$ (Figure 3 (b)), which is larger than the case of the sixth step.

Such an unbalance on the number of consecutive collaborative actions which are comparable to one adversarial action should be overcome by reducing β as small as possible (i.e., the difference becomes small by decreasing β), and by introducing an additional mechanism for the penalization. The time transition of the reputation score for different β's is illustrated in Figure 4. It could be observed that the reduction

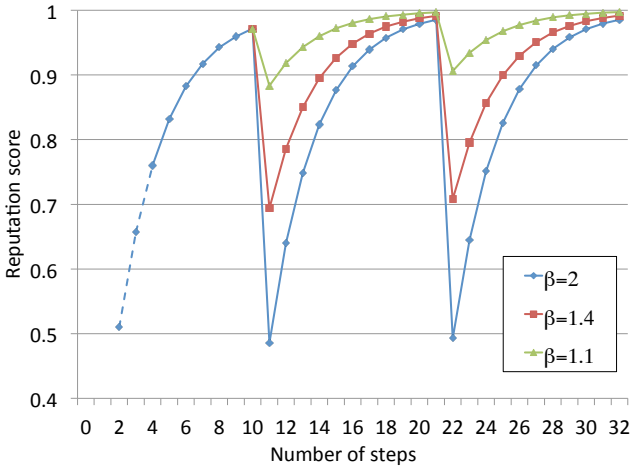


Figure 4: Time transition of the reputation score for different β ($\alpha = 0.7$ and $R_0 = 0$).

of the score significantly decreases as β approaches to one.

5.2 Scheme

Our main idea for the improvement of the basic scheme is to reduce the amount of increase of the reputation score during n consecutive rounds after detecting an adversarial action, where n is a parameter determined later. More concretely, we use the following rule instead of Equation (1) during n consecutive rounds after encountering an adversarial action:

$$R_i \ := \ \gamma R_i + (1 - \gamma) \tag{3}$$

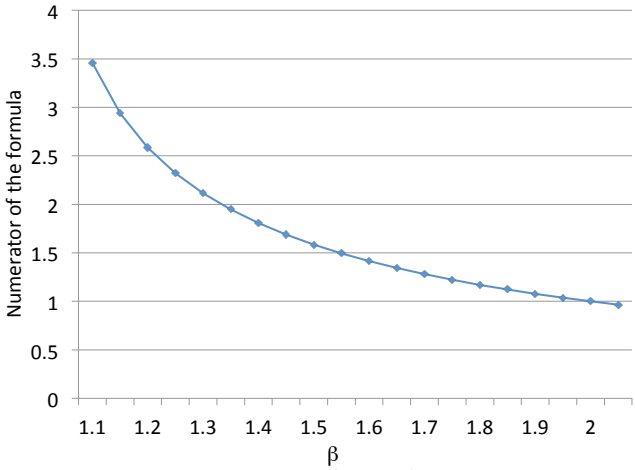
for some $\gamma > \alpha$. The reader should note that if n is too small, it does not effectively frighten peers to conduct adversarial actions, whereas if n is too large, it will encourage adversarial peers to conduct a whitewash. Thus an appropriate value of parameter n should be calculated carefully, which should depend on parameters α, β, γ, and the value of R_i at the time of encountering an adversarial action.

5.3 Analysis

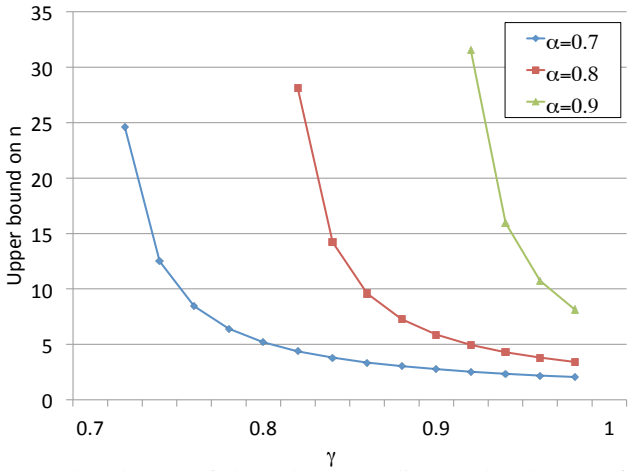
In this section, we derive an upper bound on parameter n in the sense that if it exceeds the value, it works as an incentive to conduct a whitewash. Recall that $R(S)$ denotes the reputation score after conducting an action sequence S which is represented by a ternary string in such a way that 0 and 1 indicate collaborative and adversarial actions respectively, and 2 indicates whitewash.

The following claim is easy to prove since the effect of whitewash will be maximized if it is conducted immediately after an adversarial action.

Remark 2: Let $S = a_0, a_1, a_2, \ldots, a_n$ be a sequence of actions such that $a_0 = 1$ and $a_i = 0$ for $1 \leq i \leq n$, S' be a sequence of length $n + 2$ which is obtained from S by "inserting" a whitewash at the second position. Note that in



(a) Numerator of Equation (4).



(b) The change of the value according to the change of parameters α and γ ($\beta = 2$).

Figure 5: Upper bound on n.

sequence S, n consecutive actions are penalized by reducing the increase of the reputation score. Then, the extended scheme does not encourage whitewash if $R(S) > R(S')$.

Let x be the score before conducting action sequence S. Then, we have

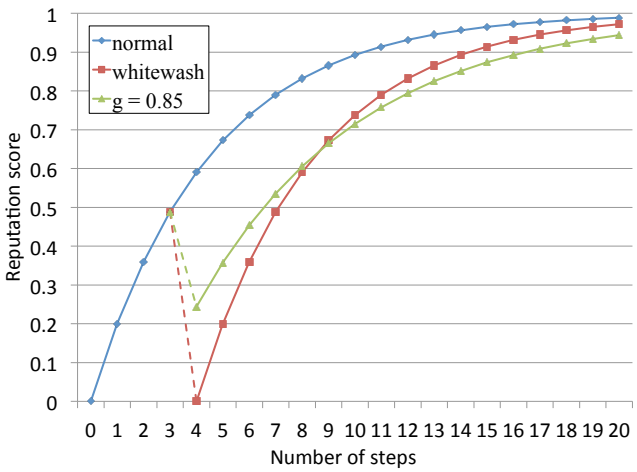
$$R(S) \ = \ \gamma^n \times \left(\frac{x - R_0}{\beta} + R_0 \right) + 1 - \gamma^n$$

and

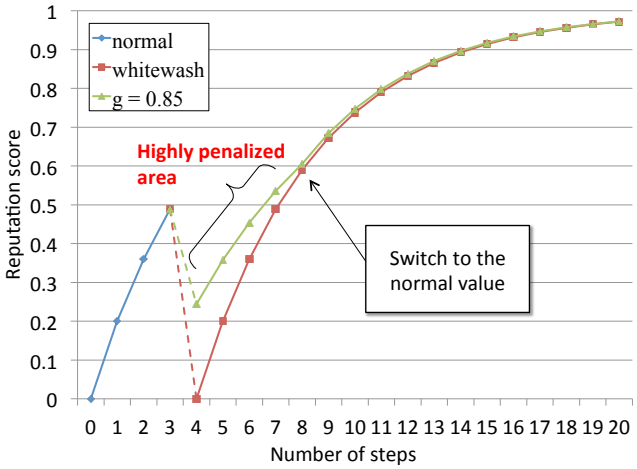
$$R(S') \ = \ \alpha^n \times R_0 + 1 - \alpha^n$$

Thus, in order to satisfy $R(S) > R(S')$, we should have

$$\gamma^n \times \left(\frac{x - R_0}{\beta} + R_0 - 1 \right) \ > \ \alpha^n \times (R_0 - 1)$$



(a) When it does not switch to Rule (1).



(b) When it switches to Rule (1) after four times of repetitions.

Figure 6: The role of parameter n.

that is,

$$\left(\frac{\alpha}{\gamma}\right)^n > \frac{1 - R_0 - \frac{x - R_0}{\beta}}{1 - R_0} = 1 - \frac{x - R_0}{\beta(1 - R_0)} > 1 - \frac{1}{\beta}$$

where the last inequality is due to $x < 1$. By taking a logarithm, we have

$$n \log(\alpha/\gamma) > \log(1 - 1/\beta)$$

Since $\alpha < \gamma$, $\log(\alpha/\gamma) < 0$. Thus,

$$n < \frac{\log \beta - \log(\beta - 1)}{\log \gamma - \log \alpha}. \quad (4)$$

The numerator of Equation (4) gradually decreases as β increases, as is shown in Figure 5 (a). In addition, for a fixed α, the right hand side of the formula decreases as γ increases from α, as is shown in Figure 5 (b) (in this figure, we fix β to two). By this figure, we can see that we could apply Rule (3) at most six times if parameters are determined as $\alpha = 0.7$, $\beta = 2$, and $\gamma = 0.78$, but it decreases to four times if we slightly increase γ to 0.82.

An example of the time transition of the reputation score is illustrated in Figure 6. This figure assumes $\alpha = 0.7$, $\beta = 2$, and $\gamma = 0.85$. If we apply Rule (3) instead of Rule (1) forever, as is shown in Figure 6 (a), the score after whitewash eventually becomes larger than the penalized score. However, by switching the rule to Rule (1) after passing an appropriate number of repetitions (e.g., in this example, by switching the rule after three times of applications), we can guarantee that the resulting score is still greater than the score after whitewash, as in shown in Figure 6 (b).

6. Schemes

In this section, we propose several reputation management schemes based on the extended update rules.

6.1 Threshold Type

The first idea is to switch the rule from Rule (3) to Rule (1) by the value of the reputation score. More concretely, it switches the rule when: 1) it encounters the upper bound on n, or 2) the reputation score exceeds a predetermined threshold (e.g., 0.8). This scheme is intended to "allow" users when their reputation score exceeds the threshold, since the fact of exceeding the threshold indicates that it has repeated sufficient number of collaborative actions. In fact, since the score after applying Rule (2) is at most $1/\beta$, to reach threshold θ ($> 1/\beta$), it should repeat at least m collaborative actions satisfying the following inequality:

$$\theta < \gamma^m(1/\beta) + 1 - \gamma^m.$$

By solving it, we have the following lower bound on m,

$$m > \frac{\log(1 - \theta) - \log(1 - 1/\beta)}{\log \gamma}.$$

6.2 Counting Type

The second idea is to (gradually) increase the number of repetitions depending on the number of adversarial actions which have been conducted by the corresponding peer. More concretely, the scheme works as follows: 1) Prepare a variable w to count the number of adversarial actions conducted by the peer. Variable w is initialized to zero and is incremented when it conducted an adversarial action. 2) The number of penalizations (i.e., the number of applications of Rule (3)) is determined as

$$\min\{f(w), n^*\}$$

where f is an appropriate monotonically increasing function such as $f(w) = w$ and $f(w) = w^2$, and n^* is an upper bound on n determined by Equation (4).

6.3 Random Type

The third scheme uses the notion of randomization. In the last two schemes, each peer can predict the strength of penalization from the outcome of past trials. For example, in the first scheme, a malicious peer knows that the penalization finishes after reaching its score to the threshold, and in the second scheme, a malicious peer knows from its experience that the strength of penalization against its next adversarial action. To effectively hide such information from malicious peers, a randomization could be used in the following manner: 1) After detecting an adversarial action of a peer, the central manager selects a random number r from set $\{1, 2, \ldots, n^*\}$. 2) It then penalizes during r consecutive rounds after reducing the score of the corresponding peer by Rule (2).

7. Concluding Remarks

In this paper, we propose new schemes for the reputation management in P2P applications which discourages whitewash while encouraging good behaviors. Our proposed scheme can control the strength of penalty against adversarial actions.

Topics for our future work are listed as follows:

- The evaluation of the proposed schemes considering the incentive of users to participate in the system. In actual P2Ps, each user reserves a right to leave from the system if she feels that it is not attractive compared with the required cost. Our current analysis misses such an issue.
- Combination with other techniques to discourage whitewash. For example, by combining the proposed schemes with Adrian and Marco's scheme described in Section 2, we could reduce the number of whitewashes in actual P2P environments.
- Detailed analysis of the fairness in the proposed schemes. We need to give a formal definition of fairness, as well as the tuning of several parameters to meet the fairness criteria.

Abstract— *Responsive Link is a communication standard as specified in ISO/IEC 24740:2008 for distributed real-time environments. Responsive Link has multiple features to meet both hard and soft real-time requirements. Unfortunately, current real-time operating systems do not support the main features of Responsive Link. In addition, distributed real-time systems in noisy environments require revealing the tolerance of Responsive Link to achieve correct communication. We present APIs for Responsive Link in RT-Est real-time operating system. Using the APIs, users can make use of the main features of Responsive Link easily. Experimental evaluations perform the voltage tolerance test against noise and reveal the tolerance of Responsive Link.*

Keywords: Responsive Link, Responsive Multithreaded Processor, Distributed Systems, Real-Time Communication, Tolerance

1. Introduction

Robots [14], [18], [2] in distributed real-time systems have many nodes and require various topologies. In distributed real-time environments such as nuclear power plants, deep sea and outer space, there is much noise to interrupt correct communication. In addition, packets must be arrived by their deadlines in such noisy environments. However, existing communication standards have various limitations such as real-time requirement, topology and tolerance.

For example, wireless communication standards such as WirelessHART [7] reduce tolerance compared to wired communication standards. On the other hand, wired communication standards such as CAN [1] and FlexRay [6] suffer from the limitations of topologies. Since there are various shapes of robots, we require a topology-free communication standard. Also, these communication standards have priority inversion problems [17] because higher priority packets cannot overtake lower priority packets. Due to priority inversion problems, higher priority packets may miss their deadlines. In order to overcome the weakness of these communication standards, we have developed Responsive Link [20].

Responsive Link is a communication standard as specified in ISO/IEC 24740:2008 for distributed real-time environments. Responsive Link has multiple features to meet both hard and soft real-time requirements. For example, Responsive Link has two communication links: event link and data link. An event link is used to transmit packets with hard real-time requirements. On the other hand, a data link is used to transmit packets with soft real-time requirements. By the separate transmission of the event link and the data link, Responsive Link is easier to support hard and soft real-time communication than other communication standards. Unfortunately, current real-time operating systems do not support the main features of Responsive Link. In addition, distributed real-time systems in noisy environments require revealing the tolerance of Responsive Link to achieve correct communication.

We present APIs for Responsive Link in RT-Est real-time operating system [5]. Using the APIs, users can make use of the main features of Responsive Link easily. Experimental evaluations perform the voltage tolerance test against noise and reveal the tolerance of Responsive link.

The contribution of this paper is to implement APIs for Responsive Link and to build the experimental environment for tolerance. We believe that the APIs for Responsive Link help users to build distributed real-time systems easily and the method to evaluate the tolerance of communication standards is widely used.

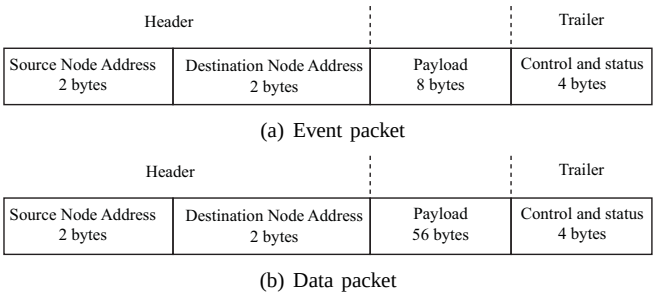
The remainder of this paper is organized as follows: Section 2 introduces the detail of Responsive Link. Section 3 presents the implementation of the APIs for Responsive Link. The effectiveness of Responsive Link is evaluated in Section 4. Section 5 compares our work with related work in distributed real-time environments. Finally we offer concluding remarks in Section 6.

2. Responsive Link

In this section, we introduce the detail of main features in Responsive Link [20].

2.1 Packet Overtaking

Real-time systems require real-time scheduling, which guarantees completing real-time tasks by their deadlines. In real-time scheduling, higher priority tasks can preempt lower priority tasks. In order to achieve this preemption in real-time communication, higher priority packets require overtaking lower priority packets in each node. Therefore, each packet in Responsive Link has a priority. If packets have the same priority, then the round-robin rule is applied. By the technique of the packet overtaking, real-time scheduling such as fixed-priority scheduling [13] and semi-fixed-priority scheduling [3], [4] can be adapted to packet scheduling.



(a) Event packet

(b) Data packet

Fig. 1: Format of packet

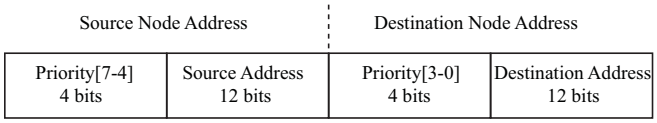


Fig. 2: Format of header

2.2 Format of Packet

Responsive Link supports two kinds of packets: event packet and data packet. Figure 1 shows the formats of the event packet and the data packet. An event packet is 16-byte length consisted of a 4-byte header, an 8-byte payload and a 4-byte trailer. The main use of the event packet is to transmit control commands and operations with hard real-time requirements. A data packet is 64-byte length consisted of a 4-byte header, a 56-byte payload and a 4-byte trailer. The main use of the data packet is to transmit image and sound data with soft real-time requirements.

Figure 2 shows the format of the header. A packet has a header that includes a 16-bit source node address and a 16-bit destination node address. The source node address includes a 4-bit priority[7-4] and a 12-bit source address. On the other hand, the destination node address includes a 4-bit priority[3-0] and a 12-bit destination address. The priority[7-4] has the 7-4 bits of the 8-bit priority and the priority[3-0] has the 3-0 bits of the 8-bit priority. Larger values have higher priorities in packets. The highest priority is 255 (0xff) and the lowest priority is 0 (0x00).

Figure 3 shows the format of the trailer. The trailer includes the following parameters.

- User Defined (UD): sets this bit to the user defined data.
- Full: sets this bit to 1 if all payload data are valid (data packet: 56 bytes, event packet: 8 bytes). Otherwise, set this bit to 0.
- Data Length: indicates the length of the valid payload data (data packet: 0-56, event packet: 0-8).
- Dirty[0-15]: indicates which word (4 bytes) in the packet has an error in case of a data packet or which byte in the packet has an error in case of an event packet. For example, if the 3^{rd} word of the data packet has an error, then set the Dirty2 bit to 1. If the 4^{th} word of the event packet has an error, then set the Dirty3 bit to 1.
- Start: sets this bit to 1 if this packet is the start packet. Otherwise, set this bit to 0.
- End: sets this bit to 1 if this packet is the end packet. Otherwise, set this bit to 0.
- Interrupt (Int.): generates an interrupt when this packet arrives the destination node if this bit is set to 1. Otherwise, set this bit to 0.
- Fatal: sets this bit to 1 by hardware if one byte in the packet has an unrecoverable fatal error. Otherwise, set this bit to 0.
- Correct: sets this bit to 1 by hardware if this packet has an error that has been corrected. Otherwise, set this bit to 0.
- Serial Number: indicates the serial number. The start packet has the serial number 0 and the serial number is incremented in the following packets. The serial number returns 0 after it arrives 7 and the sequence is repeated.

Byte	0	1	2	3	4	5	6	7
0	UD	Full	Data Length					
1	Dirty0	Dirty1	Dirty2	Dirty3	Dirty4	Dirty5	Dirty6	Dirty7
2	Dirty8	Dirty9	Dirty10	Dirty11	Dirty12	Dirty13	Dirty14	Dirty15
3	Start	End	Int.	Fatal	Correct	Serial Number		

Fig. 3: Format of trailer

2.3 Routing

Responsive Link achieves an end-to-end connection by setting the routing tables of all nodes along the transmission path from a source node to a destination node.

Figure 4 shows the routing table of Responsive Link. Each node has a routing table to control the route of the packet and the priority exchange function. The 32-bit reference part is the same as the header of the packet. On the other hand, the 16-bit referent part includes the following parts.

- Event Enable (EE): sets this bit to 1 if the event link is valid. Otherwise, set this bit to 0.
- Data Enable (DE): sets this bit to 1 if the data link is valid. Otherwise, set this bit to 0.
- Priority Exchange (PE): indicates whether the priority exchange function is valid.
- Priority[7-0] (P[7-0]): includes the new priority level (8 bits) which is valid if PE is set to 1.
- Link[4-0] (L[4-0]): indicates the output link numbers. The L[4-1] bits indicate the output link numbers of four physical ports in Responsive Link. On the other hand, the L[0] bit indicates the output link number to Dual Port Memory (DPM) in a processor. If multiple bits are

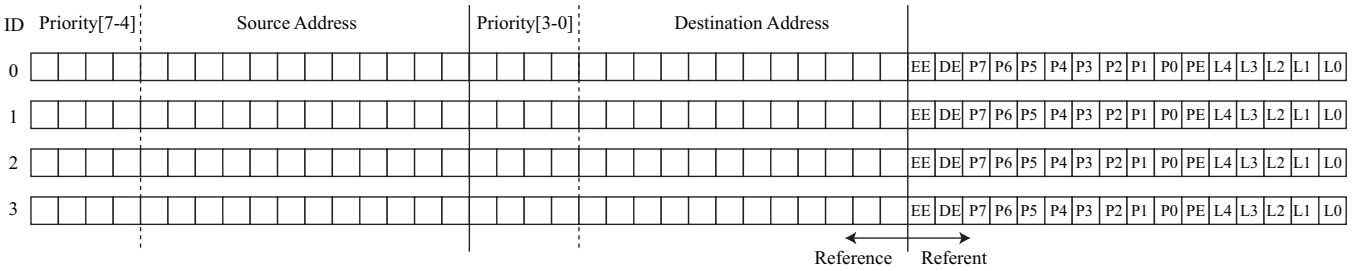

Fig. 4: Routing table

set to 1, then multicast is indicated. If all bits are set to 1, then broadcast is indicated.

Since the EE bit and the DE bit can be set independently, the event link and the data link may have different routes to the same destination.

Responsive Link supports the layer 1 to the layer 4 in OSI reference model. Using Responsive Link, we can implement communication protocols such as TCP with low overhead, compared to software implementation using other communication standards.

Unfortunately, current real-time operating systems do not support the main features of Responsive Link. Therefore, the APIs for Responsive Link are required to build distributed real-time systems easily.

3. Implementation

We implement APIs for Responsive Link in RT-Est real-time operating system [5]. Using the APIs, users can make use of the main features of Responsive Link easily.

3.1 Initialization

We implement the device driver of Responsive Link in `init_resplink` function. This function initializes the following parameters.

- SDRAM: sets the size of SDRAM for the packet overtaking by the priority of each packet selected with [None,8MB,16MB,32MB,64MB,128MB,256MB].
- Speed: sets the speed of Responsive Link selected with [50Mbps,100Mbps,200Mbps,400Mbps,800Mbps].
- Switch: initializes the switch, the encoder and the decoder of Responsive Link. The switch of Responsive Link supports the following modes.
  - Cut Through Mode: The switch starts to forward a packet before the whole packet has been received, as soon as the destination address is processed. This technique has the advantage of reducing latency and the disadvantage of decreasing tolerance.
  - Store and Forward Mode: The switch starts to forward a packet to a node where the packet is kept and sent at a later time to the destination node or another intermediate node.
- Interrupt: clears all interrupts of both the event link and the data link and enables a proper interrupt by users. For example, Responsive Link supports the following End Of Packet (EOP) interrupts.
  - Down: The cable of Responsive Link is unplugged.
  - Wakeup: The cable of Responsive Link is plugged.
  - Fatal: A fatal error occurs as described in Subsection 2.2.
  - Data-Out EOP: occurs if sending data packets in the range of the specified DPM.
  - Data-In EOP: occurs if receiving data packets in the range of the specified DPM.
  - Data Packet-In: occurs if receiving data packets, which enable their interrupt bits.
  - Event-Out EOP: occurs if sending event packets in the range of the specified DPM.
  - Event-In EOP: occurs if receiving event packets in the range of the specified DPM.
  - Event Packet-In: occurs if receiving event packets, which enable their interrupt bits.
- Link[4-0] (L[4-0]): indicates the output link numbers, as described in Subsection 2.3.
- Serial/Parallel[4-0]: indicates serial/parallel connection in each output link number. If an output link is parallel connection, set this bit to 1. If an output link is serial connection, set this bit to 0.
- DPM: initialize event in/out and data in/out registers.
  - Transmission Mode: If the transmission mode is Mode0, set this bit to 0. In Mode0, each packet includes each header and trailer. If transmission mode is Mode1, set this bit to 1. In Mode1, first of all, Responsive Link transmits the payload of each packet at the head of the DPM sequentially. After the payload of each packet, Responsive Link next transmits the header and the trailer of each packet sequentially. Therefore, all packets arrive at the same destination node address.
  - Interrupt: If this bit is set to 1, an EOP interrupt occurs.
  - Dreq: If this bit is set to 1, perform DMA transfer of the packet by the DMA counter.
  - From_Addr/To_Addr: These control registers have

```
struct resplink_header {
  unsigned int high_priority:4;
  unsigned int src_addr:12;
  unsigned int low_priority:4;
  unsigned int dst_addr:12;
} __attribute__((packed));
```

Fig. 5: struct resplink_header

```
struct eventlink_packet {
  union {
    uint32_t addr;
    struct resplink_header header;
  } u;
  uint8_t payload[8];
  uint32_t trailer;
};
```

Fig. 6: struct event_packet

```
struct datalink_packet {
  union {
    uint32_t addr;
    struct resplink_header header;
  } u;
  uint8_t payload[56];
  uint32_t trailer;
};
```

Fig. 7: struct data_packet

```
void send_eventlink(unsigned int mode,
  struct event_packet *ep);
void send_datalink(unsigned int mode,
  struct data_packet *dp);
int recv_eventlink(uint8_t *buf);
int recv_datalink(uint8_t *buf);
```

Fig. 8: send/receive functions

same features. For ease of comprehension to users, the name of each control register is different.

Users can configure the above parameters for target distributed real-time applications. Therefore, Responsive Link can support more various types of distributed real-time applications than other communication standards.

3.2 Packet

We explain the format of the event packet and the data packet.

Figure 5 shows struct resplink_header. As shown in Figure 2, struct resplink_header includes a 4-bit high_priority, a 12-bit src_addr, a 4-bit low_priority and a 12-bit dst_addr. In addition, struct resplink_header has the packed type attribute.

Figure 6 shows struct event_packet. As shown in Figure 1(a), struct event_packet has a 4-byte header, a 8-byte payload and a 4-byte trailer. In struct eventlink_packet, union u has a 4-byte address and struct resplink_header. For example, this 4-byte address is used to write header to the reference part in routing tables and this header is used to set the priority, the source address and the destination address.

Figure 7 shows struct data_packet. As shown in Figure 1(b), struct data_packet has a 4-byte header, a 56-byte payload and a 4-byte trailer. Like struct event_packet in Figure 6, struct data_packet also has union u.

Figure 8 shows send/receive functions in event link and data link. The first argument of send_eventlink and send_datalink functions is mode, which selects Mode0 or Mode1 if the first argument is 0 or 1 respectively. The second argument of send_eventlink is the pointer of struct event_packet. Also, the second argument of send_datalink is the pointer of struct data_packet. The first argument of recv_eventlink and recv_datalink functions is the pointer of the 1-byte character. This pointer indicates the head of the buffer receiving event packets and data packets respectively.

3.3 Routing Table

Figure 9 shows add/delete functions to add/delete routing tables respectively. add_rtable function adds a rule to both reference and referent parts in the routing table, as shown in Figure 4. Then the rule is set to the unique identifier. On the other hand, delete_rtable function deletes the rule selected by id.

Note that if registering the same rules of routing tables, the rule with the smallest id in the same rules is applied to routing packets.

3.4 Example

In this subsection, we explain an example of usage with APIs for Responsive Link.

Figure 10 shows an example of sending/receiving data packets in usermain function. First of all, struct datalink_packet sets the header, the payload and the trailer of the data packet. The priority of the header is 0x55, the source address is 0xa5a and the destination address is 0xa5a. Since this is an example of the loopback transmission, the source address is the same as the destination address. The trailer of the data packet sets Full bit to 1 because all payload data are valid.

Next we set new_priority to 0x11. Then init_resplink function is called to initialize the parameters of Responsive Link, as described in Subsection 3.1. Now we call add_rtable function to set the routing table. The first call of add_rtable function sets the priority, the source address and the destination address of dp. The priority exchange function is valid and changes the priority of data packet from 0x55 to 0x11. The output link of the data packet is L[1]. The second call of add_rtable

```
void add_rtable(uint32_t reference,
                uint16_t referent);
void delete_rtable(unsigned int id);
```

Fig. 9: add/delete functions

Table 1: Specification of RMTP

Clock frequency	31.25MHz
SDRAM	64MB
SRAM	256KB
I-Cache/D-Cache	each 32KB (Harvard)
Fetch width	8
Issue width	4
Integer register	32-bit × 32-entry × 8-set
Integer renaming register	32-bit × 64-entry
FP register	64-bit × 8-entry × 8-set
FP renaming register	64-bit × 64-entry
ALU	4 + 1 (Divider)
FPU	2 + 1 (Divider)
64-bit ALU	1
FP vector unit	1 (4FPU × 2line)
Branch unit	2
Memory access unit	1

function sets `new_priority`, the value of which is 0xff. The source address and the destination address are set to those of `dp`. The priority exchange function is also valid and changes the priority of data packet from 0x11 to 0xff. The output link of the data packet is L[0]. We call `send_datalink` function to send the data packet with Mode0. After sending the data packet, the program calls `recv_datalink` function repeatedly until receiving the data packet. The return value of `recv_datalink` function is the length of received data. If receiving the data packet, the busy loop is finished.

Note that the priority of the data packet is finally set to 0xff so that the header of the data packet is changed from 0x5a5a5a5a to 0xfa5afa5a. If the second call of `add_rtable` sets `new_priority`, the value of which is 0x55, the packet is not transmitted to L[0] because the original priority of the data packet is 0x55. As a result, the header of the data packet is changed to 0x5a5a5a5a and the data packet is transmitted to L[1] repeatedly.

```
void usermain(void)
{
  unsigned int cur_priority, src, dst,
    new_priority;
  /* initialize data packet */
  struct datalink_packet dp = {
    .u.header = {
       .high_priority = 0x5,
       .src_addr = 0xa5a,
       .low_priority = 0x5,
       .dst_addr = 0xa5a,
    },
    .payload = {0},
    .trailer = 0x40000000,
  };
  uint8_t buf[0x40];
  new_priority = 0x11;

  /* initialize Responsive Link */
  init_resplink();

  /* add rule to routing table */
  add_rtable(dp.u.addr,
             (0x3 << 14) |
             (new_priority << 6) |
             (0x1 << 5) | 0x1);
  cur_priority = new_priority;
  new_priority = 0xff;

  /* add rule to routing table */
  add_rtable(((cur_priority & 0xf0) << 24) |
              (dp.u.addr & 0x0fff0fff) |
              ((cur_priority & 0xf) << 12),
              (0x3 << 14) |
              (new_priority << 6) |
              (0x1 << 5) | 0x0);

  /* send data packet */
  send_datalink(0, &dp);

  /* wait until receiving packet */
  while (recv_datalink(buf) == 0)
    ;
}
```

Fig. 10: Example of sending/receiving data packets

4. Experimental Evaluations

4.1 Experimental Environments

The experimental evaluations use Responsive Multi-threaded Processor (RMTP) [19] which has prioritized SMT architecture with MIPS and RMTP-specific instructions. Table 1 shows the specification of RMTP. We implement APIs for Responsive Link [20] in RT-Est real-time operating system [5] on RMTP. In order to transform RMTP-specific instructions to machine language, we have developed a cross-compiler for RMTP, which extends `gcc` version 3.4.3 for MIPS.

Figure 11 shows our experimental environment. There are two RMTPs, which are connected by Responsive Link. The noise generator covers the cable of Responsive Link. The baud rate of Responsive Link is selected within [50Mbps,100Mbps,200Mbps,400Mbps,800Mbps]. In `init_resplink` function, the switch mode is set to the store and forward mode because the store and forward mode has higher tolerance than the cut through mode. In addition, the transmission mode is set to Mode0 and the connection method is serial. We use the data link in experimental evaluations.

We assume the actual noise in noisy environments where a humanoid robot [14] runs. Table 2 shows the specification of the noise wave.

In order to evaluate the tolerance of Responsive Link, we perform the voltage tolerance test. First of all, we set the

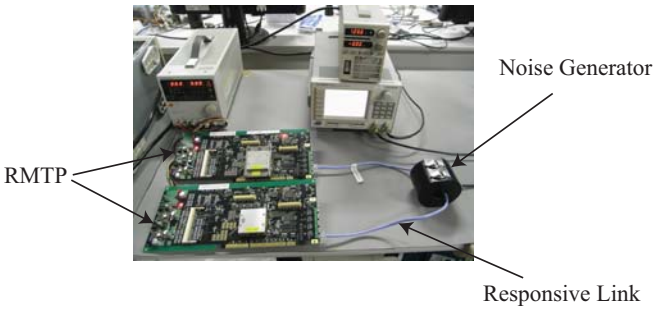

Fig. 11: Experimental environment

Table 2: Specification of noise wave

Frequency	12MHz
# of bursts	5
Wave shape	Triangle

voltage of the noise wave to 1.0V in the noise generator. Next, we check whether sending/receiving data packets in the noisy connection. If Responsive Link can send/receive data packets, we raise the voltage of the noise wave by 0.1V. If Responsive Link cannot send/receive packets due to noise, the value subtracting 0.1V from the current voltage is that of the voltage tolerance against noise in this environment. We perform this experiment by 10 times in each baud rate and measure the minimum, average and maximum values of the voltage tolerance.

4.2 Overhead

Table 3 shows the overhead of APIs for Responsive Link. `init_resplink` function sets the various parameters of Responsive Link. As a result, this function has the most cycles in evaluated functions. `add_rtable` function has low overhead because this function only writes a 32-bit reference part and a 16-bit referent part and sets the identifier of the rule which is the smallest in empty ids. `send_datalink` function also has low overhead because this function sets the control registers of the data link and the DMAC. We measure the overhead of `recv_datalink` function from entering to exiting this function. `recv_datalink` function checks whether receiving data packets. If receiving data packets, write the data packets to the specified memory. Therefore, `init_resplink` function has higher overhead than `add_rtable` and `send_datalink` functions.

4.3 Voltage Tolerance Test

Figure 12 shows the result of the voltage tolerance in the loopback transmission. If the baud rate of Responsive Link is faster and faster, the voltage tolerance is usually lower and lower.

Figure 13 shows the result of the voltage tolerance in the point-to-point transmission. Each voltage tolerance in the point-to-point transmission has slightly higher voltage

Table 3: Overhead of APIs

function	# of cycles
`init_resplink`	1,681
`add_rtable`	91
`send_datalink`	27
`recv_datalink`	344

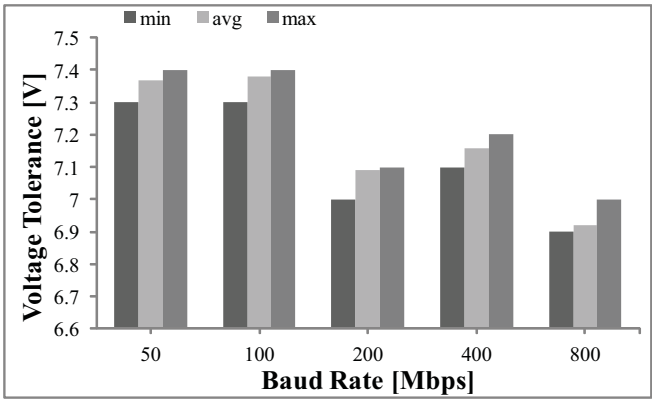

Fig. 12: Loopback transmission

tolerance than that in the loopback transmission in Figure 12. That is to say, the point-to-point transmission improves the tolerance compared to the loopback transmission. Like the loopback transmission, if the baud rate of Responsive Link is faster and faster, the voltage tolerance is also usually lower and lower.

5. Related Work

We compare our work with other work in distributed real-time environments.

TAO [16] is a middleware, which is compliant with RT-CORBA [8]. In addition, TAO implements IIOP protocol, which is an TCP/IP implementation of GIOP protocol specified in CORBA [9], [10], [11] by Ethernet. However, it is difficult to avoid packet collision by Ethernet. In contrast, Responsive Link supports layer 1 to layer 4 in OSI reference model and has four physical ports to avoid packet collision.

Except Ethernet, CAN [1] and FlexRay [6] are also wired communication standards. CAN supports only bus topology and FlexRay supports both bus and star topologies. Using these standards, a message packing algorithm is proposed [12]. Distributed control robots require various topologies so that topology-free communication standards such as Responsive Link have more compatibility than CAN and FlexRay.

In wireless communication standards, real-time packet scheduling over WirelessHART [7] is proposed [15]. Like Responsive Link, wireless communication standards are also topology-free. In general, wireless communication standards frequently occur packet collision/loss compared to wired communication standards so that the analysis of the worst case arrival time in each packet is difficult. Therefore,

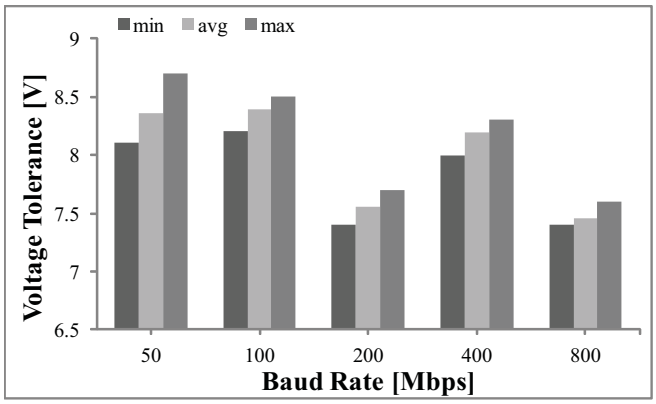

Fig. 13: Point-to-point transmission

Responsive Link is better than wireless communication standards in distributed real-time environments.

6. Concluding Remarks

We presented the APIs for Responsive Link in RT-Est real-time operating system. In particular, we explain how to use the APIs for data link. Using the APIs, users can build distributed real-time systems easily. In addition, we introduce a method to evaluate the tolerance of communication standards. Experimental evaluations reveal the voltage tolerance against noise in Responsive Link. Using the results, users can select a proper baud rate to communicate between nodes correctly in noisy environments.

In future work, we will implement the APIs for packet scheduling with fixed-priority scheduling [13] and semi-fixed-priority scheduling [3], [4] over Responsive Link. The analysis of the worst case arrival time in each packet is intriguing.

Modeling Packet Processing Time in a Multiprocessor Network Traffic Monitoring System

Luis Zabala, Armando Ferro, and Alberto Pineda
Networking, Quality and Security (NQaS) Research Group
University of the Basque Country (UPV/EHU), Bilbao, Spain

Abstract - *Nowadays traffic monitoring is a must for many purposes such as QoS monitoring, IDS, antivirus, network problem detection and so on. Deployment of high speed networks implies problems with this kind of systems to be able to cope with all the traffic in the network. Therefore, it would be interesting to know in advance whether a traffic monitoring system will be able to do its task correctly, or it needs more processing power. This paper presents a mathematical model for multiprocessor traffic monitoring systems that use commodity hardware and general purpose operating systems. In order to establish the different elements of the model we have identified the different stages of the trip of packets from wire to application, as well as the particular behavior of the system and the computational cost for each one of them. With this information, we have built up a model based on a closed queuing network that simulates these different stages of the monitoring system and the possible packet losses. This model allows us to estimate the performance of the monitoring application in terms of throughput.*

Keywords: *traffic monitoring; performance evaluation; closed queuing network; multi-server system*

1 Introduction

The performance of network traffic monitoring systems has a great importance in all kind of network devices. Moreover, there are some applications related to network security and packet analysis which are particularly sensitive to network capturing performance. These include IDS (Intrusion Detection Systems), antivirus, QoS (Quality of Service) analysis systems. In order to achieve Gigabit-order analysis capabilities, most of these systems are forced to use specific hardware and operating systems. This results in more expensive devices and longer development processes.

On the other hand, traditionally, the performance degradation of those systems based on commodity hardware and general purpose operating systems is mostly caused by a design focused on network applications, not on extensive network packets capturing [1]. However, last investigations have demonstrated that packet capture has been improved by enhancing general purpose operating systems for traffic analysis. These results are encouraging because today's commodity hardware offers features and performance that just a few years ago were only provided by costly custom hardware design [2] [3]. Even then, there are still deficiencies to adapt to new architectures such as multithreaded and multi-cored ones.

In order to continue the improvement of this second kind of systems, it is necessary to identify the design flaws that have an impact on capturing performance. So, it is also important to develop theoretic models and simulation tools that help us in the design and development cycles.

The experience of our research group in the development of a traffic capture and analysis system has encouraged our study of the packet capturing subsystem in general purpose operating systems, especially Linux and its effect on the overall packet analysis performance. In order to improve the traffic monitoring systems' performance we need data about where the packets are lost and why. These data allow us to predict the performance of our system without running real simulations and, therefore, without designing and implementing several prototypes. So, in order to help us in the design and cut down development cycles we have built a model of the different stages of the packet capturing subsystem of Linux Kernel. After obtaining real measurements of the computational costs of each stage we have developed a model that provides us with data about the packet capturing and analysis capabilities, such as the number of packet lost in each stage.

The paper is organized as follows. The background of our work is presented in Section 2. Then, Section 3 describes the analytical model of the packet processing consumptions. The model validation is explained in Section 4. Finally, we conclude the paper in Section 5.

2 Background

In the previous work [4], our research group proposed a prototype of a traffic monitoring system for high speed networks called Ksensor. It works at kernel-level and it is based on Linux. The experimental study of Ksensor has brought some aspects that are worth analyzing.

2.1 Problem Formulation

The aspects mentioned before are related to the time the system takes in order to capture or analyze a packet. We have noticed that this time depends on the network traffic rate and the analysis load which is managed by the traffic monitoring

system. In the laboratory, in order to test Ksensor, we simulate different analysis loads implementing four loops that execute 0, 1000, 5000 and 25000 cycles respectively.

Fig. 1 shows the values of a parameter measured experimentally on Ksensor. In particular, Fig. 1 presents the average softIRQ time per captured packet. This parameter belongs to the capturing stage and, as can be observed, it varies with the injection rate and the analysis loads. It is worth mentioning the three areas that we can observe on the 1 Kcycle analysis load curve. Moreover, in the graphic it can be seen that it takes more time capturing a packet with 0 Kcycle analysis load (null) than with 25 Kcycle analysis load. On the contrary, the average values of the analysis time per packet are similar for all the range of injection traffic rates.

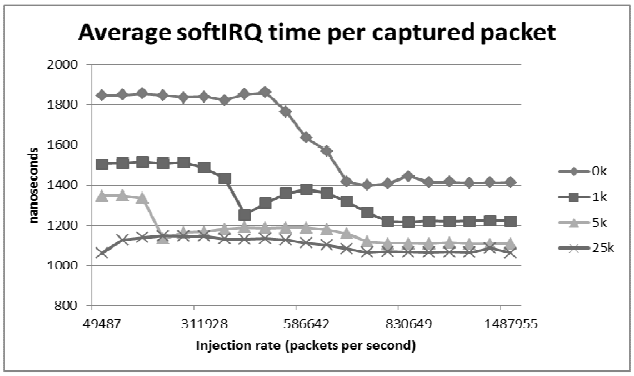

Figure 1. Average softIRQ per captured packet.

Thus, we intend to make a proposal of a mathematical model which considers the capturing and the analysis stages with their possible variability of CPU consumptions. Certain aspects correspond to our group's own development. However, we consider that these characteristics can also be extrapolated to more general systems.

Our initial hypotheses take us to consider some packet losses along the capturing stage. Hence, as it happens when duplicate packets or IP fragmentation losses are detected; some activities entail a waste of CPU. In the case that concerns us, due to the shortage of resources or, even, due to control policies of the monitoring application, some packets can be discarded in the capturing stage, producing a CPU consumption that does not result in a captured packet.

2.2 Generic Traffic Monitoring Systems

If we consider a typical traffic monitoring system, we usually come across three different phases: capture phase, basic analysis or filtering phase and complex analysis phase. The capture phase can be divided into: hardware processing stage (network interface card), driver processing stage and kernel processing stage.

The basic analysis phase is based on classifying each received packet after studying its features to determine whether the packet must be further analyzed or discarded. This task must be carried out for every captured packet. The real packet processing (e.g. intrusion detection algorithm, QoS algorithm, etc.) is applied in the complex analysis phase but only to those packets that successfully passed the basic analysis phase.

In the next section, we will focus on analyzing the parts of the Linux packet capture subsystem. Since the impact of each parameter depends on its computational costs, we work out the cost of every phase along the capture system and identify which stages would lose packets more likely.

2.3 Packet Losses

As it has been said before, we consider that there are packet losses in the capturing stage. Because of that, it is important to study the capturing system of Linux.

After a thoughtful analysis of the path followed by a packet through Linux operating system, we can identify the points where packet losses are more liable. As a result, these points must be considered in the design of packet capture model. Although Linux is a specific case, the path followed by packets in other operating systems is quite similar to this.

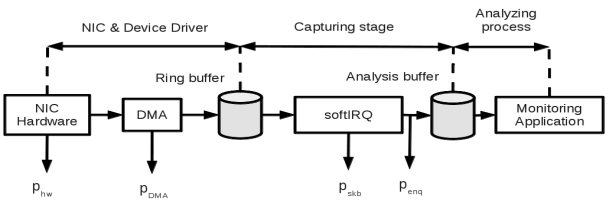

Figure 2. Packet losses in the packet receiving process with Linux networking subsystem

Fig. 2 shows the trip of a packet from its ingress into a Linux end system to its final delivery to the monitoring application, taking into account the possible packet losses along the journey. When a packet arrives to the NIC a hardware interruption (hardIRQ) is generated. The network interface card (NIC) captures packets and copies them in an internal buffer. Then, the DMA (Direct Memory Access) engine of the card, without CPU intervention, is in charge of moving these packets to a special allocation area in the main memory of the system called DMA area. The driver is in charge of attending the hardIRQ. When arrival rate is high, this interruption is generated for a bunch of packets. In order to extract the packets from the DMA area, the driver uses polling mechanism. After any interruption, a software interruption (softIRQ) is scheduled in order to complete the capture of packets. Packets are then moved, during the softIRQ, from the DMA area to another space in the main memory, creating a skb element list. Skb elements are buffers in which the kernel handles network packets [5]. Next, the softIRQ has to move the packet to the monitoring application's analysis buffer.

Packet losses due to capture deficiencies are represented by p_{hw} and are not very common. Packet losses due to DMA transfer errors are represented by p_{DMA}. A p_{DMA} will occur when packet arrival rate is very high and the NIC allocates in

main memory more packets than the system is able to manage, causing an overflow of the DMA's reserved space in main memory. When the packets are moved from the DMA area to the skb element list there can be eventual losses, which are also very uncommon. These losses are represented by p_{SKB}. Finally, p_{enq} represents the proportion of packets which cannot be enqueued in the monitoring application's analysis buffer. Obviously, the length of this queue is limited, so that an overflow of this queue becomes quite likely only at very high arrival rates.

3 Packet Process Consumptions Model

This section introduces an analytical model which works out, firstly, the different stages which have been identified in a multiprocessor traffic monitoring system and, secondly, the possible packet losses in the journey from the network card to the analysis application. For a large number of arrivals (heavy traffic conditions), the multiprocessor architecture can be modeled as a closed queuing network [6].

3.1 Description of the Model

The proposal for modeling packet process consumptions of a traffic monitoring system is showed in Fig. 3. It consists in a closed queuing network where computer consumptions are related to the service capacity of the queues. Two parts can be distinguished; the upper one has a set of multi-server queues which represents the traffic monitoring system with its different stages (capture, filtering and analysis), processing abilities (μ_{Ci}, μ_F, μ_A) and possible packet losses (p_{hw_dma}, p_{skb}, p_{enq}). The part on the left models the injection of network traffic with λ rate. This simple queue closes the network and the number of packets that are permitted is N. With heavy traffic conditions, the departure of a packet from the traffic monitoring system triggers the injection of an already waiting packet.

Four different stages have been distinguished for the closed network, each one with a specific function:

- Capture stage: it represents the functionalities provided by the operating system which is responsible for capturing packets and moving them from the NIC to the memory of the analysis application. It comprises treatments of device controllers and attention paid by kernel to interruptions (hardIRQ and softIRQ) due to packet arrival. This stage is divided into three multi-server queues with rates μ_{C1}, μ_{C2}, μ_{C3} (measured in packets per second) capacity, due to the need to differentiate the packet losses inside it. For this, p_{skb} is defined as the probability of having every ring buffer descriptor full and p_{enq} is defined as the probability of not enqueuing packets to the analysis buffer.
- Filtering stage: it is modeled by a multi-server queue with rate μ_F. According to some rules, captured packets are filtered and, finally, only selected packets are analyzed in the next stage. This stage represents the amount of time spent on this basic treatment.
- Analysis stage: it is integrated by a multi-server queue with rate μ_A. It simulates the complex analysis treatment that the system does to packets that need further analysis. As not all the packets need to be processed in this stage, a rate called q_a indicates the proportion of the received packets that has to be analyzed.
- Traffic injection stage: it is a simple queue of λ rate. This stage simulates the arrival of packets to the system with λ rate.

Since the number of packets in the closed network is fixed to N, the traffic injection queue can be empty. This situation simulates the blocking and new packets will not be introduced on the system. The model also considers the possibility of losing packets due to deficiencies at NIC or DMA's transfer errors with p_{hw_DMA} probability. However, since it is generally recognized that they are very uncommon, those losses will be negligible and $p_{hw\_DMA}=0$ for solving the model.

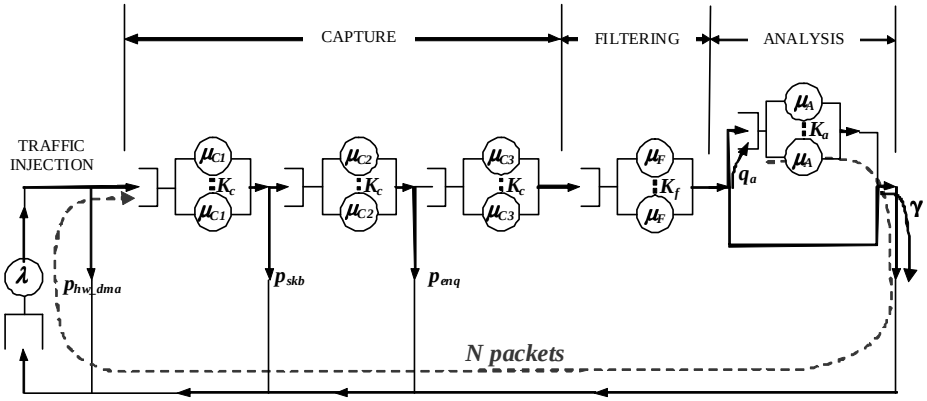

Figure 3. Model based on closed queuing network for packet process consumptions

We assume that the number of processors of the system is K and each stage can be served by a different number of processors, having K_c available processors for capturing, K_f for filtering and K_a for analysis being $K_c \leq K$, $K_f \leq K$ and $K_a \leq K$. So, the parallelizing level can be different in each phase. Another aspect to consider is that packets cannot flow freely in the closed network, because the sum of packets attended in the servers that represent the traffic monitoring system never exceeds the maximum number of processors available.

3.2 Simplifications of the Model

The model presented in Fig. 3 is very general, but some simplifications are possible. First, it is worth mentioning that both, the flowing traffic and the processing capacity at the nodes, are modeled by Poisson arrival rates and exponential service rates. Poisson's distributions are considered to be acceptable for certain types of network traffic, for instance, modeling the voice traffic, as explained in [7]. This assumption can be relaxed to more general processes such as MAPs (Markov Arrival Processes) [8] or non-homogeneous Poisson processes. However, for some other types of traffic such as Ethernet network, packet arrivals do not follow a Poisson process but are rather bursty [9]. The case we are dealing with is slightly different because the packet arrival is not directly the traffic of the Ethernet network, but it is the incoming packets from the network card's buffer to the kernel memory area via DMA. Regarding service rate modeling, although program's code has a quite deterministic behavior, some randomness is introduced by Poisson incoming traffic, variable length of packets and kernel scheduler uncertainty. An analytical solution can become unmanageable when considering non-Poisson arrivals, even presuming general service times. Despite of these limitations, we will keep working with these assumptions for simplicity of the analysis and, as will be demonstrated in Section 4, the results obtained from our models were closely matching to results obtained from real experimental measurements.

Apart from that, the main feasible simplification preserving the identity of the system is to replace the whole traffic monitoring system with its Norton equivalent [10]. Our theoretical model has exponential service rates in all stages, so applying the Norton equivalence, the new equivalent queue will have a state-dependent service rate $\mu_{eq\_TMS}(n)$.

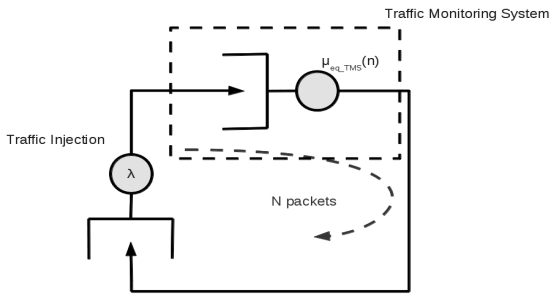

Figure 4. Simplified model with the Norton equivalent.

Therefore, with the aim to obtain the simplified model of Fig. 4, we apply the calculation of the Norton equivalent to the general model of Fig. 3 several times as we will see later.

In the study of this model, we observe that the same topology is repeated at different levels of abstraction. This topology corresponds with a closed network model with two multi-server queues where the output flow of the first queue goes to the second one with a probability of 1-p, whereas it comes back to the first one with a probability of p, as shown in Fig. 5. This structure usually occurs in every processing stage.

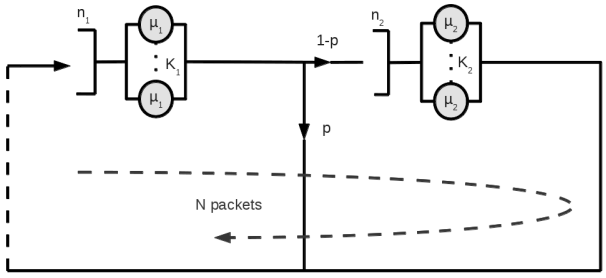

Figure 5. Topology repeated at different levels of abstraction.

3.3 Equations of the Repeated Topology

In order to get the Norton equivalent of the traffic monitoring system, first, we calculate the state probabilities for the repeated topology (see Fig. 5), putting N packets in circulation through the closed network, but assuming that the total system can have at most K packets being served and the rest waiting in the queue. We also take into account the limitation of K_c, K_f and K_a processors in each stage.

The state diagram for this topology is presented in Fig. 6. In this model we are representing the state i of the multi-server queue on the left of Fig. 5 and we will consider μ_i as the service capacity for the state i. N packets are flowing through the closed network and when there are i packets in the multi-server queue on the left, the rest, N-i, are in the multi-server queue on the right. The probability of that state i is represented as $p_N(i)$. Finally, the output of the multi-server queue with rate $\mu_2(n_2)$ is the input of the multi-server queue with rate $\mu_1(n_1)$.

It is possible to deduce the balance equations from the diagram of states and, subsequently, the expression of the probability of any state i as a function of the probability of state zero $p_N(0)$.

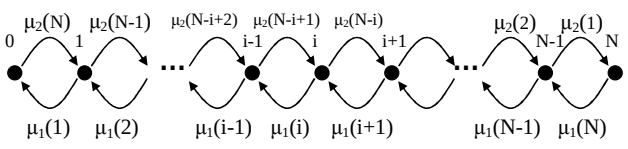

Figure 6. State diagram for the multiple queue with K_1 servers ($N \leq K$).

$$\left.\begin{array}{l} p_N(0)\cdot\dfrac{\mu_2(N)}{q}=p_N(1)\cdot\mu_1(1) \\ p_N(1)\cdot\dfrac{\mu_2(N-1)}{q}=p_N(2)\cdot\mu_1(2) \\ \ldots\ldots\ldots\ldots \\ p_N(N-1)\cdot\dfrac{\mu_2(1)}{q}=p_N(N)\cdot\mu_1(N) \end{array}\right\} \Rightarrow p_N(n+1)=\frac{\mu_2(N-n)}{q\cdot\mu_1(n+1)}\cdot p_N(n) \quad \forall n=1,\cdots,N \quad (1)$$

The term $p_N(n)$ indicates the probability of having n packets at queue 1 being N the number of packets in the closed network. For $N \leq K$ (being K the total number of processors):

$$p_N(n)=\frac{\prod_{i=N-n+1}^{N}\mu_2(i)}{q^n\cdot\prod_{i=1}^{n}\mu_1(i)}\cdot p_N(0) \quad \text{with } p_N(0)=\frac{1}{S_N}$$
$$S_n=1+\sum_{i=1}^{n}\frac{\prod_{j=n-i+1}^{n}\mu_2(j)}{q^i\cdot\prod_{j=1}^{i}\mu_1(j)} \quad 1\leq n\leq N \quad (2)$$

For every value of N, we calculate the throughput of the closed network and it will be the Norton equivalent which we want.

$$\mu_{eq}(N=1)=\sum_{i=1}^{N=1}\mu_1(i)\cdot p_1(i)=\mu_1(1)\cdot p_1(1)$$
$$\mu_{eq}(N=2)=\sum_{i=1}^{N=2}\mu_1(i)\cdot p_2(i)=\mu_1(1)\cdot p_2(1)+\mu_1(2)\cdot p_2(2) \quad (3)$$
...
$$\mu_{eq}(N)=\sum_{i=1}^{N}\mu_1(i)\cdot p_N(i)=\mu_1(1)\cdot p_N(1)+\mu_1(2)\cdot p_N(2)+..+\mu_1(N)\cdot p_N(N)$$

Taking into account these expressions, we can develop the equations of the whole model as will be detailed below.

3.4 Calculation of the Norton equivalent of the traffic monitoring system with losses

In order to calculate the Norton equivalence of the traffic monitoring system with losses, it is necessary to apply equations (1) and (2) several times.

First we compute the Norton equivalent for the filtering and the analysis stages. Then a second Norton equivalent is computed with the result of the first Norton equivalent and the multi-server queue with rate μ_{C3}. Later, a third Norton equivalent is computed with the result of the second Norton equivalent and the multi-server queue with rate μ_{C2}. Finally, a fourth Norton equivalent is computed with the result of the third Norton equivalent and the multi-server queue with rate μ_{C1}. This last result is the Norton equivalent of the traffic monitoring system. The service rate of the traffic monitoring system will be different for every value of N, i.e. it will be a state-dependent service rate.

For the calculation of the Norton equivalence, it must be remembered that the state diagram makes sense for values of N that are less or equal to the highest number of processors.

3.5 Solution for the Closed Network Model with Incoming Traffic

The previously explained Norton equivalence takes into consideration the internal problems of the traffic monitoring system related to the number of available processors. Now we complete the model adding the traffic injection queue to the equivalent system calculated before and the model of the entire system with incoming traffic corresponds with Fig. 4. Hence, the entire system under traffic load is modeled as a closed network with an upper queue, which is the Norton equivalent of the traffic monitoring system, and a simple queue on the left of the diagram, simulating the injection of network traffic with λ rate. In this closed network, a finite number N of packets circulates. This number N is greater than K, the number of available processors.

The analytical solution of this model is similar to that proposed for the repeated topology, taking into account the following: the arrival rate is λ and it is not state-dependent; the service rates μ_1, μ_2..., μ_p correspond with the calculation of the Norton equivalent of the traffic monitoring system, thus $\mu_n=\mu_{eq\_TMS}(n)$ with values of n from 1 to p; for states n with $K<n\leq N$, $\mu_n=\mu_K=\mu_{eq\_TMS}(K)$.

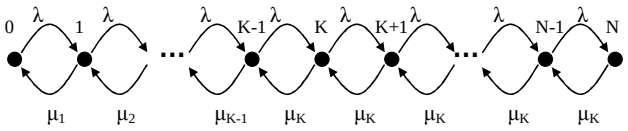

Figure 7. State diagram for the traffic monitoring system with incoming traffic (N>K).

Fig. 7 shows the related state diagram. This model allows us to calculate the theoretical throughput of the traffic monitoring system for different loads of network traffic.

$$\gamma=\lambda\cdot(1-p(N)) \quad (4)$$

4 Model Validation

This section explains the validation tests of the analytical model presented in this paper. The aim is to compare theoretical results with those obtained by experimental tests over a real traffic monitoring system. Although the model is proposed for a generic traffic monitoring system, in this section, the model is adapted and validated for the prototype called Ksensor. We expect to continue with the model validation over other platforms in the near future. It is also worth mentioning that some initial values are needed to assess

the theoretical model. They have been extracted from experimental measurements of Ksensor too.

4.1 Test Setup

Our hardware setup consists, as Fig. 8 shows, of four computers: one for traffic generation (injector), a second one for capturing and analyzing the traffic (Ksensor), a third one for packet reception (receiver) and the last one (manager) for managing, configuring and launching the tests. All they are physically connected to the same Gigabit Ethernet switch.

The basic idea is to overwhelm the system under test, Ksensor, with high traffic generated from the injector. In order to inject traffic bursts, we have installed an Endace 4.3GE DAG card [11] on the injector. Regarding software, we use a testing architecture designed by our research group [12]. The computer called manager is in charge of doing all the necessary tasks in order to automate the tests and measure the performance metrics of interest.

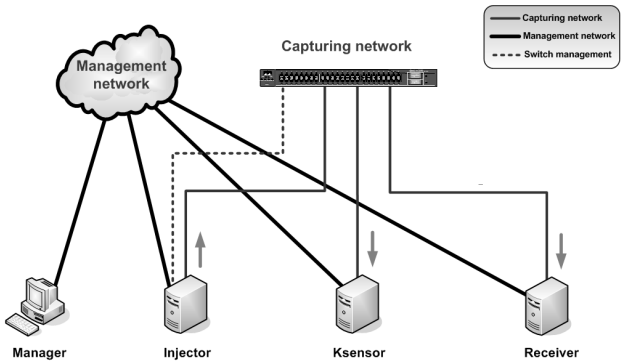

Figure 8. Hardware setup for validation tests.

The prototype Ksensor is a two-processor probe. One of the CPUs is responsible for capturing all the possible packets and analyzing some of them, whereas the other CPU is responsible only for analyzing packets.

4.2 Experimental Estimation for Certain Input Parameters of the Model

The model explained in Section 3 requires some input parameters such as μ_{C1}, μ_{C2}, μ_{C3}, μ_F, μ_A, p_{skb}, p_{enq} and q_a. We are referring to the service rates and probabilities that appear in the model (see Fig. 3) and are needed to obtain theoretical results.

At the end of every test, the manager (see Fig. 8) collects the measurements from Ksensor and the injector. Based on some of these experimental measurements (e.g. mean time consumed by a packet in every stage identified in the model, number of captured packets in softIRQ), we can estimate the model's input parameters. For example, the service rates μ_{C1}, μ_{C2}, μ_{C3}, μ_F and μ_A are computed as the inverses of the mean times experimentally obtained.

We have made tests varying the packet injection rate between 49487 and 1488000 packets per second, with packets of 40 bytes mean length and variable analysis loads (null, 1K, 5K, 25K) and we have observed that both the service rates and the probabilities are dependent on the injection rate and the analysis load. The exception is the probability q_a, because it is set before the test starts.

4.3 Performance Measurement Evaluation

After calculating the necessary values of the input parameters, the analytical expressions of Section 3 are assessed numerically. Table I and Fig. 9 illustrate this process showing, as an example, some numerical values for the case of 1K analysis load.

First, we have some experimental measurements obtained from Ksensor and the injector (e.g. the injection rate λ and the number of captured packets in softIRQ in Table I). Based on those measurements, we calculate the needed input parameters like the probability p_{enq} (see Table I).

TABLE I. EXAMPLES OF NUMERICAL VALUES USED IN THE EVALUATION OF THE ANALYTICAL MODEL

Experimental measurements from Ksensor and the injector			**Input param.**	**Intermediate result**	
Injection λ (pps)	***Captured Packets***	***Test seconds***	**p_{enq}**	**$\mu_{TMS}(1)$ (pps)**	**$\mu_{TMS}(2)$ (pps)**
49487	11924238	240,97	0,00	210690	383526
151298	36457717	240,97	0,00	210195	382273
255954	61678719	240,97	0,00	210546	383161
356470	85898013	240,98	0,00	213581	390861
453538	100799835	240,97	0,08	219462	399052
586642	100799835	240,97	0,29	216803	403453
664903	100037774	240,97	0,36	218532	405820
906022	105326168	240,97	0,51	224472	417279
1244992	104778112	240,97	0,65	223863	418296
1488000	108023963	245,25	0,70	224372	418332

Values for the case with packets of 40 bytes mean length and 1K analysis load in Ksensor (two-processor probe)

After that, the Norton equivalent of the traffic monitoring system is obtained. As explained before, it is necessary to compute the expressions of the repeated topology several times. Since we validate the model for Ksensor, the values of the parameters related to the number of processors are K_c=1 and K_f= K_a=2. Regarding the probability q_a, every test has been configured with q_a=1. Table I shows the values of the Norton equivalent of the traffic monitoring system as intermediate results. As they are state-dependent service rates, they have two values, for n=1 and n=2.

Finally, applying the solution for the closed network model with incoming traffic, we get the system throughput and it can be plotted like in Fig. 9.

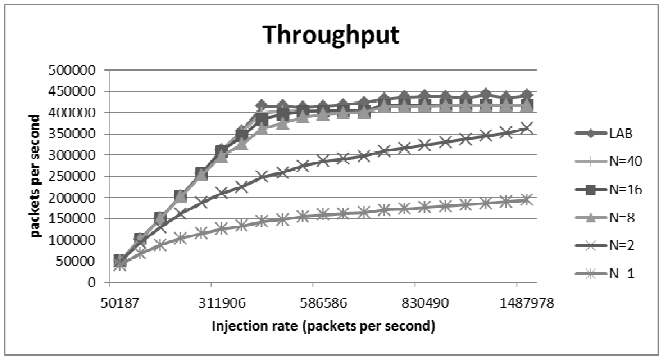

Figure 9. Theoretical and experimental throughputs with 1K analysis load in Ksensor (two-processor probe).

As mentioned, the model's main result is the theoretical throughput and, as seen in Fig. 9, it can be compared to the throughput measured by the experimental tests (LAB in Fig. 9). As we can observe, with N=40, the results are nearly the same. This process, which has been illustrated for the case of 1K analysis load, has also been done for the other cases (null, 5K and 25K). Acceptable results are obtained too.

5 Conclusions and Future Work

In this paper we have presented and analytical model that represents multiprocessor traffic monitoring systems. The model is generic and quantifies the system performance.

Initially, we detect experimentally an apparently strange behavior of the parameter called softIRQ times per packet in the traffic monitoring system. This addresses us to set out a model based in a closed queuing network which considers the capturing, filtering and analysis stages as well as the possible packet losses while the packet goes from the network to the monitoring application. We obtain the model's analytic solution, identifying a topology repeated at different levels of abstraction and applying the Norton equivalent to simplify the model. Then, the model is validated comparing theoretical results with experimental measurements over a prototype called Ksensor. In the validation process we make use of a testing architecture that not only measures the performance, it also provides values for some necessary input parameters of the mathematical model. As seen in the validation section, the obtained results are acceptable. Therefore, the model is able to represent precisely the behavior experimentally observed and also to evaluate the performance of the network traffic monitoring system, considering the most representative parameters like throughput, number of processors, analysis load and so on.

Moreover, the model is useful to interpret the variability of the processing time per packet in the capturing stage. The key is the parameter identified as p_{enq} in the model. In this work which combines the analytical study with experimental measurements, we have observed that this parameter is the most significant in the packet losses of the capturing stage. So, with high network rates, packet losses can be important and the smaller number of packets that reach the monitoring application require, in average, less CPU time.

Despite the fact that the conclusions have been satisfactory with regard to the behavior of the model, there are some aspects to be considered in the near future:

- We have presented a generic model for a traffic monitoring system, but we have only validated with the prototype Ksensor. We expect to adapt and validate the model to other platforms with more than two processors and over higher speed networks. We are especially interested in multicore systems and software probes under virtual machines.
- We have assumed Poisson processes and exponential service times and the results have been acceptable. However, we consider interesting to study the application of other distributions

All in all, we believe this work is one step for a better understanding of co-locating capturing process and monitoring applications. We can understand how to best process packets and whether new modeling techniques can be applied to perform network measurement.

A Power Controlled MAC Protocol with Improved Throughput for Ad hoc Networks

Santosh Kumar Yadav, A. K. Sarje

Roorkee, Uttarakhand, India
santosh.amh@gmail.com
sarjefec@iitr.ernet.in

Abstract - *Most of the devices in wireless ad hoc networks use battery power as the energy source; it makes the energy consumption as an important issue for such networks. Though energy maintenance can be performed at each layer but in the past, most of the researchers have focussed on MAC layer to minimize the energy consumption. The existing power controlled MAC protocols stress on reducing the energy consumption but they suffer from the disadvantage of throughput degradation of the network. In this paper, we have proposed a power controlled MAC protocol for wireless ad hoc networks that not only reduces the power consumption of each node in the network but also improves the throughput of the network. Our protocol involves two phases of work. Initially the protocol minimizes the power consumption of each node by sending the RTS packet with maximum power and CTS, DATA, ACK packets with minimum necessary power. DATA packets are periodically sent with maximum power to avoid unnecessary collisions. In the second phase, to improve the throughput of network, the spatial reuse is increased by changing the virtual carrier sensing mechanism of IEEE 802.11 protocol.*

Keywords: *ad hoc networks, energy consumption, MAC protocol*

1 Introduction

Ad hoc networks [1] are the wireless networks in which computing or electronic devices (referred as 'nodes') join together dynamically for transmitting the information from one node to another node in the form of data packets. The main characteristic which differentiates ad hoc networks from its counterpart infrastructure based network is the absence of any base-station in the ad hoc networks.

Wireless nodes use battery as the source of energy. As the battery power for any node is limited, it gives rise to the need of minimizing the battery power consumption for each node in the network. Minimizing the energy consumption of each node is the key to keep the ad hoc network functional for a long period of time.

Though energy consumption can be handled at each network layer, most of its maintenance is done at medium access control (MAC) layer. There are mainly two categories of MAC protocols for reducing the energy consumption at each node in ad hoc networks; first being 'Power saving MAC protocols' [2], [3] and second 'Power controlled MAC protocols' [4], [5], [6]. The first category i.e. 'Power saving MAC protocols' uses the concept of alternative sleep and wake up modes for wireless nodes. The nodes in ad hoc network remain in one of the three states: active, idle or sleep. Since power consumption in sleep state is less compared to other two states, we keep the nodes in sleep mode which are not participating in data transmission. On the other hand; in a network, power is consumed during computation and transmission of packets. But the computation power is negligible as compared to transmission power; hence efforts are made to reduce the transmission power. This is what 'Power control MAC protocols' uses and sends different packet types with different transmission power.

In this paper, we have focused on 'Power controlled MAC protocols' in which varying transmission power is used for transmitting the packets depending on whether the packet is RTS (request-to-send), CTS (clear-to-send), DATA or ACK (acknowledgement). In the past, most of the Power controlled MAC protocols focused on reducing the energy consumption of the wireless nodes without considering the aspect of network throughput which degraded on applying those power control techniques.

Our proposed power control MAC protocol not only reduces the power consumption of each wireless node of the network but also achieves improved throughput as compared to previous power controlled protocols. We have made some modifications in the virtual carrier sensing (VCS) scheme of IEEE 802.11 protocol to improve the spatial reuse of the network allowing more number of nodes to transmit frames at a time, which in turn, improves the throughput.

Our paper starts with a brief introduction of MAC protocols for ad hoc networks and the issues associated with them. Section 2 gives related works on power controlled MAC protocols. Section 3 covers the overview of IEEE 802.11

protocol which has been used as the base for power controlled MAC protocols. In section 4 our proposed power controlled MAC protocol is described. Simulation and results have been given in section 5. Finally, section 6 concludes the paper.

2 Related Works

Most of the existing Power control MAC protocols are based on IEEE 802.11 protocol. It uses CSMA/CA (carrier sense multiple access with collision avoidance) scheme, where carrier sensing is done using physical (air interface) as well as virtual carrier sensing. IEEE 802.11 involves four kind of packets namely RTS, CTS, DATA and ACK. Each packet's header contains a duration field that tells the time for which the transmission will take place. This duration field is used by virtual carrier sensing scheme to avoid collisions. Since IEEE 802.11 transmits each packet with the same maximum default power without taking any consideration of packet type, the energy consumption of each node is very high.

The PCMA protocol [8] allows different nodes in the network to send the packets with different transmission power levels. It uses four kinds of packets namely RPTS (Request-power-to-send), APTS (Acceptable-power-to-send), DATA and ACK. It follows the sequence RPTS-APTS-DATA-ACK for sending DATA packets. It uses two separate channels: *data channel* for RPTS-APTS-DATA-ACK sequence and *busy tone channel* for sending the busy tones while the node is receiving DATA packets. It uses busy tones to handle Hidden Node Problem instead of RTS-CTS handshake. Whenever a node is receiving DATA packets, busy tones are sent periodically by receiving node. Busy tone acts as a noise tolerance advertisement that can be tolerated by receiver. The drawback of PCMA is that it requires a separate signalling channel for busy tones. It also creates asymmetric links between nodes because each node sends packets with different power levels so it is possible that some node N1 can reach to any node N2 but not vice versa.

As a modification to IEEE 802.11 protocol, other power controlled protocols use maximum default power for transmitting the RTS and CTS packets while DATA and ACK packets are sent by minimum required power. This scheme has been termed as 'Basic Power Control Protocol' [5], [6]. Hence, it is possible that nodes in the CSZ (carrier sensing zone) that sense RTS-CTS transmission may not be able to sense any signal during DATA-ACK. Thus, when these nodes start a new transmission by sending RTS with max power, collision may occur with both the DATA packet at receiver as well as with the ACK packet at sender. This triggers retransmission of packets which results in more energy consumption and reduced throughput.

Power Control MAC (PCM) protocol [5] was given to remove the deficiency of Basic power control protocols. It is similar to the Basic power control protocol, but in addition to improving the throughput of the network, the DATA packets are sent with the maximum default power periodically.

F-PCM protocol [6] uses the fragmentation technique along with PCM protocol to further improve the throughput. It allows fragmenting of large DATA and ACK packets. Here also, the RTS and CTS packets are sent with maximum default power while the DATA and ACK packets are sent with minimum necessary power. But during the beginning of sending the DATA packet, the initial DATA fragments are sent with maximum power. A similar approach is applied to ACK packets.

Thus, by analysing the previous power control MAC protocols, we notice that though they reduce the energy consumption of each node but none of them improves the throughput of network in comparison to IEEE 802.11 MAC protocol. Our work includes both, reducing the power consumption of each node and improving the throughput of the networks.

3 IEEE 802.11 MAC Protocol

To understand IEEE 802.11 protocol [5], [6], some of the basic terms have been defined as follows:

(i) *Transmission range*: The range in which any other node can both receive the packets as well as decode the information contained in the header of packets correctly, those were sent by the sender. For example, duration field contained in the header of a packet.

(ii) *Carrier sensing range*: The range in which any other node can sense the packets sent by the sender. The transmission range is a subset of carrier sensing range.

(iii) *Carrier sensing zone*: The zone which is outside the transmission range but within the carrier sensing range of the sender is called carrier sensing zone. In this zone, any node can sense the transmission of packets by sender but cannot decode the packet's header correctly.

IEEE 802.11 protocol is based on CSMA/CA scheme and it uses four kinds of packets RTS-CTS-DATA-ACK. The virtual carrier sensing scheme uses duration field of these packets to determine the time for which the current transmission would remain continues and the channel would remain busy. To avoid any collisions, each node maintains an NAV (Network Allocation Vector) in which the remaining time of the current transmission is maintained. The NAV handling at each node is done as shown in Fig. 1.

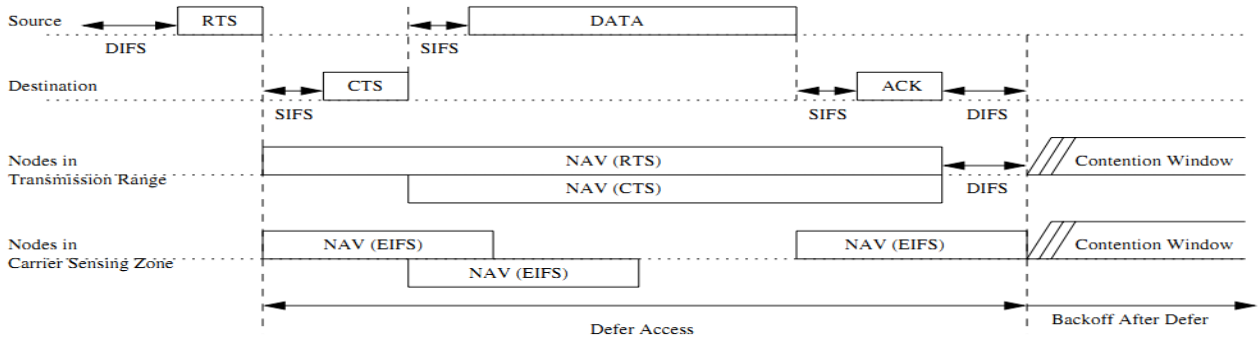

Fig. 1. RTS-CTS-DATA-ACK handshaking process in IEEE 802.11 [5]

4 Proposed Power Controlled MAC Protocol with Improved Throughput

The existing power control MAC protocols reduce the energy consumption of each node but they fail to obtain the high throughput compared to IEEE 802.11 protocol. The purpose of our work is to design a new power control MAC protocol that minimizes the energy consumption of each node as well as improves the throughput of the network compared to IEEE 802.11 protocol. The work of the paper is divided into two phases:

Phase I: Design a power controlled protocol that minimizes the energy consumption of each node.

Phase II: Associate the designed power control MAC protocol with the modified VCS scheme of IEEE 802.11 protocol for increasing the spatial reuse that will improve the throughput of the network.

4.1 Minimizing the Energy Consumption of Each Node

Like most of the power control MAC protocols, in our paper also, the reduction of power consumption for each node can be achieved by sending the packets with optimum power (the minimum energy to reach the packets at their receiver). IEEE 802.11 sends each kind of packet irrespective of RTS, CTS, DATA or ACK with the same maximum power. Other power controlled protocols send the RTS and CTS packets at maximum power level while DATA and ACK packets are sent with minimum necessary power that results in the degradation of throughput due to increased number of collisions. Hence, in our protocol, considering the throughput improvement and minimizing the energy consumption, we send the RTS packet with the maximum power but all other packets i.e. CTS, DATA and ACK are sent with optimum power. DATA packets are periodically sent with maximum power to avoid unnecessary collisions.

Implementation of our protocol requires the addition of a new field *P_RTS* to the RTS packet and *P_DATA* field to the CTS packet; where *P_RTS* is the power level at which RTS is sent and *P_DATA* is the optimum power level at which the DATA packets are required to be sent for successful receiving. CTS and ACK are also sent with the same optimum power. The structures of RTS and CTS packets are as shown in the Fig. 2 for IEEE 802.11 and our proposed protocol:

Frame control	Duration	RA	TA	CRC

RTS frame format in IEEE 802.11 protocol

Frame control	Duration	RA	TA	CRC	P_RTS

RTS frame format in proposed protocol

Frame control	Duration	RA	CRC

CTS frame format in IEEE 802.11 protocol

Frame control	Duration	RA	CRC	P_DATA

CTS frame format in proposed protocol

Fig. 2. Structure of RTS and CTS frames

The working procedure of our protocol for minimizing the energy consumption is as follows:

- The transmitter node broadcasts the RTS packet at a power level *P_RTS*. Here, *P_RTS* is equal to the maximum transmitted power used in IEEE 802.11 protocol.
- The receiver receives the RTS packet at a received power *Pr*. For two ray propagation model, *Pr* at a distance *d* is calculated as follows

$$Pr = \frac{Pt \times Gt \times Gr \times Ht^2 \times Hr^2}{d^4 L}$$

  Where, *Pt* is the transmitted power, *Gt* and *Gr* are the transmitter and receiver gains, *Ht* and *Hr* are the heights of transmitter and receiver antennas and *L* is the loss factor.
- The receiver extracts *P_RTS* from the received RTS packet and calculates the value of *P_DATA* as follows and appends it in the CTS packet

$$P\_DATA = \frac{P\_RTS}{\mathrm{Pr}} \times RxThreshold$$

  Where *RxThreshold* is the receiving threshold of signal strength at which the receiver can decode the signal.
- The receiver sends the CTS packet at a power level *P_DATA*.

- The transmitter sends the DATA packets at the power level *P_DATA* extracted from the received CTS packet.
- The receiver after receiving the DATA packet sends the ACK packet at same power which was used to send the CTS packet.

DATA packets are periodically sent with maximum power to avoid the unnecessary collisions with ACK packets at source node.

4.2 Throughput Improvement over IEEE 802.11

As mentioned in the above section, the nodes use different power level for different transmissions based on the packet type which may degrade the throughput of the network. The throughput of a network can be improved by increasing the spatial reuse in the network. In order to increase spatial reuse, we modify the VCS (virtual carrier sensing) scheme of IEEE 802.11 protocol.

In 802.11 VCS scheme, if a node overhears an RTS or CTS packet, it assumes the channel as busy and sets its NAV. Thus, if the node which overhears has any packet to send, it defers the transmission for the time of duration field's value extracted from the overheard packet. In our protocol, we improve this VCS scheme.

A node can overhear an RTS packet only or a CTS packet only or both RTS and CTS packets. In our protocol, since CTS transmission range is less compared to RTS transmission range, there is a chance that a node overhears the RTS packet only and it has to send a CTS packet, then it sends the CTS packet immediately. It doesn't affect the ongoing transmission. For example, consider Fig. 3; suppose node N1 has data to send to node N2. So node N1 sends an RTS packet to node N2. Since N3 is in transmission range of node N1, node N3 will overhear the RTS packet. After receiving RTS from node N1, node N2 will respond by a CTS packet. Since the transmission range of its CTS is small, it will not be overheard by node N3 and therefore N3 will not set its NAV. Now, if node N3 receives an RTS packet from node N4, it can respond immediately with a CTS packet. Thus, it will improve spatial reuse because more nodes can send packets at a time which, in turn, will improve the throughput of the network.

To achieve our goal, we propose some modifications in the VCS scheme of IEEE 802.11 which are as follows

- As IEEE 802.11 VCS scheme uses NAV, we introduce one more parameter NAVR along with NAV.
- If a node in the transmission range overhears an RTS packet, it sets its NAV to a slot time and NAVR to the value of duration field extracted from the RTS packet. The slot time includes the time to sense the channel creating and transmitting the response.

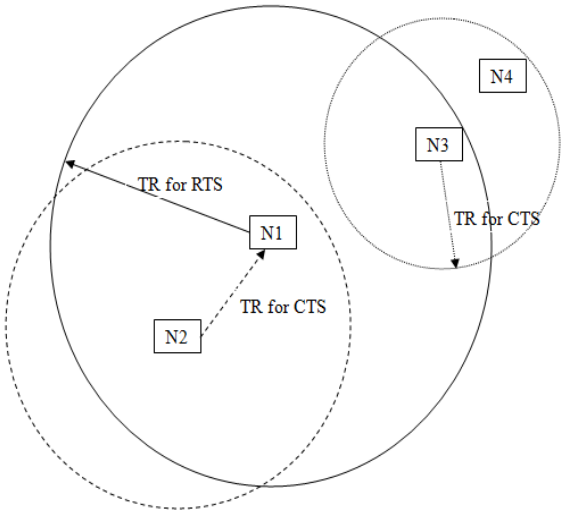

Fig. 3. An example to show transmission ranges of RTS and CTS

- If a node overhears a CTS packet before the NAV expires, it sets the NAV to the value of duration field extracted from the CTS packet.
- Suppose, a node in the transmission range wants to send a packet then first of all, it checks the packet type. If it is an RTS packet, it can send only if NAVR has expired, otherwise, it has to wait for backoff time. While, if it is a CTS or DATA packet, it can send only if NAV has expired. Like IEEE 802.11, ACK packets are sent immediately in our protocol also.

5 Simulation and Results

We have implemented our proposed protocol on NS-2.34 network simulator [7]. The metrics, on which we have focused, are energy consumption of each node and throughput of the network. We setup the scenario of 50 nodes placed randomly in a terrain size of 800m X 800m. The routing protocol used is DSDV. The packet size used is 512 bytes. We have simulated the same scenario for both IEEE 802.11 and our proposed protocol and observed the changes in energy consumption and throughput. The simulation parameters is be tabulated as below

TABLE I
Simulation Parameters

Terrain size	800m X 800m
Number of nodes	50
Application	CBR
Packet size	512 bytes
Routing protocol	DSDV
Antenna model	Omni directional
Propagation model	Two ray ground

Fig. 4, Fig. 5 and Fig. 6 show the results obtained at the end of simulation. Fig. 4 shows that the energy consumption of each node in our proposed protocol is less compared to IEEE 802.11. To compare the throughput of the network in IEEE 802.11 and our proposed protocol, we run the same scenario for different packet sizes. Fig. 5 shows the results of total energy consumption in the network system at the end of simulation on varying the packet sizes. It depicts that for each kind of packet size, the total energy consumption in the network for our proposed protocol remains lesser than IEEE 802.11 protocol. Fig. 6 clearly shows an improvement in the throughput of the network for our proposed protocol in comparison to IEEE 802.11.

6 Conclusions

In this paper, we have proposed a power controlled MAC protocol with improved throughput for wireless ad hoc networks. MAC protocols given in the past were mainly focused on reducing the energy consumption only. But the disadvantage associated with those protocols is the degradation in the throughput of network while reducing the energy consumption of each node. We have developed a protocol which improves the throughput of the network along with minimizing power consumption of each node. For this purpose, we first changed the power levels of transmissions for different kind of packets and associated it with the modified VCS scheme of IEEE 802.11 protocol to increase the spatial reuse allowing more number of simultaneous transmissions which ultimately results in the increase in throughput of the network. The protocol has been simulated on NS-2.34 and the results obtained at the end of simulation satisfy the goal of our paper.

Abstract— *Wireless sensor networks (WSNs) are used to collect various data in environment monitoring applications. The most comprehensive way of data collection is to make every sensor node report periodically its sensing data to a base node. To reduce the energy consumption due to excessive communication, the network is partitioned into a set of spatial clusters with similar sensing data. For each cluster, only a few sensor nodes (samplers) report their sensing data to the base node. The base node may predict the missed data of non-samplers using the spatial correlation between sensor nodes. The spatial clustering is vulnerable to internal security threat such as node compromise. If the samplers are compromised and report incorrect data intentionally, then the WSN should be contaminated rapidly due to the process of data prediction at the base node. In this paper, we propose intrusion detection algorithms for secure data collection in the WSN. The algorithms consist of cluster head monitoring and member node monitoring to cope with security attacks where either a cluster head or member nodes are compromised.*

Keywords: Wireless Sensor Network, Data Collection, Spatial Clustering, Security, Attack Detection

1. Introduction

A wireless sensor networks (WSN) typically consist of a large number of small battery-powered sensor nodes. In order to sustain sensor nodes to run for a long period, it is critical to save energy in sensor operations [1]. The primary functions of WSN are to collect data for observation and analysis of physical phenomena. There are two types of data collection in WSN: *event-based* and *periodic* approach [5]. In event-based data collection, sensor nodes are responsible for detecting and reporting (to a base node) events such as spotting moving targets. They perform local filtering and sometimes collaborate with each other to detect events. On the other hand, in periodic data collection, every node reports periodically its sensing data to the base node. Many researches prefer the periodic approach because it enables arbitrary data analysis at the base node [3], [5].

Extracting the vast amounts of data generated by large-scale, high-density WSN can cause a wide range of problems. Sensing always and transmitting every data would cause sensor nodes to drain their batteries soon. Furthermore, the limited communication bandwidth prevents all the acquired data from being propagated successfully toward the base node. This means that we need an energy-efficient way of data collection to prolong the lifetime of WSN by keeping the energy consumption at minimum.

Spatial clustering is a representative way of saving energy in periodic data collection [6], [9]. It partitions the network into a set of clusters where a cluster includes sensor nodes with similar sensing data. For each cluster, only a few sensor nodes (samplers) report their data to the base node. All the rest of sensor nodes can save their energy by keeping in sleep mode. The base node may predict the missed data using the spatial correlation between sensor nodes. To balance the energy consumption, sensor nodes within a cluster can share the workload equally.

The WSN is vulnerable to security threats both external and internal due to unreliable wireless channels, unattended operation of sensor nodes, and resource constraint [2], [12]. *Node compromise* is a major type of internal attacks. Compromised sensor nodes release all the security information to the adversary. Then, the adversary can easily launch internal attacks with data alteration, message negligence, selective forwarding, and jamming [4], [8], [10]. Note that the node compromise is especially problematic for periodic data collection applications, where only the samplers may report data to the base node. If the samplers are compromised and report incorrect data intentionally, then the WSN should be contaminated rapidly due to the process of missing data prediction at the base node. This means that detecting and defending against node compromise are inevitable tasks to guarantee the correctness of data collection at WSN.

In this paper, we propose intrusion detection algorithms for secure data collection in the WSN. The algorithms consist of *cluster head monitoring* and *sampler monitoring* to cope with internal security attacks where either a cluster head or member nodes are compromised. In the cluster head monitoring, neighbor nodes of a cluster head collaboratively monitor their cluster head. The member node monitoring algorithm is divided into two variants: *monitoring by neighbors* (MBN) and *monitoring by cluster head* (MBCH). They are based on spatial clustering and try to detect compromised nodes with energy-efficient manner. The MBN explores the spatial correlation with a sampler and its neighbors. Neighbors have a role to watchdog. They listen promiscuously to the sampler's broadcasting transmission and monitor whether the sampler is compromised or not. The MBCH does not impose any additional roles to sensor nodes for security. Instead, the cluster head has to monitor the transmitted data

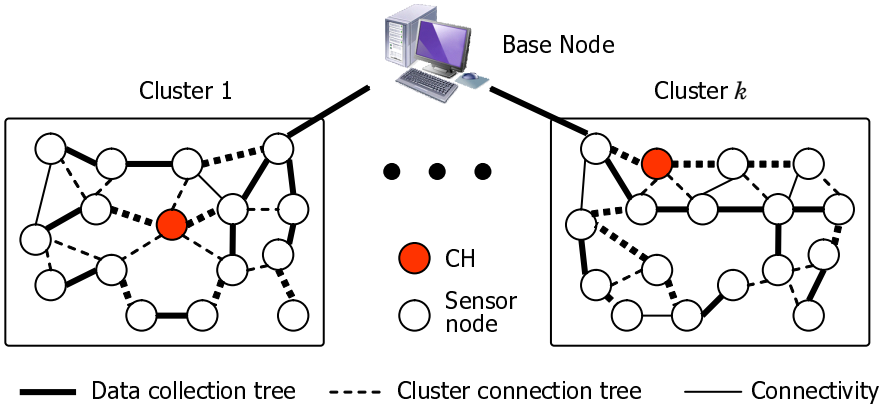

Fig. 1: Model of a WSN

of samplers and compares them with the sensor readings of non-sampler nodes.

The rest of this paper is organized as follows. Section 2 presents the related work. Section 3 describes our model of the WSN and the data collection. Section 4 describes the proposed algorithms in detail and discusses some performance issues. Finally, Section 5 concludes this paper.

2. Related Work

Most of previous intrusion detection algorithms proposed for the WSN did not consider the underlying data collection architectures [4], [8], [10]. The two exceptions are [7] and [11]. Authors of [7] partition the WSN into several δ-groups by extending the distributed spatial clustering algorithm [9]. Sensor nodes within the same group are physically close to each other and their sensed data are dissimilar by at most δ. To detect compromised nodes, they partition the δ-group into equal-sized sub-groups. Each sub-group monitors the entire δ-group in turn to reduce the total power consumption. However, they did not consider the location information of monitoring nodes and reporting nodes. If a monitoring node is not located in the routing path between a reporting node and the base node, it cannot detect whether the reporting node is compromised or not. Furthermore, there is no central decision point and thus every node in the cluster has to decide the node compromise if alert messages are broadcast from the monitoring nodes.

Authors of [11] proposed a collaboration-based intrusion detection algorithm to detect and revoke compromised nodes in a cluster through less energy consumption. Similar to this paper, they propose separate algorithms for cluster head monitoring and member node monitoring. To monitor cluster head, all member nodes of a cluster are divided into several groups. Then every monitor group takes turns to monitor the cluster head in a cluster round time. The cluster head monitors its member nodes and is responsible to detect the compromised member nodes. Note that this is contrary to [7] where every node has to decide the node compromise. The main problem of [11] is that they did not present how to detect the misbehavior of each sensor node. This should be performed on the basis of several monitoring attributes about sensed data and communication behaviors [7], [8], [10]. Furthermore, for cluster head monitoring, they did not consider the location information of monitoring nodes and the cluster head. This should cause to decrease the detection accuracy.

Unlike previous cluster-based intrusion detection algorithms, our algorithm is completely integrated into the underlying data collection architecture. Our algorithm considers the WSN structure, cluster formation, and data collection procedures. This enables our algorithms to optimize energy consumption for message transmission and sampling.

3. Model of WSN and Data Collection

Figure 1 shows our model of a WSN. The WSN follows layered network architectures [5]. Let $S = \{s_1, \ldots, s_n\}$ be a set of all sensor nodes in the WSN. A *data collection tree* is used to propagate the sensed data of each node to the base node. The base node is the root of the data collection tree. The WSN is partitioned into disjoint clusters, where a sensor node is selected as a *cluster head* (CH). A *cluster connection tree* is used to establish the communication between the CH and the other nodes in the cluster. Each sensor node is assumed to be able to communicate only with its neighbors. The set of neighbor nodes of sensor node s_i is denoted by $nbr(s_i)$. The nodes that can communicate with each other form a *connectivity graph*. s_i is forced to sample periodically, and let $D[s_i]$ be a vector of sampled readings of s_i and L be its length. The correlation of two sensor nodes s_i and s_j are defined as [5]:

$$\text{Corr}(s_i, s_j) = \frac{(D[s_i] - \text{E}[D[s_i]]) * (D[s_j] - \text{E}[D[s_j]])^T}{L * \sqrt{\text{Var}(D[s_i])} * \sqrt{\text{Var}(D[s_j])}} \quad (1)$$

Definition 1. Two sensor nodes, s_i and s_j, are *strongly correlated* if $1 - |\text{Corr}(s_i, s_j)| \leq \delta$, where $0 \leq \delta \leq 1$.

Definition 2. A set of sensor nodes C is called a *cluster* it the following two conditions hold for every pair of $s_i \in C$ and $s_j \in C$: (1) s_i can communicate with s_j directly or via any nodes in C, and (2) s_i and s_j are strongly correlated.

The construction of clusters based on spatial correlation is an interesting research issue and has been studied by many researchers [3], [5], [6], [9]. In this paper, we assume that the WSN is already partitioned into several clusters as Figure 1 shows.

For each cluster, the CH maintains the correlation information for every pair of sensor nodes in the cluster. When a new cluster is established, the CH sends a data mean vector (E[D[s_i]]) and a data covariance matrix (Corr(s_i, s_j)$*$ $\sqrt{\text{Var}(D[s_i])} * \sqrt{\text{Var}(D[s_j])}$) for every pair of sensor nodes s_i and s_j to the base node. Each sensor node in the cluster periodically samples its sensor data and sends it to the CH. We call the period of sampling as a *forced-sampling period* (τ_f). The CH evaluates the degree of correlation periodically and starts a new cluster construction phase if sensor nodes in the cluster are not strongly correlated anymore.

Each node in a cluster becomes a sampler with a probability λ. Combining this randomized scheduling with the round robin scheduling, we can guarantee that at least one node becomes a sampler for each cluster. A sampler sends its sensing data to the base node for every τ_d through the data collection tree. Then the base node can predict the sensing data of non-sampler nodes with the data mean vector and the data covariance matrix [5]. We call τ_d as a *data-sampling period*. Note that we can save energy significantly by setting τ_f to be much longer than τ_d.

4. Secure Data Collection Algorithms

In this section, we first present a cluster head monitoring algorithm. Then we describe two sampler monitoring algorithms, *monitoring by neighbors* (MBN) and *monitoring by cluster head* (MBCH). Finally, we analyze our algorithms qualitatively.

4.1 Cluster Head Monitoring

In periodic data collection framework, the CH has a primary role and thus its security demand is higher than that of the other sensor nodes. The role of the CH can be summarized as follows.

- The CH constructs a cluster that consists of sensor nodes which are strongly correlated to that of the CH.
- After constructing the cluster, the CH sends a data mean vector (E[D[s_i]]) and a data covariance matrix (Corr(s_i, s_j) $* \sqrt{\text{Var}(D[s_i])} * \sqrt{\text{Var}(D[s_j])}$) for every pair of sensor nodes s_i and s_j to the base node. The base node will use them to derive the parameters of the probabilistic models used in predicting the values of non-sampler nodes.
- For each forced-sampling period, the CH evaluates the degree of correlation periodically and starts a new cluster construction phase if sensor nodes in the cluster are not strongly correlated anymore.
- The CH is responsible to detect compromised nodes in its cluster.

The first three roles of the CH correspond to the cluster maintenance. Detecting the misbehavior of the CH at the cluster maintenance is a challenge, since most decisions of the CH comes from the raw information of member nodes such as the history of sensor readings. This cannot be done simply by neighbor based detection of communication behavior [8], [10]. A potential solution is to assign several CHs in a cluster and to make them monitor with each other. However, member nodes must suffer from heavy communication overhead to report their sensor readings to every CH. We let this issue as a future work of this paper.

In this paper, we concentrate the last role of the CH. Some sensor nodes will report the monitoring information to the CH using the member node monitoring algorithm of Section 4.2. Then the CH checks the information and announces to every member node in the cluster when some sampler is compromised. This decision could be incorrect if the CH itself is compromised. Suppose that *nbr*(CH) is the set of neighbor nodes of the CH. Then each sensor node s_i in *nbr*(CH) executes the following steps.

1) For each data-sampling period, s_i overhears the monitoring information sent to the CH. It delivers the information to every other node in *nbr*(CH).
2) s_i also overhears the decision message sent from the CH. If the decision is different from that of itself, it decides that the CH is compromised and announces its decision to every other node in *nbr*(CH).
3) If more than a predefined percentage of sensor nodes in *nbr*(CH) decide that the CH is compromised, one of them reports it to the base node. Then the base node segregates the CH from the WSN by broadcasting the decision to every node and assigns a new CH for the cluster.

Note that neighbor nodes of the CH would drain its battery rapidly due to the monitoring task. The primary source of energy consumption is to make consensus among neighbor nodes. We can reduce the energy consumption by considering the type of false alarm. For examples, if we allow false negative errors where a correct node is determined as compromised, neighbor nodes need not exchange their decisions when the CH announces that some node is compromised. Furthermore, most data collection algorithms select new CH periodically to prolong the lifetime of the WSN. This means that the energy consumption of neighbor nodes can also be distributed to other nodes.

4.2 Sampler Monitoring

The CH has a role to decide whether a sampler is compromised or not. For each data-sampling period, samplers report their sensor readings to the base node through the data collection tree. If the CH does not locate on the routing path from the sampler to the base node, it cannot detect the compromised sampler. Hence, we modify the data collection process by reporting the monitoring information to the CH. In this paper, we propose two sampler monitoring algorithms. The algorithms have different strategies to select monitoring nodes that report to the CH and to define monitoring information to be reported.

4.2.1 Monitoring by Neighbors (MBN)

In the MBN, every neighbor node of a sampler has a role to a watchdog that monitors the message sent from the sampler. The following modifications of data collection procedures are required for the MBN to determine whether a sampler is compromised or not.

- The CH has complete location information for every sensor node in its cluster to identify neighbor nodes of the sampler.
- Each sensor node has a correlation vector to every other sensor node in the cluster.

Suppose that a sensor node s_s is selected as a sampler. s_s notifies itself to the CH[1], and the CH wakes up the sensor nodes in $nbr(s_s)$. For each node $s_i \in nbr(s_s)$, it reads its sensing data for every τ_d. Then s_i overhears the message from s_s no matter whether or not s_i is involved in the communication. If the sensor reading sent from s_s is not strongly correlated to that of s_i, s_i reports to the CH. If more than half sensor nodes of $nbr(s_s)$ report to the CH, the CH decides that s_s is compromised and reports it to the base node. After that, the base node ignores the data sent from s_s. Each sensor node also excludes the compromised node in selecting the next-hop forwarder to realize the secure routing.

4.2.2 Monitoring by Cluster Head (MBCH)

In the MBCH, the CH has a role to detect the compromised node. The following modifications of data collection procedures are required for the MBCH to determine whether a sampler is compromised or not.

- For each cluster, at least two samplers should be selected for every data-sampling period.
- Samplers are required to send its sensor readings to the CH.

In the MBCH, the CH performs the detection of compromised node by two ways: (1) comparison between samplers and (2) comparison between sampler and non-samplers. Suppose that two sensor nodes, s_i and s_j, are selected as samplers of a cluster. For every data-sampling period, s_i and s_j send their sensor readings to the CH. The CH then forwards the message to the base node only if they are strongly correlated. Otherwise, one of samplers could be compromised. In this case, the CH does not forward the message and waits until the next forced-sampling period to collect every sampling data and to determine the compromised node.

Note that two samplers are not enough if both of them could be compromised. To check if such condition happens, the CH compares the validity of samplers with sensor readings of every non-sampler node for some forced-sampling period. If the samplers are compromised, the CH reports them to the base node. Then the base node invalidates previous sensing data sent from the compromised samplers. If we increase the number of samplers, the WSN should be more secure at the cost of increased energy consumption. This shows an interesting tradeoff between energy consumption and security enforcement.

4.3 Qualitative Analysis

The performance of MBN and MBCH depends on several factors of WSN, such as network density, capacity of sensor nodes, sampling cost, and so on. In this section, we analyze the pros and cons of two algorithms for each factor.

- ***Network density***: The MBN is effective only if there are sufficient neighbor nodes for each sampler. This is because the majority vote is performed to determine if the sampler is compromised. If the number of neighbor nodes is not enough, the MBN may be exposed to the unsafe case when both the sampler and its neighbor nodes are compromised at the same time. On the other hand, the MBCH is less dependent on the network density due to the additional step of comparison at the forced-sampling period. Note that the MBN does not support the comparison at the forced-sampling period, since the sampler is not required to send its sensor readings to the CH.
- ***Capacity of sensor nodes***: The MBN requires that every sensor node can store correlation information to every other sensor node in the cluster. Furthermore, neighbor nodes of a sampler has to (1) sample at each data-sampling period, (2) overhear the message sent from the sampler, (3) calculates the correlation between itself and the sampler, and (4) report to the CH in case of correlation mismatch. This means that the MBN spends a lot of memory resources and computing resources of sensor nodes. On the other hand, the MBCH does not spend any additional memory space of sensor nodes for security enforcement. It just requires more samplers. However, since the CH detects the node compromise for itself, the CH can drain its energy more rapidly. This

[1]To force this procedure to compromised node, the CH may assign some unique id to the sampler in response to the notification. The base node should reject a message from the sampler if it does not contain the id.

means that the MBCH depends on the CH replacement algorithm to prolong the lifetime of WSN.

- ***Sampling cost***: If the sampling cost is not expensive, the overhead of the MBN to make neighbor nodes sample at every data-sampling period is not significant. In this case, maintaining additional samplers at the MBCH may take much overhead due to communication cost of the samplers. Note that the message overhearing at promiscuous mode of the MBN spends much less energy compared with the message transmission at samplers. However, if the sampling cost is high, sensor nodes of the MBN would spend more energy especially for the dense network.
- ***Detection time of compromised node***: The MBN can detect the comprised node as soon as the majority of neighbor nodes vote. On the other hand, the MBCH cannot determine the compromised node promptly until the next forced-sampling period. Note that the MBCH can reduce the delay if it operates many samplers and applies majority vote between them. However, many samplers should result in increased energy consumption and network traffic.

5. Conclusions

In this paper, we propose intrusion detection algorithms for secure data collection in the WSN. The proposed algorithms are composed of cluster head monitoring algorithm and sampler monitoring algorithm. The sampler monitoring algorithm is also composed of two sub-algorithms, monitoring by neighbors (MBN) and monitoring by cluster head (MBCH). They are based on spatial clustering and try to detect compromised nodes with energy-efficient manner. Unlike previous security algorithms for WSN, our algorithms consider the underlying data collection architectures. The security task is completely integrated to data collection algorithm. This enables our algorithms to optimize energy consumption for message transmission and sampling.

We are investigating quantitative analysis of the secure data collection using our simulation model. The simulation model is developed with CSIM package and implements variety of WSN configurations and workloads.

ON BANDWIDTH CAPABILITES OF MULTIPROCESSOR INTERCONNECTION NETWORKS

Dr. Sandeep Sharma

Department of Computer Science and Engineering, Guru Nanak Dev University, Amritsar,Punjab, India

Abstract - *In this paper the general characteristics and bandwidth capabilities of Multiprocessor Interconnection Networks have been analyzed. We have examined some popular FT(Four Tree)[8],MFT(Modified Four Tree)[2],THN(Theta Network)[13],NFT(New Four Tree)[4], IFT(Improved Four Tree)[5], IASN(Irregular Augmented Shuffle Network)[14] and IIASN(Improved Irregular Augmented Shuffle Netwrok) [3] networks which are irregular in nature[11]. The structural characteristics comparison of these networks is presented in terms of number of switches, links and stages etc. The bandwidth [15] and probability of acceptance of all the networks evaluated by using probabilistic approach [6] and their simulation results are compared.*

Keywords: *Multistage Interconnection Network, Permutation , Bandwidth , Probability of acceptance ,IIASN, Four Tree Network, NFT,THN,IFT*

1 Introduction

Parallel processing systems have a huge number of processors and an interconnection network to provide interprocess communication. One of the major design issues of these system to make these system fault tolerant[12], reliable and excellent in performance wise. Multistage interconnection networks (MINs) which are widely used in designing of multi processor architecture are attracting much concentration from parallel processing. The MINs are categorized as regular and irregular depending on the internal arrangement of switching elements SEs. In irregular the number of switches in each stage can vary. Most previous work has focused on evolution of the performance of regular MINs like as OMEGA, ESC, Multistage Cube, ASEN[11] and ABN[7] etc., but little work has been done for irregular class of Networks. In this paper we have considered some popular irregular networks which are multipath in nature. In this paper it is assumed that each processor is attached to an input port and an output port of considered MINs. However these results are also applicable to processor-memory interaction. The performance of all surveyed MINs is evaluated on the basis of bandwidth utilization and probability of acceptance of request which are coming from source processor to destination processor. The structural characteristics of surveyed MINs are also summarized in terms of number of switches, link and mux/demux used for the construction of them.

The rest of the paper is organized as follows. Section 2 discusses the structural characteristics of the surveyed MINs. Section 3 discuses the analytical model of probability of acceptance and bandwidth analysis of considered MINs. Finally conclusions have been given in Section 4.

2 Structural Characteristics of MINs

Table 1 summarizes the structural characteristics of surveyed MINs and it has been observed that all the networks which are used for inter processor communication are fault tolerant. One can choose the network on behalf of number of switches, number of links, multiplexers, demultiplexers and express links to reduce the cost. In later discussion it is summarized that the network with more switches and links have great failure rate in comparison to a network with lesser switches and links.

3 Probability of acceptance and Bandwidth

Probability of acceptance (POA) is defined as the fraction of incoming requests accepted by the output stage of network [7].It is the ratio of expected band-width (i.e. total no of successful requests) to the expected number of requests generated per cycle. Patel et al. suggested a probabilistic

approach[6] to evaluate these parameters with following assumptions:

- At each cycle, packets are generated at each source independently with probability p.
- Each packet is send with equal probability to any destination.
- The packet rate i.e the number of packets issued per cycle by a processing element , is p where p<=1
- Requests that are not accepted during a memory cycle are discarded.

For a system with N processors and M memory modules , if a processor generates a request with probability p in a cycle directed to each memory with equal probability then the bandwidth is given by Strecker et al. as :

$$BW = M(1-(1-p/M)^N) \quad (1)$$

Table 1: Summary of Structural Characteristics of MINs

MIN	Number of 2x2 Switches	Number of links/stage excluding express links	Number of switches with conjugate loops	Number of Stages	Type/ Number of mux	Type/ Number of demux	Redundant paths
FT	N/2	N(input and output stages) 2N+4 (interior)	N+2	Log_2N+1	2:1/N	1:2/N	Yes
MFT	N/2	N(input and output stages) 2N+4 (interior)	N+4	Log_2N+1	2:1/N	1:2 /N	Yes
THN	N+N/2	N(input and output stages) 2N (interior)	Zero	Log_2N	2:1/N	1:2 /N	Yes
NFT	N/2	N(input and output stages) 2N (interior)	N	Log_2N+1	2:1/N	1:2 /N	Yes
IFT	N/2	N(input and output stages) N+N/2 (interior)	N-N/4	Log_2N-1	4:1/N	1:2 /N	Yes
IASN	N/2	N(input and output stages) N+N/2 (interior)	N-N/4	Log_2N-1	4:1/N	1:2 /N	Yes
IIASN	N/2+2	N(input and output stages) N+N/4 interior	N/2	Log_2N-1	4:1/N	1:2 /N	Yes

Table 2 : Summary of Bandwidth Analysis of Various MINs when n=4

Probability of issuing a request	FT	MFT	THN	NFT	IFT	IASN	IIASN
0.1	1.2	1.4224	0.9621	1.4784	1.136	1.136	1.4928
0.2	2.1264	2.5536	1.8518	2.744	2.152	2.152	2.7888
0.3	3.0144	3.4624	2.6737	3.832	3.064	3.064	3.9152
0.4	3.8032	4.2032	3.4317	4.7712	3.8784	3.8784	4.896
0.5	4.5072	4.8112	4.1295	5.584	4.6096	4.6096	5.7504
0.6	5.1344	5.3152	4.7702	6.2912	5.2624	5.2624	6.496
0.7	5.696	5.736	5.3567	6.9072	5.848	5.848	7.1456
0.8	6.1968	6.0896	5.8913	7.4448	6.3696	6.3696	7.712
0.9	6.6432	6.3872	6.3763	7.9152	6.8352	6.8352	8.2064
1.0	7.0416	6.64	6.8135	8.3264	7.248	7.248	8.6368

Where p/M is the probability that a processor requests a particular memory module, $[1-(p/M)]^N$ is the probability that none of the N processors requests the memory module in a particular cycle.

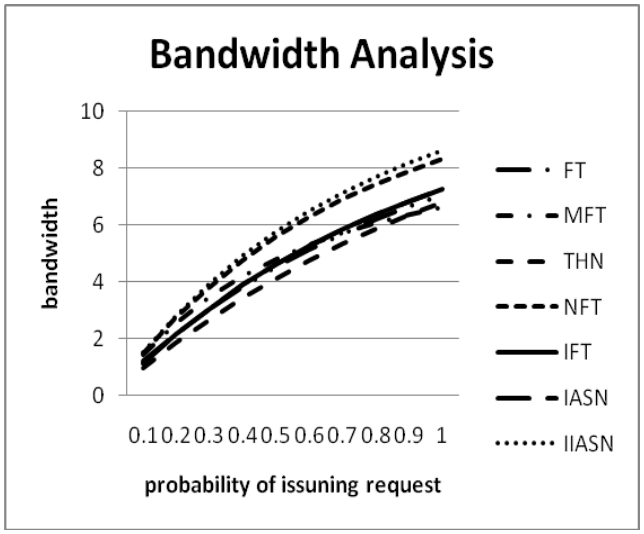

Figure 1: Bandwidth Analysis of various MINs

The table no. 2 shows that the bandwidth grows with the increase of probability of issuing the request. The graph in figure 1 shows that the probability of acceptance of various MINs remains constant when the probability of issuing the request is higher. It has been also observed that at the last stages when the probability of issuing of requests is 0.9 and 1.0 the difference between bandwidth in case of IIASN is 0.4304 quite less in comparison to 1.296 at very earlier states when probability of issuing the request was 0.1 and 0.2 which also lesser costlier[16] among all MINs.

4 Conclusions

The general characteristics in terms of structural characteristics has been analyzed one can choose the interconnection networks on the behalf of compared results. The performance in terms of bandwidth, probability of acceptance has been analyzed in this paper. The results for bandwidth show that the probability of maximum passing of request of IIASN network is higher than other networks. The bandwidth of IIASN gradually increases with the increase of probability of issuing a request.

Abstract - *Mobility and quality of service (QoS) are becoming the more important issues in wireless communications. The traditional Internet service is expanding into new access media and applications. Since wireless communication services are accompanied by frequent handovers at remote sites, scalable and fast handover has become a prerequisite for ubiquitous communication.*

In this paper, the differentiated service (Diffserv) model is deployed in heterogeneous proxy mobile IPv6 (PMIPv6) networks to satisfy the QoS guaranteed service and fast handover requirements. The operational procedures for QoS guaranteed global roaming are presented. In addition, QoS management and handover cost evaluation schemes based on a mobile host's movement scope are proposed. This paper analyzes the reduction in handover delay in a network-based localized mobility management framework. We propose and analyze a PMIPv6 optimized with a global mobile access gateway (G-MAG), which is a network-based entity, to further improve the handover performance in terms of handover delay while maintaining minimal signaling overhead in the air interface among converged heterogeneous wireless networks. The handover signaling procedures with host-based MIPv6 are compared with network-based proxy MIPv6 (PMIPv6) and fast PMIPv6 assisted by G-MAG to show how much handover delay reduction can be achieved. Analytical results show that the handover delay is significantly reduced.

Keywords: QoS, PMIPv6, handover, global roaming, cost evaluation.

1. Introduction

Traditional Internet service does not consider issues with host mobility and QoS such as transmission delay, packet loss ratio, and bandwidth. However, providing secure and seamless mobility and guaranteed QoS become more critical issues in wireless mobile services. Furthermore, the services that are now being used on mobile networks, including, Internet broadcasting, teleconferencing, interactive role playing, and telemedicine, tend to require a predefined QoS.

In the near future, wireless networks are going to fully integrate different wireless access technologies to enable their users to exploit advantages of these various technologies and satisfy the QoS requirements of new applications. Various wireless communication protocols developed for different purposes are integrating and converging to ubiquitous communications, which request QoS-guaranteed, fast, and seamless roaming services. The increasing demands for ubiquitous and mobile computing will require the integration of various wireless access technologies such as WLAN (wireless LAN), 3GPP (3rd generation partnership project), 3GPP2 (3rd generation partnership project 2), and IEEE 802.16. To visualize these access technologies, wireless networks have been converging to the Internet Protocol (IP). For instance, the mobile IPv4 (MIPv4) [1] and mobile IPv6 (MIPv6) [2] protocols were already standardized by IETF (Internet Engineering Task Force). In addition, the IEEE 802.16e amendment [3] enhances IEEE 802.16 with mobility support for users moving at vehicular speeds, and the WiMAX (Worldwide Interoperability for Microwave Access) Forum has adopted IP mobility [4]. An IP level mobility protocol is needed to enable the users of these future wireless networks to roam freely between various access networks. Global roaming, guaranteed QoS, and vertical handover will be prevalent in the near future.

The Internet protocol IPv4 has been slowly progressing toward IPv6, and during this period both protocols have become a part of the Internet service infrastructure. The existing wired core Internet architecture that is linked to wireless access networks is going to evolve into wireless Internet environments. A large number of different wireless access networks are linked using a multi-hop infrastructure, including notebook PCs, PDAs, and small sensors, and are being served actively. The MIP (mobile Internet protocol) has been developed to provide mobile Internet services based on host mobility. Although it is a stable and mature technology, there are some obstacles to overcome to be widely deployed. It is too heavy to be implemented on small mobile devices and complicated message exchange procedures must be handled by the mobile host itself. As a network-based localized mobility protocol, PMIPv6 has been proposed to overcome the problems with MIP's host-based mobility and long handover latency [5]. The goal of PMIPv6 is specifying a simple extension of MIPv6 that would support network-based mobility for IPv6 hosts, while reusing the signaling and features of MIPv6. As an alternative to MIP, PMIPv6 reuses the MIPv6 entities and concepts as much as possible, but the mobility management procedures are carried by the network devices. Moreover, the mobility infrastructure in the PMIPv6 domain can provide mobility to an MN operating in IPv4, IPv6, or dual mode, even if the transport network is not an IPv4 or IPv6 network. As a result, a new standard for supporting an IPv4 host and IPv4 network in PMIPv6 was released [6] and a new protocol for supporting MIPv6 hosts attached in PMIPv6 is actively being discussed[7]. PMIPv6 is

applicable to various networks but is inappropriate for global roaming applications.

To solve the long handover latency of MIPv6 and localized movement in PMIPv6, we propose a new scheme that provides appropriate QoS and global roaming. This scheme adopts a QoS management server and global MAG. It extends the localized movement scope of PMIPv6 to heterogeneous global networks such as different ISPs or international regions without considering the MN's location and movement. It also analyzes the host mobility costs based on the MN's movement scope.

The rest of this paper is organized as follows. Section 2 describes the related works for reducing handover cost and providing QoS schemes in MIP networks. In section 3, we describe the architecture and functionality of PMIPv6 networks deploying Diffserv. The mobility management procedures for handover cost evaluation and supporting differentiated services are discussed. Section 4 presents the analytical results for Diffserv and the handover cost based on the MN's movement. Conclusions and remarks are presented in section 5.

2. Related Works

In MIPv4, an MN is identified by its home address, regardless of its current point of attachment in the network, and the MN is associated with a care-of-address (CoA) when it is away from home [1]. This triangular routing causes significant delay that degrades the handover performance. It is important for the mobility management to support fast and seamless handover with negligible delay, which enables active services without disruption. Thus, improvements were made and incorporated in a newer version of MIP called mobile IPv6 (MIPv6) to overcome some of the drawbacks [2]. It has been discovered that mobility can be more efficiently handled if the mobility management is divided into global mobility management and localized mobility management. Extensions of MIPv6 such as hierarchical mobile IPv6 (HMIPv6) [8] and fast handover for mobile IPv6 (FMIPv6) [9] have been proposed by IETF for efficient localized mobility management. The main goal of these localized mobility management protocols is to reduce the handover delay by localizing the registration of an MN [8] so that seamless service continuity can be achieved during roaming across wireless networks. Handover latency is mainly the result of delays caused by the discovery, configuration, authentication, and binding update procedures associated with a mobility event. Most of the recently proposed mobility management schemes have been host based, that is, the MN is directly involved in mobility-related signaling. Studies on handover cost evaluation to reduce these delays have been performed in various MIPv6 networks [10-16]. Handover anticipation based on layer 2 (L2) trigger information is used to reduce the registration delay [10-14]. M. Lopez *et al.* proposed a proactive handover scheme [10] that only considers the predictive mode. Both the predictive and reactive modes are considered to optimize the handover delay in PMIPv6, but the performance was analyzed separately for each mode [11-12]. To enhance the handover performance, K. Lee [13] proposed a cross-layering mechanism combined with IEEE 802.16e networks. For a more accurate performance evaluation in FMIPv6, S. Ryu *et al.* proposed combining the two modes and considered the probability of predictive mode failure (PPMF), which is affected by the radius of a cell, velocity of a mobile host, and L2 triggering time [14]. To enhance the handover performance in PMIPv6, they proposed optimizing the authentication delay and predicting the optimized route in [15, 16], respectively. Although PMIPv6 performs better than the typical host-based MIPv6 and its extensions in terms of handover performance [11, 12], it has a long handover delay when an MN moves away from its local area.

Mobile Internet traffic has recently increased at an exponential rate, and the new class of applications increases the need for QoS guarantees, which pose big challenges for the current wireless communication environments. The gap between QoS provisioning and demand has been significantly enlarged. Integrated services (Intserv) [17] and Diffserv [18] were proposed to solve the QoS problem in IP networks [19, 20]. Most QoS-providing models in wired and wireless networks focused on the buffer scheduling mechanisms based on traffic types. Various QoS provisioning schemes have been proposed for mobile IP networks [21-24]. However, these studies did not consider the MN's movement. In this paper, we propose a new scheme that allows an MN to move wherever it wants while receiving a guaranteed QoS. A priority queue model is used to provide differentiated QoS in our model. Because the BE traffic has the lowest priority, the highest and medium priorities are allocated to the EF class and AF class, respectively. To enable a performance analysis of the priority queue, we use the M/G/1 [25] queuing model.

3. QoS Guaranteed Global Roaming Model in Heterogeneous PMIPv6 Networks

3.1. Basic Operation of PMIPv6

PMIPv6 reuses the infrastructure of existing MIPv6 protocols but adopts new entities such as a mobile access gateway (MAG) and local mobility agent (LMA) for network-based mobility management. The MAG monitors the MN's movement in access links and sends signaling messages to LMA instead of the MN. The LMA is an anchor point of the MN that assigns a home network prefix to the MN and performs the HA role in PMIPv6 domain. It also manages the MN's reachability state in the domain. Typically, the MAG functionalities are embedded in an access router and the LMA is stacked in the gateway. There is an IP tunnel for transferring signals and data packets between an MAG and LMA. When an MN is attached to the PMIPv6 domain, the MAG tries to acquire the MN's profile from the policy server. That profile contains the MN's ID and IP address configuration method for access link and may include the MN's home network address of IPv6. When the MAG acquires the profile of the MN, it

sends a proxy binding update message to register the MN's location to the LMA. After receiving the proxy binding update message, the LMA sends a proxy binding acknowledge message, including the MN's home prefix information, and creates a bi-directional tunnel to the MAG. It also manages a routing table for transferring data to the MN and maintains the MN's reachability. Then, the MN sets up its IP address through a router advertisement procedure to get information about its home network prefix and address configuration method. When an LMA receives external packets from the PMIPv6 domain for the MN, it forwards them through the tunnel to the MAG, which will eventually forward them to the MN.

3.2. QoS Guaranteed Handover Scheme for Global Roaming

PMIPv6 provides mobility without the participation of the host, but its mobility management scope is restricted within an LMA domain. However, the host needs inter-LMA and inter-Internet service provider (ISP) movement, as well as global roaming. In this section, we propose a roaming scheme which includes global roaming. Based on the MN's movement scope, which might be intra-LMA, inter-LMAs, or inter-ISP domains, we analyze the QoS guaranteed handover costs.

Fig. 1 illustrates the proposed network architecture for QoS-guaranteed, fast, global roaming in heterogeneous PMIPv6. In this model, we adopt new entities: a QoS agent (QA) to support differentiated service and global MAG (G-MAG) for fast handover when an MN moves between ISP domains. This scheme could provide QoS guaranteed services depending on a subscriber's service level agreement (SLA) in PMIPv6 networks. More details of the procedures for an MN's movement and SLA management are provided in [26, 27]. We assume that an ISP network is composed of various access infrastructures according to its QoS level and locality. An ISP has a global QoS agent (GQA or QA) that acts as a global QoS manager, like a bandwidth broker in a Diffserv network. Neighboring GQAs can communicate with each other to establish an inter-domain QoS association such as SLAs. Each subnet of an ISP may have its own local QoS agent (LQA or QA) and HA for QoS and mobility management within its local area. Each LQA can manage the resources within its subnet, and serves the MN with a service profile.

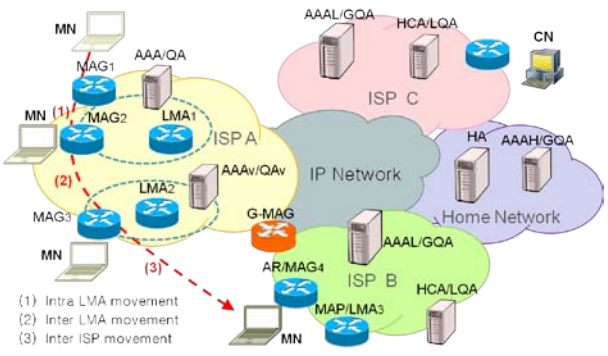

Fig. 1 **Network architecture for QoS-guaranteed, fast, global roaming.**

Three MN movement scope cases are shown in Fig. 1. In the first two cases, an MN moves around within the same ISP domain, while it moves into a neighboring ISP domain in the other case. In this figure, (1) indicates intra-LMA movement, which means that an MN attached to MAG1 moves into the new access point (AP) linked to MAG2, where both MAGs are managed by the same LMA1. Movement (2) represents inter-LMA movement. This means that the MN attached to MAG2 moves into MAG3, where the MAGs are managed by different LMAs, but both of them belong to the same ISP domain. Movement (3) shows inter-ISP movement, which means that an MN moves into another ISP domain's access point. This movement is called global roaming, which causes complicated procedures for handover. It causes long delays and QoS degradation. A global MAG (G-MAG) may solve this problem. It is geographically located on the border between ISP domains and used to connect the domains with a security association (SA). Thus, the G-MAG can manage the LMAs, AAAs, and QAs of both domains. In addition, it is able to transfer its profile and authentication information from one LMA to the other LMA during the pre-inter-domain handover. The G-MAG is able to estimate the MN's location and detect its movement by tracing the access point where the MN is attached. Thus, it can properly predict the point of the inter-domain handover execution. If the MN's inter-domain handover is imminent, the G-MAG performs a pre-inter-domain handover in advance of the inter-domain handover between the previous MAG and new MAG while the MN is still connected to the G-MAG.

3.3. Performance Analysis

This section describes a QoS-guaranteed handover cost analysis model that depends on an MN's movement scope. The handover cost of PMIPv6 C_{HO} can be expressed as the sum of movement detection latency T_{MD}, proxy binding update latency T_{PBND}, and router advertisement latency T_{RA}:

$$C_{HO} = T_{MD} + T_{PBND} + T_{RA}, \qquad T_{PBND} = T_{AUTH} + T_{QoS} + T_{CONF} \tag{1}$$

where T_{PBND} can be expressed as the sum of authentication delay T_{AUTH}, QoS management delay T_{QoS}, and address configuration delay T_{CONF}.

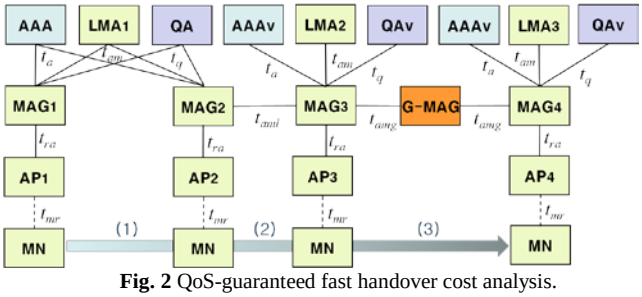

Fig. 2 QoS-guaranteed fast handover cost analysis.

Fig. 2 shows the QoS-guaranteed handover cost analysis model based on Fig. 1, which shows all three MN movement scenarios. The notations (1), (2), and (3) represent intra-LMA,

inter-LMA, and inter-ISP movements, respectively.

As shown in (1) of Fig. 1, when an MN moves to MAG2 from MAG1, MAG2 should register the MN to its LMA. Since the handover procedure is performed by the MN's movement detection, when an MN attaches to a new AP that is covered by a new MAG (MAG2), the AP sends L2 handover messages to the MAG2. This causes MN movement detection delay T_{MD}. When MAG2 detects the MN's movement, it sends authentication and QoS profile request messages for the MN to the AAA and QA servers, respectively. After receiving the authentication and QoS acknowledgement messages for the above queries, MAG2 sends a proxy binding update (PBU) message to its LMA. If the LMA can allocate the home network prefix to the MN, it sends a proxy binding acknowledgement (PBA) message to MAG2. MAG2 sends a router advertisement (RA) message to the MN when it receives a PBA message from the LMA. The intra-LMA handover in PMIPv6 is now completed. In this case, both MAGs (MAG1 and MAG2) are in the same region of LMA1, and the MN's registration procedures follow the conventional PMIPv6 protocol [5]. The QoS-guaranteed handover cost of intra-LMA movement in PMIPv6 network $C_{P\_HO}^{INTRA\_LMA}$ can be described in expression (2):

$$\begin{aligned}
C_{P_HO}^{INTRA_LMA} &= T_{P_MD}^{INTRA_LMA} + T_{P_PBNB}^{INTRA_LMA} + T_{P_RA}^{INTRA_LMA} \\
&= 2(t_{ra} + t_a + t_q + t_{am}) + t_{mr}, \\
T_{P_MD}^{INTRA_LMA} &= t_{ra},\ T_{P_RA}^{INTRA_LMA} = t_{ra} + t_{mr}, \\
T_{P_PBND}^{INTRA_LMA} &= T_{P_AUTH}^{INTRA_LMA} + T_{P_QoS}^{INTRA_LMA} + T_{P_CONF}^{INTRA_LMA} \\
&= 2(t_a + t_q + t_{am}), \\
T_{P_AUTH}^{INTRA_LMA} &= 2t_a,\ T_{P_QoS}^{INTRA_LMA} = 2t_q, \\
T_{P_CONF}^{INTRA_LMA} &= 2t_{am},
\end{aligned} \tag{2}$$

where t_{ra} is the movement detection delay, t_{mr} and t_{am} are wireless and wired delays, and t_a and t_q are authentication and QoS setup delays, respectively.

An inter-LMA handover cost analysis is shown in (2) of Fig. 2. Since PMIPv6 is designed to manage local area movement, if an MN is away from its current LMA domain, registration procedures for the MN should be carried out through its home network. This causes a long delay and QoS degradation. To reduce the handover delay through the MN's home network, we propose the use of a pre-handover mechanism before detaching the current MAG (MAG2). When an MN receives a new router advertisement message with a network prefix that is different from its current one, it sends a request to its current MAG (MAG2) to send its profile to the new MAG (MAG3) before detaching from MAG2.

In this message, the MN's profile is included for movement management without link disruption. Since MAG3 receives the MN's profile from MAG2, it does not need to request authentication and QoS properties from its home network entities. Thus, we can significantly reduce the handover cost. When an MN moves to a new MAG that belongs to a new LMA domain, the proposed fast handover cost is represented by equation (3):

$$\begin{aligned}
C_{fP_HO}^{INTER_LMA} &= T_{fP_MD}^{INTER_LMA} + T_{fP_PBND}^{INTER_LMA} + T_{fP_RA}^{INTER_LMA} \\
&= 2(t_{ra} + t_a + t_q + t_{am}) + t_{mr} + 6t_{aml}, \\
T_{fP_MD}^{INTER_LMA} &= t_{ra},\ T_{fP_RA}^{INTER_LMA} = t_{ra} + t_{mr}, \\
T_{fP_PBND}^{INTER_LMA} &= T_{fP_AUTH}^{INTER_LMA} + T_{fP_QoS}^{INTER_LMA} + T_{fP_CONF}^{INTER_LMA} + T_{fP_PRE_REG}^{INTER_LMA} \\
T_{fP_AUTH}^{INTER_LMA} &= 2(t_a + t_{aml}),\ T_{fP_QoS}^{INTER_LMA} = 2(t_q + t_{aml}), \\
T_{fP_CONF}^{INTRA_LMA} &= 2(t_{am} + t_{aml}), \\
T_{fP_PRE_REG}^{INTER_LMA} &= t_{mr} + t_{ra},
\end{aligned} \tag{3}$$

where t_{aml} is the delay for the MN's profile transfer between the two MAGs and pre-handover delay $T_{fP\_PRE\_REG}^{INTER\_LMA}$, which occurs before the MN's movement to support for the MN's movement between LMAs, can be neglected. An inter-ISP handover cost analysis is shown in (3) of Fig. 2. If it has to be executed in the conventional PMIPv6 schemes, the MN suffers from a long service disruption because of the home registration of the MN. When the MN moves from MAG3 to MAG4, the inter-ISP handover latency becomes too long to support seamless service continuity. To reduce this long inter-ISP handover latency, we propose a new scheme that adopts a network entity called G-MAG, as shown in Fig. 1. The G-MAG is located between ISP domains and is connected to both domains with a security association (SA). Upon predicting an imminent inter-domain handover for the MN, it performs the inter-domain handover while the MN is connected to the previous MAG (MAG3) in the previous domain (ISP A). Since the G-MAG has dual connections between ISP domains, it can gather and manage the LMA information of both domains. It can also transfer the MN's profile and authentication information from one LMA to the other LMA during the pre-inter-domain handover. The G-MAG is able to estimate the MN's location and movement direction by tracing the AP where the MN attaches. Consequently, the G-MAG can properly predict the inter-domain handover execution point. Thus, because the new MAG (MAG4) receives the MN's profile from the G-MAG, it does not need to request authentication and setup QoS properties from its home network.

Therefore, the proposed scheme can reduce the inter-domain handover latency by avoiding the signaling to the MN's home network. When an MN moves to a new MAG that belongs to a new ISP domain, the handover cost of the proposed scheme is represented by equation (4):

$$\begin{aligned}
C_{fP_HO}^{INTER_ISP} &= T_{fP_MD}^{NTER_ISP} + T_{fP_PBND}^{NTER_ISP} + T_{fP_RA}^{NTER_ISP} \\
&= 2(t_{ra} + t_{am} + t_a + t_q) + 6t_{amg} + t_{mr}, \\
T_{fP_MD}^{INTER_ISP} &= t_{ra},\ T_{fP_RA}^{NTER_ISP} = t_{ra} + t_{mr}, \\
T_{fP_PBND}^{INTER_ISP} &= T_{fP_AUTH}^{INTER_ISP} + T_{fP_QoS}^{INTER_ISP} + T_{fP_CONF}^{INTER_ISP}, \\
T_{fP_AUTH}^{INTER_ISP} &= 2(t_{amg} + t_a),\ T_{fP_QoS}^{INTER_ISP} = 2(t_{amg} + t_q), \\
T_{fP_CONF}^{INTER_ISP} &= 2(t_{am} + t_{amg}),
\end{aligned} \tag{4}$$

where t_{amg} is the delay between MAGs that belong to

different ISP domains.

To show our model's handover cost effectiveness, we present a handover cost analysis model for the conventional PMPv6 in Fig. 3. It shows a cost evaluation for inter-LMA and inter-ISP handovers in the conventional PMIPv6. As can be seen in this figure, the intra-LMA handover cost is identical to (1) of Fig. 2. Thus, the intra-LMA handover cost in the conventional PMIPv6 is the same as expression (1). However, when an MN moves to LMA2 from its previous LMA (LMA1), the new MAG (MAG3) and LMA2 have no information about the MN if these events occur in conventional PMIPv6 networks. The delay associated with acquiring the MN's profile, authentication, and QoS information through the MN's home network should be taken into account, in addition to the handover costs for inter-LMA and inter-ISP movements in the conventional PMIPv6.

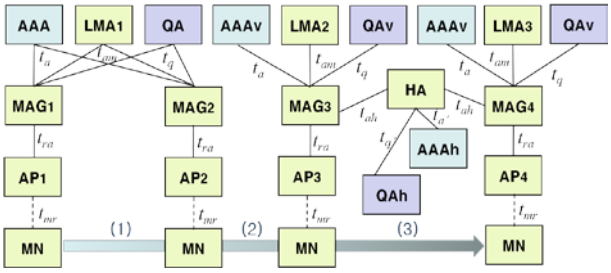

Fig. 3 **Handover cost analysis in conventional PMIPv6.**

In Fig.3, (2) and (3) represent the inter-LMA and inter-ISP handover cost evaluations. When an MN moves into a new LMA or new ISP domain that does not belong to its previous network, there are no benefits to PMIPv6 because it was developed as a local movement management scheme. Thus, all of the mobility procedures have to be carried out like in MIPv6 networks. When a new MAG such as MAG2 or MAG3 detects an MN's movement, it has to acquire the MN's profile, authentication, and QoS information through the MN's home network. After receiving the MN's profile from its home network, the new MAG sends a PBU message to its LMA (LMA2 or LMA3). After receiving the PBA message from the new LMA, the new MAG sends an RA message to the MN, and the inter-LMA or inter-ISP handover is completed. The handover costs for these two cases are the same because the handover procedures for inter-LMA and inter-ISP movements are identical. The handover cost is expressed by (5):

$$
\begin{aligned}
C_{cP\_HO}^{INTER\_LMA,ISP} &= T_{cP\_MD}^{INTER\_LMA,ISP} + T_{cP\_PBNB}^{INTER\_LMA,ISP} + T_{cP\_RA}^{INTER\_LMA,ISP} \\
&= 2(t_{ra} + t_a + t_q + t_{a'} + t_{q'} + t_{am}) + 6t_{ah} + t_{mr}, \\
T_{cP\_MD}^{INTER\_LMA,ISP} &= t_{ra}, \quad T_{cP\_RA}^{INTER\_LMA,ISP} = t_{ra} + t_{mr}, \\
T_{cP\_PBND}^{INTER\_LMA,ISP} &= T_{cP\_AUTH}^{INTER\_LMA,ISP} + T_{cP\_QoS}^{INTER\_LMA,ISP} + T_{cP\_CONF}^{IINTER\_LMA,ISP} \\
&= 2(t_a + t_q + t_{a'} + t_{q'} + t_{am}) + 6t_{ah}, \\
T_{cP\_AUTH}^{INTER\_LMA,ISP} &= 2(t_a + t_{ah} + t_{a'}), \; T_{cP\_QoS}^{INTER\_LMA,ISP} = 2(t_q + t_{ah} + t_{q'}), \\
T_{cP\_CONF}^{INTER\_LMA,ISP} &= 2(t_{am} + t_{ah}),
\end{aligned}
\tag{5}
$$

where t_{ah}, $t_{a'}$, and $t_{q'}$ are the delays for the MN's registration, authentication, and QoS management through its home network, respectively.

4. Cost Evaluation Results

In this section, we compare the handover costs of the conventional scheme and our proposed models in heterogeneous PMIPv6 networks by service types and the MN's movement scope. The parameters used in this handover cost analysis are defined as follows. Let's assume that a CN generates data packets destined for an MN at mean rate α and an MN moves from one subnet to the other at mean rate β. The packet to Mobility Ratio (PMR), $\rho = \alpha/\beta$, is defined as the mean number of packets received by an MN from a CN per movement. The parameters l_c and l_d are defined as the average length of a control packet and data packet, respectively. Then, their ratio, l, can be defined as l_c/l_d. The cost of transmitting a control packet is given by the distance between a sender and a receiver. The cost of transmitting a data packet is l0 times greater than the average cost of processing a control packet at any host (and forwarding data packets at an HA). The average delay time and packet loss probability are very important factors for QoS. In Diffserv networks, ingress edges classify the traffic by SLA. We assume three service levels: EF, AF, and BE. We also assume that an access router accommodates different types of data packets from numerous connections. To serve these three types of traffic, we use 3 buffers in the output buffer module of each node. In this paper, each node has an M/G/1 queuing model for evaluating the performance of prioritized packets. Packets are summed to arrive in the queue according to a Poisson process with mean rates λ_1, λ_2, and λ_3 for EF, AF, and BE packets, respectively. The service times for packets from each traffic class follow exponential distributions, with mean rates of $1/\mu_1$, $1/\mu_2$, and $1/\mu_3$ for EF, AF, and BE packets, respectively. The mean offered load of the EF, AF, and BE packets in the buffer are $\rho_1=\lambda_1/\mu_1$, $\rho_2=\lambda_2/\mu_2$, and $\rho_3=\lambda_3/\mu_3$, respectively. The packet scheduling at the buffer module is as follows. First, the server visits an EF buffer. If packets exist in the EF buffer, it serves them until the buffer is empty. Otherwise, the server visits an AF buffer, and serves the packets in that buffer. After the service is finished for the AF buffer, BE packets are served.

To compare our QoS-guaranteed model with the existing extensions of MIPv6, we use the wired and wireless experimental results in [11, 12]. The values are $t_{mr} = t_{am} = t_{hc} = 10$ *ms*, $t_a = t_q = t_{a'} = t_{q'} = t_{ah} = t_{ac} = 20$ *ms*, $t_{ra} = 2$ *ms*, $t_{amg} = 6$ *ms*, and $t_{aml} = 4$ *ms*. The control packet size and data packet size are assumed to be 100 bytes and 1,024 bytes, respectively, and the buffer size, K, is assumed to be 100. The traffic arrival rates are $\lambda_1 = 0.5$, $\lambda_2 = 0.3$, and $\lambda_3 = 0.2$ under a work-load of 0.5.

Figs. 4, 5, and 6 show the handover costs according to service type and MN movement scope. Fig. 4 shows the intra-

LMA handover costs of MIPv6 and PMIPv6. In this case, we represent the cost of handover from the conventional PMIPv6 (cPMIPv6) and proposed fast PMIPv6 (fPMIPv6) as PMIPv6 because when an MN moves around in an LMA domain, the handover procedures are identical, and thus the handover costs are the same. As can be seen, the difference between the handover costs of MIPv6 and PMIPv6 is significant because of the MN's CoA registration in MIPv6 networks. It also shows the service types are a significant element influencing the handover costs. As shown in Fig. 4, the main factor for the handover cost is the service policy. PMIPv6 shows very good performance compared to MIPv6. In the PMIPv6 network, the handover costs for the EF, AF, and BE services are 9.64 times smaller than MIPv6's for all of the traffic.

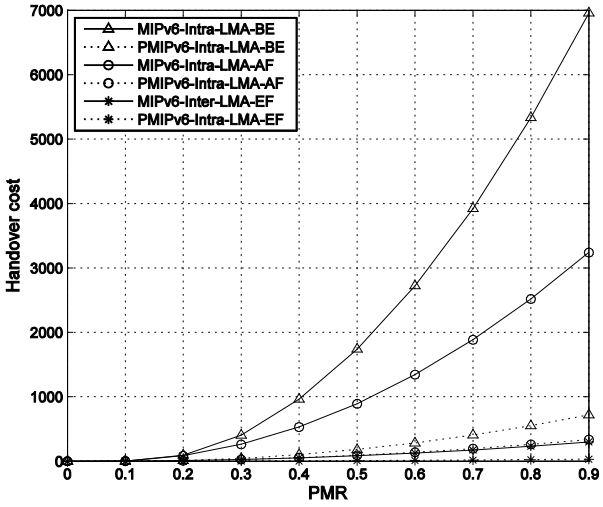

Fig. 4 Intra-LMA handover costs in PMIPv6 networks.

The inter-LMA and inter-ISP handover costs in PMIPv6 are shown in Fig. 5 and Fig. 6, respectively. In these figures, we omit the MIPv6 costs because the results are the same as those of Fig. 4. Thus, we compare the results of the conventional PMIPv6 and proposed fast PMIPv6 schemes. When an MN moves between LMAs, the handover costs of fPMIPv6 are significantly lower than those of cPMIPv6. This is because when an MN moves to a different LMA in a cPMIPv6 network, additional handover procedures to acquire the MN's profile are needed, as in MIPv6. All of the fPMIPv6 service types show better performance than the AF service of cPMIPv6. The handover costs of fMIPv6 are 2.15 times smaller than those of cPMIPv6 for all of the traffic. This shows that our scheme is effective for inter-LMA movement.

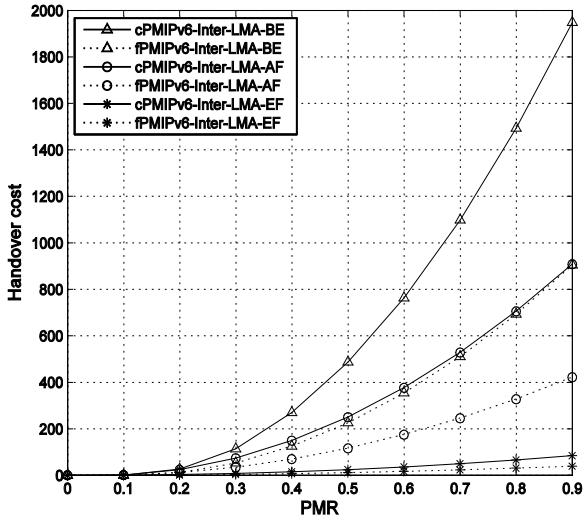

Fig. 5 Inter-LMA handover costs in PMIPv6 networks.

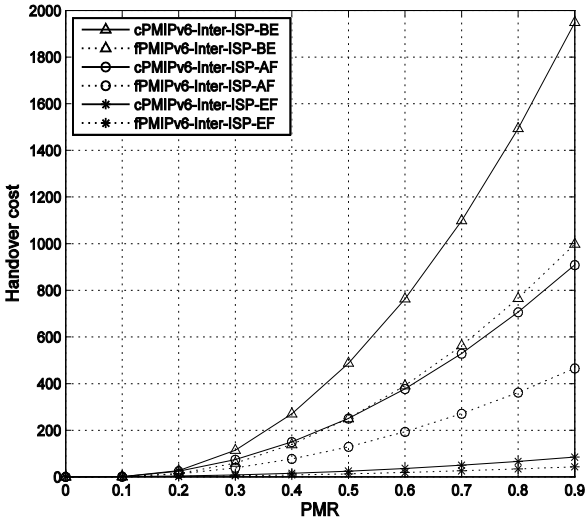

Fig. 6 Inter-ISP handover costs.

Fig. 6 shows the inter-ISP handover costs. In this case, we adopt a G-MAG to eliminate the MN authentication process and QoS setup delay involving its home network. The handover costs are shown for BE, AF, and EF traffic in the conventional and fast PMIPv6. Our scheme reduces the handover cost by 1.65 times compared to cPMIPv6. The results show that fPMIPv6 is effective under global roaming circumstances and could be adopted in future global networks that require an MN that is fast and QoS-guaranteed roaming.

5. Conclusions

Various applications and portable communication devices demand various QoS and mobility levels under different circumstances. To provide a guaranteed QoS and fast mobility, we propose procedures for mobility and QoS management in heterogeneous PMIPv6 networks. When Diffserv is deployed in a mobile IP network, various problems are encountered. The most significant problem is related to the acquisition of the service profile for the MN when it moves into a different ISP domain. Since the first-hop router does not have any information about the newly attached MN, a guaranteed QoS could not be provided. To solve this problem, we present procedures for acquiring the MN's service profile and additional information based on the MN's movement scope. Through a guaranteed-QoS handover cost analysis and evaluation, we reduce the handover cost by 9.64 times compare to MIPv6 for intra-LMA movement. Moreover, our scheme shows handover cost efficiencies for inter-LMA and inter-ISP movements that are 2.15 and 1.64 times better than the conventional PMIPv6, respectively. Consequently, our scheme is effective under global roaming circumstances and could be adopted in future global networks that require a fast speed, guaranteed QoS, and roaming. In future work, we will refine the message types and registration procedures to manage the MN's mobility more effectively and reduce the total communication cost. An authentication mechanism for seamless handover will also be considered to construct a service that is more efficient and secure, with a guaranteed QoS in heterogeneous PMIPv6 networks.

Abstract - *The reconfigurable mesh (R-Mesh) was shown to be a very powerful model capable of extremely fast solutions to many problems. R-Mesh has a wide range of applications such as arithmetic problems, image processing and robotics. The 2D R-Mesh was shown to be able to solve the path planning problem very fast.*

In this paper, we propose an algorithm to compute a collision-free path between a source and a destination in an environment with the existence of obstacles. Independent of the number of obstacles, k, the proposed algorithm runs in constant time and requires O(log ^{2}N) pre-processing time where N is the size of the R-Mesh. This is in contrast to the previous work that requires O(k) time with the same pre-processing time. We then make a modification to the obtained path to enhance its length. This enhancement also requires constant time.

Keywords-*parallel algorithms, reconfigurable mesh, path planning*

1 Introduction

Reconfiguration is a very powerful computing paradigm, capable of extremely fast solutions to many problems. Models such as the reconfigurable mesh (R-Mesh) [9] (shown in Figure 1) have the ability to change the interconnection between processors at every step of the computation to allow efficient communication as well as performing computation faster than conventional non-reconfigurable models. A 2D R-Mesh is an array of processors with fixed external connections between each two neighboring processors. Also it has dynamically reconfigurable internal connections within each processor. This allows altering the interconnection among processors very fast, possibly at each step of the computation.

Robot motion planning algorithms aim to plan a path for a moving robot from a source location to a target location. The environment that the robot navigates through may have obstacles. The main target for the robot is to maneuver without colliding with obstacles if any. In general, the existent obstacles may be static or dynamic obstacles; *i.e.* moving obstacles. Restrictions on the robot movement from source to destination may take into account a number of factors. These include the robot shape and type of movement; for example translational or rotational. To simply handle the path planning problem, the image of robot and obstacles are digitized and stored in the R-Mesh, with one processor holding one pixel of the image. The R-Mesh was shown to handle these kinds of problems very fast. Also some techniques use first an algorithm to generate the *configuration space*. The configuration space is a slightly different image for the robot and the obstacles than the original image. It can be obtained by expanding the obstacles based on the shape of the robot and its movement. This way, the robot that is not point-like can be converted to a point-like robot. This greatly simplifies the design and analysis of the algorithm.

Since path planning problem is computationally intensive, many parallel algorithms have been proposed using various algorithmic models and assumed different robot shapes. These models include R-Mesh, hypercube computers, etc.

Tzionas *et al*. assumed a diamond-shaped robot and presented a parallel algorithm for collision-free path planning [12]. Jenq and Li [4] used hypercube to compute the configuration space optimally. The algorithm was shown to be optimal where it requires O(log n) time for an $n \times n$ image by using $n \times n$ Mesh of processors. D. Wang [14] proposed efficient algorithms for solving the reachability problem in one dimensional space. Dehne *et al*. [3] presented a systolic algorithm for computing the configuration space for obstacles in a plane for a rectilinear convex robot. The algorithm takes O(n) time for an $n \times n$ image on an $n \times n$ mesh of processors.

H.C. Lee [7] studied the maze-routing problem and it was shown that the R-Mesh is suitable for developing efficient and fast algorithms to solve the maze-routing problem. The maze-routing problem has its application in the path planning problem.

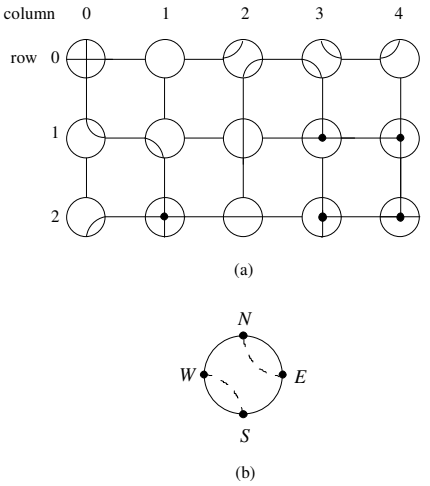

Fig.1 (a) Example of buses in a 3 × 5 R-Mesh (b) Processor ports

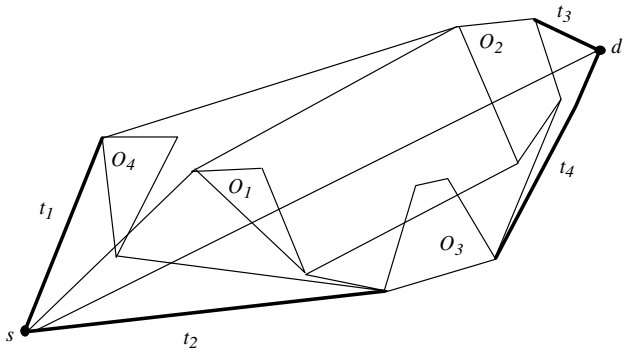

Fig.2 Illustration of the linear time algorithm [15]

Recently, D. Wang [15], used the 2D R-Mesh to compute a collision-free path. The obstacles are assumed to be disjoint convex or concave polygons. The algorithm starts by drawing a line from the source location to the destination location. Then, it finds the obstacles that intersect with that line if any. If more than one obstacle is found, then the algorithm combines these obstacles into one big obstacle. If only one obstacle is found or using the combined obstacle, the algorithm finds the tangent lines to that obstacle and finds if new obstacles intersect with these tangent lines. The mentioned operation is repeated till the four tangent lines to the combined obstacle from the source and destination do not intersect with any obstacles. At the end, there will be two possible collision-free paths from the source to destination. This operation requires all obstacles to be convex or concave polygons. The algorithm runs in O(k) time with preprocessing O(log ^2N) time. Figure 2 shows the two possible paths from the source s to the destination d for the given environment. In the figure, there are four obstacles labeled O_1, O_2, O_3 and O_4. The obstacles are combined into one obstacle, then the tangents t_1, t_2, t_3 and t_4 from the source and the destination are drawn to this combined obstacle. Thus there are two possible paths between s and d. Intuitively, the work in [15] finds a path that goes around the obstacles in the area between the source and the destination. With an O(log^2N) preprocessing time for the given obstacle image, the algorithm uses O(k) time to compute a path from a source to a destination while avoiding all obstacles in the environment, where N is the total number of processors (pixels) and k is the number of obstacles.

In this paper, we consider the R-Mesh for computing a collision-free path between a source and a destination in the presence of obstacles. Independent of the number of obstacles, k, the algorithm runs in constant time and requires O(log ^2N) pre-processing time where N is the size of the R-Mesh. This is in contrast to the work of Wang [15] that requires O(k) time with the same pre-processing time. The main idea is to start with a straight line between the source s and the destination d. We denote this line segment $\overline{sd}$. The path is generated such that it follows the straight line segment $\overline{sd}$ with going around each obstacle that intersects with this path. The algorithm generates 2^m possible paths where m is the number of obstacles that intersects with $\overline{sd}$, $1 \le m \le k$. Then an enhancement to the generated path is proposed. This enhancement tends to decrease the length of the generated path.

The next section presents some preliminaries and definitions. Section 3 describes the preprocessing operations that are applied before running the proposed algorithm. In Section 4, we describe the proposed algorithm and its time analysis. Section 5 presents an enhancement to the algorithm that could reduce the length of the generated path. In Section 6, we summarize our results and make some concluding remarks.

2 Preliminaries

In this section we introduce some preliminaries and definitions that are used through out this paper.

2.1 Reconfigurable Mesh

An $R \times C$ *reconfigurable mesh* or *R-Mesh* [13] consists of an R-row, C-column array of processors connected by an underlying mesh (see Figure 1). Number the rows (resp., columns) 0,1..., R-1 (resp., 0,1..., C-1) as shown in Figure 1. Each processor has four ports (called North, South, East, and West ports in the obvious manner, and abbreviated N, S, E, and W (see Figure 1(b)).

Each processor can independently partition its ports to connect certain ports together leaving other ports unconnected. For example, in Figure 1(a) the top left processor connects its N port to its S port, and its E port to its W port. The corresponding partition is denoted by $\{\overline{NS}, \overline{EW}\}$.

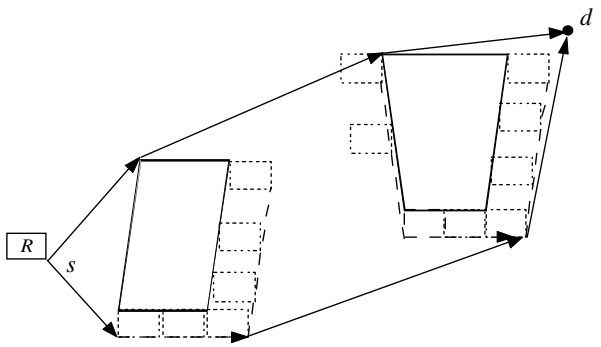

Fig.3 Expanding the original obstacles and reducing the robot to a point *s*

Figure 1(a) shows the fifteen possible port partitions of the R-Mesh.

An assignment of a port partition to each R-Mesh processor is called a *configuration*. Figure 1(a) shows one possible configuration. The port partitions along with the underlying mesh connections between neighboring processors form buses connecting processors. Figure 1 shows buses connecting sets of processors. An assumption central to all traditional R-Mesh algorithms is that buses have constant delay, regardless of the number of processors they span which enables us to design very fast algorithms. An R-Mesh making this assumption is called a unit-cost R-Mesh. In this paper we consider the unit-cost R-Mesh.

At each step of an R-Mesh algorithm, a processor could perform the following actions: (1) configure (partition) its ports, (2) read from or write to its ports, and (3) perform a local computation. An R-Mesh could permit concurrent reads and writes. If more than one processor is allowed to write to a bus at the same time, then the R-Mesh has concurrent write ability and the concurrent write rules [13] are used to resolve the values written to the bus. In this paper, we consider exclusive read exclusive write (EREW) R-Mesh.

2.2 Configuration Space

Usually the robot that navigates from a source to a destination has a certain shape and size. To be able to find a path without colliding with the existing obstacles, we need to take into account the shape and the size of the robot. One way to simplify handling the robot shape and size is to create what is called a *configuration space*. Instead of dealing with the robot as an object with a certain shape and size, we deal with it as a point and try to find a path from the source to destination. The configuration space is a slightly different image for the robot and the obstacles than the original image. It can be obtained by expanding the size of the obstacles that account for the shape and size of the robot. Thus, the robot can be reduced to a point. Many algorithms have been proposed to compute the configuration space for different robot shape and size [6]. For example if the robot is of polygon shape, the configuration space can be computed using the R-Mesh in O(1) time. In this paper we deal with the configuration space directly; i.e. we assume it has been already computed. Figure 3 shows the expanded obstacles for a rectangular robot.

3 Pre-processing Operations

The preprocessing operation, convexaziation, handles all the obstacles in the environment. The process builds a convex hull for each obstacle and enumerate the extreme points of each convex. Figure 4 shows an obstacle after applying the operation of convexaziation. The target is to identify the extreme points of the convex hull of the given polygon *H*. The figure shows the polygon after enumerating its extreme points. The work of Miller *et al*. [9] performs this operation on all the obstacles in the environment in $O(log^2 N)$ time where N is the size of the R-Mesh. After enumerating the extreme points, each extreme point processor has a flag to identify it as extreme point. Each extreme point processor has the following information (1) The ID number of the polygon this extreme point belongs to. (2) The number of the extreme point in the polygon. (3) The locations of the previous and the following extreme points. In other words, each extreme point contains segments information associated with it.

We assume that after convexization, *s* and *d* are not covered by any convex polygon. If that is not the case, a constant time operation treatment discussed later in section 6 reduces the problem to the assumed situation.

4 Constant Time Algorithm

In this section we describe a constant time algorithm to solve the path planning problem on the R-Mesh. In section 5, we propose a constant time operation that enhances the generated path. Given an environment in the presence of obstacles, it is required to find a collision-free path from a source location *s*, to a destination location *d*. We assume that the obstacles to be disjoint convex or concave polygons. If two polygon images intersect, we consider them one polygon. The input to the R-Mesh is an $n \times n$ image that represents the environment. The image is digitized, stored to the R-MESH, one pixel per processor. There is a flag associated with each processor. The flag has a value of 1 or 0 based on the digitized image. We use an $n \times n$ R-Mesh to solve the path planning problem.

Generally speaking, the idea is to start with a straight line between the source *s* and the destination *d*. The final path tries to follow the line segment $\overline{sd}$. If $\overline{sd}$ does not intersect with any obstacle, then $\overline{sd}$ represents the final path. If $\overline{sd}$ intersects with a number of obstacles, then the final path follows the straight line segment $\overline{sd}$ with going around each

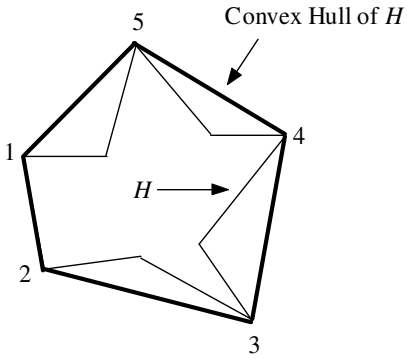

Fig.4 Enumerating the extreme points of a polygon *H*. The bold edges represent the convex hull of *H*.

obstacle that intersects with this path. We show that this path can be computed in constant time. Since going around an obstacle could be in clockwise or counter clockwise direction, then there are 2^m possible paths from *s* to *d* where *m* is the number of obstacles that intersects with segment $\overline{sd}$, $1 \le m \le k$.

Figure 5 shows the same environment as the presented in Figure 2. Figure 5 shows the path from the *s* to the destination *d* provided by the proposed algorithm.

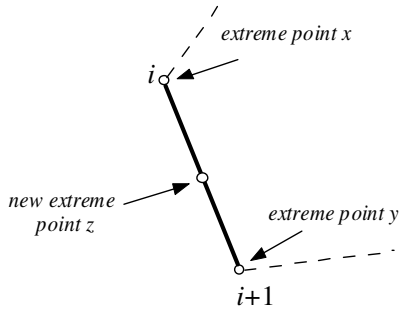

Fig.6 Addition of a new extreme point to a convex hull of an obstacle

4.1 Basic Operations

In this section we develop some operations on the R-Mesh that will be used in the proposed algorithm in Section 4.2.

- **Broadcasting Data**

Once the buses of R-Mesh are constructed, data movement on the R-Mesh requires constant time. The information written on the bus by any processor incident on the bus reaches all the processors incident on the bus in constant time. To broadcast data to all processors of the R-Mesh, partition all processors as $\overline{NSEW}$. If any processor write information on the any port, it reaches all processors in O(1) time. Thus broadcasting data to all processors requires constant time.

- **Adding a new point as an extreme point**

Let *H* be the convex hull of an obstacle *O*. Assume that the extreme points are enumerated in counter clockwise direction. Each extreme point knows its ID and the locations of preceding and following extreme points. In other words, each extreme point contains segments information associated with it. Consider an edge *e* with two extreme points *x* and *y* enumerated as *i* and *i*+1. The target is to add a new point *z* that is located on the segment as an extreme point. The operation uses the local bus via convex hull *H*. Let the processor representing *z* cut the local bus from *x* to *y*. The processor *z* exchanges the data with extreme points *x* and *y* using the local bus. The data exchanged include IDs of extreme points and their locations. Now processor *x* sets its following extreme point as *z* and processor *y* sets its preceding extreme point as *z*. Processor *z* sets its preceding and following extreme points as *x* and *y* respectively while the processors *x* and *y* keep their IDs. The processor *z* sets its ID to a special ID to indicate that *z* is an added extreme point. The described operations require constant time. Figure 6 shows the operation of adding a new extreme point to a polygon.

- **Constructing a bus from *s* to *d***

The target is to construct a bus from *s* to *d* on the R-Mesh that represents the segment $\overline{sd}$ as follows. Given that the locations *s* and *d* are known to all processors in the R-Mesh, each processor determines whether or not it belongs to the segment $\overline{sd}$. Then each processor that belongs to the segment $\overline{sd}$ computes the position of its preceding processor and the position of its following processor on the path from *s* and *d*. This allows each processor to configure its ports to connect its preceding processor and its following processor. For example, if a processor *p* finds that its preceding (resp. following) processor is the processor on its West (resp. North), then processor *p* configure its ports $\{\overline{NW}, E, S\}$ to connect the preceding and following processors. Constructing the bus includes a constant number of operations which can be done in constant time.

4.2 The Proposed Algorithm

In this section, we describe the proposed constant-time algorithm. We assume an $n \times n$ R-Mesh as the working environment. Again, the image of the obstacles is digitized, input and stored one pixel per processor. There are k disjoint polygonal obstacles. Also, we assume that the robot has been reduced to a point using the constant time algorithm proposed in [6]. Given the source point s and the destination point d, it is required to compute a collision-free path between s and d. Let P_s and P_d be the two processors that represent the positions of s and d respectively. The high level description of the proposed algorithm is as follows.

Collision-Free Path Algorithm

Input: The image of the obstacles, the positions of source s and destination d.
Output: A collision-free path between s and d.
Model: An N-processor, 2D-EREW R-Mesh

Step 1. Processors P_s and P_d broadcast their positions to all processors of the R-Mesh.
Step 2. All edges of all convex hulls calculate whether they intersect with the segment $\overline{sd}$ or not and determine the points of intersections if any. Let convex hull H_i intersects with $\overline{sd}$ at points l_i (l-point) and r_i (r-point) where $i \in \{1,..,k\}$. Let $S = \{H_i \mid i \in 1..k\}$ be the set of convex hulls that intersect with $\overline{sd}$ where $|S| = m$.
Step 3. For all $H_i \in S$, add points l_i *and* r_i to the extreme points of convex hull H_i.
Step 4. Construct a bus from s to d, *default bus*, and let all processors l_i and r_i cut the bus. Now, the bus from s to d consists of a number of segments. The first segment is from s to an l-point and the last segment is from r-point to d.
Step 5. Each two neighbouring processors cutting the default bus exchange their positions.
Step 6. Determine the collision-free path from s to d as a number of consecutive segments as follows.

- First segment is from s to the following l-point along $\overline{sd}$.
- The segment from any r-point processor to the following l-point processor is along $\overline{sd}$.
- The segment from any l-point processor to the following r-point processor is composed of a number of sub-segments along the convex hull of the obstacle and taken from the enumeration in the pre-processing.
- Last segment is from an r-point to d along $\overline{sd}$.

Now we describe the algorithm in detail. Step 1 broadcasts the positions of the source point and the destination point to all the processors on the R-Mesh. This enables all processors to compute the line segment $\overline{sd}$. In Step 2, each edge belongs to a polygon determine whether or not it intersects with segment $\overline{sd}$. If an edge e intersects with segment $\overline{sd}$, then the terminal points of the edge e determine the intersection point. Note that if a polygon H_i intersects with segment $\overline{sd}$, then it intersects in two points l_i (l-point) and r_i (r-point). The l-point (resp. r-point) is the one that is on the side of the source (resp. destination). Figure 7 shows four intersection points for the obstacles O_1 and O_2 with $\overline{sd}$. Let the set W contains all the intersection points; i.e. $W=\{l_i,,r_i \mid i \in 1..k\}$. Step 3 adds the two points l_i and r_i to the extreme points of the polygon H_i, $i \in 1..k$. Thus, each point l_i knows its preceding and following extreme point in the convex hull of the obstacle, same for point r_i. Since there are two paths around the obstacle to reach r_i from l_i, then a certain rotation direction should be decided. Here we assume, without loss of generality, that we go around the obstacle in clockwise direction. Note that the counter clockwise direction could be also followed. In Step 4, the algorithm constructs a bus, *default bus*, on the R-Mesh from s to d, as shown in Section 4.1 and let all processors l_i and r_i, $i \in 1..k$, cut the bus. In other words, the constructed bus now consists of a number of segments. There is a processor belongs to the set W between each two consecutive segments. In Step 5, each two neighbouring processors in W exchange their positions. This enables the start point, s, to know the following extreme point (an l-point) and also enables the last intersection point (an r-point) to know that the next point is the destination, d. Now the point s knows the first intersection extreme point (an l-point) and the last intersection extreme point (an r-point) knows the following point, d. Also along the path from s to d, each extreme point knows the following extreme point. Step 6 determines the final collision-free path from s to d. The path is composed of a number of segments. All the points l_i and r_i, $i \in 1..k$, belong to the final path and each represents a turning point on the path from s to d.

The first segment is from s to the following l-point and follows the segment $\overline{sd}$. The last segment is from an r-point to d and follows the segment $\overline{sd}$. A segment from any r-point processor to the following l-point processor follows the segment $\overline{sd}$. A segment from any l-point processor to the following r-point processor follows the convex hull of the obstacle and is taken from the enumeration in the pre-processing in Section 3.

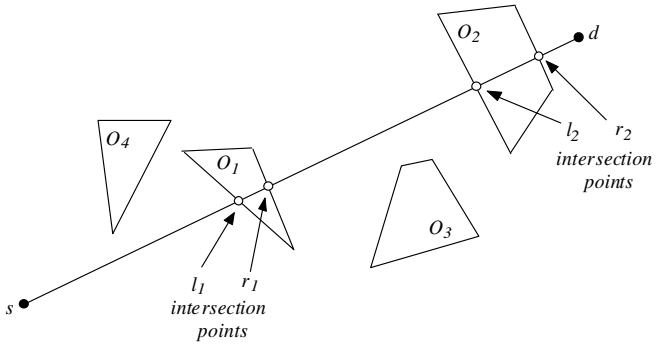

Fig.7 Intersection points for obstacles with segment $\overline{sd}$

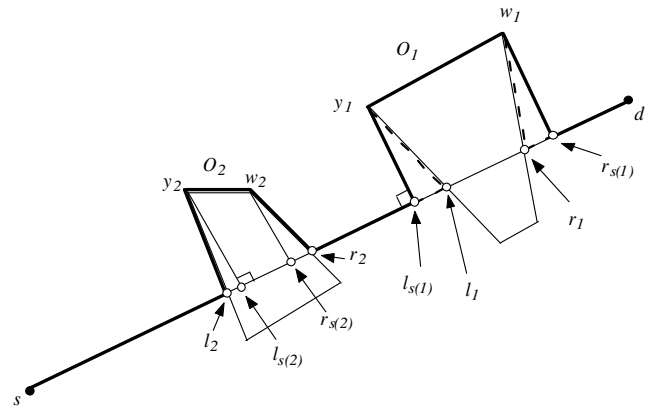

Fig.8 Replacing segments of the path generated by the proposed algorithm

4.3 Time Analysis

In this section, we show that the algorithm runs in constant time. Step 1 broadcasts the two positions for s and d to all processors of the R-Mesh. Broadcasting on the R-Mesh requires constant time as shown in Section 3. Step 2 calculates the intersection points for every edge with segment $\overline{sd}$. Since each extreme point in a convex hull contains the information of the two segments on which it is incident. Therefore, all the intersection points can be computed in parallel in O(1) time. Step 3 uses the sub bus within the polygon to add l_i and r_i to the extreme points of the polygon as shown before in O(1) time. In step 4, all processors use the positions of s and d to configure their ports in parallel such that the segment $\overline{sd}$ is constructed. The computation and configuration is done in constant time. Step 5 sends information on the constructed segments between each two neighbouring processors from Step 2. Sending constant number of variables on the bus requires O(1) time. Step 6 requires local computation at all points l_i and r_i, $1 \le i \le h$, $h \le k$ and this requires O(1) time. Thus, the whole algorithm runs in constant time.

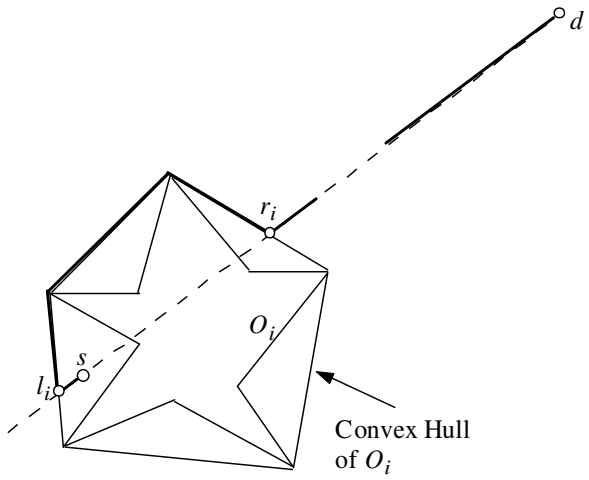

Fig.9 Handling the case if s or d is within a convex hull of an obstacle

5 Enhancing the path length

In this section, we present an enhancement to the proposed algorithm that could make a modification to the generated path. The target is to decrease the length of the generated path using constant time operations. The operations try to replace a segment of the path by another segment if this would shorten the path length. In particular, the operation tries to replace the segment $\overline{l_i y_i}$ of the path, by another segment $\overline{l_{s(i)} y_i}$ if the segment of $\overline{l_{s(i)} y_i}$ is outside obstacle O_i. Point $l_{s(i)}$ is the point of intersection between the segment $\overline{sd}$ and the perpendicular line to $\overline{sd}$ that passes through y. Figure 8 shows an example of the segment $\overline{sd}$ that intersects with two obstacles O_1 and O_2. The path generated by the algorithm is shown in bold. However, when applying the operation to the segment $\overline{l_1 y_1}$ of the path, this segment is replaced by another segment $\overline{l_{s(1)} y_1}$ that would make the path shorter. The same operation is applied to the segment $\overline{w_1 r_1}$ and is replaced by the segment $\overline{w_1 r_{s(1)}}$ because it happened to be of shorter length. If the new segment lies within the obstacle itself, then no replacement is done. This is the case for O_2 in Figure 8. The figure shows the path in bold when applying this operation to the path of Figure 5.

The above operation of replacing one segment by another can be done in constant time. Point y_i (respectively w_i) computes the point $l_{s(i)}$ (respectively $r_{s(i)}$) in constant time. If the computed point lies within the obstacle O_i then no replacement is done. If the computed point, for example $l_{s(i)}$, lies outside the obstacle O_i then the replacement would make the path shorter. In this case, y_i informs l_i and $l_{s(i)}$ by this replacement over the local buses in constant time.

6 Source and Destination within convex hulls

In section 4 we proposed the algorithm assuming that the source and destination points, *s* and *d*, are outside any convex hull. In other words, after preprocessing phase neither *s* nor *d* is located within any convex hull of an obstacle. In this section, we deal with the case that *s* or *d* or both are within a convex hull. Figure 9 shows an example where the source *s* is within convex hull of obstacle O_i. In such case, a minor change to the algorithm handles this situation. In Step 2 of the algorithm, after determining the intersection points, the source *s* and the first intersection point exchange information about their status. The status of a point could be an *l*-point (resp. *r*-point). If the source *s* found that the next point is an *l*-point, then the algorithm continues as described in Section 4. The *l*-point reaches the *r*-point through the convex hull of the obstacle. If the source *s* found that the next point is an *r*-point, then the source *s* decides that the next point on the path is on the other side from the destination point *d* and the algorithm continues. The above operation could also be applied for the destination *d* and it requires a constant number of steps and can be done in O(1) time. Figure 9 shows the generated path in bold in the case where *s* is within the convex hull of obstacle O_i.

7 Concluding Remarks

In this paper, we proposed an algorithm to compute a collision-free path between a source and a destination in an environment with the existence of obstacles. We used the EREW R-Mesh as the underlying architecture. The algorithm was shown to run in constant time and requires $O(\log^2 N)$ pre-processing time. This outperforms the previous method that required a linear time in the number of obstacles with the same pre-processing time. We also proposed a method that could shorten the length of the path generated by the proposed algorithm.

One possible extension to this work is to design algorithms that get the shortest path between the source position and the destination position in the existence of obstacles. Other directions include enhancing the preprocessing time and using other parallel models to solve the path planning problem.

Abstract

The mutual exclusion (MX) paradigm can be used as a building block in many practical problems such as group communication, atomic commitment and replicated data management where the exclusive use of an object might be useful. The problem has been widely studied in the research community since one reason for this wide interest is that many distributed protocols need a mutual exclusion protocol. However, despite its usefulness, to our knowledge there is no work that has been devoted to this problem in a mobile computing environment. In this paper, we describe a solution to the mutual exclusion problem from mobile computing systems. This solution is based on the token-based mutual exclusion algorithm.

Key-words: Synchronous Distributed Systems, Mutual exclusion, Fault Tolerance, Mobile Computing System.

1. Introduction

The wide use of small portable computers and the advances in wireless networking technologies have made mobile computing today a reality. There are different types of wireless media: cellar (analog and digital phones), wireless LAN, and unused portions of FM radio or satellite services. A mobile host can interact with the three different types of wireless networks at different point of time. Mobile systems are more often subject to environmental adversities which can cause loss of messages or data [8]. In particular, a mobile host can fail or disconnect from the rest of the network. Designing fault-tolerant distributed applications in such an environment is a complex endeavor.

In recent years, several paradigms have been identified to simplify the design of fault-tolerant distributed applications in a conventional static system. Mutual exclusion, simply MX, is among the most noticeable, particularly since it is closely related to accessing shared resource called the critical section (CS) [7], which (among other uses) provides an exclusive access basis for implementing the critical section.

The mutual exclusion problem [1] requires two properties, safety and liveness, from a given set of processes. The problem has been widely studied in the research community [2,3,4,5,6] since one reason for this wide interest is that many distributed protocols need an mutual exclusion protocol. However, despite its usefulness, to our knowledge there is no work that has been devoted to this problem in a mobile computing environment.

The aim of this paper is to propose a solution to the mutual exclusion problem in a specific mobile computing environment. This solution is based on the token-based mutual exclusion algorithm that is a classical one for distributed systems. The rest of this paper is organized as follows: in Section 2, a solution to the mutual exclusion problem in a conventional synchronous system is presented. Section 3 describes the mobile system model we use. A protocol to solve the mutual exclusion problem in a mobile computing system is presented in Section 4. We conclude in Section 5.

2. Mutual Exclusion in a Static System

2.1 Model and Definitions

We consider a synchronous distributed system composed of a finite set of process $\Pi = \{p_1, p_2,., p_n\}$ connected by a logical ring. Communication is by message passing, synchronous and reliable. A process fails by simply stopping the execution

(*crashing*), and the failed process does not recover. A correct process is the one that does not crash. Synchrony means that there is a bound on communication delays or process relative speeds. Between any two processes there exist two unidirectional channels. Processes communicate by sending and receiving messages over these channels.

The mutual exclusion problem is specified as following two properties. One is for *safety* and the other is for *liveness*. The *safety* requirement asserts that any two processes connected the system should not have permission to use the critical section simultaneously. The *liveness* requirement asserts that every request for critical section is eventually granted. A mutual exclusion protocol is a protocol that generates runs that satisfy the mutual exclusion specification.

2.2 Token-based Mutual Exclusion Algorithm

As a classic paper, the token-based mutual exclusion algorithm, which was published by M. Raynal, specifies the mutual exclusion problem for synchronous distributed systems with crash failures and gives an elegant algorithm for the system; this algorithm is called the token-based MX Algorithm [2]. The basic idea in the token-based MX algorithm is that the any process holding the token can use the critical section exclusively. The token-based MX algorithm is described as follows.

- A distributed system is connected by a logical ring. Each process has a unique ID that is known by its neighborhood processes.
- The CS is exclusively used by the process holding the token.
- The token is circulated on the logical ring. If a process wants to use the CS, then it just waits until receiving a token from its neighborhood. Only when it has received the token, it has a right to use the CS exclusively.
- When the process with the token finished its use of CS, it immediately passes the token to its neighborhood.
- If a process doesn't to use a CS when it received the token, it just pass the token to it neighborhood.
- There exists only one token and the token is continuously circulated upon the logical ring.
- By doing this, any process eventually receives the token and it can use the CS exclusively, which means that this algorithm satisfies both of the safety and the liveness properties.

3. Mobile System Model

A distributed mobile system consists of two set of entities: a large number of mobile hosts (*MH*) and a set of fixed hosts, some of which act as mobile support stations (MSS_s) or base stations. The non *MSS* fixed hosts can be viewed as MSS_s whose cells are never visited by any mobile host. All fixed hosts and all communication paths connect them from the static network. Each *MSS* is able to communicate directly with mobile hosts located within its cell via a wireless medium. A cell is the geographical area covered by a *MSS*. A *MH* can directly communicate with a *MSS* (and vice versa) only if the *MH* is physically located within the cell serviced by the *MSS*. At any given instant of time, a *MH* can belong to one and only one cell. In order to send message to another *MH* that is not in the same cell, the source *MH* must contact its local *MSS* which forwards the messages to the local *MSS* of the target *MH* over the wireless network. The receiving *MSS*, in its turn, forwards the messages over the wireless network to the target *MH*. When a *MH* moves from one cell to another, a *Handoff procedure* is executed by the MSS_s of the two cells. Message propagation delay on the wired network is arbitrary but finite and channels between a *MSS* and each of its local mobile hosts ensure FIFO delivery of messages.

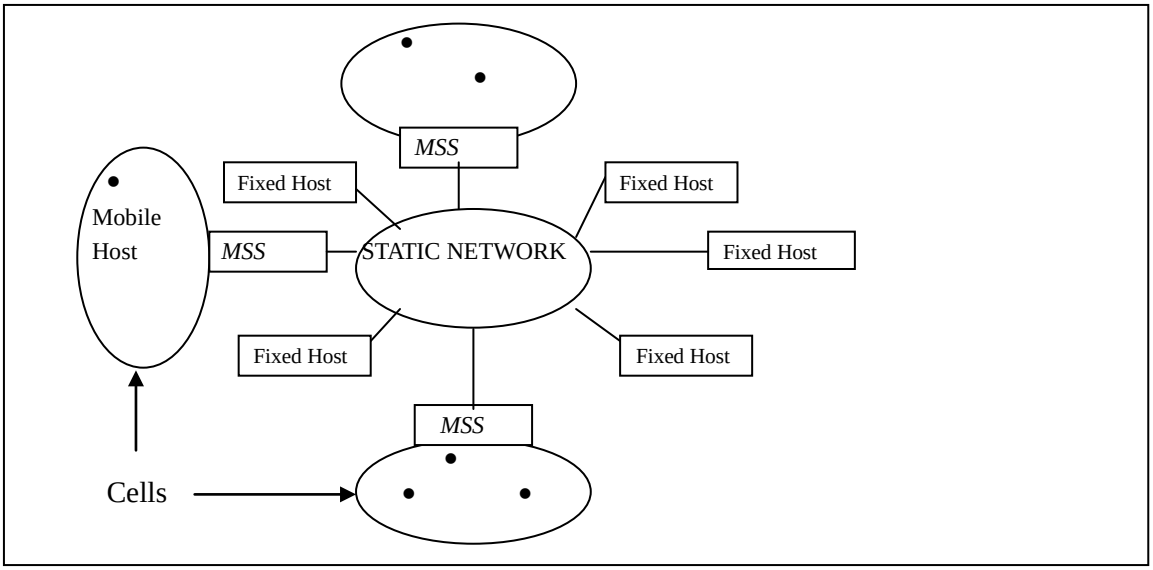

Figure 1: Mobile System Model

- The amount of computation performed by a mobile host should be kept low
- The communication overhead in the wireless medium should be minimal.
- Algorithm should be scalable with respect to the number of mobile hosts.
- Algorithm should be able to easily handle the effect of mobile host disconnections and connections.

4. Mutual exclusion in a Mobile System

In the following, we consider a broadcast group G = (G_MSS, G_MH) of communicating mobile hosts, where G_MH and G_MSS are respectively a set of m mobile hosts roaming in a geographical area (like a campus area) covered by a fixed set of n MSS_s. In so far, local mobile hosts of base station MSS_i, which currently residing in MSS_i cell, will refer to mobile hosts that belong to group G.

A mobile host can move from one cell to another. If its current base station fails, the connection between the mobile host and the rest of system is broken. To recover its connection, a mobile host must move into another cell covered by an operational or correct base station. So, unless it crashes, a mobile host can always reconnect to the network. A mobile host may fail or voluntarily disconnect from the system. When a mobile host fails, its volatile state is lost.

In this environment, the mutual exclusion problem is defined over the set G_MH of mobile hosts. When a mobile host h_k wants to use the *CS*, it sends the request message to a *MSS*. In this case, the mobile host eventually should get the permission from the *MSS* and use the *CS*. Due to the resources constraints of mobile hosts and the limited bandwidth of wireless links, the distributed algorithm to solve mutual exclusion is executed by the set of *MSS* on behalf of the set G_MH of mobile hosts. In a first phase, the *MH* which wants to use the CS has to request the permission from the *MSS* in the cell which it belonging to. The *MSS* receiving those requests from the subset of G_MH of mobile hosts roaming in their respective cells keeps them in its queue. A token is circulated through the logical ring which consists of the fixed *MSS*s. In the second phase, when each *MSS* receives the token from its neighborhood, it sends the token to a mobile host h_k to give permission for the CS.

Finally, the h_k received the permission from the *MSS* uses the CS and after using it returns the permission to the *MSS*. The *MSS* which has got the permission back from the h_k sends the token to the next turn of *MSS*s.

4.1 Principle

The mutual exclusion protocol proposed in this paper is based on the solution described by

Raynal in Token-based MX algorithm [2]. The outlines of their protocol have been described in Section 2. In this section, we give an overview of our protocol and identify the major differences compared with the original token-based MX algorithm. We assume that the mutual exclusion is initiated by a mobile host which requests its current base station a token to use the CS. The contacted base station saves the request into the queue until it receives the token from its neighborhood.

During the mutual exclusion, each base station on one hand interacts with the mobile hosts located in its cell to gather the request of each mobile host for CS and on the other hand interacts with the other neighboring base stations to send and receive a token. In our approach, a base station *MSS* which participates in the mutual exclusion protocol, always acts on behalf of a subset of mobile hosts.

More precisely, the initial value of $Token\_Holdek_k$ is false but the value of it is changed true as a mobile host h_k that resides in MSS_i receives the token from its MSS_i. After returning the token to its base station, the mobile host h_k changes the value of its $Token\_Holder_k$ into false again.

The mutual exclusion protocol in such an environment consists of two cases depending on who the token holder is. As the first case, that is when a base station received a token from its neighboring base station or its mobile hosts. When it received the token from its neighboring base station, then it just sends the token to a mobile host with highest priority among the mobile hosts connected to the base station. In case of returning the token from its mobile hosts, it just sends the token to the next base station.

In this case the base station is doing two tasks concurrently, i.e., sending a token a mobile host with highest priority among the mobile hosts connected to the base station and receiving the token request message from mobile hosts concurrently. Thus the base stations play a role of a mutual exclusion coordinator during the mutual exclusion period.

During the mutual exclusion in a mobile computing environment, a base station playing a role of a mutual exclusion coordinator is needed to reduce the message traffic among mobile hosts. The mutual exclusion algorithm among base stations is similar to the token-based MX in static distributed systems. That is, only the base station holding the token has a permission to use the *CS*.

In the second case, that is when a mobile host received a token from its host base station. Then it just uses the *CS* for a while and returns the token to its host base station after finishing it.

In above scenario, we don't consider the mobility of the mobile host in the MX algorithm. But if we consider the mobility of the mobile host, then it makes the MX problem more complicated than the one of static distributed systems.

The differences of mutual exclusions between mobile computing environments and static distributed systems are as follows:

1) During the period of the MH using the CS, the MH changes its base station from the one that it received the token to the other base station. In this case, the MH simply sends the token the base station of the cell in which it resides. But the base station that received the token takes some action to keep the fairness of the MX. The base station that did not send the token but received the token from its MH simply sends it to the base station which waits for the token to keep the fairness of the MX. Because, as a big difference between mobile computing environments and static distributed systems, the mobile host with token will appear in any cell whenever mutual exclusion protocol has started. Therefore, every base station should check all other base stations to know which base station cover the mobile host holding the token in the cell. That causes message traffics among base stations.
2) In mobile computing environment, a handoff algorithm is needed to perform mutual exclusions correctly, but it is not needed in static distributed systems.
3) Due to the resource constraints of mobile hosts and the limited bandwidth of wireless links, the distributed algorithm to solve mutual exclusion is executed by the set of MSS_s on behalf of the set *G_MH* of mobile hosts.

4.2 Protocol

The protocol is composed of three parts and each part contains a defined set of actions. Part A

(figure 2) describes the role of an arbitrary mobile host h_k. Part B (figure 3) presents the protocol executed by a base station MSS_i.

```
% Mobile host h_k is located in MSS_i cell %
(1) Upon receipt of the request for CS from
    the application
      Send Req_Token to MSS_i
(2) Upon receipt of Token from MSS_i
% The mobile host (h_k) gets into CS   %
      CS (h_k)
(3) Upon receipt of the release for CS from
    the application
      Send Release_Token to MSS_i
```

Figure 2: Protocol Executed by a Mobile Host h_k (Part A)

Part B is related to the interactions between a base station and its local mobile hosts on one hand and the other base station on the other hand. Thus, Part B is based on the traditional Token-based MX protocol adapted to our environment.

Finally, the part C of the protocol is the handoff protocol destined to handle mobility of hosts between different cells.

In figure 2, the three actions performed by an arbitrary mobile host are:

(1) A mobile host executes this action when it receives a request from an upper application program to initiate a mutual exclusion.
(2) Token message is sent to a mobile host h_k by the mobile support systems MSS_i when it had requested a token from the local base station where it resides. Upon receipt of such a message, the mobile host gets into the *Critical Section*.
(3) When the application program terminates the mutual exclusion protocol, the Token is released to the mobile support system, MSS_i.

Actions of the protocol in figure 3 numbered from (4) to (7) are executed a mobile support system, i.e., a base station MSS_i. They have the following meaning:

(4) When a base station is asked by a mobile host to send a Token, it inserts the request into the rear of its queue.

```
My_Staus_i := 0;
My_Queue_i := ∅;
Cobegin
(4) || Upon receipt of Req_Token( h_k )
       insert Req_Token(h_k) to rear (My_Queue_i);
(5) || Upon receipt of Token (MSS_i-1)
        if My_Queue_i ≠ ∅ then
          My_Status_i := 1;
           send Token to front (My_Queue_i);
           delete front (My_Queue_i);
        else
          send Token to MSS_i+1;
        end-if
(6) || Upon receipt of Token ( h_k )
      if ( Phase_i = 0 ∧ My_Queue_i ≠ ∅ ) then
           My_Status_i:= 1;
           send Token to front (My_Queue_i);
           delete front (My_Queue_i);
         else
           My_Status_i:= 0;
           send Token to MSS_i+1;
      end-if
(7) || Upon receipt of Req_Token ( MSS_j )
       insert Req_Token(h_k) to Rear(My_Queue_i);
```

Figure 3: Protocol Executed by a mobile support station MSS_i (Part B)

(5) In case of receiving a Token from other base station, the base station checks its queue *My_Queue*$_i$ to confirm whether the queue is empty or not. If the queue is not empty, then the base station sends the Token to the mobile host that is positioned at the front of the queue. And it deletes the element from the queue and sets its status to true that means it holding Token, i.e., *My_Status*$_i$:= 1. But if the queue is empty, then the base station just passes the Token to the next base station.
(6) When a base station receives a Token from a mobile host h_k, it checks its queue and status. If both (*Phase*$_i$ = 0 ∧ *My_Queue*$_i$ ≠ ∅) are true, which means that it does not hold the token and at the same time the queue is not empty, then the base station sends the Token to the mobile host that is the front element of the queue. And it deletes the element from the queue and sets its status to true. Otherwise it sends the Token to the next base station and sets its status to false.

(7) On receiving the Token request message from other mobile support system, the MSS_i insert the request message into its queue.

As shown in Figure 4, the handoff protocol is described.

(8) When a mobile host h_k moves from MSS_j cell to MSS_i cell, the handoff protocol execution is triggered. Mobile host h_k has to identify itself to its base station by sending a message GUEST(h_k, MSS_j).
(9) Upon receiving this message, MSS_i learns that a new mobile host h_k, coming from MSS_j cell has entered in its cell. With BEGIN_ HANDOFF(h_k, MSS_i) message, MSS_i informs MSS_j that it removes h_k from the set of mobile hosts that reside in its cell.
(10) Upon receiving such a message, MSS_j checks its queue to confirm that the token request of h_k is in the queue. If it is in its queue, then it transfers the token request to MSS_i and deletes the token request from the queue.

Cobegin
% Role of h_k %
(8) || **Upon** entry in MSS_i cell
s**end** Guest(h_k, MSS_j) to MSS_i
% Role of MSS_i
(9) || **Upon** receipt of GUEST(h_k, MSS_j)
Local_MH_i := Local_MH_i ∪ {h_k};
send BEGIN_HANDOFF(h_k, MSS_i) to MSS_j;
% Role of MSS_j
(10)||**Upon** receipt of BEGIN_HANFOFF(h_k, MSS_i)
$Local\_MH_j$:= $Loacl\_MH_j$ – {h_k};
If (Req_Token(h_k) ∈ My_Queue$_i$) **then**
send Req_Token(h_k) to MSS_i;
delete Req_Token(h_k) from My_Queue$_i$;
end-if

Figure 4: Handoff Procedure (Part C)

4.3 Correctness Proof

As our protocol is based on the Token-based logical ring algorithm proposed by M. Raynal, some statements of lemmas and theorems that follow are similar to the ones encountered in [2].

Theorem 1 No two different processes can have permission to use the critical section simultaneously (safety property).

Proof (proof by contradiction). Let assume that there exist two mobile hosts to get a permission to use the critical section. A mobile host can use the *CS* only if it received a permission token from the *MSS* of the cell to which it belonging (action 2). In this case, the assumption means that there exist two *MSS*s holding the token or one *MSS* sends the token twice to two different mobile hosts each. The first case is false since there is only one token circulating under the logical ring. The second case is also false since the *MSS* holding the token sends it to mobile host h_k only once (action 5). So it is a contradiction. □*Theorem* 1

Theorem 2 Every request for the critical section is eventually granted (liveliness property).

Proof If a mobile host sends a message to request a token (action 1), at least one *MSS* eventually receives it and inserts it into the queue (action 4). After that, there are two cases. In first case, if the mobile host h_k sent the message does not move to other cell, then the message Req_Token eventually will be positioned at the front of the queue and the *MSS* received the message sends the token. Thus, the mobile host sent the message eventually receives the token and uses the *CS*. In a second case, when the mobile host h_k sent a message Req_Token moves from MSS_j cell to another MSS_i cell before receiving the token, then the handoff protocol execution is triggered (action 8-10). Mobile host h_k has to identify itself to its base station by sending a message GUEST(h_k, MSS_j). In this case, by (action 10) the request message will be transferred to the MSS of the cell to which the mobile host has moved. Consequently, the mobile host will receive the Token and use the CS when the *MSS* sends the Token. □*Theorem* 2

5. Conclusion

The communication over wireless links are limited to a few messages (in the best case, three messages: one to request a token and the others to get the token and release the token respectively)

and the consumption of mobile hosts CPU time is low since the actual mutual exclusion is run by the base stations. The protocol is then more energy efficient. The protocol is also independent from the overall number of mobile hosts and all needed data structures are managed by the base stations. Therefore, the protocol is scalable and can not be affected by mobile host failures.

In addition, other interesting characteristics of the protocol are as follows. 1) During the mutual exclusion period, a base station should keep track of every mobile host within its cell to manage the request messages and the token. 2) In such a mobile computing environment, a handoff algorithm is needed to perform mutual exclusions efficiently and correctly, but it is not needed in static distributed systems.

The mutual exclusion algorithm in a mobile computing environment consists of two important phases. One is a local mutual exclusion phase in which a mobile host holds and uses the CS. The other phase is a global mutual exclusion phase in which each *MSS* takes part in the mutual exclusion by passing the token to another *MSS*.

Cloudlet Seeding: Spatial Deployment for High Performance Tactical Clouds

D. Shires, B. Henz, S. Park, and J. Clarke
U. S. Army Research Laboratory, Computational Sciences Division, APG, MD, USA.

Abstract— *Geospatially aware mobile devices, such as smart phones, rely on an architecture that is power constrained and processing power limited. The utility of these devices can be increased by offloading compute-intensive applications to parallel high performance computing (HPC) architectures, thus limiting battery drain, allowing access to large data, and providing faster time to solution. Such a paradigm can be achieved through tactical cloudlets that must operate in environments dominated by mobile* ad hoc *infrastructure (common in remote environments or military applications). Executing this paradigm is further complicated in that HPC nodes themselves (with some reduced mobility) are now deployable through the use of ruggedized hybrid core technologies. This paper discusses our concept for cloudlet seeding: the static strategic placement of HPC assets in deployed settings in such a way to balance computational load and limit hops to both stationary and mobile HPC nodes.*

Keywords: cloudlets, cloud computing, tactical computing, network emulation, high performance computing

1. Introduction

Army soldiers rely on mobile, fast, and up-to-date processing capabilities to be able to complete a myriad of mission assignments and tasks. This is often done in remote areas starved of computing and networking infrastructure or in urban environments where civilian infrastructure operates on differing protocols with security risks. Hence, mobile *ad hoc* networks (MANETs) will most often provide the operation frameworks for soldiers and military commanders [1]. It is within this operational realm that we are conducting basic and applied research to address how to field High Performance Computing (HPC) capacity within this MANET topology while at the same time increasing capabilities that leverage this new level of computing power. Coupling size, weight, and power with MANET-based operational requirements leads us to the establishment of tactical cloudlets as a way to deliver the required computing power to today's soldier [2].

Tactical cloudlets couple traditional connotations of cloud-based technology with the overarching goal of maximizing processing power and limiting the time to solution. This is all done in a mobile environment. Cloud computing has a history of focusing predominately on providing computing services with distributed processing and access to data. Commercial processing using high capacity network infrastructure paid little attention to time to solution as a key operational metric, although this is changing a bit with a new-found focus on streaming access speed to data. Military processing requirements push traditional cloud-based processing to new requirements in every dimension. For example, streaming content (such as sensor feeds) to a hand-held mobile smart phone poses numerous problems. First, forcing too much processing through mobile devices will quickly drain power. In a tactical cloudlet the option of piggybacking on other friendly devices may be beneficial. Second, the web of deployed devices must be flexible as signal loss and connectivity maintenance are known problems in deployed environments. Cyber foraging and possible process migration within the tactical cloudlet become critical. These issues are just the start of a long list of differences between commercial cloud systems and deployed tactical cloudlets.

The viability and overall success of tactical cloudlets depends largely on several intertwinded technical challenges including power-aware computing, cyber foraging (scheduling and process migration), and processing node optimization and characterization. In this paper we put forth another goal that should remain central in the development of tactical cloudlet technology; especially with regards to pushing HPC-level processing to the tactical edge. Tactical cloudlet seeding is an approach that recognizes the importance of spatial proximity for high performance servers to those mobile nodes that they serve. Simply put, cyber foraging will be greatly enhanced if assets are positioned in a way to limit hopping between and promote load balance within districts served by HPC nodes formed by this seeding approach. We discuss the importance of cloudlet seeding as a way to enhance the overall effectiveness of tactical cloudlets. In particular, we describe a methodology to perform cloudlet formation to enhance opportunities for cyber foraging algorithms within a realistic framework for mobile, ad hoc computing devices. This research directly impacts efforts to extend Army cloud computing and the capabilities of analysts and warfighters to the tactical edge.

2. Tactical Cloudlet Seeding

Unlike conventional developed infrastructure, usually consisting of a mix of wired and cellular networks, MANETS are often the only way of ensuring communication between entities deploying to remote areas or to areas with different infrastructure characteristics. Mobile networks are also important to the military mission as they can provide higher security profiles since the network is self-contained.

Deployed devices with the MANETS will be digital, vary in computational power, and operate over networks of varying data rates. Power figures heavily in this deployment as mobile nodes will be drained of battery at varying rates due to connectivity loss, network contention and collisions, computing load, and other operational conditions.

To address this problem, cloudlets have been proposed to address resource poor mobile hardware [3]. The central goal of this paradigm is to leverage computationally powerful resources with infinite power reserves by way of a cloud, but to do so by positioning the resources physically close to the mobile devices to limit the number of hops required for connectivity. That is, reduced latency between mobile device and data center will ensure longer battery life for mobile devices with fast access to information being processed by proximate computing resources.

Carrying this one step further, and by incorporating new heterogeneous and advanced computing methodologies, it is now possible to field near high performance computing (HPC)-level capabilities to soldiers and others in deployed settings. For military planners, HPC modeling and simulation have been useful tools for strategic planning. With tactical HPC using the cloudlet approach, dynamic and real-time processing of live data feeds can be possible for mounted and dismounted soldiers in operational environments. This can have real benefits to improve situational awareness and thus limit fog of war effects during mission execution.

This is a key point in our conceptualization of tactical cloudlet design. By incorporating HPC capacity, along with localized access to the fullest extent possible of mission-critical data at the HPC node, the overall bandwidth allocation dilemma faced by military planners if greatly mitigated. Bandwidth is a scarce commodity in deployed settings using MANETs [4]. Planning and optimizing the distribution is mainly relegated to a strictly strategic exercise subject to lack of complete information, possible exaggerated need from participants, and overall uncertainty. Cloudlet design with HPC-node centralization allows for a greedy-type optimization at the local level that can carry through to allow for an overall optimized network design.

However, access to these powerful devices will be key. While cyber foraging is a way to look for assets to help with processing demand, it does not address spatial locality of HPC to nodes requesting processing service. Tactical cloudlet seeding does just that; it attempts to localize access and balance demand on deployed HPC resources. Done properly, the overall goal is to limit foraging to predefined, seeded HPC districts where the processing load will be sufficient and balanced.

2.1 HPC Node Characteristics

Tactical networks of the future will be built upon a hierarchy of connectivity and capabilities. Hand-held radios and computing devices used by dismounted soldiers will obviously have different profiles and capabilities when compared to those housed in vehicles and stationary encampments. Overall connectivity will depend largely on signal strength, data transfer rates, contention, and positioning of nodes to reduce critical node formation.

Highly mobile compute nodes will always be lagging behind larger, less mobile nodes when it comes to sheer computing power. However, new hybrid architectures are being designed that allow for higher FLOP counts in shrinking footprints. These custom-engineered solutions can be ruggedized and provide a tiered capability for HPC in military applications. More fixed locations, such as Tactical Operations Centers (TOCs), have greater infrastructure and can support elaborate hybrid machines for applications tailored to them. Larger scale traditional multi-core systems, as well as more elaborate custom-engineered solutions like a seven card, water cooled, overclocked GPU-based system shown in Figure 1, can easily be supported in such a facility. Mobile and ruggedized GPU hardware can also easily be supported in platforms such as the High Mobility Multipurpose Wheeled Vehicles (HMMWV) or certain Unmanned Aerial Vehicles (UAVs).

Fig. 1: Customized GPU-accelerated workstation.

2.2 Network Goals

Tactical cloudlets have numerous measures of success measured largely on security and quality of service (QoS). Numerous techniques have been developed and proposed to enhance, improve, and ensure connectivity of MANETs [5], [6]. HPC nodes within the deployed MANET have special characteristics and specialized goals. While they should ideally posses access to large data rate channels, they should also be configured and distributed in a way that limits the number of hops that might be required of low-power hand-helds to reach them. In this regard, placement becomes critical as these resources should be spatially near assets that they serve. This is the main point of seeding the tactical cloudlets. Done properly, it will ensure speedy turnaround of queries and responses from powerful distributed computing nodes.

3. Problem Formulation

We are given a network based of mobile and fixed connected nodes. For the time being we assume that connections are static and once established are maintained during our period of interest. We are concerned with the connected graph $G = (V, E)$ that represents this network. In practice this will be a geographically constrained subgraph within a larger, distributed network. The vertices, V, represent the radios, computing devices, or other electronic systems capable of communicating within the system. These nodes will vary in computing capability, power requirements, etc. The edges, E, represent the communication links between these devices. We assume only one link edge between devices. The properties of these edges will vary based on data rates and other network characteristics. These parameters can become quite complex as various parts of this network will consist of mobile *ad hoc* nodes (MANETs) where geographic and weather effects can impact link capacity due to signal strength, packet loss, etc.

The vertex set, that is the networked components, is the set $V = 1, 2, \ldots, n$. We are concerned with fielding tactical HPC within the cloudlet infrastructure, hence we are actually attempting to determine how to classify the nodes of V. In this case, the set V is actually comprised of three disjoint subsets. These include the set of fixed HPC capable nodes, V_F, that could reside in deployed settings such as a Tactical Operations Center (TOC), the set V_H of mobile HPC nodes such as those deployable on vehicles, and the set V_M of mobile and/or deployed nodes that are not HPC capable. That is, we have V such that $\forall x \in V, x \in V_F \vee x \in V_H \vee x \in V_M$. For simplicity we assume nodes of overall equal properties within these subsets.

Strategically speaking, and for the static nature of the problem we are currently defining, the initial graph is constructed based on areas where HPC processing capability will be required, where HPC nodes exist in fixed locations, and other areas where dismounted soldier or other sensors and processors will be located. Node locations will therefore be a combination of known locations (such as the fixed nodes) and also areas where some type of coverage is required. Initial node locations will also be based historical or geographical data. In practice, HPC-capable mobile nodes will be positioned in safe areas, be restricted in total number due to cost or other issues, and be within a limited hop range from nodes requesting high rates of compute services. Any node that is not a fixed HPC node has the capability of being assigned to HPC mobile node status. Recognizing the fact that these nodes may reside in areas not amiable to that classification, we also define a set V_R that includes those node numbers that should not be allowed within the set V_H. Determining the initial graph configuration, including node placement and edge connectivity, is part of a larger research effort we are undertaking for tactical cloudlet configuration. How this is being performed through network simulation and emulation research will be discussed in a later section.

Our problem, therefore, is to assign every vertex v in V to an HPC node, whether it be mobile or fixed. All elements in V_M are assigned to an element in V_H or V_F. Since communication and data transfer happens along these graph edges, the path traversal becomes very important to fielding an ideal system. The weight of any path $p = v_0 \rightarrow v_1 \rightarrow \ldots \rightarrow v_m$ is the sum of the weights of the edges that it contains:

$$w(p) = \sum_{i=1}^{m} w(v_{i-1}, v_i) \tag{1}$$

The shortest path from u to v is therefore defined as:

$$\delta(u, v) = \min\{w(p) : u \overset{p}{\rightsquigarrow} v\} \tag{2}$$

3.1 Constraints

Since we only have a limited number of HPC-deployed nodes, our goal is to assign every node in our graph to some HPC-computing node. That is, we are attempting to determine a partitioning of the set V into k disjoint subsets $V_1, V_2, \ldots, V_k$ to form a k-way partitioning of V. In this case k will be equal to $|V_F| + |V_H|$.

Optimal deployment of HPC computing capability to the tactical edge will require the solution of a multi-constrained problem. First, we deal with path traversal or the number of hops a device must travel to reach HPC capable computing nodes. Ideally this number should be as small as possible for several reasons, including amount of data that must be transferred, risks of intermediate node drop-off, etc. Let u_i be the HPC node within partition i. We are searching for a total minimum hop count across all k partitions:

$$\min \sum_{i=1}^{k} \sum_{j=1}^{|V_i|} w(u_i, v_j) \tag{3}$$

In certain cases, it may also be necessary to balance the data rates as well as hop counts. Depending on the amount of data stored local on mobile hand-helds versus the HPC node, the impact of these network links will vary considerably. Scalar data based on GPS location, or the transmission of static browser images, will require less total bit transmission with delay and hop counts taking higher priority. We see this as the more common operational case, but are currently in the process of further modifications to equation 3 to better account for those cases where data rates retain a high importance. These cases pose extra difficulties since overall data movement capabilities between two nodes is restricted to the bottleneck link in the path. In the current formulation we only concern ourselves with hop counts or distance from HPC node to the nodes it serves. That is, $\forall e \in E, w(e) = 1$.

Second, we want the overall offered computing load to be balanced within the k-way partitions. Doing so will ensure that HPC resources will not be overwhelmed by the nodes that they serve. This computational load is analogous to the partition weight of the ith partition, denoted by $w(V_i)$, which is equal to the sum of the weights of the vertices in that partition. Load imbalance then becomes a critical metric and a number that needs to be minimized. In a k-way partition, this load imbalance, LI, is a ratio of the highest partition weight divided by the average partition weight [7].

With some generality and assuming an average, distributed computational load, we arrive at $\forall v \in V, w(v) = 1$. An ideal distribution of computing load is hence analogous to seeking approximately equal cardinality of the subsets formed by the k-way partitions.

4. Tactical Cloudlet Seeding

Using the constraints developed in the previous section, we describe the approach specified in algorithm CLOUDLET-SEEDING that can be used to specify the location of HPC mobile nodes within the deployed network. The inputs to the algorithm include the $n \times n$ adjacency matrix A of the graph G, the set V_F of fixed HPC nodes, the set V_R of restricted nodes that cannot be designated as mobile HPC nodes, and the scalar q representing the total number of mobile HPC nodes that are allowed.

The algorithm builds the matrix $D[1\,..\,n, 1\,..\,n]$ that gives the shortest path distance between all pairs of vertices. The algorithm also builds and iterates over the power set (set of sets) $B = \{x \in 2^V : (|x| = q) \wedge (\forall y \in x, y \notin V_F \wedge y \notin V_R)\}$. The matrix B is therefore all possible q-way combinations of the vertices in V excluding the nodes that cannot serve as HPC mobile nodes and those fixed HPC nodes. The number of these sets is given by the binomial coefficient and in this case is $\binom{n-(|V_F|+|V_R|)}{q}$.

In order to hold information about the various partitions, we also define a partition type p_type containing a scalar value of the HPC node in that partition, a scalar keeping count of the number of nodes assigned to that partition, and a list of those nodes assigned to the partition. The variables p and Z are of this type.

The procedure makes use of several ancillary functions. The function INIT-PART returns an initialized array of structures of length $q + |V_F|$ containing information as defined in the p_type data structure. At each iteration of the loop, this structure is initialized with the fixed HPC node location data and also the current combination of possible HPC nodes selected from the set B. MIN-HOPS is a straightforward iteration down the rows of shortest path matrix where every possible HPC vertex location specified in p is compared against the other for hop counts. In cases where there is a clear winner, the vertex is assigned to that partition immediately. The case where the row happens to correspond to one of the possible HPC locations is a clear example. In this case the hop value will be 0 and that vertex is assigned to that corresponding partition. In cases where there are more than one possible HPC locations with the same minimum hop, the decision is delayed until the function BAL-PART. At this time, the value of $part.count$ becomes important. Partitions with a lower total weight (number of vertices served) win and are assigned that row. In cases of further ties, we arbitrarily pick the lowest numbered vertex as the winner. The procedure returns a partition structure Z that tells the q-way partition assignment of $a[v_1\,..\,v_n]$.

```
CLOUDLET-SEEDING(G, V_F, V_R, q)
 1  A ← ADJACENCY-MATRIX(G)
 2  D ← ALL-PAIRS-SHORTEST-PATHS(A)
 3  h ← ∞
 4  for i ← 1 to (n−(|V_F|+|V_R|) choose q)
 5       do p ← INIT-PART(i, V, V_F, V_R, q)
 6          for j ← 1 to n
 7               do MIN-HOPS(p, D)
 8          for j ← 1 to n
 9               do BAL-PART(p, D)
10          if HOPS(p) < h
11            then h ← HOPS(p)
12                 Z ← p
13            else if (HOPS(p) = h)
                   ∧(LI < LOAD-BAL(p))
14                   then h ← HOPS(p)
15                        Z ← p
16          return Z
```

Consider the graph as shown in Figure 2 as an input to this algorithm. We assume uniform computational load on all nodes and equal weight on all edges. Nodes 4 and 7 are special; they represent fixed HPC-enabled compute nodes within this graph. All other nodes in the graph represent locations for possible mobile HPC placement (the vector r is empty). In this case we can field one mobile HPC node ($|V_H| = 1$). We start by computing the all-pairs shortest paths to determine hop distance between the nodes. Since HPC nodes under consideration or those fixed will have a hop distance of 0, they will by default be the HPC element of their respective partition. We then generate the possible subsets of size 1 (nodes 1, 2, 3, 5, 6, 8, 9, 10, 11, 12, and 13). Each of these is analyzed according to the criteria in lines 7 and 9. On the first pass, nodes with a clear shortest hop to an HPC node are assigned to that node's partition. On cases of a tie, the assignment is deferred to the next pass. Here, the weight of both partitions is assessed and the node is assigned to the partition with the lower weight. The weight of this partition is then incremented by that node's weight.

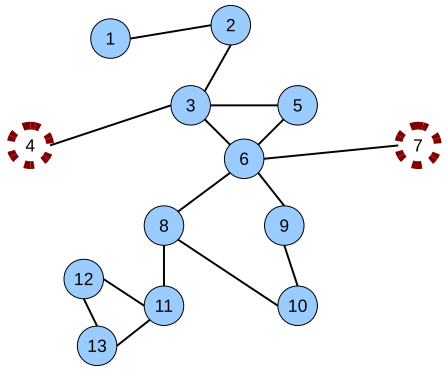

Fig. 2: Example MANET connectivity graph. Nodes 4 and 7 are HPC fixed locations.

The result of this algorithm is shown in Figure 3. Partition 1 is based at HPC node 4, partition 2 at HPC node 7, and partition 3 at HPC node 11. The solution gives a path no longer than 3 in partition 1 (P1, total hops = 6), no longer than 2 in partition 2 (P2, total hops = 5), and no longer than 2 in partition 3 (P3, total hops = 5). The total hop count is 16 for this partitioning. Partition weights are 4, 4, and 5 for partitions 1, 2, and 3 respectively. The load imbalance in this 3-way partition is 15%.

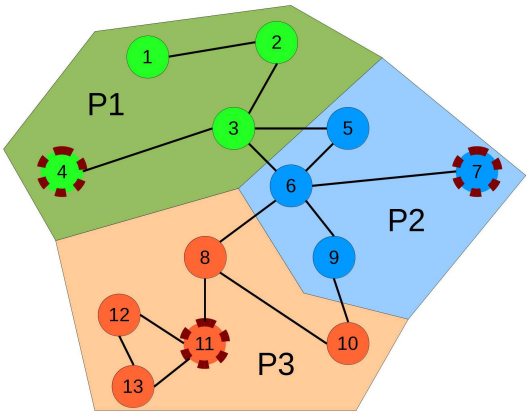

Fig. 3: An optimal three-way partition of the graph in Figure 2. Nodes 4 and 7 are assisted by a mobile HPC node at location 11.

Contrast this to the worst mobile HPC node assignment discovered by the algorithm which is shown in Figure 4. The mobile HPC node in this case is node 5. LI is also 15% (not uncommon for such a small problem set), the total hops is 25 (4 for partition P1 serviced by node 4, 10 for partition P2 serviced by node 7, and 11 for partition P3 serviced by node 5). The maximum path length in this case is 4. There is another major problem with this solution. The cloudlet concept of localized access to HPC nodes is severely violated. Several nodes, such as node 1, require connectivity through external cloudlets to connect to their assigned HPC resource. Such a situation will probably be experienced, at least transiently, in a tactical situation. However, strategic solutions should not produce such assignments and routing.

While nodes v_1 and v_m within the path $p = v_1 \rightarrow v_2 \rightarrow \ldots \rightarrow v_m$ will be members of the same partition set, more rigorous analysis will be needed to verify that nodes $v_2 \ldots v_m$ will reside in the same partition. In a static analysis, this is not overly important as membership to a partition is not as important as minimizing the overall hops and load imbalance. It may become more important if further refinements for dynamic optimization require members of partitions to move in such a way to maintain connectivity.

4.1 Analysis

The algorithm CLOUDLET-SEEDING is a combination of all-pairs shortest path, brute-force methods for generating the possible subset configurations, and a 2-phase peephole greedy method optimization for resolving partition assignment. The data structures required will generally include

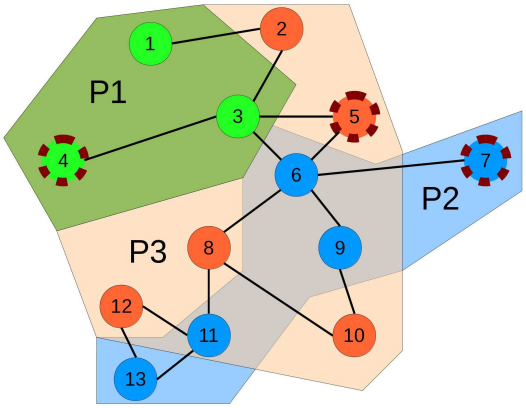

Fig. 4: A poor three-way partition of the graph in Figure 2. Nodes 4 and 7 are assisted by a mobile HPC node at location 5.

simple scalars, vectors of size n, and arrays and structured data types not exceeding sizes of $n \times n$. Space can also be conserved through the use of more elaborate sparse structures such as linked lists.

We can compute a simple upper bound on the running time of CLOUDLET-SEEDING. Forming the adjacency matrix takes $O(n^2)$ since there can be at most one edge between any two vertices. Ideal computation of all pairs shortest path will depend on restrictions to edge weights (currently uniform at cost 1). Dijkstra's algorithm or the Bellman-Ford algorithm will suffice with varying data structures impacting overall performance (binary heap versus Fibonacci heap in the binary-heap implementations). In general though this runtime will be $O(n^2 \lg n)$. These times are all incurred once outside of the main loop.

The generation of the combinations of subsets of size $q-(|V_F|+|V_R|)$ becomes more complex and corresponds to the beginning of the main processing loop (iteration counter i). The function INIT-PART is responsible for generating and initializing partitions for evaluation as HPC nodes. This function will omit nodes already selected as stationary HPC nodes (V_F) and nodes that are restricted (V_R). This function could generate these subsets by maintaining a list of static pointers to the vertices where these pointers are incremented at each call for the next iteration's subsets. Of primary concern, however, is the iteration count to generate these combinations. In practice we expect the number of HPC nodes to be a very small percentage of the overall number of fielded binary systems, and we assume the number of fixed HPC nodes and restricted nodes are relatively small. Since the number of HPC nodes within the problem set will be small, we recognize that q will be some fraction of n. We can then rewrite $\binom{n}{q}$ as $\binom{n}{\lambda n}$, where $0 \leq \lambda \leq 1$, with a bounds of $O(2^{n\,H(\lambda)})$ where H is the binary entropy function $H(\lambda) = -\lambda \lg \lambda - (1-\lambda) \lg (1-\lambda)$ [8].

The calls to procedures MIN-HOPS and BAL-PART each must iterate over all rows of the shortest path matrix doing simple minimization comparisons and assignments. Thus

the time for each of these is $O(n\,(q + |V_F|))$. HOPS and LOAD-BAL simply return the current hop count and nodal balance of the partitions, respectively. The overall runtime of CLOUDLET-SEEDING is thus $O(n\,(q + |V_F|)2^{n\,H(\lambda)})$.

Some trivial optimizations are possible. For instance, should the result of MIN-HOPS yield a result greater than the already established minimum hop count, there is no need to try to balance the partitions. Rather the next iteration of the outer loop can begin immediately.

5. Initial Graph Construction and Optimization

The current static formulation for cloudlet seeding requires some initial configuration of network asset placement with a corresponding assessment as to how the nodes will be linked. The heterogeneous nature of the deployed binary computing devices, from unattended sensors to powerful systems in areas with supporting infrastructure, makes this assessment both tedious and difficult. Often this is done by hand and through empirical data. Locations are based on historical, geographical, meteorological, and sometimes "best guess" estimates based on characteristics of the devices to be deployed.

We are currently designing a system based on network emulation with real-time radio frequency propagation analysis to determine signal loss of devices communicating wirelessly and determine the impact on data transmission to HPC nodes. This will require modifications to the cloudlet seeding approach where communication edges could be weighted to better account for the physical problem.

Furthermore, we are also performing calculations based on line-of-sight (LOS) as a threat assessment tool in an effort to determine areas that are out of harms way. These areas will in most cases be the better candidates for districting HPC resources. Furthermore, with a feedback mechanism built into the network emulator, areas will be chosen such that they provide shelter and enhanced network connectivity. Tactical cloudlet seeding therefore quickly grows into a multifaceted constraint-based optimization problem.

6. Future Work

While this initial assessment attempts to keep the cardinality of the subsets formed roughly equal and limit hops, we recognize that further research is justified as we move forward in our goal to push HPC to the edge. For example, we may wish to specify numerous characteristics to the edges of this connectivity graph. Bandwidth and latency characteristics will differ significantly based on the properties of the nodes (radios versus sensors versus etc.). It should also be noted that the computational capabilities of the nodes in the system will be highly disparate, and the needs of different resources will need to be further developed and represented to the optimization engine. Computational request load will create a dynamic situation where the weights of the nodes will need to be considered. Computing load and demand must also be further defined.

Furthermore, the current strategy serves a strategic goal and is static in nature. We are looking into ways to extend methods to tactical scenarios that are dynamic. Changes on the ground may require mobile HPC assets to be moved. Failure of certain nodes, due to loss of battery or signal loss due to movement, will necessitate a need to recompute HPC-directed network traffic. Compensating for these situations will greatly extend the capabilities of this system.

The computational complexity for optimization problems such as this highlights the need for heuristics especially moving into dynamic real-time adjustments to the deployed network. Accordingly, we plan on investigating other approaches such as those found in multi-level partitioning in graph partitioners to reduce the time complexity of CYBER-DISTRICT [9]. Discovering ways to include parameters such as shortest path distance, along with other parameters deemed important from network science research, into these heuristic-based methods will greatly enhance confidence in an optimally deployed system.

7. Conclusions

Situational awareness and applications demanding at or near real-time processing speeds will continue to push the capabilities of hand-held computing devices. This will continue to be the case even as processor technologies for these devices continue to improve. However, with advanced computing architectures constructed of hybrid accelerators, a new higher level of computing is possible and can be deployed in operational and mobile environments. Accessing these technologies, connected via wired and wireless networks, becomes key as hand-held devices try to off-load processing to both save power and increase computational efficiency.

Tactical cloudlet seeding puts forth an important augmentation to concepts in cyber foraging. Seeking to reduce network node hops in reaching an HPC-enhanced node and balance the workload of these servers, it provides a methodology to greatly increase the abilities of mobile resources in resource-poor areas. We have laid the initial groundwork for this concept, and look forward to expanding the challenging optimization problems that it presents for both static and dynamic, strategic and tactical total network capability.

Abstract - *This paper describes the development of a high throughput and reliable Cloud Service to perform on-demand structural analysis over the Windows Azure-based Cloud infrastructure provided by the EC VENUS-C project. All the simulations in the Cloud are governed by Architrave®, an advanced software environment for the design and analysis of buildings and civil engineering structures. The migration to the Cloud has been implemented by means of the Generic Worker component, a web-role implementation for Windows Azure that manages the execution of the remote tasks. The CDMI standard has been used for uploading and downloading data. A GUI Client has also been implemented, in charge of defining and managing the remote simulations, transferring the data and informing the user about the status of the simulations. A real large building has been chosen as a case study to show the advantages of the cost-effective Cloud system with respect to the sequential approach.*

Keywords: Cloud Computing, Cloud Service, structural analysis, VENUS-C Project

1 Introduction

Structural analysis of buildings, or civil engineering structures, is the process to determine the response of a structure to different prescribed applied loads. This response is usually measured by establishing the stresses, tensions and displacements at any point of the structural elements.

In a linear dynamic analysis [1], where the external loads (earthquake, wind load, etc.) change along the time, the second order differential equations in time that governs the motion of structural problems must be solved. Direct time integration algorithms are techniques usually applied for solving this computationally demanding equation of motion, using a time step-by-step numerical integration procedure that provides the response of the structure along the time. The accuracy of the results depends on the time increment employed.

The realistic 3D structural dynamic analysis of large scale structures can demand an important computational power, give place a huge volume of data and become one of the most time consuming phases in the design cycle of a building or a civil engineering structure. For this reason, this analysis has been traditionally solved by introducing a variety of simplifications (unsuitable for complex structures) in order to reduce the problem size and the volume of the data, and obtain the results in reasonable simulation times.

Architects and structural engineers need thus powerful software applications able to simulate efficiently the accurate response of the structure. High Performance Computing (HPC) techniques provide powerful numerical and programming tools to develop applications able to simulate, efficiently and in a realistic way, large dimension structures, in very reasonable response times. However, commercial applications usually offer traditional approaches, computing sequential structural analysis on the user's local machine. As a result, the size and the complexity of the structure to be analysed, the type of structural analysis employed and the total number of the different structural solutions or even earthquakes evaluated are limited by the performance of the computational resources used by the users. With the purpose of overcoming these limitations, Architrave® [2], an advanced software environment for the design, 3D linear static and dynamic analysis and visualisation of buildings and civil engineering structures, was developed. Architrave is composed of these three different and independent components, although interacting among them:

- The Design Component: An interactive AutoCAD-based application where the user can draw the model and define the structural properties and the external loads.
- The Analysis Component: An interactive GUI application, where the user can modify the structural properties and the external loads, analyse the structure and visualise the results.
- The Structural Simulator: A batch MPI-based parallel application used by the Analysis Component to simulate the response of the structure by means of the Finite Element Method.

Notwithstanding, studios for architecture and engineering rarely own parallel platforms to execute an HPC-based application. Thus, the users install and run Architrave in their personal computers, and the time spent on the calculations by means of the Structural Simulator component depends on the performance of their machines.

Fortunately, Cloud Computing technology has emerged as a solution for the computational requirements of organizations, enabling the usage of non-owned remote resources which delivers enough power and storage space to satisfy the computational and disk requirements of the resource-starved dynamic structural simulations of high-rise buildings. Moreover, Cloud technology allows sharing not only computing power, but also another kind of resources such as storage space, data and even software packages.

This document is composed of the following sections. First of all, the VENUS-C project and the Generic Worker component are described in Section 2. The porting of a structural analysis application to the Cloud is explained in Section 3. This section describes the design adopted for the Generic Worker execution model and the software architecture. The different VENUS-C components used are explained and the details of the deployment in the platform tested are finally exposed. Section 4 presents the representative case study selected in order to validate the solution implemented in this work. Finally, the Section 5 contains the conclusions.

2 The VENUS-C project and the Generic Worker component

VENUS-C (Virtual multidisciplinary EnviroNments USing Cloud infrastructures) [3] is a European Research Infrastructure Project that aims at providing an easy-to-use computing platform, based on the virtualisation and service orientation. In simple terms, it allows researchers to use the Cloud Computing model in science.

VENUS-C is associated with the concept of PaaS (Platform as a Service), which means that an application is inserted into an existing Virtual Machine (VM) image with an appropriate runtime environment, and then executed. The developer need not to maintain, manage or update the VM's operating system or runtime environment. Instead, he focuses on the functionality of his application. Also, this application can be easily scalable, secure and ensure high availability.

This is what provides other platforms like Windows Azure [4] or Google App Engine. However, the novelty of this initiative is, among other ones, the easiness of porting an existing application to the Cloud and the interoperability between different infrastructures without having to adapt the application. In this regard, VENUS-C exposes an OGF BES/JSDL [5][6] compliant web service interface and client libraries for Java and .NET.

VENUS-C is a platform composed by several components which provide different services. The two essential services are data and job management. The data management service includes transferring input data to the Cloud and retrieval of output results. It supports the Cloud Data Management Interface (CDMI) specification [7], developed by the SNIA, and considers also blobs from Windows Azure Storage for transferring data.

The job management service allows the scientist to allocate compute resources in the Cloud, submit tasks, and to manage a job's lifecycle, i.e. to monitor the execution status and terminate a job if necessary. Other services provided are Elasticity, Monitoring, Accounting, Billing, and traffic redundancy elimination.

There are two components available that support the job management service (Figure 1): the Generic Worker (GW) [8][9] from Microsoft Research, and the PMES-COMPSs [10] from the Barcelona Supercomputing Center (BSC). Each of these components has a different programming model. In the implementation for this work, the first of them has been used, which is intended to be deployed on the Windows Azure platform, running over VMs with Windows Server 2008 and .NET framework.

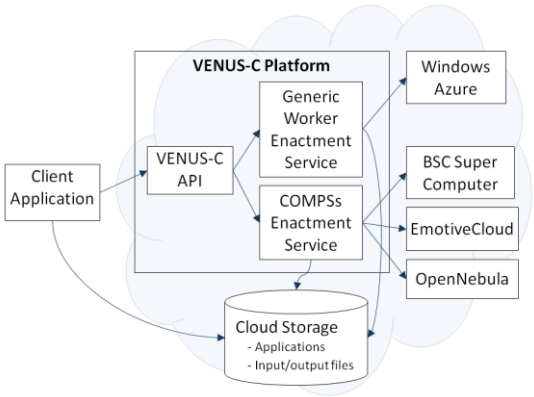

Fig. 1. The basic architecture of VENUS-C.

Actually, the GW is a Windows Azure web role attending for requests of registering a job, getting the status of a task, terminating a job, etc. (supporting, in this way, the VENUS-C API). In addition, this same web role has another process running that checks for new jobs registered to be processed. Obviously, one or many instances of this web role can be deployed working together in coordination.

The GW provides the common glue code that the developers have to write in order to port their applications to Windows Azure. The difference is that this service executes *generic* jobs, i.e. every job has a description that specifies the application to run, the input/output files and the parameters to be passed to the executable binary.

All interactions with the GW can be authenticated by the username and password mechanism and controlled by authorization policies, based on certain user roles previously defined and a table that specifies which roles has each of the users. Also, the communications can be protected through WS-Security with security tokens.

The GW exposes an additional interface to the administrator, through which the number of running instances can be scaled up/down to ensure the computational resource demands of the clients. Thus, the scaling decisions can be taken automatically according to different criteria.

3 Design and implementation

This section describes the design adopted to offer the capability to carry out remote structural analysis in the Cloud. The implementation was structured in different components and layers considering usability and easiness to adaptation to the features provided by the VENUS-C software.

The architecture of the Cloud Service implemented, based on the GW component, is shown in the Figure 2.

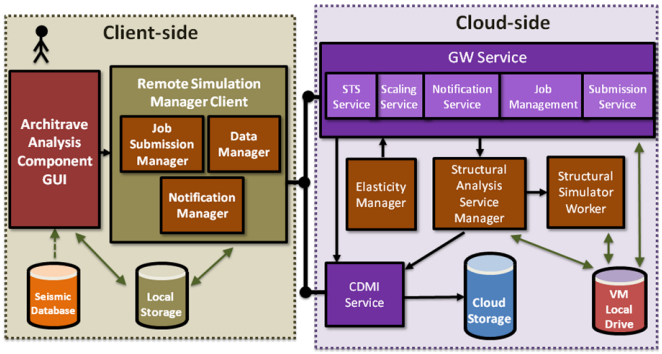

Fig. 2. Software architecture of the GW-based Cloud system.

Firstly, it consists on a Windows client that executes the Architrave Analysis Component to modify the structural properties, apply the external actions, define the simulation and visualise the results. In addition, a GUI tool, called as the Remote Simulation Manager Client, has been implemented to submit and manage the simulations in the Cloud and receive the results. Data communications between the local client and the Cloud service are carried out by means of the standard CDMI service [11]. On the Cloud-side, user authentication is implemented by means of the Security Token Service of the GW, and a Notification Service, also belonging to the GW, is used to inform the user about the status changes of the simulations. Remote jobs are managed and submitted thanks to the Job Management and Submission Service components of the GW. Structural simulations in the Cloud are executed by means of the Architrave Structural Simulator component. A Structural Analysis Service Manager module, in charge of launching the Architrave Structural Simulator Worker with the appropriate parameters, depending on the type of analysis, and managing the needed simulation input and output data has been implemented. Finally, an Elasticity Manager component has been developed to provide the system with the elasticity capability, using the Scaling Service of the GW. A more detail explanation is given in the following subsections.

3.1 The Remote Simulation Manager Client

On the client-side, the local or remote simulations are defined exactly in the same way, using the Architrave Analysis Component, the GUI application where the structural properties can be modified and response of the structures is visualized, after the simulation. This application now incorporates the Remote Simulation Manager Client, a tool developed also for .NET with a comprehensive GUI to configure and manage the simulations in the Cloud, to know in real-time the status of the remote executions and to download the results. This new application is launched by Architrave Analysis Component as an independent executable binary, which can even continue running (for downloading results, for example) when Architrave Analysis Component application is closed. In this tool, some modules can be distinguished:

- The Job Submission Manager: When the Remote Simulation Manager Client is launched, for the first time, this module checks the status of all the simulations in the Cloud (submitting, pending, running, finished, failed, downloading, downloaded) and informs the user. Then, this module will be responsible for submitting each new simulation to the Cloud.
- The Data Manager: This component uploads the input data and downloads the corresponding results and meta-data using a CDMI service or directly the Windows Azure Storage service.
- The Notification Manager: It obtains the changes in the simulation status and updates the associated information.

Every time the Remote Simulation Manager Client is launched, the user must be authenticated in the Cloud by means of the username and the password. If the user has permission to use the Cloud Service, i.e. he has been registered in the users table, then a list of his remote simulations will be shown, and he will be able to submit new simulation jobs, download results, cancel executions, and so on. For each simulation, geometric information related to the structure analysed, the type of analysis, the kind of data to be retrieved, the way of downloaded the results, etc. is exposed, including the current status, which is updated every time with a configurable frequency by the Notification Manager.

When the user submits a simulation to be executed in the Cloud, the following steps take place: First of all, the Architrave Analysis Component writes a binary file containing the building geometry, the external loads applied (such as an earthquake) and the simulation parameters, and sends a message containing the file path to the Remote Simulation Manager Client. Then, the Remote Simulation Manager Client reads the input binary file and the remote simulation is registered. Next, the Data Manager uploads the input binary file using the CDMI service to the CS. Finally, the Job Submission Manager submits the job to the Cloud Service in the way of a .jsdl document and the Notification Manager consults periodically the significant status changes in the Cloud Service. When the results are ready, the Data Manager will download them also by means of the CDMI service.

The user can configure the amount of results to be generated in the Cloud and to be received in the local machine, and the way to be downloaded. Thus, the Data Manager can be demanded to retrieve the simulation results automatically (when they are available) or manually (when the user requests them by clicking on the corresponding button). Also, in a dynamic analysis, the user can save on the CS the simulation results for all the time steps; the simulation results of just the 3 most unfavourable time steps according to the X, Y and module base shears or, finally, a video with the graphical response of the structure along the time. Besides, the user can configure the amount of data to be downloaded, obviously depending on the results previously computed and stored in the Cloud. In any case, a list with the X, Y and module base shears for all time steps will be always downloaded in order to allow the user to retrieve subsequently the amount of unfavourable and most significant simulation time step results that he desires.

Moreover, the Remote Simulation Manager Client can indicate the Data Manager to remove the input and output simulation data automatically (when the data results have been successfully received) or manually (when the user desires), to cancel the execution of a structural analysis or cancel the retrieval of the results.

3.2 The Structural Analysis Cloud Service

On the Cloud-side, the Structural Analysis Cloud Service is composed of the following components:

- The GW Service, i.e. a web-role implementation for Windows Azure that manages the execution of the remote tasks. This Service is composed of the Security Token Service (to perform the user authentication and allow that just authorized users can use it), the Scaling Service (to increase or decrease dynamically the number of worker instances), the Notification Service (to inform the user about the status of the jobs), the Submission Service (to send the simulations to the worker instances) and the Job Management (to provide information related to the status of the tasks).
- The Structural Analysis Service Manager, which generates the input files needed by the Structural Simulator and launches it and encapsulates the results.
- The Structural Simulator Worker, i.e. the HPC Architrave module that runs the simulations in the Cloud.
- The CDMI Service, which uploads and downloads the data using the standard CDMI protocol.
- The Elasticity Manager, which sets automatically the number of worker instances according to the workload.

For each simulation request, the associated input binary file is moved from the CS to the local drive of the VM by the GW Service, and the Structural Analysis Service Manager is launched. This executable file reads the input archive and generates the input file needed by the Structural Simulator Worker. Next, the Structural Simulator Worker is executed with the appropriate parameters, depending on the type of analysis, defined by the user. As a result, the structure is analysed and the output files are periodically generated and saved on the local drive. For each simulation time step, in case of a dynamic analysis with response along the time, all the multiple output files generated are encapsulated in just a single output file and sent to the CS during the execution by the Structural Analysis Service Manager.

A notification scheme is employed, where the Notification Service of the GW puts the status changes of the simulations into an Azure queue, which is consulted periodically by the Notification Manager component of the Remote Simulation Manager Client. In this way, the Remote Simulation Manager Client informs properly the user and downloads the output files to the local machine when the execution has finished, or when each simulation time step is ready to be retrieved, following a data-driven model. As a consequence, the remote simulation execution and the result retrieval phase are overlapped in time and, thereby, the whole time involved in the simulation is dramatically reduced.

The Structural Analysis Cloud Service contains an Elasticity Manager component able to adjust the number of available worker resources through the Scaling Service of the GW, depending on the workload in the system. Specifically, this component monitors continually the number of workers in execution, and a new instance worker is launched automatically when the processing workload is increasing. For that, when the number of instances waiting for jobs is lower than two, a new worker is deployed. On the other hand, if all the worker instances are idle, most of them will be terminated and the number of workers will reduced to the minimum.

4 Execution results and performance analysis

This section explains the representative case study applied to validate the Cloud system. The following subsections describe the structural and computational interest of the case study and the expected improvement benefits that provides the Cloud Computing solution.

4.1 Introduction to the case study

For the case study, we have selected a structure (Figure 3) corresponding to a reinterpretation, according to the current usages and regulations, of the original structure of the Nordic Bank, located in Helsinki. This is a work of the Finnish architect Alvar Aalto in 1962. It consists on a portal frame structure, solved by means of slabs over interior concrete columns and steel columns at the facade. The core of the vertical communication is materialized as reinforced concrete walls serving as vertical structure and lateral bracing. The spans are moderated, except in some zones at lowest levels where the foundation lab is

reinforced with hanging concrete beams. The facade steel columns are disposed to half spans, with beams of diversion at the level of first floor. The foundation consists of a slab, due to the presence of the phreatic stratum. The model has been designed with bars for columns and beams, and 2D medium sized finite elements for slabs and walls. For the slabs, a Delaunay mesh has been employed, while the walls are solved with a simple mesh.

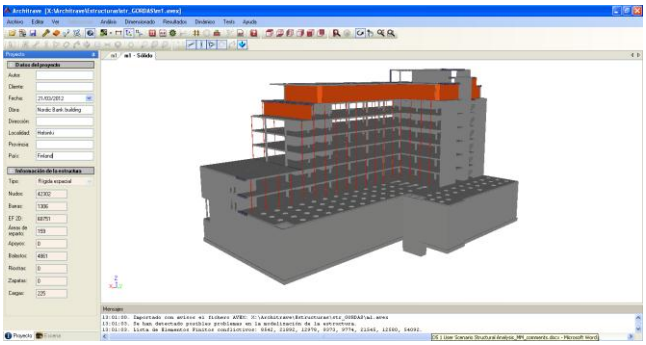

Fig. 3. Nordic Bank building.

The case study presented consisted on testing and simulating 10 different structural solutions that came from the same structural design, composed of 253812 degrees of freedom, with 1306 columns and beams, and 68751 2D finite elements. Each structural solution was composed of a variation of the column dimensions, and the slab and wall thickness. Moreover, each of them was dynamically tested under the influence of 5 representative earthquakes of 12 seconds of duration, with a simulation time increment of 0.01 seconds. These results were stored every 0.05 seconds. In this way, 1200 times steps were simulated and 240 of them were saved on disk. It should be noted that the aim of this case study was to select the best one of the 10 structural solutions that accomplished the structural and safety regulations and presented the most economic final cost.

Therefore, for the case study execution, a set of 50 independent 3D dynamic simulations were launched and computed, firstly locally in a conventional PC (Intel core i5, CPU@ 3.20 GHz and 4 Gbytes of RAM), and then in the Cloud, following two different configurations. On the configuration A, all the simulation time steps remotely saved were retrieved by the client; and on the configuration B, only the 3 most unfavourable time steps were saved and retrieved by the user. Furthermore, the two configurations were tested over different deployments composed of 1, 10, 25 and 50 medium-sized Web role Azure instances (CPU@ 1.60 GHz and 3.5 Gbytes of RAM).

4.2 Performance analysis

The validation tests demonstrate the behaviour of the VENUS-C platform according to the case study described in the previous section. For that, a quantitative evaluation has been carried out, measuring the efficiency of the platform by means of the response time and the speed-up, obtained by the Cloud approach with respect to the local approach and with respect to employ just one Azure instance in the Cloud.

Before executing the whole case study, the simulation of one of these structural solutions was computed firstly on premises and then in the Cloud. The Table 1 shows the results when computing the structural solution in the local machine of the user, together with the response time, the size of the input data and the amount of data downloaded by the local client, for the two described configurations.

Table 1: Results corresponding to the simulation of one of the structural solutions in the Cloud.

Type of execution	Response time (minutes)	Input data (Mbytes)	Output data (Gbytes)
Local execution - Saving the results of the 240 time steps	120.03	5.43	2.48
Configuration A	279.48	5.43	2.48
Configuration B	277.46	5.43	0.12

It should be clear that, for the configuration A, all the needed data movements (from the VM local disk to the CS and from the CS to the user machine) were overlapped with the execution. However, for the configuration B, the data transference just could start once the simulation had finished and the most adverse results had been computed.

The results of the Table 1 show a big difference between the local response time (120.03 minutes) and the remote response time (279.48 minutes for the configuration A, and 277.46 minutes for the configuration B).

For the itemization of the overhead times, the stages that give place to an overhead faced with the local execution have been analysed. Table 2 shows the time involved in each of the stages that compose the simulation of a single structural solution, where only the most unfavourable results are moved to the CS and downloaded later (configuration B). As it can be seen, the time involved in computation implies a delay of 155.28 minutes, with respect to the local execution.

Table 2: Execution times of each of the different stages involved in the simulation in the Cloud (configuration B).

	Data and job submission	Application download and job initialization	Structural Simulator Worker execution and result encapsulation	Result upload to the CS	Result download to the client machine
Local execution	-	-	120m 02s	-	-
Remote execution	6s	39s	275m 19s	50s	34s
Overhead time	6s	39s	155m 17s	50s	34s

The values of the Table 2 reflect that the most of the overhead time resides on the execution of the Structural

Simulator Worker, responsible of analysing the structure, and the Structural Analysis Service Manager, in charge of encapsulating the results generated. As the computational complexity is similar on the local and the Cloud simulation execution, it can be assumed that the main overhead resides on the difference on hardware characteristics, especially on the CPU features and the speed of accessing the disk for the read and write operations.

The overhead times at the configuration A shows a similar behaviour than in the case of the configuration B, as reflected in the Table 3. However, this is due to the fact that, as indicated above, the Structural Simulator Worker execution time is overlapped with the output data upload to the CS and with the result download to the client machine. In this way, the column 4 includes the time spent on the simulation execution, where the results of most of the time steps had been transferred simultaneously to the CS and received by the client. On the other hand, the column 5 shows the time required for the data upload to the CS and the result download to the client for the last time steps, i.e. once the Structural Simulator Worker execution has finished. Therefore, the main overhead appears during the simulation of the structure, with a delay of 154.88 minutes with respect to the local execution.

Table 3: Execution times of each of the different stages involved in the simulation in the Cloud (configuration A).

	Data and job submission	Application download and job initialization	Structural Simulator Worker execution and result encapsulation	Result upload to the CS and download to the client machine
Local execution	-	-	120m 02s	-
Remote execution	6s	39s	274m 55s	3m 49s
Overhead time	6s	39s	154m 53s	3m 49s

Once analysed the execution times of a single structural solution, the whole case study execution was performed, whose fifty different simulations were launched at the same time, and the status of the simulations were consulted periodically by means the Remote Simulation Manager Client. The evaluation compares the response time of the local execution, considering that each structural solution is analysed after another in the machine of the user, with the remote response time, for the two different previous configurations, over a set of different Cloud deployments composed of 1, 10, 25 and 50 medium-sized Azure instances. The response time was measured as the difference of time between the first job submission and the final result data downloaded corresponding to the last simulation.

The execution of the 50 simulations that compose the case study spent 100.03 CPU hours in a traditional approach, generating output results in the order of 124.04 Gbytes. In the Cloud deployment, the execution of the whole case use configuration A required 271.5 Mbytes as input data and 124.04 Gbytes of output data were produced. For the configuration B, 271.5 Mbytes were required as input data and 5.75 Gbytes of output data were generated.

Figure 4 shows the execution times of the whole case use, for both configurations and over a Cloud deployment composed of different number of Azure instances.

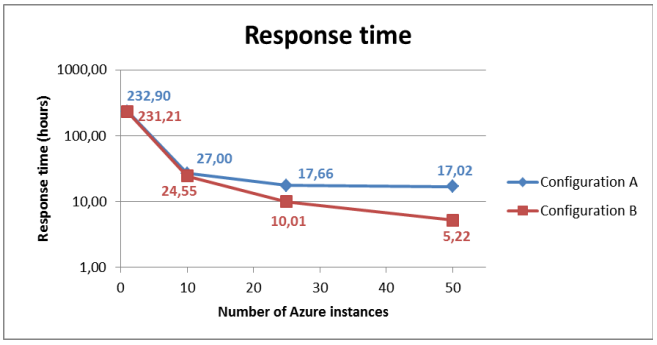

Fig. 4. Response time in hours for the whole case use.

As it can be noticed, the response time decreases gradually when the number of Azure instances is increased at the configuration B. In the case of the configuration A, the results show initially a similar trend. However, when the number of Azure instances that executes the case study is greater than 25, the results acquire a value of around 17 hours. This is due to the bottleneck of the network in the retrieval of this large volume of output data by the client, since the time required for downloading all the results generated is much greater than the time required for executing the simulations. Therefore, although the execution and the result retrieval stages are properly overlapped, the time required for the complete case study is mainly determined by the time spent on the reception of the 124.04 Gbytes of results generated.

In any case, it should be taken into account the dramatically reduction of the total time required for the execution. Whereas more than 4 days were needed in the traditional approach, just 17.02 and 5.22 hours were spent, respectively for the configurations A and B, when computing remotely all the simulations in the Cloud.

Figure 5 shows the behaviour of the Cloud system, when the number of Azure instances is increased, in terms of speed-up, with respect to the sequential approach (each structural solution analysed after another in the client local machine) and with regard to the results of the execution over just a single Azure instance. In this figure, it can be appreciated how the results of the speed-up, compared with the sequential approach, are much lower than results of the execution in an Azure instance, at the two configurations. This difference in the results is mainly due to the difference in the hardware characteristics between the local testing machine and the Azure instances.

Whereas the speed-up at the configuration B with regard to an Azure instance obtains values near to the ideal case (44.29 for 50 machines), the speed-up with respect to

the sequential approach is far from these values (19.16 when using 50 instances). In the case of the configuration A, it can be appreciated how the value of the speed-up does not increase appreciably when the number of Azure instances is greater than 25, due to the reasons exposed above related to the bottleneck of the network in the retrieval of the results.

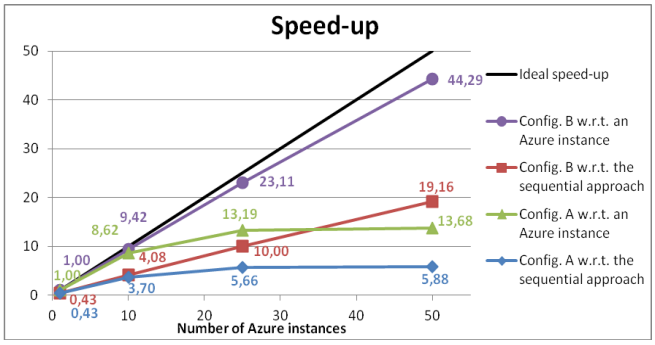

Fig. 5. Speed-up for the whole case use.

The behaviour, in terms of efficiency, of the Cloud system is reflected in the Figure 6, with respect to the sequential approach and with regard to an Azure instance.

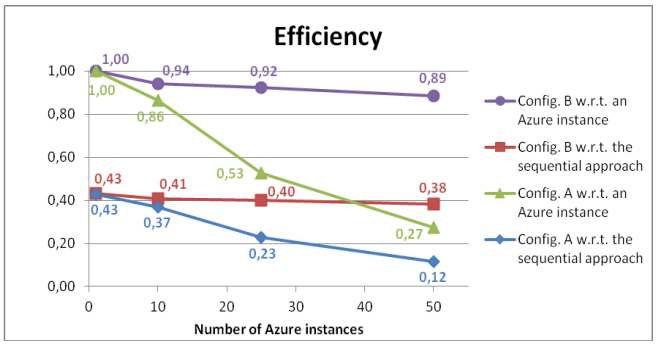

Fig. 6. Efficiency for the whole case use.

As expected, excellent efficiencies were obtained for the configuration B, but worse efficiencies were computed for the configuration A. Clearly, it can be noticed how the efficiency decrement is very low at the configuration B when the number of Azure instances is increased, whereas the tendency of the decrement at the configuration A is much more pronounced.

5 Conclusions

In this work, a Structural Analysis Cloud Service has been implemented, based on the GW component developed of the VENUS-C project, and deployed for Windows Azure. The software architecture of Cloud system is described, together with its design and the different elements that composed it.

All the remote simulations are managed by Architrave, an advanced software for structural analysis. The Architrave Analysis Component and the Architrave Structural Simulator have been properly adapted to work in the Cloud. In order to launch and manage the executions, the Remote Simulation Manager Client application has been implemented.

Thanks to the high throughput and reliable Structural Analysis Cloud Service implemented, researchers will have available a huge number of computational resources to be on-demand employed and lots of cost-effective simulations will be launched simultaneously. Thus, more experiments will be analysed per time unit, increasing the number of structures simulated and speeding up the research process.

The structural community will be able to solve larger scale problems, increase the complexity of the structure to be analysed, and carry out a larger number of realistic dynamic simulations. In this way, the reliability and safety of the results obtained will be improved and new structural problems will be tackled. Since the time spent on the design of buildings and civil engineering structures will be reduced, the engineering companies and the architectural studios will increase their productivity and volume of business.

Finally, there will be no need of acquiring software licenses in property and expensive hardware for solving large-scale structural problems (just pay per use), and the users will not be worried about new software updates.

Power Saving for Fast Deployment Private Cloud Toolkit – Ezilla with Infrastructure Services

Chang-Hsing Wu[1], Yi-Lun Pan[1], Hsi-En Yu[1], Hui-Shan Chen[1] and Weicheng Huang[1]
National Center for High-performance Computing, Taiwan, R.O.C.
{hsing, serenapan, yun, chwhs, whuang}@nchc.narl.org.tw

Abstract – *As virtualization technologies become more prevalent, Cloud users usually encounter the problem of how to build his/her own virtual cluster form cloud environment. We provided easy installation toolkit for building cloud environment with friendly user interface. Ezilla toolkit has been developed by the Pervasive Computing Team at the National Center for High-Performance Computing (NCHC). Ezilla toolkit integrates the de facto Cloud middleware, Web-based Operating System (WebOS), and coordinated Cloud infrastructure services (hypervisor, storage, and networking) to form a cloud environment. With a click, Cloud users can easily customize and configure the specified cloud environment via Ezilla toolkit. The main feature of Ezilla is simplifying a lot complexity of utilizing Clouds. Our goal is to make scientists or users painlessly run their works on Clouds.*

Keywords: Virtualization Techniques; WebOS; Virtual Cluster.

1 Introduction

Cloud users have to manually build specified virtual cluster of cloud environment with the console mode in order to manage or generate virtual resources. To improve this condition, an *Ezilla* toolkit has been developed by the Pervasive Computing (PerComp) Team at the National Center for High-Performance Computing (NCHC). Ezilla is built on the "Carry-On-Cloud" concept. On this platform, Cloud users can build on demand virtual clusters with one click. Furthermore, Ezilla leverages unattended installation technique, Cloud middleware, WebOS (Web-based Operating System), and DRBL - SSI mode (Diskless Remote Boot in Linux - Single System Image) [1], to provide the software infrastructure of the Ezilla system. Therefore, Cloud users can build the whole Cloud environment very easily.

Ezilla toolkit provides a user-friendly interface that is WebOS. The WebOS infrastructure offers a seamless and unified access to geographical distributed resources connected via Internet, and it can supply most basic operating system services [2]. Thus, with one click, Ezilla toolkit helps Cloud users to make their own private Cloud easily. The progress of Ezilla helps to lower the barrier for using Cloud computing environment. The designed Ezilla toolkit has become necessary to provide Cloud users with an interface that is both user-friendly and straightforward. This research focuses on virtual resources management with an interactive graphical user environment.

Furthermore, the "Green Computing," is especially important and timely. As Cloud Computing becomes increasingly pervasive, the energy consumption attributable to computing is climbing, despite the clarion call to action to reduce consumption and reverse greenhouse effects. To echo today's energy saving issues, we also developed a power saving approach in Ezilla toolkit to reduce energy utilization in Cloud Computing resources. We do this work on the integration of local scheduler that aims at reducing power consumption such that they suffice for meeting the minimizing quality of service required by local cluster or physical machines.

According to the above scenario, those issues encourage the motivation of our research and development. Specifically, the design and implementation of the proposed Ezilla toolkit includes Cloud middleware, WebOS, DRBL – SSI mode, and power saving mechanism. The rest of the paper is organized as follows. Section 2 presents related works, including existing Web-based Operating system, virtualization technologies, and Diskless Remote Boot in Linux (DRBL). In Sections 3, we propose the implementation of Ezilla toolkit and power saving Mechanism that we developed. In Section 4, the research results. The conclusion and future directions are presented in Section 5.

2 Related Works

2.1 Existing Web-based Operating System (WebOS) Projects

Recently, a famous WebOS - Chrome OS, developed based on AJAX technique [3]. It can be used to implement a web application that communicates with a server in the background, without interfering with the current state of the page. The developments of Cloud WebOS platform via AJAX technique become practicable. However, Chrome OS does not provide on-demand applications and computing services to users in Clouds.

A Web-based Operating System (WebOS) project started as part of Network of Workstations [4] at the University of California, Berkeley in 1996. So far, there are several typical commercial projects of WebOS, such as FlyakiteOSX [5], Glide OS [6], Xindesktop [7], … etc. All of these systems are online OS with AJAX and PHP

techniques adopted. However, these projects are not open source and lack of the management of distributed computing resources. To tackle the technical issues of distributed computing resource management, the Cloud WebOS platform is developed in this work, upholding the spirit of open source, open standard, and is distributed under GNU/GPL license.

2.2 Virtualization Technologies

The virtualization technology is not a brand new technology. In the late 1990s, virtualization was achieved by complex software (binary translation) techniques given the fact that the virtualization technique was not supported by processors at the moment and obtained reasonable performance. In the late 2006, both the Intel and the AMD created new processor extensions to their processors and enhanced the support of the virtualization. Furthermore, they also implemented the I/O virtualization technology that covers memory, disk and network by the chipset. The technology was called hardware-assisted virtualization. This approach increases the performance by removing a layer of complex software techniques between the guest OS and hardware. Examples of virtualization platforms that are adapted to such hardware include Linux KVM, VMware Workstation, Microsoft Hyper-V, to name a few.

In the arena of virtualization technology, hypervisor is considered as a crucial part of the technology. It is software that manages multiple virtual machines on a single computer system. Hypervisor is a layer resides between the existing operating system and hardware to manage the computing hardware and virtual machines.

Generally, modern implementations of hypervisor are divided into two categories, including Host-based and Bare-metal approaches. The host-based approach uses modified operating systems to provide virtual machine monitoring, such as Linux-VServer [8], Solaris Zones [9], and Kernel-based Virtual Machine (KVM) [10]. On the other hand, the bare-metal approach employs small-dedicated hypervisors to directly run on physical machines. The VMware ESX server [11] and the XenServer [12] are the famous examples of the bare-metal approach.

2.3 Diskless Remote Boot in Linux (DRBL)

Diskless remote boot in Linux (DRBL) environment is based on the network boot mechanism, network file system, and centralized authentication mechanism. To boot the computing node remotely, a mechanism that can download program over network is required. There are many programs fulfill this need, such as Preboot Execution Environment (PXE) [13], etherboot [14], gPXE [15], and iPXE [16]. The DRBL is compatible with all of them. Once the DRBL server is ready, the whole computing cluster is ready. It is not necessary to install the OS onto computing nodes at all. Services, such as dhcp, tftp, NFS, and NIS are executed in the DRBL server to serve all the computing nodes.

By setting computing nodes to boot from network, IP addresses will be assigned from server when nodes during the booting procedure. Once a computing node gets its IP address and kernel, it will boot from the kernel and the initialized RAM disk "initrd". The computing node will then load the driver for NIC in the initrd, mount its root directory and other necessary directories via NFS. Once the procedure is completed, the computing node has all the necessary files. Then, the normal boot procedure, just like that of regular Linux boot steps in the diskfull nodes, will follow. Standardized procedure and packages needed to setup a DRBL server has been developed for various Linux distributions, including Debian, Red Hat, Fedora, and Mandrake. The whole setup procedure is easy, straightforward and productive. Following the documentation on the DRBL project website, one can setup a DRBL server in about half an hour, depending on the packages chosen to be installed and the network speed.

To boost the performance of a DRBL cluster, performance tuning in the DRBL setup program was carried out. One of the examples is that, there are more than 100 device files under the directory /dev in a diskless node. If these small but numerous devices files exist in the NFS server and share with the clients via NFS, the cluster performance won't be good. So the tmpfs file system in the diskless clients is used and these device files are created in this tmpfs file system when diskless clients boot. With most of these tmpfs files systems for directories /etc/, /var, /tmp/, and /dev/ included in the DRBL clients, which is called Single System Image (SSI) mod, loading of the file server is greatly reduced.

With success of the virtual technologies, we integrate virtualization technology – KVM, WebOS, and DRBL. This research comes up with a new and lightweight approach to access virtual computing services via the Ezilla toolkit.

3 The Implementation of Fast Deployment Ezilla Toolkit and Power Saving Mechanism

3.1 Research Objective

The key idea of Cloud Computing lies in its component-based nature, which are reusability, substitutability and user friendly. By integrating virtualization technologies, DRBL – SSI mode, and WebOS, a web environment to access Cloud services via Ezilla WebOS Interface is provided. This progress helps to lower the barrier for using Clouds. This research focuses on virtual resources management with an interactive graphical user environment. More specifically, the Ezilla toolkit implements an autonomic virtual computing resources management system based on decentralized resource

discovery architecture. At the same time, a power saving mechanism is also crucial to the utilization of Cloud resource. Therefore, the designed power saving mechanism is used for the virtual cluster and physical cluster.

3.2 Implementation of Fast Deployment Ezilla Toolkit

There are three components in the Ezilla toolkit, including Ezilla Server, Ezilla Client and intuitive Ezilla WebOS Interface, as sketched in the Figure 1. The Ezilla Server responses for orchestrating computing resources and monitors the status both of physical and virtual machines via cloud middleware. In addition, the most important feature is the image file server used to manage virtual machine images. The VM images are stored in the file system that controlled by the Ezilla server. Responding to the request from Cloud users, the images will be dispatched to Ezilla clients and used to generate virtual machines in turn by Ezilla clients. A Cloud user can use his personal Ezilla WebOS interface to create a Cloud environment linking storage, networking, and computing power timely and easily.

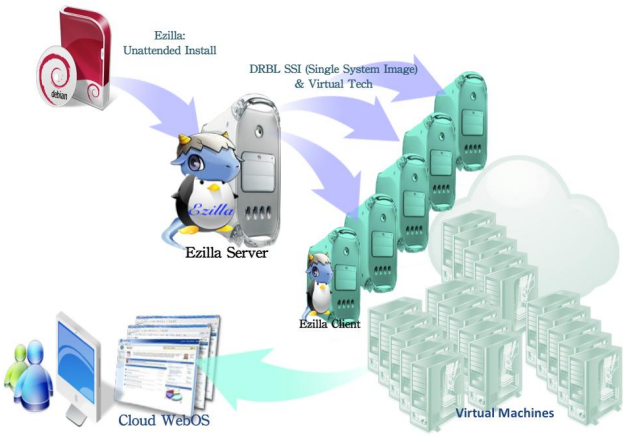

Figure 1. The System Architecture of Ezilla

The Cloud users can create dynamically a virtual cluster consisting of VMs through Ezilla WebOS Interface. Users determine the scale and the life span of the virtual cluster. Once the virtual cluster is no longer needed, it can be dismissed subjected to the decision of the user. The computing resource is then released for other users to use. Due to the adoption of the XML-RPC based API for the development of the WebOS; the whole operation can be manipulated via a web browser, such as Chrome. There are several middlewares embedded in the designed Ezilla Toolkit:

- Integration with basic Operation System and packages – The Ezilla toolkit supports the Debian OS and basic packages, including KVM hypervisor, and Libvirt [17]. In order to improve the performance, the Virtio [18] driver is also adopted in the virtual machines created by the Ezilla. Virtio driver provides paravirtualized functions for network virtualization and disk I/O virtualization. On the scenario of Network, the Bridge mode is configured by Ezilla toolkit as well.

- Integration with *OpenNebula* [19] – OpenNebula is used as central cloud management. It is responsible for allocating available computing resources, creating VMs based on user selected VM image, and deploying the image onto the physical computing resources. It also manages unique MAC address, IP address, and virtual network (vNet) ID. Therefore, each user's virtual cluster lives on its own vNet without interfering with other virtual clusters.

Once the Ezilla Server is in place, Ezilla Clients can be setup automatically via the DRBL–SSI Mode and existing virtualization technologies. With such a mechanism implemented, a physical machine can be easily turned into Ezilla Client via PXE (Preboot Execution Environment) with the local disk untouched. Hence, computing resources can be added dynamically without any reconfiguration, thus to enhance the flexibility of Cloud resource allocation.

3.3 Power Saving Mechanism

We developed an approach to reduce energy utilization in Ezilla cluster. We do this work on the integration of OpenNebula and remote power management system that aims at reducing power consumption such that they suffice for meeting the minimizing quality of service required by cluster. In particular, our approach relies on recalling services dynamically onto appropriate amount of the Ezilla Clients according to user's job request (virtual machines request) and temporarily shutting down the Ezilla Clients after finish in order to conserve energy.

As shown in Figure 6, the power saving mechanism will wake up every minute to check job (virtual machines request) queue if there exist jobs, and make sure Ezilla Client become available, the power saving mechanism then will fetch the applicable jobs, parses the requirements, and remotely powers on the correct number of machines by Wake-on-LAN [20] protocol or IPMI [21]. After the job completes, the power saving mechanism powers the machines down. Our implementation currently relies on checking the scheduler's job pool and then decides to shut down which Ezilla Client when no new job was submitted. By powering off idle Ezilla Client, it can significantly save more energy than always keeping all Ezilla clients running.

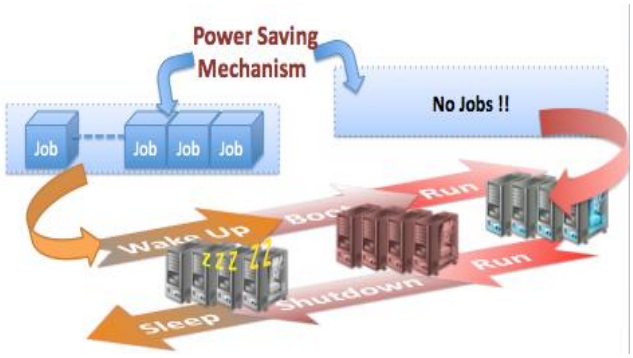

Figure 2. Scenario of Power Saving Mechanism

4 Research Results

4.1 Fast Deployment of the Ezilla Toolkit

The installation of the Ezilla was designed to be as effortless as possible so that a Cloud environment can be deployed quickly and easily. In fact, an Ezilla Server can be deployed in just three simple steps via DRBL – SSI mode, as shown in the following Figure 3, 4, and 5.

- Step1 – Boot the server with a genuine Debian CD-ROM and select "Help", for example, in Figure 3.

Figure 3. Step1 - boot the server with a genuine Debian CD-ROM and select "Help"

- Step2 – Key in "auto url=ezilla-nchc.sf.net" once the system enter the "Help Index", in Figure 4. The installation of the server is fully automated with all the needed packages and source codes downloaded.

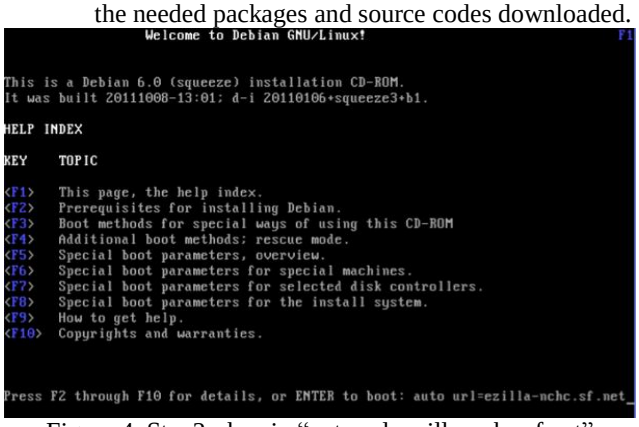

Figure 4. Step2 - key in "auto url=ezilla-nchc.sf.net"

- Step3 - Per the illustration in the Figure 5, the Local Area Network requires static IP instead of the DHCP.

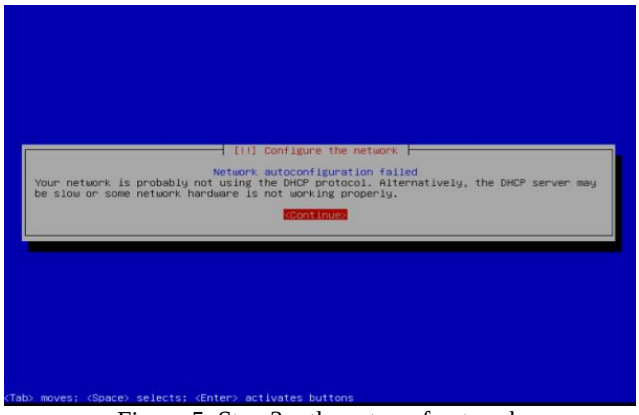

Figure 5. Step 3 – the setup of network

After completion of all the three steps above when the Ezilla server is ready for further use, the automatic installation process for building the Ezilla environment takes over. The installation will proceed without requiring the attention from system admin. The installation is completed and the Ezilla Cloud environment is ready for use once the boot menu page is shown, as in the Figure 6.

Figure 6. The boot menu on Ezilla Client with PXE

4.2 Ezilla WebOS Interface and Widgets

More advanced Cloud Computing Widgets are attempted as well. One of the most important results in this paper is that we have developed many Cloud Widgets with friendly graphical user interface via Ezilla WebOS Interface. The kernel of this system architecture consists of four Widgets, including Image Creator Widget, VM Creator Widget, VM Monitor Widget, and VM Control Widget. Users without much learning effort can easily manage all of these widgets. These Widgets allow users to customize and to arrange their complicated computing tasks according to their requirements.

The Image Creator Widget, in the figure 7, is to generate the customized base image and on-demand/specified application from the end users' requirements. This Widget provides a complete and integrated HPC software stack that

consists of operating system, management tools, resource monitor, and even commercial package, such as the Matlab. VM Creator Widget - with the profile of virtual cluster demanded by the user provided, it will generate a specification, shown in the figure 8, which in turn is parsed by the VM Creator engine to create an on-demand virtual Cluster on the physical computing resources.

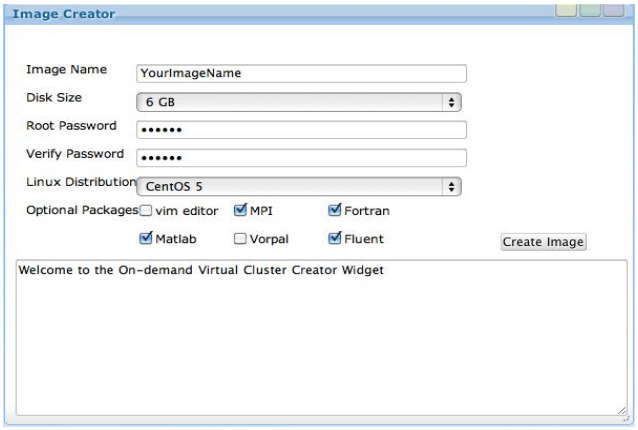

Figure 7. Image Creator Widget

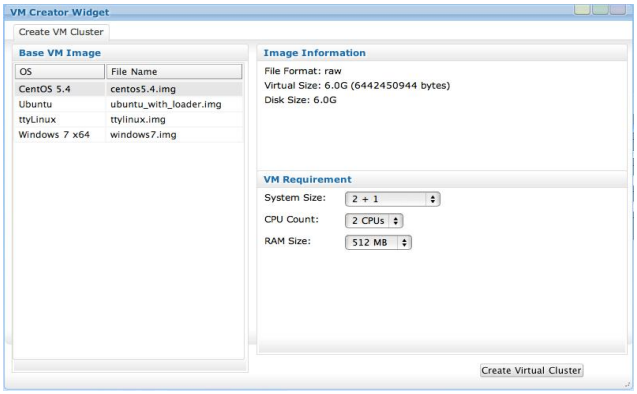

Figure 8. VM Creator Widget

In the figure 9, the main task of the VM Monitor Widget is to monitor the all the status of virtual machines, Networks, and the physical hardware. In addition, this Widget makes use of the information and the status provided by the Monitoring & Reporting Cloud Middleware. The VM Control Widget is designed for such a purpose with Cloud visualizer integrated as the core of its Cloud service, as shown in the figure 10.

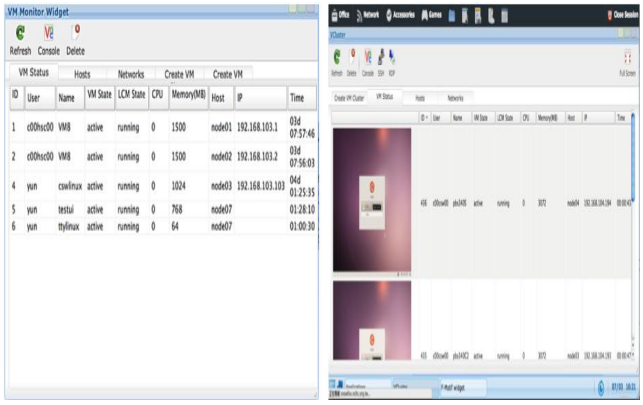

Figure 9. VM Monitor Widget

Figure 10. VM Control Widget Cloud Visualizer – Windows 7 Booting Status

Moreover, we used Ezilla toolkit to implement the following two customized applications for biological simulation and information security simulation in Eziila WebOS. The F-motif Simulation Widget provides specialized Cloud services to search and analyze the sequence of gene in real time, in figure 11. The other customized Cloud Widget about information security is called ICAS (IDS-log Cloud Analysis System) Widget. As long as user selects the ICAS base image, the Hadoop DB and virtual cluster are constructed automatically, and then users can analyze the IDS-log as the figure 12 shown.

In the figure 13 and 14, Ezilla WebOS also provides two methods to control virtual machines. One is VNC, the other is SSH on Web.

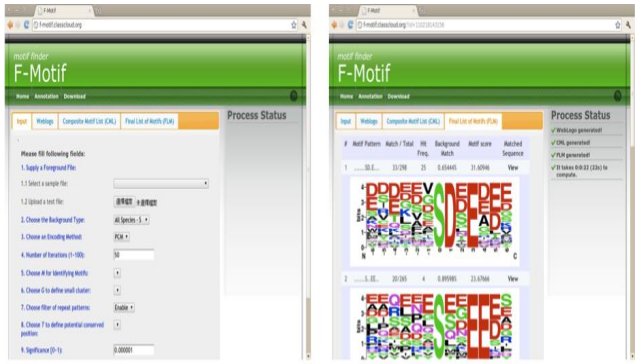

Figure 11. F-motif Widget in Ezilla WebOS

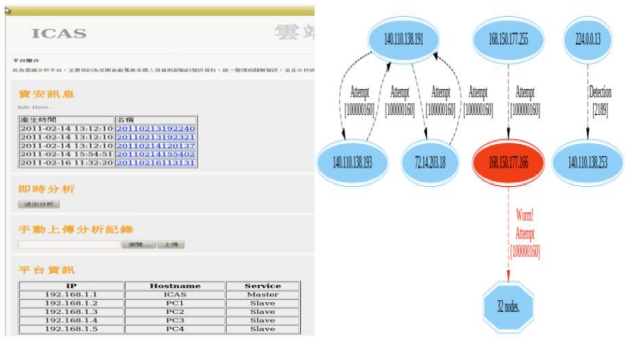

Figure 12. ICAS Widget in Eziila WebOS

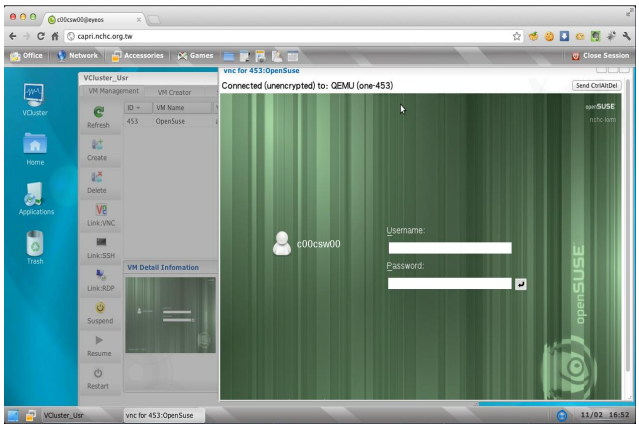

Figure 13. Using VNC to Control VM

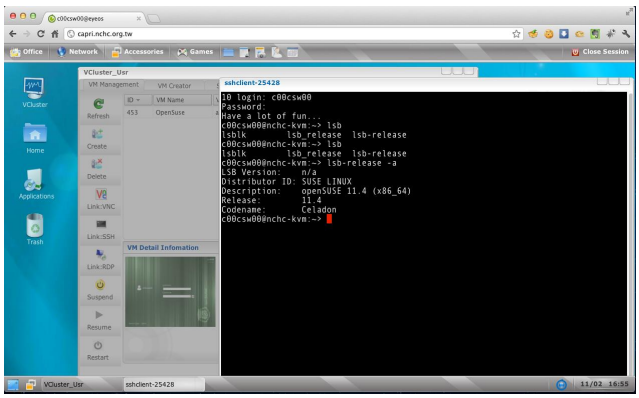

Figure 14. Using SSH to Control VM

5 Conclusions Conclusion and Future Work

The proposed toolkit – Ezilla [22], it not only helps user to build virtual cluster easily and automatically, but also provides different varieties of computing environment such as Linux, Win7, and so on. Furthermore, the ability to distribute and balance the workload across multiple physical as well as virtual computing resources will be tackled in the future development of this research.

The NCHC's Ezilla Development Team hopes that others will use Ezilla to create diverse applications, which incorporate additional Cloud services that can be accessed anytime. The ultimate goal of Ezilla is to achieve "Every as a Service" usability.

Resource Assignment in Computational Grid Based on Grid Market Equilibrium

Xi XIE[1] **and Satoshi FUJITA**[1]
[1]Department of Information Engineering, Hiroshima University
Higashi-Hiroshima, 739-8527, Japan

Abstract— *In this paper, we propose a resource assignment scheme in the computational grid based on the notion of market equilibrium. Market equilibrium is a key concept commonly used in the field of game theory, and in this framework, we determine the "price" of resources owned by the service providers so that it fulfills the Nash equilibrium of the given market consisting of clients and service providers. The degree of satisfaction of clients is modeled as a linear utility function of acquired resources, and as a constraint concerned with the clients, we use the notion of budgets. Our proposed scheme a semi-algorithm which finds an assignment of resources to the clients so that it maximizes the utility of the clients provided that: 1) all resources are completely exhausted and 2) the surplus of the clients is at most ϵ using $O(n \log(nM/\epsilon))$ maximum flow computations, where M is the total amount of budgets given to the clients at the initial state and ϵ is a positive real representing the accuracy of approximation.*

1. Introduction

1.1 Background

Our daily life is being enriched with the aid of advanced distributed systems such as cloud computing (e.g., Google Apps and Amazon EC2), social networking services (e.g., Twitter and Facebook), and on-line streaming services (e.g., YouTube and Ustream) which have a high computational availability compared with classical distributed systems with respect to the performance, reliability, usability, and the fault-tolerance. As the availability of such advanced systems increases, however, it has raised another crucial issue so that how to utilize miscellaneous resources distributed over the network in an efficient and productive manner. In fact, the resource management has been recognized as a key issue to realize an efficient utilization of fully distributed systems such as volunteer computing and peer-to-peer systems, and in the past three decades, a huge number of resource management schemes have been proposed (see [11], [3] for survey).

Computational grid, which is often called Grid, is an emerging technology to improve the utilization of shared resources in large-scale distributed systems. Grid has been used to solve many important problems in the field of business, finance, medicine, and Grand Challenge applications in many fields of science and technology. In addition, there are several national projects concerned with the development and the utilization of Grid, e.g., Fusion Collaboratory Project in United States [14], EU DataGrid in EU [15], China National Grid in China [12], NAREGI in Japan [13], and others. The reader should note that the resource management in Grid should satisfy the requirement from both of "clients" and "service providers." More specifically, from the client side, it is required that spending the least money and getting the highest satisfaction. On the other hand, from the service provider side, it is required to make a full utilization of given resources.

There are many resource management schemes proposed in the literature, and some of them could certainly improve the *efficiency of resource utilization* in Grid. Agent-based scheme [7] and reputation-based scheme [1] are two representatives in this direction. A resource management based on the notion of economics, which is referred to as Grid Economy, has also received considerable attention in the past few years [16], [8]. The Grid Economy provides mechanisms to trade-off QoS parameters, deadline and computational cost, and offers an incentive for relaxing their requirements. However, most of those conventional schemes are based on a classical model of distributed systems such that *resources should be assigned to clients so that a certain cost function is optimized subject to a certain constraint*. In other words, it defines the problem from the viewpoint of the system manager and ignores the "emotion" of individual clients (clients) such as incentive, satisfaction, and regret.

1.2 Our Contribution

To overcome such a critical problem existing in conventional schemes, in this paper, we adopt the notion of *market equilibrium* to satisfy requirements issued by clients and service providers. Market equilibrium is a key concept commonly used in the field of game theory. In this framework, we will determine the "price" of each resource owned by the service providers so that it fulfills the Nash equilibrium of the given market consisting of clients and service providers. More concretely, we assume the existence of a centralized manager, and instead of determining the price of resources using an autonomous (but one-sided) mechanism such as buyer initiated or seller initiated auction,

the price of resources will be determined by the centralized manager so that:

1) the satisfaction of each client is maximized, and
2) given resources are fully utilized.

The degree of satisfaction is modeled as a linear utility function which is independently defined for each client, and as a constraint concerned with the clients, we use the notion of budget in the price determination process.

As a concrete method to calculate such a market equilibrium, we focus on a polynomial time algorithm proposed by Devanur *et al.* in 2002 [9]. This algorithm calculates a market equilibrium using $O(n^4(\log n + n \log U + \log M))$ max-flow (maximum flow) computations, where n is the number of service providers, U is the maximum coefficient in the utility functions and M is the total money possessed by the clients at the initial state (the details of the algorithm will be described in Section 4). Thus, although it is in fact polynomial time and always outputs an exact solution, it rapidly glows as the size of the given instance increases. In this paper, we reduce the time complexity of Devanur *et al.*'s algorithm using the notion of *approximation*. More precisely, our proposed scheme is a *semi-algorithm* which calculates the price of resources maximizing the utility of clients provided that: 1) all resources are completely exhausted and 2) the surplus of the clients is at most ϵ for any $\epsilon > 0$, using $O(n \log(nM/\epsilon))$ max-flow computations. The reader should note that our scheme solves (slightly) different problem from the original problem in the sense that we allow the remaining of very small surplus (of at most ϵ) whereas such surplus is strictly prohibited in the original problem.

The performance of the proposed scheme is experimentally evaluated with respect to the following factors: 1) the percentage of instances successfully solved by the proposed scheme (recall that our scheme is not an algorithm but a semi-algorithm), 2) comparison of the execution time with the Devanur *et al.*'s algorithm, and 3) certification on the approximation, i.e., whether or not the surplus in the resultant solution is certainly smaller than given ϵ.

The reminder of this paper is organized as follows. Section 2 overviews related work. Section 3 defines a service model of Grid adopted in this paper. Section 4 outlines the primal-dual algorithm proposed by Devanur *et al.* Section 5 describes our proposed scheme. Section 6 shows the result of experiments. Finally, Section 7 concludes the paper with topics for future work.

2. Related Work

This section overviews several resource management schemes proposed in the literature which can be applied to the resource management in the Grid.

2.1 Economic Model

In order to encourage the incentive of the clients, Buyya *et al.* introduced the notion of economy to the grid environment [6]. In their model, the manager can increase the degree of satisfaction of the clients by allocating resources to the clients through an auction mechanism. The auction mechanism supports one-to-many negotiation between a service provider and a set of clients, and will derive a single value (i.e. price) as an outcome of the negotiation. The manager regulates rules of the auction, which should be acceptable for both of clients and service providers, and uses the "force from the market" so that the negotiation should derive a clearing price for the service.

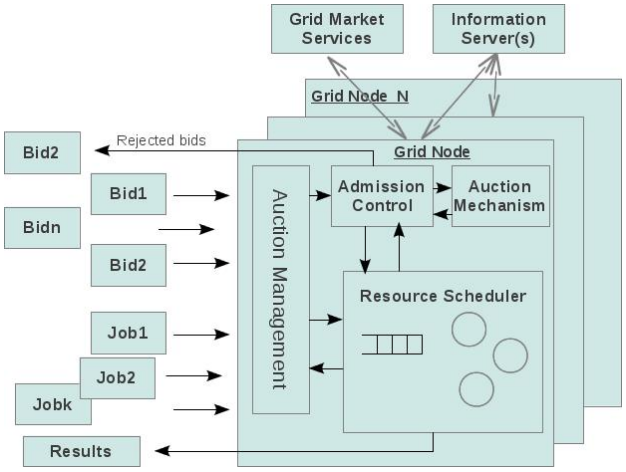

Figure 1: An auction mechanism proposed by Buyya *et al.*

An outline of the auction mechanism is illustrated in Figure 1. The steps of an auction process are as follows:

Step 1: A service provider (GSP in the figure) announces available services and invites bids from clients.
Step 2: Clients offer their bids (and they can see what other clients offer if it is an open auction).
Step 3: Step 2 goes on until no one is willing to bid a higher price or the auctioneer stops if the minimum price line is not met.
Step 4: The GSP offers the service to the one who wins.
Step 5: The consumer uses the offered resource.

To evaluate the performance of the scheme, Buyya *et al.* conducted experiments on the World-Wide Grid (WWG). From the experiments it can be observed that, the manager selects the most powerful but cheapest resources to process a given job, as cost minimization was the top priority as long as the deadline of all jobs could be met. This indicates that their economic model certainly realizes a mechanism to effectively control the trade-off among QoS parameters, deadline and the computational cost. However, this model has a flaw such that it could not fully utilize the given resources (i.e., it may waste a huge amount of resources) since it commonly occurs a situation in which the request of clients will concentrate on specific high quality resources. In addition, it could not maximize the satisfaction of the clients

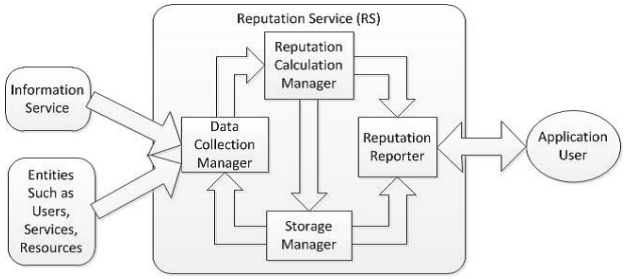

Figure 2: Architecture of a reputation service proposed by Alunkal *et al.*

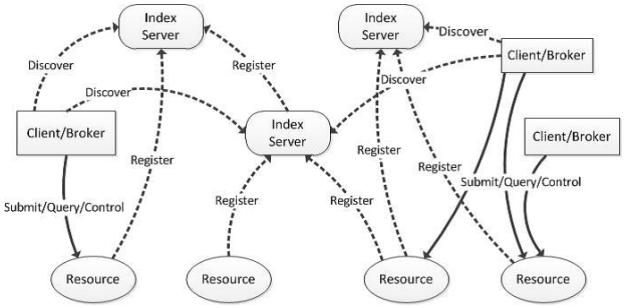

Figure 3: Interactions between resources, index servers and brokers.

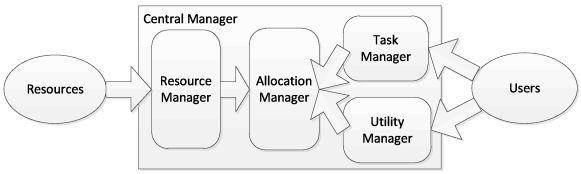

Figure 4: The structure of the central manager.

since under the auction mechanism, each client should pay much money to get a good resource although there may exist resources that are less attractive but with a reasonable price.

2.2 Reputation Model

Alunkal *et al.* introduced the notion of reputation to the resource management in Grid [1]. More concretely, their resource management scheme adopts the concepts of dynamic trust and reputation adaptation, which are based on the community experiences such as the classification, selection, and the tuning of the allocation of entities such as resources and services. They proposed a sophisticated architecture to select trusted resources which best satisfies the application requirements with respect to a predefined trust metric.

The overview of an individual reputation service is shown in Figure 2. It consists of a calculation manager, collection manager, storage manager and reputation reporter. The calculation manager is responsible for calculating the reputation value of the entities according to a prespecified context and providing the calculated values to the storage manager which stores them to maintain a global and historical view. The collection manager evaluates the quality statement, describes the requested reputation, and collects relevant data from the entities. The reporter contacts the storage manager to make a report whenever it is requested by the other clients in the Grid.

With the aid of reputation, Alunkal *et al.*'s model can reduce the influence of malicious entities, while it still ignores the satisfaction of clients. In addition, it faces to the same problem with the economic model such that the given resources could not be fully utilized in many cases.

2.3 Broker Model

Elmroth proposed a resource management scheme based on the notion of decentralized brokers [10]. The role of a broker is to select a resource which minimizes the completion time of a given job, considering the time for file staging, batch queue waiting, and the job execution. A grid architecture based on decentralized brokers is shown in Figure 3. In this architecture, each resource registers itself to at least one index server, where each index server can also register itself to index servers at a higher level; i.e., it forms a hierarchy of index servers. All clients can access resources only through their own broker, where each broker contacts index servers to discover what resources are available in the system. After acquiring the name and the contact of the resources from index servers, a broker requests individual resources for their detailed information, and performs job submission and job control by directly communicating with the resources.

3. Service Model

3.1 Model

The objective of resource management considered in this paper is described as follows. Consider a distributed system consisting of a set of resources A, a set of clients B, and a central manager C. Each resource in A models a particular service provided by the grid computer, e.g., disk space, CPU power, peripheral devices, and so on. Let $n = |A|$ denote the number of resources and $n' = |B|$ denote the number of clients. For each resource $j \in A$, the price p_j of the resource (per unit) is determined by the manager. Each client $i \in B$ is given budget e_i, and client i can request several kind of resources to maximize her profit, provided that the total expense does not exceed e_i.

The main role of central manager C is to manage the assignment of resources to the clients so that *all resources are completely assigned to the clients while maximizing the profit of each client*. In this system, such an assignment is realized by using a market model. More concretely, each

client selfishly tries to maximize its profit, and the total cost of requested resources does not exceed her budget. In order to "clear" such a market (i.e., in order to realize a situation in which all resources are assigned to clients and all clients exhaust their budget), central manager C can "control" the price of each resource. That is, by increasing the price of a resource, it becomes less attractive for all clients and it relaxes the congestion of requests to the resource, and by decreasing the price of a resource, we could attain a full utilization of the resource since it becomes attractive for all clients interested in the resource.

The objective of the central manager is to find a *market clearing price* such that a collection of selfish requests which maximizes the satisfaction of clients clears the market. In other words, under a market clearing price $\vec{p} = (p_1, \ldots, p_n)$, after each client is assigned an optimal set of resources relative to these prices, there is no surplus or deficiency of any of the resources. The structure of the central manager is illustrated in Figure 4. As shown in the figure, it consists of four components, i.e. task manager, utility manager, resource manager and the allocation manager, where the most important part is the allocation manager which is responsible for computing and allocating resources to the clients. Task manager is responsible for receiving tasks from the clients and utility manager is responsible for receiving the utility function from the clients. Finally, the role of resource manager is to manage the resources coming to or leaving from the system.

3.2 Utility Function

As was described previously, we model the satisfaction of clients by a collection of utility functions. In this paper, we assume that the utility functions are linear with respect to the amount of assigned resources. Let $x_{i,j}$ be the amount of resource j assigned to client i under price vector $\vec{p}$. Then, the utility of client i with respect to the assignment is represented by

$$\sum_{j=1}^{n} u_{i,j} \times x_{i,j}$$

using n constants $u_{i,1}, \ldots, u_{i,n}$. The reader should note that such an assumption on the linearity of utility functions makes the analysis of algorithms much easier than the case of other utility functions such as concave ones, although it is less practical than those general ones. In fact, in actual situations in the real world, it is unlikely that the degree of satisfaction "linearly" increases as increasing the amount of acquired resources, e.g., although a kid could increase her satisfaction twice as increasing the number of candies from one to two, her satisfaction does not increase to the twice by increasing the number of candies from one hundred to two hundreds.

3.3 Match Making in Grid

A typical scenario for the match making in Grid proceeds as follows. At first, all clients register their utility function to C. Tasks issued by the clients are managed by C in a synchronous manner i.e., C repeats synchronous rounds in each of which:

1) tasks issued by the clients are received at the beginning of a round,
2) tasks are assigned resources, and
3) assigned resources are used by the tasks until the beginning of the next round.

As was mentioned previously, how to calculate an appropriate assignment is the main concern in this paper.

4. Original Algorithm

4.1 Graph $N(\vec{p})$

The following price determination algorithm is borrowed from [9]. The goal of this algorithm is to find a price vector $\vec{p^*}$ such that both resources and budgets are exhausted under $\vec{p^*}$. Since the budget is limited and we are assuming linear utility functions, for any price vector $\vec{p}$, a reasonable client wishing to maximize her profit must spend her money to the resources which maximize her profit per price, i.e., $u_{i,j}/p_j$. In other words, $\alpha_i = \max_j \{u_{i,j}/p_j\}$ is considered to be the *bang per buck* for client i. Note that client i is interested in any resource j such that $u_{i,j}/p_j = \alpha_i$, and if there are several such resources, she is equally happy with any combination of such resources.

To represent such a preference of clients (under price vector $\vec{p}$), we use a directed capacitated graph $N(\vec{p}) = (V, E)$, which is defined as follows:

- $V = A \cup B \cup \{s, t\}$, where A is the set of resources, B is the set of clients, and s and t are vertices which are not contained in $A \cup B$.
- For any $j \in A$ and $i \in B$, $(i, j) \in E$, $(s, j) \in E$, and $(i, t) \in E$.
- Edge (i, j) connecting vertices in $A \cup B$ is given infinite capacity, edge (s, j) is given capacity p_j, and edge (i, t) is given capacity e_i. Note that p_j is the price of resource j and e_i is the budget given to client i.

By definition, any combination of resources allocated along the edges of $N(\vec{p})$ will make clients happiest under price vector $\vec{p}$. Computing the largest amount of resources which can be allocated in this manner, without exceeding the budget of clients or the amount of resources available, can be accomplished by computing a max-flow in $N(\vec{p})$.

With graph $N(\vec{p})$, the algorithm tries to increase the price of each resource starting from an initial price vector, by keeping an invariant such that

"$(\{s\}, A \cup B \cup \{t\})$ is a min-cut of graph $N(p)$."

See Figure 5 for illustration. This invariant ensures that all resources can be allocated to some clients (i.e., exhausted)

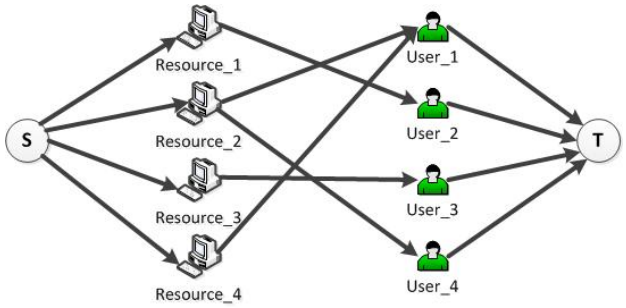

Figure 5: Network $N(p)$.

and an increase of the price vector monotonically decreases the surplus money of each client. In other words, it guarantees that when the surplus vanishes, a market clearing price vector which exhausts all resources and all budgets, is obtained.

4.2 Tight Sets

The second idea of the algorithm is to identify a set of resources whose price is to be "frozen" during the succeeding steps of the algorithm. Such a set of resources is called a tight set, which is formally defined as follows: For a set $S \subseteq A$ of resources, let $p(S)$ denote the total expense of resources in S, and for a set $T \subseteq B$ of clients, let $m(T)$ denote the total money possessed by the clients in T. Let $\Gamma(S)$ denote the set of clients adjacent to S; i.e., $\Gamma(S)$ is the set of clients who are interested in a resource in S at the current price vector $\vec{p}$. A resource set S is said to be **tight** if it holds $p(S) = m(\Gamma(S))$, i.e., if the expense of S exactly equals to the money possessed by the clients interested in S. The reader should note that clients in $\Gamma(S)$ are completely satisfied with the current prices of S, and such a satisfaction does not change even if we increase the price of the other unfrozen resources.

In the algorithm, the price of unfrozen resources monotonically increases, where instead of increasing the price of all resources at the same time, we focus on a subgraph of $N(\vec{p})$ called active graph, and try to increase the price of resources in the graph (detailed definition of the active graph will be given later). The price of resources in the active graph is conducted in such a way that it ensures that *the edges in the active graph are retained during the increasing process* (i.e., it does not become "too high"). To this end, we (uniformly) multiply the price of these resources by x and gradually increase x. It is shown in [9] that we will have a tight set when x is set to the following value:

$$x^* = min_{S \subseteq A} \frac{m(\Gamma(S))}{m(S)}.$$

Here value x^* and the corresponding tight set S^* can be found in polynomial time using n max-flow computations.

4.3 Balanced Flows

Given a flow f in network $N(\vec{p})$, the **surplus** of client i denoted by $\gamma_i(\vec{p}, f)$, is the residual capacity of edge (i, t) with respect to f, which equals to e_i minus the flow sent through (i, t). Let $\gamma(\vec{p}, f) := (\gamma_1(\vec{p}, f), \gamma_2(\vec{p}, f), \ldots, \gamma_n(\vec{p}, f))$ denote the surplus vector of clients with respect to $\vec{p}$ and f. In order to accelerate the increase of $\vec{p}$, the algorithm focuses on resources adjacent to "high-surplus" clients, since it would increase the chance of significantly increasing the price while keeping the invariant. However, the surplus of clients may take different values for different maximum flows even in the same graph. Thus, in order to well-define the surplus of clients, the algorithm defines a kind of canonical flow defined as follows: Given a price vector p, a maximum flow that minimizes $||\gamma(\vec{p}, f)||$ over all choices of f is called a **balanced flow**, where $||\vec{v}||$ denotes the l_2 norm of vector $\vec{v}$. If $||\gamma(\vec{p}, f)|| < ||\gamma(\vec{p}, f')||$, then we say f is more balanced than f', and for a given $\vec{p}$ and a flow f in $N(\vec{p})$, we denote the residual network of $N(\vec{p})$ with respect to f by $R(\vec{p}, f)$.

4.4 Main Algorithm

The main idea of the algorithm is to reduce $||\gamma(\vec{p}, f)||$ in every phase. This goal is achieved by finding a set of high-surplus clients in the balanced flow and by increasing the price of resources interested by the clients, i.e., resources adjacent to the high-surplus clients in $N(\vec{p})$. If a subset of resources becomes tight after such an increase, then we have reduced $||\gamma(\vec{p}, f)||$ since the surplus of high-surplus clients is now dropped to zero. Another possibility is that a new edge is added to $N(\vec{p})$, but such an edge will also help us to make the surplus vector more balanced.

In each phase, it identifies a subgraph of $N(\vec{p})$ induced by a set of clients $H \subset B$ and a set of resources $H' \subset A$ where initially, H is the set of clients whose surplus equals to the maximum surplus δ in B and H' is the set of resources adjacent to H. Such a subgraph is called **active graph**. As was previously described, the price of resources in the active graph increases in such a way that all edges in the graph retained, which can be ensured by multiplying the price of resources in the subgraph by x, and by gradually increasing x. Each phase is divided into several iterations. In each iteration, x increases until either a new edge is added to $N(\vec{p})$ or a subset of resources becomes tight. In the former case, we recompute the balanced flow f, and add all vertices which can reach a member of H in $R(\vec{p}, f) \setminus \{s, t\}$ to subset H. If a subset becomes tight as a result of increase, the iteration terminates. If A becomes tight, the algorithm terminates.

Finally, the initial price vector satisfying the invariant is determined as follows [9]:

- Fix the price of each resource to $1/n$.
- If there exists $j \in A$ such that $\Gamma(\{j\}) = \emptyset$ (i.e., if no client is interested in resource j due to high price), then

reduce the price of j to $\max_i\{\frac{u_{i,j}}{\alpha_i}\}$, and repeat such a modification until no such resource exists.

5. Proposed Scheme

In this section, we propose a scheme to find a market-clearing price vector in an approximated manner. The time complexity of the proposed (semi-)algorithm is mush lower than the original (exact) algorithm described in Section 4, although it merely generates an approximated solution to the problem in the sense that the amount of remaining budget is at most ϵ for any $\epsilon > 0$. Similar to the previous section, in the following explanation, we will continue to use graph $N(\vec{p})$ to represent the relation between the set of resources A and the set of clients B under the given price vector $\vec{p}$, while there are two additional vertices s and t, as before. The reader should remind that in graph $N(\vec{p})$, client i is connected with resource j by an edge if and only if j is a resource which maximizes u_{ij}/p_j.

5.1 Algorithm

Similar to the original algorithm, the proposed algorithm starts with finding a price vector which does not violate the invariant, which is ensured by making the sum of prices is less than or equal to the surplus of clients. The algorithm is divided into phases. In each phase, it identifies an active graph consisting of a set of clients $H \subset B$ and a set of resources $H' \subset A$, and increases the price of resources contained in H', i.e., the price of resources not in H' is not increased. Such an increase of the price is conducted in such a way that the edges in the active graph are retained, which is ensured by multiplying the price of all resources in H' by x and by gradually increasing x from 1, as before. Let δ be the maximum surplus in B (under current price vector $\vec{p}$). Initially, active graph is constructed such that H is a set of clients whose surplus equals to δ and H' is the set of resources adjacent to H. Let $p(H')$ be the sum of prices of resources in H' and $m(H)$ be the total money possessed by the clients in H. In order to accelerate the increase of parameter x, in the proposed algorithm, we repeat to "double" the value of x to find a sufficiently large value, and then conduct a binary search to find a value satisfying the given approximation ratio.

More concretely, in the first step, we double the value of x until one of the following conditions holds:

Case 1: $m(H) - \epsilon/n < p(H') \leq m(H)$,
Case 2: $p(H') > m(H)$, or
Case 3: (i, j) with $i \in H$ and $j \in A \setminus H'$ becomes an edge in the active graph.

In Case 1, it terminates the phase by moving all resources in H' to the frozen set. It then recomputes the balanced flow to obtain a new active graph for the next phase. If we met Case 2 for the first time, on the other hand, it starts a binary search to find x satisfying Case 1. For example, if $x = 128$, the value of x is updated as $(128 + 64)/2 = 96$. If the updated value still meets Case 2, the value further reduces to $(64 + 96)/2 = 80$ while it increases to $(128 + 96)/2 = 112$ if it meets neither of Cases 1 and 2 at $x = 96$. Such an update-and-check is repeated until it meets Case 1.

Finally, in Case 3, it tries to find the largest x using another binary search such that all resources existing in the last active graph are still being members of the new active graph, i.e., every resource in the active graph consisting of old and new resources is connected to the clients in the active graph so that the mount of budgets of those clients is at least the current price of the resource (such a condition is necessary to guarantee that all resources are exhausted). If it could not identify such x, *it terminates the algorithm without outputting a solution*. However, if there is such x, after adding new resources and all clients interested in the set of resources to the active graph, and starts the procedure from the beginning of the phase.

5.2 Analysis

The correctness and the time complexity of the algorithm are proved in the following claims.

Theorem 1: If the proposed algorithm outputs a price vector $\vec{p^*}$ as the solution, it guarantees that under $\vec{p^*}$ all resources are exhausted and the surplus of the users is at most ϵ.

Proof: By the description of the algorithm, when resources in set H' is moved to the frozen set, the surplus in H, which is the set of clients interested in H', is at most ϵ/n. Set H' is not empty even in the worst case. In addition, each user is interested in at least one resource at the initial price and all resources in A should be eventually moved to the frozen set if it outputs a solution. Thus, we can conclude that the surplus of users in B is at most ϵ after the termination of the algorithm. ■

Let M denote the total budget initially given to the clients in B, i.e., $M = m(B)$. Let k be the number of iterations spent to meet Case 1 in a phase. An upper bound on k could be given as in the following lemma.

Lemma 1: $k = O(\log \frac{nM}{\epsilon})$.

Proof: Since the doubling of x is repeated at most $\lceil \log_2 M \rceil$ times, it takes $O(\log M)$ time to identify an upper bound on the target value. After identifying the upper bound, it takes $O(\log M)$ time to identify a range of size one including the target value since the upper bound is at most M, and it needs $O(\log(n/\epsilon))$ additional time to identify the target within a range of size at most ϵ/n. Thus the lemma follows. ■

The time complexity of the proposed scheme is proved in the following theorem.

Theorem 2: The proposed scheme executes at most $O(n \log \frac{nM}{\epsilon})$ max-flow computations.

Proof: Since each phase moves at least one resource to the frozen set, the algorithm repeats the phase at most n

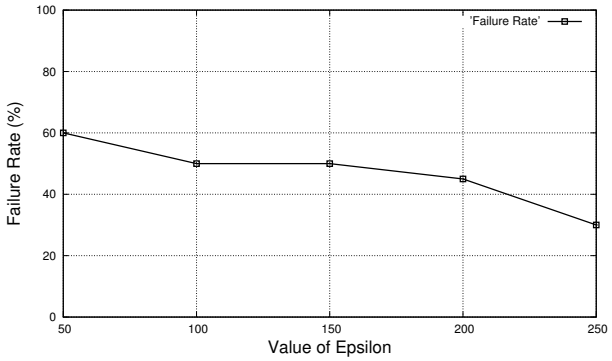

Figure 6: Failure ratio of the proposed algorithm.

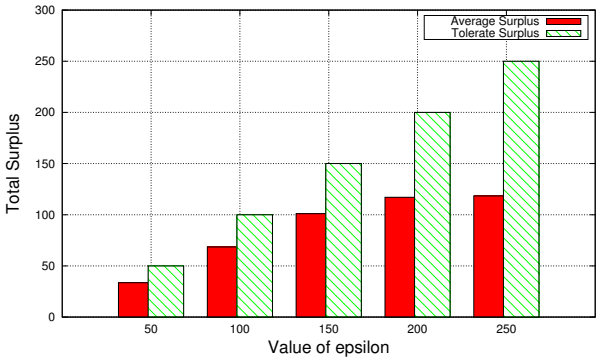

Figure 7: Guaranteed surplus and average surplus.

times. In each phase, it executes the max-flow computation in one of the following three cases: 1) at the beginning of the phase to identify an initial active graph, 2) after increasing the value of x to check which of Cases 1, 2 and 3 is met, and 3) after encountering Case 3 to identify an updated active graph. The third case occurs at most n times during the execution of the algorithm, since once a resource is included in an active graph in a phase, it is moved to the frozen set at the end of the phase or the algorithm gives up to output a solution. By Lemma 1, the increase of x is repeated $O(\log \frac{nM}{\epsilon})$ times in each phase. Thus the total number of executions of max-flow computation is given by $O(n \log \frac{nM}{\epsilon})$. Hence the theorem follows. ■

6. Experiments

6.1 Setup

We experimentally evaluated the performance of the proposed scheme using GridSim environment [5]. In the simulation, we consider a Grid consisting of 100 resources and 100 users (i.e., $n = n' = 100$). The budget of each user is 100 dollars, so that the total budget is 10000 dollars, and the initial price of each resource is randomly selected from 10 to 50 dollars. We use MIPS (Million Instructions Per Second) value to represent the characteristic of resources. The MIPS value of each resource is randomly selected from range $[300, 500]$ and the MIPS value requested by each user is randomly selected from range $[200, 400]$. The value of ϵ is varied as 50, 100, 150, 200 and 250, and for each value of ϵ, we conducted 20 runs. Finally, as the concrete max-flow algorithm, we used the Edmonds-Karp algorithm [17].

6.2 Results

The result of simulations is summarized as follows. At first, we evaluated the ratio of failed instances for each ϵ. The result is shown in Figure 6. The ratio gradually decreases as ϵ increases, and in total, it successfully outputs an approximated solution for 53% of the examined instances (even if ϵ is set to 0.5% of the given budget, it successfully outputs an approximated solution for 40% of the instances). As for the average execution time, we found that for any ϵ, it takes less than 3 sec for succeeded instances whereas it takes less than 0.5 sec for failed instances. Since the original exact algorithm proposed by Devanur *et al.* takes more than 5 min for the same instances, we can conclude that the proposed scheme effectively gives an approximated solution provided that it is executed as a preprocessor of Devanur *et al.*'s algorithm.

Parameter ϵ represents the maximal surplus at the end of succeeded computation. Thus finally, we evaluated the average surplus for the succeeded instances. Figure 7 shows the results. From the figure, we can observe that the average surplus is much less than ϵ, and specifically, we could attain an average surplus of 120 when we set ϵ to 250.

7. Concluding Remarks

In this paper, we propose a resource assignment scheme for computational grid based on the notion of market equilibrium. The proposed scheme is a semi-algorithm which outputs an approximated solution by using $O(n \log(nM/\epsilon))$ max-flow computations if it successfully terminates.

There are several issued to be addressed as the future work. The first issue is to increase the success ratio of the proposed scheme. To this end, we need to refine the scheme so that the change of the configuration of the active graph is appropriately managed. The second issue is to reduce the execution time. Although it could certainly reduce the number of max-flow computations in the original algorithm, it is still too large since the max-flow computation is an expensive task.

Dynamic Farm Skeleton Task Allocation Through Task Mobility

Turkey Alsalkini[1], Greg Michaelson[1]
[1]Computer Science Department, Heriot-Watt University, Edinburgh, UK
(ta160, G.Michaelson) @ hw.ac.uk

Abstract—*Demand for multi-process resource invariably outstrips supply and users must often share some common provision. Where batch-based, whole processor allocation proves inflexible, user programs must compete at runtime for the same resource so the load is changeable and unpredictable. We are exploring a mechanism to balance the runtime load by moving computations between processors to optimize resource use. In this paper, we present a generic algorithmic farm skeleton which is able to move worker tasks between processors in a heterogeneous architecture at runtime guided by a simple dynamic load model. Our experiments suggest that this mechanism is able to effectively compensate for unpredictable load variations.*

1 Introduction

In recent years, there has been a dramatic increase in the amount of available computing and storage, but dedicated High-Performance Computers are expensive and rare resources. Emerging multiprocessor architecture techniques offer the opportunity to integrate individual high-performance computers into a unitary high-performance system. This entails several technical challenges: difficulty of effective utilization, high communication latency, and unpredictable effective speeds.

Researchers are investigating the possibility of exploiting the computational power and resources available in global networks. Mobile computation is a way to use the resources available on both local and global networks. Mobile computation gives the programmer control over the placement of code or active computations across a network to chart and better use the available computational resources. A mobile program can transport its state and code to another location where it resumes execution [27], so in an application that uses mobile computation, the program can move between locations for better utilisation of computational resources. By using load management techniques, the program has a mechanism for distributing the tasks to worker locations to achieve performance goals (balancing the load or minimising the execution time).

The main obstacle to the commercial uptake of parallel computing is the complexity and cost of the associated software development process. A promising way to overcome the problems of parallel programming is to exploit generic programs structures, called skeleton [17]. Skeletons capture common algorithms which can be used as components for building programs. The main advantage of the skeleton approach is that all the parallelism and communication are embedded in the set of skeletons.

We are exploring a mechanism to balance the runtime load by moving computations between processors to optimize resource use. In this paper, we present a generic algorithmic farm skeleton which is able to move worker tasks between processors in a heterogeneous architecture at runtime guided by a simple dynamic load model. Our experiments suggest that this mechanism is able to effectively compensate for unpredictable load variations.

2 Background and related work

Mobility, which refers to the change of location achieved by system entities [10], involves moving computations amongst processors on a network to distribute the load, giving better use of resources and a faster performance [25, 27]. Mobility has different forms: hardware and software mobility, process migration, mobile languages, weak and strong mobility. Hardware mobility means the mobility of devices, such as laptops and PDAs. In contrast, software mobility moves the computations from one location to another location [6], typically through process migration or mobile languages. In process migration, the system determines load movement e.g. MOSIX [4], which is an operating system that supports process migration. In contrast, in mobile languages, the system gives the programmer the ability to control load movement. Weak and strong mobility are alternative forms of mobility defined by Fuggutta and Picco and Vigna [5]. Weak mobility involves moving the code from one location to another. Strong mobility involves moving the code and state information from one location to another and resuming the execution from the stop state [26]. Strong mobility is also known as transparent migration. Many mobile languages support weak and strong mobility, e.g. JavaGo [2], but Java Voyager [3] supports only weak mobility. Checkpointing is the main operation in mobile systems

to move computations amongst processors in a network or cluster by snapshotting the state of application [14], e.g. CONDOR [11].

A novel Autonomous Mobile Program (AMP) decentralised load management technique has been developed by Deng [25]. AMPs seek to execute on "better" locations and take movement decisions depending on whether the resource needs can be served locally or on another location. This movement decision also depends on future resource needs, and whether it is better to continue locally or to move to another location.

Algorithmic skeletons offer an approach in parallel programming to abstract the complexities that exist in the parallel implementations [17]. They are common parallel programming patterns that avoid the parallel and communications details for the programmer so that they are not responsible for the synchronization between the application parts. Skeletons are closely related to functional languages, so higher order functional structures can be produced by using skeletons [9]. Each skeleton has an implicit parallel implementation hidden from the application user. The main advantages of using skeletons are having a higher order programming interface and a general implementation for portability and efficiency.

Skeletons are polymorphic higher order functions, so that there are various kinds of skeletons to cover different program classes over different data types [13]. These functions are implemented by libraries. Many implementations of computations on distributed and parallel architectures support skeletal libraries which offer task parallel and data parallel skeletons. An example of a C library with MPI functions is eSkel [18], and an example of a C++ library with MPI functions is SkeTo [16].

Google developed a C++ library that offers parallel programming model, called MapReduce [12]. The MapReduce skeleton is a programming model for processing large sets of data. This model has an abstraction level where it is possible to perform computational operations while hiding communication and parallelism details, fault-tolerance, and data distribution. This model has two primitives *map* and *reduce*. The *map* operation applies a function to pairs of key/value to produce output key/value; the *reduce* operation combines the shared key results to produce the final result. The mapped function is written by the user, and the user specifies the data sets with pairs. Similarly, the reduced function is also written by the user. The closely related open-source Apache Hadoop is a Java library used to process large data sets on distributed parallel architecture such as cluster [1].

A cost or performance model may be used to estimate the costs of programs such as time and space [24, 7]. While algorithmic skeletons involve the parallelism process, communication and coordination [8], their cost models typically measure the computation and communication cost. Many cost models have been developed for algorithmic skeletons on parallel architecture. Some models determine the task placement statically [15], while others determine the whole skeleton placement dynamically [24].

Our approach is based on dynamic task placement for skeletal programming. We have developed a parallel farm skeleton using C with MPI functions which is able to move tasks between workers while preserving the execution state during moving operation. We have explored three approaches to implementing mobility in our skeleton: data mobility, data and state mobility, and data, state and code mobility.

Data mobility involves moving the data between locations on a network [14]. For state mobility, the program can correctly save its state and resume work from the saved point properly. Code mobility involves moving the whole program code, as well as the data and execution state, to a different machine [5]. This paper proposes as task mobility approach of moving the data and state for a sub-computation between processors, rather than the whole program. Our skeleton is implemented using C and MPI, but MPI clones the code to the workers so there is no need for moving the code. Code mobility is difficult to implement in heterogeneous structures, and this remains future work for our research: our work is a first step in implementing a skeleton fully able to move arbitrary code amongst machines on a network.

3 An overview of hwFarm skeleton

Our skeleton has the name *hwFarm.* In general, the main idea of skeleton is to abstract all the parallelism and communication details, but the *hwFarm* skeleton is also able to move tasks amongst the worker processors at run-time.

The hwFarm skeleton:

- is self-mobile which means that our skeleton is able to mobilize the task from one worker to another one during task execution when the overhead increases;
- supports parallelism on a distributed memory, high-performance architecture;
- hides parallelism and communication details from the program;
- presents a high-level function implemented using C and MPI [20].

3.1 Definition of hwFarm skeleton

The term task farming is used to describe parallel applications that have specific properties. Ordered and structured collections of data items, known as tasks, are each processed by the same operation. Processing the task can be performed in parallel because the tasks are independent [19]. In general, the static scheduling

of tasks to a similar number of processes gives poor load balancing. A task farm solves this by implementing dynamic scheduling to ensure a better balance. The farmer acts as the scheduler while the workers process the tasks assigned by the farmer. The h*wfarm* skeleton has the same characteristics but with the ability to move its tasks amongst workers.

The implementation is divided into three steps:

1) *Implementing skeleton with workers without mobility*: This is a simple skeleton which contains a farmer responsible for distributing the tasks to the workers executing these tasks, as shown in "Fig. 1".

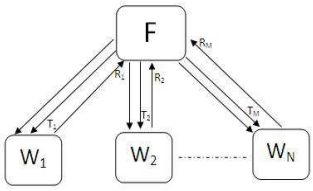

Figure 1. Standard skeleton

2) *Implementing skeleton where data has been sent between two workers*: This is the first step in making a task mobile, but the task will be processed by the worker from the beginning. See "Fig. 2".

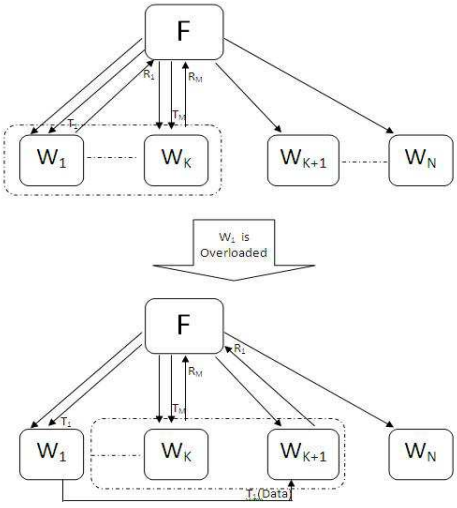

Figure 2. Skeleton with task mobility (data only)

3) *Implementing skeleton where data and state have been sent between two workers*: The skeleton can move the data and state of the task between workers. The moved elements contain the processed data and unprocessed data, so the target machine will start processing not from the beginning of the data but from the beginning of the unprocessed data. A fuller explanation of the implementation will be given in the next section. See "Fig. 3".

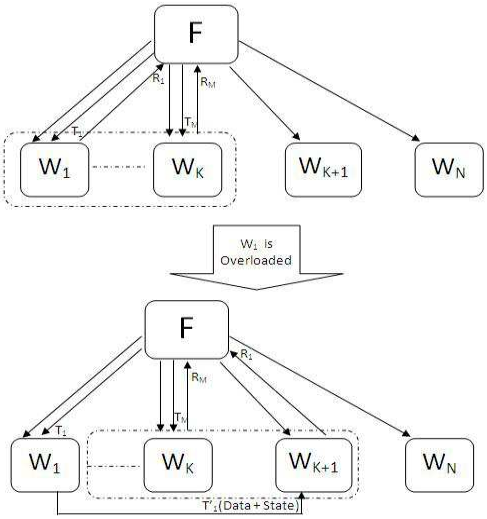

Figure 3. Skeleton with task mobility (data and state)

3.2 How to move state?

The mobility process needs to save the state of execution to continue working from the stop state. As noted, the skeleton hides the parallel and communication details from the programmer so that the programmer is not responsible for the synchronisation between application parts. The programmer has to write their own general function that should be executed by the skeleton. This function has three arguments: the input data to be processed, the output data which is the result, and parameters for the user function. An array of parameters contains the variables that the function needs to process the data. The state of execution depends on the values of these parameters. During mobility, the skeleton moves the input data that was not yet processed by the first worker, the sub-the result of the processed data and the array of parameters for the function at stop point. The new worker receives this data and continues processing from the stop point.

3.3 Movement decision:

One of the biggest issues in parallel and distributed systems is developing techniques for distributing processes to multiple locations [24, 23], to minimize the execution time and increase performance. Our skeleton balances load by using information collected from machines at run time to move a task from heavily loaded processors to lightly loaded processors.

The movable element in our skeleton is the task. The task computes the function for specific data so for task mobility we should move the function and the data. Since the function already exists in all workers, we only move the data and state between workers.

A movement decision by a skeleton depends on several polices:

- Information policy: Determines the load information to make a task placement or task mobility. This information is collected from the processors at runtime to know their load changes.
- Selection policy: Decides what task should be moved. The movement decision is taken by collaboration between the master and workers. A worker decides if its task should be moved depending on its load and the load on free workers. When the worker decides to move its task, it sends a request to the master.
- Placement policy: Identifies where a task should be transferred. The worker, after deciding that it is unable to process its task, or becomes heavily-loaded, determines the best free worker available to process the task.

3.4 Activities of hwFarm skeleton:

The sequence of activities that may happen during the execution of the skeleton is:

- The load of all workers in a system is acquired;
- The best workers are chosen where the number of workers is static. The system load in a worker, also known as its load average, is the measure of the amount of work that a computer system performs. The load average represents the average system load over a period of time. It is most easily available from a host operating system in the form of three numbers which represent the system load during the last one, five-, and fifteen-minute period [21]. The hwFarm skeleton assumes that the load for the last one-minute period;
- Each worker sends load information to the master, and then the master sends the load information to all workers;
- The tasks are distributed to the chosen workers;
- The master (farmer) awaits the results from workers and distributes new tasks;
- When the master receives a result, it will check the load for all free workers and then choose the best one to send the next task to;
- Depending on the load and percentage of increased load in this worker and the load on free workers, the worker decides if the task should be moved to a free worker or not.
- The task may then be moved from one worker to a new worker, and the destination worker continues executing the task from the stop point.

4 Experiments

In these experiments, we evaluate the performance and the behaviour of the hwFarm skeleton on heterogeneous distributed memory architecture. We use a ray tracer program that generates the image for 100 rays for 150000 objects in the scene. A ray tracing algorithm is used to produce an image by imaginary rays of light from the viewer's eye through pixels to the objects in the scene [22].

4.1 Platform:

The hwFarm skeleton is tested with a Beowulf cluster located at Heriot-Watt University. The cluster consists of 32 eight-core machines (8 quad-core Intel(R) Xeon(R) CPU E5504, running GNU/Linux at 2.00GHz with 4096 kb L2 cache and using 12GB RAM).

4.2 Evaluation:

The skeleton is tested in 4 modes:

- *Static task allocation*: The skeleton places the tasks without using load information; we will refer to this mode as *Static*. See "Table 1".
- *Dynamic task allocation*: The skeleton depends on load information collected from [processors for placing the tasks but without mobility; we will refer to this mode as *Dynamic*. See "Table 2".
- *Dynamic task allocation with load and no mobility*: The skeleton uses the load information for placing the tasks but without mobility. In this case, additional loads will be applied in different periods to some workers; we will refer to this mode as *Load*. See "Table 3".
- *Dynamic task allocation with load and mobility*: The skeleton balances the load by moving tasks from heavily loaded workers to lightly loaded workers where additional loads are applied to workers; we will refer to this mode as *Mobility*. See "Table 4".

The results of these experiments presented in the following tables:

Table 1. STATIC TASK ALLOCATION TIME(SEC)

Tasks / Workers	1	2	3	4	5
1	186.363	184.034	188.476	187.443	188.626
2	186.681	97.948	121.437	97.304	110.800
3	187.031	97.580	68.674	88.795	74.177
4	186.276	97.411	69.121	50.945	71.665
5	186.321	97.707	68.602	51.323	43.105

Table 1 shows that our skeleton gives good speed with the ray tracer program and static task allocation.

Table 2. DYNAMIC TASK ALLOCATION TIME(SEC)

Tasks / Workers	1	2	3	4	5
1	193.168	186.973	185.559	187.703	185.978
2	193.227	96.788	120.203	93.854	107.920
3	193.664	97.462	70.462	87.707	74.052
4	194.076	98.460	69.216	53.102	71.751
5	193.043	98.474	69.074	52.977	43.500

Table 2 shows show that our skeleton retains good speed with some modest difference in result from collecting and computing load information.

Table 3. DYNAMIC TASK ALLOCATION WITH LOAD AND NO MOBILITY TIME(SEC)

Tasks / Workers	1	2	3	4	5
1	335.513	292.372	316.453	309.019	294.252
2	332.121	166.745	192.063	154.189	162.842
3	297.927	167.259	113.712	140.200	121.476
4	298.318	163.596	116.965	95.658	80.906
5	300.889	151.549	110.554	93.430	79.428

Table 3 shows that the skeleton may retain speed when there is additional external load but worker performance deteriorates and execution time became slower.

Table 4. DYNAMIC TASK ALLOCATION WITH LOAD AND MOBILITY TIME(SEC)

Tasks / Workers	1	2	3	4	5
1	329.445	315.098	312.860	311.969	291.501
2	195.449	137.300	131.514	135.443	121.701
3	196.673	127.245	103.468	93.554	94.028
4	197.781	109.565	92.112	71.096	73.512
5	197.454	105.680	83.069	69.257	62.329

Table 4 shows that the performance is improved with task mobility when local loads change. However, the performance is still worse than for the *static* and *dynamic* modes.

The following graphs compare the execution time of the program with different numbers of tasks on different numbers of workers.

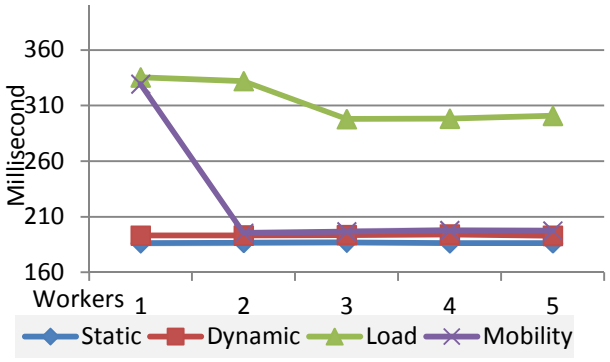

Figure 4. 1-5 Workers, 1 Tasks

Figure 4 shows the time for executing one task on 1 - 5 workers. The execution time in the *static* and *dynamic* modes is approximately the same; the difference comes from the cost of computing and collecting load. The execution time in the *load* mode depends on the load applied to the workers. In the *mobility* mode, the task is moved to a free worker when the current worker becomes unable to effectively process the task, so the execution time will be smaller. The task will not be moved when there are no free workers.

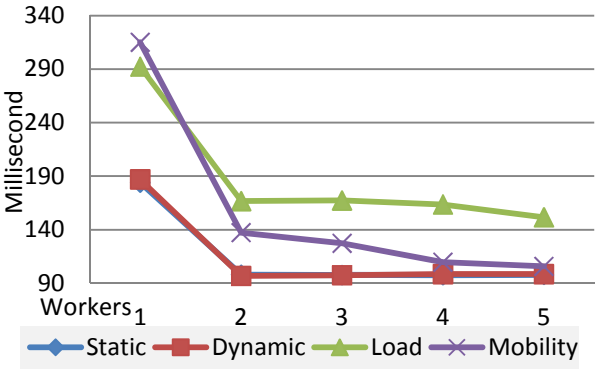

Figure 5. 1-5 Workers, 2 Tasks

Figure 5 shows the time for executing two tasks on 1 - 5 workers. In the *static* and *dynamic* modes, the execution time is approximately the same. The improvement in the *mobility* mode comes from moving the tasks from heavily loaded workers to lightly loaded workers.

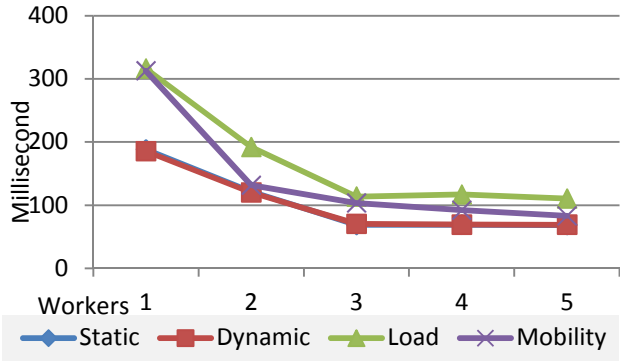

Figure 6. 1-5 Workers, 3 Task

Figure 6 shows the time for executing three tasks on 1 - 5 workers. The improvement of execution time in the *mobility* mode is related to the availability of free workers.

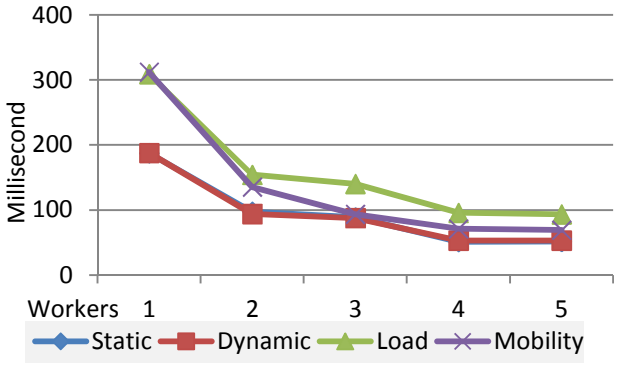

Figure 7. 1-5 Workers, 4 Tasks

Figure 7 shows the time for executing four tasks on 1 - 5 workers. The time in the *mobility* mode approaches the time in the *static* and *dynamic* modes.

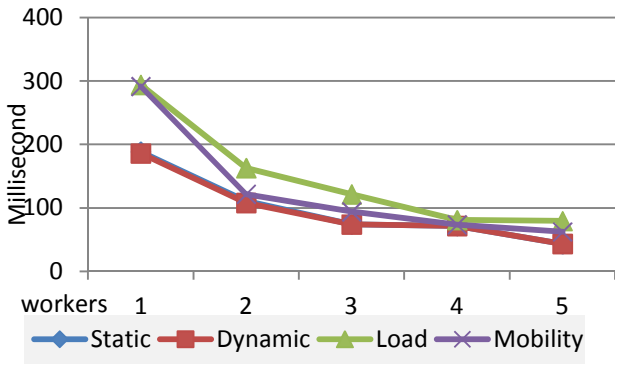

Figure 8. 1-5 Workers, 5 Tasks

Figure 8 shows the time for executing five tasks on 1 - 5 workers. The executing time in *mobility* mode is better than the executing time in *load* mode but is still worse than the *static* and *dynamic* modes.

5 Conclution and future work

We have proposed a new type of skeleton for high performance, distributed memory architecture. This skeleton is implemented using C and MPI library. This skeleton is self-mobile and able to move tasks from a heavily- loaded to a lightly-loaded worker. Our experiments show that, for the ray tracer program with small numbers of processors, the hwFarm skeleton is able to mitigate the performance effects of external load on individual processors by dynamically moving tasks across processors

We next intend to conduct considerably larger scale experiments, on much larger numbers of processors, with a variety of applications, systematically exploring mobile task behaviour in the presence of different patterns of external load. To aid this, we propose to construct a "load skeleton" which runs alongside an hwFarm application program to apply additional loads in predictable ways.

In future work, the hwFarm skeleton will be extended to be able to move code, as well as data and state, amongst processing units. In addition, we will define a richer cost model for the skeleton to take account of heterogeneity in the processing environment.

Appendix:

Using *hwFarm* skeleton

The prototype of hwFarm skeleton is implemented in C and MPI. Our skeleton gives the programmer the ability to write their program in a sequential manner in C . They should specify the input data and identify the high-ordered function which represents our skeleton to run the program with all data in an implicit, parallel manner. Our implementation uses the MPI library to provide the communication, so we need to initialise the library before calling the skeleton.

There are some constraints on the programmer in writing the function which must have six parameters: the input data and its length, the output data and its length, and an array of parameters used in the function and its length, and these values should be initialised before function.

The main steps to write a parallel program using hwFarm skeleton are:

- Write the sequential code that should be executed in parallel on the data items as a parameterised function above.
- Initialise the MPI library.
- Initialise the input data.
- Call the hwFarm skeleton.
- Finalise the MPI library.

The prototype of the main function of hwFarm skeleton is :

```
void hwfarm(fp worker, int tasks,
        void *input,int inSize,
        int inLen, MPI_Datatype taskType,
        void* output, int outSize,
        int outLen, MPI_Datatype
        resultType, void*FunPars,
        int parsSize, int procCount)
        {...}
```

Glossary of parameters:

```
worker:     worker function.
tasks:      total number of tasks.
input:      array of input data.
inSize:     size of input data type.
inLen:      size of one task.
taskType:   type of MPI input data.
output:     array to output data.
outSize:    size of output data type
outLen:     size of data in one
resultType: type of MPI output data
FunPars:    array of function parameters
parsSize:   size of parameters
procCount:  number of processors
```

We assume that the chunk size and number of workers are static but may be made dynamic by the skeleton.

The prototype of the general function that the user writes to be called from the hwFarm skeleton is:

```
void doProcessing(
      void *inputData,int inputLen,
      void *result, int outputLen,
      void* pars, int parsSize)
      {...}
```

Glossary of parameters:

```
inputData:  input data.
inputLen:   length of input data.
result:     output data.
outputLen:  length of input data.
pars:       array of paremeters.
parsSize:   length of parameters.
```

Each worker will execute their task by calling the *doProcessing* function on their data chunk. All variables the function need should be parameterised so we can save the execution state of the function.

Scheduling Data- and Compute-intensive Applications in Hierarchical Distributed Systems

Abstract*— *The growing computerization in modern academic and industrial sectors is generating huge volumes of electronic data. Hierarchical distributed systems based on Grid and Cloud technologies promise to meet the tremendously rising resource requirements of heterogeneous, large-scale and distributed data mining applications. Scheduling plays a pivotal role in such environments. While most schedulers addressing these new challenges have a strong focus on compute-intensive applications, we introduce a new scheduling algorithm to support both compute- and data-intensive applications in dynamic, heterogeneous, hierarchical environments. The developed data-aware scheduling algorithm aims to minimize the completion times of the applications as well as their costs leading to an efficient utilization of all available resources. The algorithm is specifically designed for combined storage and compute resources as these allow jobs to be executed on resources storing the data sets and thus are the key to avoid time-consuming and expensive data transfers. Simulations and first real-world usage experiences in the Fleet Data Acquisition Miner for analyzing the data generated by the Daimler fuel cell vehicle fleet show that the algorithm is suited for the different aspects of today's data analysis challenges.

Keywords- data-intensive; scheduling; Cloud; Grid.

I. INTRODUCTION

Increasing data volumes in many industrial and academic sectors are fueling the need for novel data analysis solutions to extract valuable information. Data mining, as the key methodology to address these information needs, requires effective and efficient resource management to transform the growing data into knowledge. There have been multitudes of efforts to provide specialized resource management solutions for complex data mining scenarios, including peer-to-peer data mining, distributed data stream mining and parallel data mining [1] [2].

Recently, data mining research and development has put a focus on highly data-intensive applications. Google's publications on MapReduce [3][4] inspired many projects working on large data sets. MapReduce frameworks, like Hadoop [5], simplify the development and deployment of peta-scale data mining applications leveraging thousands of machines. MapReduce frameworks are highly scalable because the scheduler uses data location information to avoid data movement and rather send the algorithms to the data.

Other current distributed data mining research is motivated by the sharing of heterogeneous, geographic distributed, dynamic resources from multiple administrative domains to support the cooperation of different organizations [6] [7] [8]. This field is generally referred to as data mining in Grid computing environments and is highly related to the Cloud computing paradigm. Most research focused on compute-intensive applications following scheduling principles that are correct for compute-intensive, but not for data-intensive data mining applications. Though different scheduling algorithms have been proposed to optimize the relation between data transfer and execution time [9][10] [11], for data-intensive applications where the limiting factor is not CPU-power but rather storage and network speed, the underlying architecture and environment assumptions may lead to non-optimal schedules. In addition, with the almost unlimited resources available through Cloud providers the traditional scheduling concept where jobs have to be assigned to a set of limited resources is not valid any more. Instead the scheduler has to assign jobs to the resource(s) that best fits the needs of the job while considering the cost to execution time ratio.

As current data mining applications are both compute-*and* data-intensive we developed an architecture based on the notion of combined compute and storage resources to bring the advantages of the MapReduce paradigm into worldwide, heterogeneous general-purpose computing environments [12]. In this article we present a multi-objective scheduling algorithm for this dynamic, hierarchical Grid architecture incorporating the Cloud computing resource concepts. This article is organized as follows: First, we briefly introduce the generalized architecture and the implications to data- and compute-intensive scheduling. Then we describe the developed multi-objective scheduling algorithm and compare it with existing Grid scheduling algorithms. Finally, we present the simulation results of the developed scheduling algorithm.

II. A GENERALIZED GRID SCHEDULING ARCHITECTURE

Grid scheduling algorithms are responsible for mapping application resource requests to available resources. In com-

parison with other scheduling problems the scheduler has to make a decision under the following environmental characteristics:

- An application is represented by one or more jobs which might have dependencies. Each job consists of an executable with parameters, a set of input and output data specifications and requirements. The execution time for a given job is not known in general. A job may require one or more compute resources.
- A data set may be stored on multiple storage resources.
- The Grid environment is dynamic and resources are heterogeneous. There is no reliable source of information.
- Jobs arrive at an unpredictable rate.

The main goal of the Grid scheduler is to produce a schedule for all jobs arriving over time that minimizes a given objective function - makespan, average completion time or cost - under these constraints. As this scheduling problem is related to problems that are known to be NP-complete, there is little chance a polynomial algorithm exists to solve it [13]. Therefore Grid Scheduling algorithms use the structure of the Grid environment to implement heuristics or approximations.

For compute-intensive application scenarios the main resource and the limiting factor is CPU-power and the focus of the Grid scheduler is to efficiently use the compute power of multiple compute clusters. In these scenarios it is commonly assumed that the time needed to transfer the input and output data is relatively small compared to the overall execution time. These assumptions lead to the following architecture which forms the basis of current Grid schedulers:
(1) Specialized storage servers to store input and output data as well as executables. (2) A set of compute clusters from different organizations each composed of multiple compute nodes for running the algorithms. To provide a high level of transparency, these clusters are treated as one multi-CPU resource. (3) In a traditional Grid scheduling setup multiple clusters from different organisations are connected through relatively slow wide area networks whereas the network bandwidth within an organization is assumed to be infinite. A setup like this fits the needs of compute-intensive applications: To schedule a compute-intensive application requesting n computational resources, the scheduler only has to look for a cluster that has the best n free compute resources. As data transfer time is small compared to the execution time the transfer overhead is sometimes neglected.

For most data-intensive applications this assumption can not be hold. In contrary, not CPU-power but storage and network speed are the limiting factors of data-intensive applications. Data-intensive applications therefore require new scheduling strategies as the input data transfer time may well exceed execution time. Now, the scheduler should choose compute and storage resources so that the overall time or cost - depending on the scheduling objective - is minimized. Obviously, a scheduler assuming infinite bandwidth within an organization may produce non-optimal schedules.

Another aspect of traditional Grid schedulers is the assumption that there is only a very limited resource set the jobs have to be scheduled to. But with the advances in Cloud computing almost unlimited (compute-) resources are available to the scheduler.

We identified the need for some major conceptual enhancements to traditional Grid scheduling architectures to efficiently support compute- and data-intensive applications considering Cloud resources:

(1) As the amount of data increases, data can not be efficiently stored and processed from a single storage server within a cluster but has to be distributed over multiple machines. Therefore any resource may provide storage and compute capacity. This combined resource type forms the basis for scalable data-intensive applications as data can be processed directly on the storage location. To increase storage capacity and speed, computational resources of compute clusters may become combined resources by storing data on their local disks. It is important to point out that the combined resources are suitable for data- *and* compute-intensive applications as only new functionality is added.

(2) The environment is hierarchical. Resources are mainly organized within a cluster; an organization may have multiple clusters on-site or in the Cloud; and multiple organisations may want to share their resources. This not only implies an administrative hierarchy but also the network connecting the different entities has a hierarchical structure. Resources within a cluster are generally connected through a high-bandwidth low-latency interconnect (Infiniband), whereas inter-cluster or inter-organization network speed is typically much slower.

(3) Data-intensive applications are limited by two factors: the storage and network speed. Scheduling algorithms should efficiently use these resources and avoid unnecessary input data transfer through processing the data directly on the resources storing the data or resources nearby.

(4) There exist internal and external resources. There are only a limited number of internal resources while any number of external resources may be added at an additional cost.

III. A MULTI-OBJECTIVE SCHEDULING ALGORITHM

A basic algorithm trying to minimize the average runtime of all jobs (J) for combined compute and storage resources in Grids was presented in [14]. With the increasing availability of Cloud resources this basic scheduling has to be adopted to include the cost of the Cloud resources as well as the cost associated to the wide area networks needed to integrate these resources. Also internal resources might be assigned with costs to encourage a more efficient usage. In addition to low job execution costs (K_j), the users are

interested in getting their results as soon as possible so that the completion time of the jobs (C_j is another dimension of the scheduling problem. To balance between the cost and the completion time of all jobs the scheduler should minimize the following objective function:

$$F(J) = \sum_{j \in J} C_j \cdot K_j \quad (1)$$

As not all jobs are known to the scheduler in advance (offline-scheduling) but rather appear over time (online-scheduling) the minimum of $F(J)$ can only be computed retrospectively. Therefore the scheduler can only schedule a subset of the jobs at a time and can only approximate the minimum of $F(J)$.

Data-intensive jobs might be defined as a tuple $j = (p, D)$ where $D = d_1, ..., d_m$ are the data sets to be processed by program p. The task of the scheduler is to select a tuple (r, S) for each job minimizing the objective function, where r is a compute resource and $S = (s_1, ..., s_m)$ is the set of storage resources providing the m data subsets. It is assumed that all data subsets $d \in D$ have to be available on the execution resource before they can be processed by p.

The algorithm presented in this paper uses the hierarchical structure of the environment and a cost to completion time ratio to decide what set of resources should be used for a job. This dual-objective hierarchical scheduling algorithm (DOHS) is depicted in Figure 1. As described above, the algorithm has to produce a schedule with little information about the current state of the system and the jobs. Therefore the algorithm was designed to only require relative storage and compute speeds of the resources as well as the corresponding relative costs.

The inputs of the scheduling algorithm are the set of input data D, the program p, the data transfer scheduling weights α_1 to α_4 and the data to compute ratio weights β_1, β_2. As all data subsets $d \in D$ have to be available on one execution resource, the scheduler has to select a tuple (r, S) for each job where r is a compute resource and S is the set of storage resources providing the data subsets. First, the algorithm produces the set of candidate execution resources as the best (highest compute speed to cost ratio f_c) resources from each cluster in the Grid and all resources storing at least one of the data sets $d \in D$. For each of these candidate resources the set of storage resources with minimal aggregated transfer overhead f_s with regard to D is generated. From all candidates the scheduler chooses the one with the highest priority. The priority of a resource assignment (r, S, t, c) is computed as the weighted sum of the normalized transfer (t) and compute overhead (c).

The algorithm and the functions are based on the following definitions:
$P :=$ all programs available in the Grid;
$R := \{r_1, \ldots, r_n\}$ is the set of all n resources;
$D := \{d_1, ..., d_m\}$ is the m data sets of the job;
$N := \{(r, s) | r, s \in R$, r and s can exchange data directly$\}$;
$R^d := \{\ r \mid r \in R$ stores $d \in D\ \}$;
$D^r := \{\ d \mid d \in D$ is stored on $r \in R\ \}$;
c_r is the cluster of resource r;
g_r is the grid site of resource r;
sp_r is the storage speed of resources r and sc_r is its corresponding cost;
and cp_r is the compute power and cc_r is the compute cost of resource r with respect to program p, where $cp_r = 0$ and $cc_r = \infty$ if r does not fulfill all requirements of p. Different properties of a resource may be used to define the computing and storage power and cost of a resource, but at least the current usage has to be taken into account.

The data transfer overhead of a candidate resource tuple (r, S) is computed as the sum of all transfer overheads (r, s). Due to the incomplete environment information, especially missing or imprecise network information, the scheduler uses the weights α_1 to α_4 that represent the hierarchical structure. The data transfer overhead function f_s 13 assigns the weights α_1 to α_4 to the product of storage power and cost of s according to the distance between s and r: α_1 if d is stored on the resource itself $r = s$; α_2 if d is stored on a resource on the same cluster $c_r = c_s$; α_3 if d is on the same Grid instance $g_r = g_s$; and α_4 if d is on another Grid instance $g_r \neq g_s$. In case both resources are not able to exchange data directly, each resource needed to transfer the data set d from s to r is also considered.

FUNCTION $f_s(r \in R, s \in R, d \in D^+)$
  Choose shortest path $s_1, \ldots, s_k$ from s to r with
  $s_0 = s$ so that $(s_0, s_1), \ldots, (s_k, r) \in N$
  $t \leftarrow size(d) \cdot \sum_{i=0}^{k} sc_{s_i}/sp_{s_i}$
  if $r = s$ **then**
    $t \leftarrow \alpha_1 \cdot t$
  else if $c_r = c_s$ **then**
    $t \leftarrow \alpha_2 \cdot t$
  else if $g_r = g_s$ **then**
    $t \leftarrow \alpha_3 \cdot t$
  else
    $t \leftarrow \alpha_4 \cdot t$
  end if
  return t
END FUNCTION

As can easily be seen the data transfer scheduling weights α_1 to α_4 may be chosen to approximate the actual network bandwidth topology and cost or can be used minimize inter-cluster or inter-organization transfers.

FUNCTION $f_c(p \in P, r \in R)$
  if r fullfils not all requirements of p **then**
    return ∞
  end if
  $nc_r \leftarrow$ number of CPUs of r

FUNCTION DOHS ($p \in P$, R, $D \subseteq D^+$, α_{1-4}, β_{1-2})
  $R_m \leftarrow \{\, \hat{r} \mid \hat{r} \in R \wedge f_c(p,\hat{r}) = \min\{f_c(p,r) \mid r \in R \wedge c_{\hat{r}} = c_r\}\,\}$
  $R_s \leftarrow \{\, r \mid r \in R^D \wedge f_c(p,r) < \infty\,\}$
  $Z \leftarrow \emptyset$
  for all $r \in R_m \cup R_s$ **do**
    $t_r \leftarrow 0\,, \quad S_r \leftarrow \emptyset$
    for all $d \in D$ **do**
      Find $\hat{s} \in R^d$ with $f_s(r,\hat{s},d) = \min\{f_s(r,s,d) \mid s \in R^d\}$
      $t_r \leftarrow t_r + f_s(r,\,\hat{s},\,d)$
      $S_r \leftarrow S_r \cup \{\hat{s}\}$
    end for
    $Z \leftarrow Z \cup \{(\, r,\, S_r,\, t_r,\, f_c(p,r)\,)\}$
  end for
  $t_{min} \leftarrow \min\{\, t \mid (r,S,t,c) \in Z\,\}$
  $c_{min} \leftarrow \max\{\, c \mid (r,S,t,c) \in Z\,\}$
  Find $(\hat{r},\hat{S},\hat{t},\hat{c}) \in Z$ with $\beta_1 \cdot \frac{t_{min}}{\hat{t}} + \beta_2 \cdot \frac{c_{min}}{\hat{c}} = \max\{\beta_1 \cdot \frac{t_{min}}{t} + \beta_2 \cdot \frac{c_{min}}{c} \mid (r,S,t,c) \in Z\}$
  return $(\hat{r},\hat{S},\hat{t},\hat{c})$
END FUNCTION

Figure 1. DOHS algorithm for scheduling a program with multiple data sets

  $u_r \leftarrow$ currently reserved CPUs of r
  $cpu_r \leftarrow$ CPUs speed of r
  $cpu_{min} \leftarrow \min\{cpu_o \mid o \in R \wedge nc_o > u_o\}$
  if $nc_r = u_r$ **then**
    $cp_r \leftarrow cpu_r$
  else if $nc_r \leq u_r \wedge \exists o \in R$ with $nc_o > u_o$ **then**
    $cp_r \leftarrow (nc_r \cdot cpu_{min})/(nc_r + u_r)$
  else
    $cp_r \leftarrow (nc_r \cdot cpu_r)/(nc_r + u_r)$
  end if
  return cc_r/cp_r
END FUNCTION

The compute overhead function f_c 15 returns the compute power to cost ratio of the resource with respect to program p. If r does not fulfill all requirements of p the function returns ∞. In case there is at least one free CPU, the compute power is simply the CPU speed of the resource. If all CPUs are used but another resource in the Grid has a free CPU, the compute power is defined as the product of the number of CPUs times the CPU speed of the slowest available resource divided by the number of CPUs plus the reserved CPUs. Using the speed of the slowest available resource ensures, that the compute power of a busy resource is never higher then the compute power of a resource with free CPUs. If there is no free CPU in the Grid, the compute power is defined using the resource's CPU speed.

IV. Simulation results

To evaluate the presented algorithm we developed a simulation environment for executing data- and compute-intensive jobs in Grids with additional Cloud resources. In the first step of a simulation a random number of resources (> 100), clusters and organisations are created. Compute, storage and network speeds of each resource are randomly generated as well. Also the number of jobs, the number of computations per MB and the data sets per job are generated randomly. In the next step different scheduling algorithms are used to schedule the jobs as they arrive over time in the created Grid environment. For each algorithm the resulting schedule is simulated and the exact cost and time consumption of each job is computed. Based on the consumed cost and time $F(J)$ is calculated for each algorithm.

Following the Monte Carlo simulation approach 20 of these simulations were conducted and the $\sum_{j \in J} C_j \cdot K_j$ of each was recorded. As a benchmark we use a brute-force algorithm evaluating all possible resource combinations for each job minimizing different objective functions. As this requires $n \cdot s^m$ (n compute resources, jobs have in average m data sets and each data set is stored in average on s resources) objective function evaluations it is not feasible to use this algorithm for real-world scheduling. But as a benchmark, it ensures that the (locally) optimal resources are chosen according to the objective function. In contrast to the developed algorithm the benchmark algorithm is also provided with all environment and job information, including exact network bandwidth and the job's execution time. The

benchmark algorithm is used to compute a schedule based on the following objective functions that are commonly used for grid scheduling:

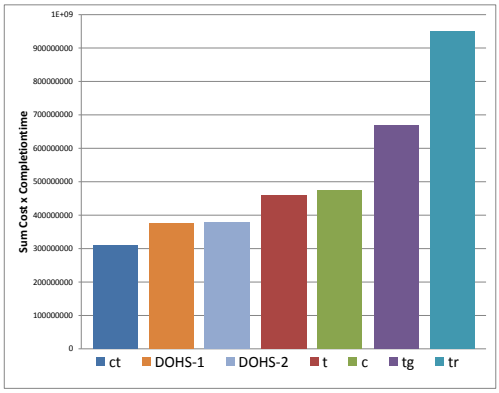
- *Cost-Time*. Minimize the product of the jobs cost and completion time.
- *Time*. Minimize the completion time of the job.
- *Cost*. Minimize the cost of the job.
- *Transfer*. The scheduler chooses an execution resource that has a minimum transfer overhead.
- *Time-Grid*. Minimize the completion time of the job based the assumption that transfer overhead and cost is zero within an organisation.

As shown in Figure 2 the developed DOHS scheduling algorithm provides good performance compared to the benchmark algorithm using the different objective functions. The DOHS algorithm achieves almost the same performance as the benchmark algorithm using the Cost-Time objective function and all information. The Time-Grid objective function may be regarded as a representative of current Grid schedulers that assume that transfer overhead and cost is zero within an organisation. It does not only require the more execution time but also consumes the more costs as the Time objective function, especially for data-intensive applications. Only the Transfer objective function, which can be seen as a generalization of the MapReduce scheduling approach of minimizing the transfer overhead, is worse. We evaluated the algorithms for a mix of compute- and data-intensive jobs. Figure 2 a) shows two different values for the DOHS algorithm. The DOHS-1 represents a scenario where users classify the jobs as compute-intensive ($\beta_1 = 0.9$, $\beta_2 = 1$) or data-intensive ($\beta_1 = 1$, $\beta_2 = 0.9$). DOHS-2 shows the results for a scenario where users do not provide any classification ($\beta_1 = 1$, $\beta_2 = 1$). As the DOHS algorithm provides parameters to adapt to different resource environments and job characteristics it was configured with the following parameters: $\alpha_1 = 1$, $\alpha_2 = 1.5$, $\alpha_3 = 5$ and $\alpha_4 = 50$.

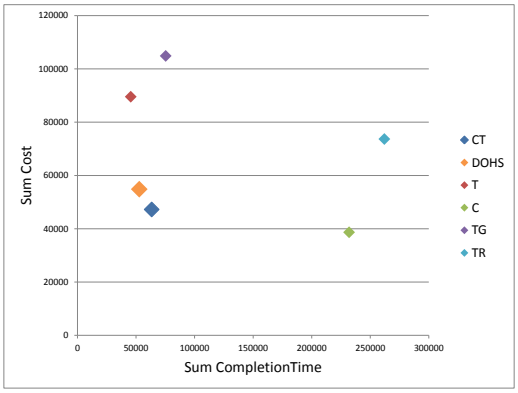
V. Related work

Recently, various systems and approaches to grid-based data mining and data-intensive scheduling have been reported in the literature. Some of those that are particularly relevant to this work are briefly reviewed here.

The GridBus resource broker [15] provides functions for scheduling data- and compute-intensive applications. In combination with the Storage Resource Broker[16] GridBus is able schedule data-intensive jobs based on various different metrics, including network bandwidth and utilization. The GridBus scheduler as most heutistic Grid schedulers, including the DIANA scheduler [9], follows the common separation between storage and compute resources, requires detailed information about the jobs and the environment and also assumes that transfer overhead within an organization is zero.



(a) $\sum_{j \in J} C_j \cdot K_j$



(b) $\sum_{j \in J} K_j$ vs $\sum_{j \in J} C_j$

Figure 2. Scheduling simulation results.

Another class of Grid schedulers uses genetic algorithms to solve the data-intensive scheduling problem [17][18]. The main disadvantages of these approaches are the computational complexity of the genetic algorithm and the requirement to have detailed information about the environment.

Hadoop [5] is the most well known open source implementation of Google's MapReduce paradigm. Hadoop's MapReduce framework is build on top of the Hadoop distributed file system (HDFS) containing all data to be mined. The map and reduce functions are typically written in Java, but also executables can be integrated via a streaming mechanism. MapReduce frameworks like Hadoop do not offer the functionality to efficiently execute compute-intensive applications on a cluster, making them unsuitable for a general-purpose data mining system. Hadoop On Demand in combination with the SUN Grid Engine try to overcome these limitations by running Hadoop on top of

a cluster management system, thus adding another layer of complexity. Still, the resources to use for MapReduce are reserved exclusively for Hadoop and can not be used by other compute-intensive jobs. Hadoop and similar MapReduce frameworks simplify the development and deployment of data-intensive applications on local clusters and cloud resources but are currently not suited for large-scale, heterogeneous environments comprised of multiple independent organizations.

Anteater [1] is a web-service-based system to handle large data sets and high computational loads. Anteater applications have to be implemented in a filter-stream structure. This processing concept and its capability to distribute fine-grained parallel task make it a highly scalable system. Due to the restriction on a filter-stream structure Anteater shares some downsides of MapReduce frameworks: Applications have to be ported to this platform which makes it almost impossible to integrate existing applications.

VI. Conclusion

In this article we introduced a multi-objective scheduling algorithm for data-intensive applications in Grid environments. The new concept of combined Grid resources in combination with the developed data location aware scheduling algorithm provides an infrastructure to build scalable data-intensive applications in worldwide, heterogeneous environments. The scheduling algorithm also supports compute-intensive applications so that a single environment can be used for both data- and compute-intensive applications. In addition the DOHS algorithm is specifically designed for Grid environments with Cloud resources where information is generally scarce. The simulation results show that the algorithm is competitive or even surpasses current Grid schedulers requiring detailed information.

Future work may focus on additional Cloud related topics such as setup time of a resource or dynamic cost.

A SLA-based Cloud Computing Framework: Workload and Location Aware Resource Allocation to Distributed Data Centers in a Cloud

Seokho Son, Gihun Jung, and Sung Chan Jun
School of Information and Communications,
Gwangju Institute of Science and Technology, Gwangju, Republic of Korea

Abstract - *As the number of users of cloud services increase all over the world, cloud service providers keep deploying geographically distributed data centers more. Since resource capacity of a data center is limited, cloud service providers need to distribute load to data centers. However, when the provider distributes load, SLAs (service level agreements) established with consumers should be guaranteed in an environment where a cloud provider operates geographically distributed data centers. Therefore, this paper proposes a SLA-based cloud computing framework to facilitate temporal and locational load-aware resource allocation. The contributions of this paper include 1) design of a cloud computing framework including an automated SLA negotiation mechanism and a workload and location aware resource allocation (WLARA) and 2) implementation of an agent-based cloud test bed of the proposed framework. Empirical results using the test bed show the proposed WLARA performs better than other related approaches in terms of guaranteed SLAs.*

Keywords: Cloud computing, Distributed data centers, Resource allocation, VM placement, SLA negotiation, SLA management

1 Introduction

Cloud computing is a computing paradigm that provides computing resources as services through a network to Cloud users. A cloud consists of a type of parallel or distributed systems that consists of combinations of interconnected computing resources and virtualized computing resources [1]. There are many existing cloud computing environments such as Amazon EC2 and Amazon S3 [2]. Considering such interests and business willingness of IT leaders, cloud computing paradigm is already important and to be essential in various business. In such cloud computing environments, a cloud service user consumes cloud resources as a cloud service and pay for the usage of the service. Before a cloud provider provisions a service to a consumer, the cloud provider and consumer need to establish a SLA in advance. The SLA is an agreement including the level of QoS (quality of service) between a service provider and a consumer. Usually, an SLA includes the price of a service, and the level of QoS can be adjusted by the price of the service. For instance, a cloud provider can charge a higher price to a consumer who requires a high level of QoS.

According to the increased number of cloud service users all over the world, cloud service providers keep implementing geographically distributed data centers. Since the resource capacity is limited in a data center, a cloud providers need to distribute resource load to the data centers for system performance and stability. In addition, resource load can be distributed in temporal manner since resource load in a cloud generally fluctuates by time [3]. Because of the limited resource capacity, it is hard for cloud providers to handle resource demand that exceeds the resource capacity. Therefore, to cloud providers, a load balancing scheme is a very important issue to design a cloud computing framework, and it is directly related with cloud providers' profit. Whereas it is important to design a cloud computing framework that facilitates efficiency and stability of a system, SLA-based cloud computing framework considering both temporal and locational resource load have not been sufficiently studied so far. Also we need to consider a load distribution for a cloud provider who operates geographically distributed data centers.

In [4], B. Sotomayor, R. S. Montero, I. M. Llorente, and I. Foster provided a comparison between OpenNebula and several well-known virtual infrastructure managers such as Amazon EC2, vSphere, Nimbus, and so on. The comparison includes several resource placement policies (i.e., resource allocation policies) of virtual infrastructure managers. For example, there are static-greedy resource selection, round robin resource selection, and placement considering average CPU load. However, whereas the resource placement schemes are focused on placing resources in a data center, they are not focused on resource placement in which a cloud provider operates geographically distributed data centers. With geographically distributed data centers, we need to consider response time violation because of geographical distance. In addition, [5] investigated energy-aware resource provisioning and allocation algorithms that provision data center resources to client applications in a way that improves the energy efficiency of the data center. However, whereas [5] guides research directions in resource allocations, [5] does not consider a cloud provider that operates multiple

geographically distributed data centers to balance resource load and response time by geographical distance, and [5] does not include a specific negotiation mechanism.

[6] considers load placement policies on cooling and maximum data center temperatures in cloud providers that operate multiple geographically distributed data centers. Whereas [6] proposes dynamic load distribution policies that consider all electricity-related costs as well as transient cooling effects, [6] does not focus on guarantees of SLA. [6] noted that the policies delay jobs to avoid overheating or overloading data centers and violate SLAs sometimes in their simulation configuration. Moreover current providers such as Amazon EC2 do not employ sophisticated load placement policies, and the consumers themselves manually select a data center to place their virtual machines.

There are several automated negotiation mechanisms for grid or cloud resource negotiation ([7] for a survey). These negotiation mechanisms are designed for price negotiation, but these mechanisms have a lack in considering other SLA issues such as service time slot and response time. Also, they do not consider both temporal and locational load distributions to geographically distributed data centers.

Hence, this paper proposes a cloud computing framework to facilitate temporal and locational load-aware resource allocation, and we implement a test bed of the proposed cloud framework to verify the usefulness of the proposed framework in a case study. The contribution of this paper are 1) design of a cloud computing framework to facilitate temporal and locational load-aware resource allocation, and 2) implementation of a test bed of the proposed cloud computing framework. Using the proposed system, a cloud consumer can establish SLA about service price, time slot, and response time by an automated SLA negotiation scheme, besides a cloud provider can facilitate load balancing by a pricing strategy. As such, the purpose of this work is to: design a cloud computing framework facilitating resource allocation (Section 2). Also, Section 2 includes both SLA negotiation mechanism and workload and location aware resource allocation. In Section 3, we introduce the implementation of a simulation test bed for the proposed framework and evaluate performances of the proposed framework in terms of the SLA violation in Section 4. Finally, Section 5 concludes this paper with a list of future works.

2 A cloud computing framework to facilitate resource allocations

2.1 SLA-based cloud computing framework

The proposed cloud framework adopts an automated SLA negotiation mechanism to support establishing SLA. Whereas the variety of SLA options is limited for consumers within enforced SLA strategies, the different preferences between a consumer and a provider can be efficiently narrowed with an automated SLA negotiation mechanism. In case of price of a service, a negotiation mechanism between both a consumer and a provider helps to find an equilibrium satisfaction state for price. Whereas there should be many SLA issues or options in cloud services in practice, this paper focuses on 1) service price, 2) time slot to specify range of service time, and 3) service response time among several SLA issues in designing the SLA-based cloud framework. In addition to the SLA negotiation mechanism, service providers need a SLA management scheme to guarantee established SLA with a consumer. In the proposed cloud framework considers service response time to consumers as QoS. To guarantee service response time agreed with a consumer, a SLA management scheme in the proposed framework considers geographical distance between a consumer and distributed data centers of a provider when the cloud provider select a data center to allocate resources for the consumer.

In Fig. 1, the proposed framework consists of cloud service broker and cloud provider. Cloud service broker is an interface between a consumer and a cloud provider. The cloud service broker gets information of a consumer's preference for services and proceeds for cloud service discovery to find a matched service with the consumer's preference. After the broker finishes service discovery, the broker can be connected to a cloud provider who own the service. The next step is establishing SLA between the provider and the service broker on behalf of the consumer by the SLA negotiation component. If the negotiation is successful regarding service price, time slot, and response time, the broker makes the consumer pay

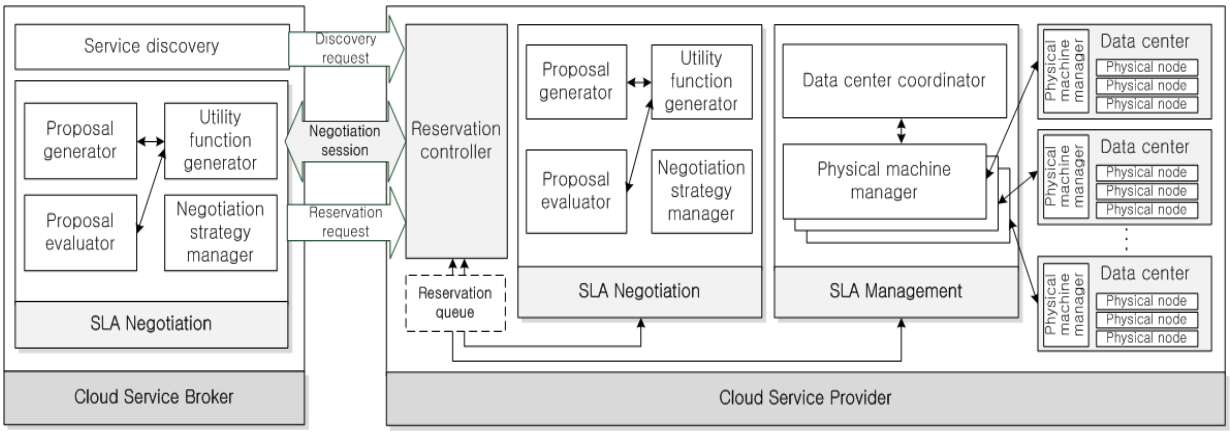

Figure 1. Design of SLA negotiation and management based cloud computing framework.

for the service in the agreed price and reserves the service.

A cloud provider consists of four components: 1) reservation controller, 2) SLA negotiation mechanism, 3) SLA management, and 4) distributed data centers. Cloud provider responds to service broker's service discovery requests. And SLA negotiation component makes a negotiation session between the provider and the broker to establish SLA. If the automated negotiation is successful, which means they came to a mutually acceptable agreement regarding price, time slot, and response time, so that an SLA has been established, the provider receives charge from the consumer through the broker.

Service reservation controller reserves the requested service by input information of the name of consumer, the service type, the start time of service, the end time of service, and the threshold of response time to the service reservation queue which is reservation list. Reservation controller sequentially checks the reservation queue to initiate the start of the services according to the start time of services. It forwards agreed response time for the services to SLA management component.

The SLA management component selects a data center among distributed data centers to allocate requested service. The conditions of selecting a data center are specified in the SLA (response time in this paper). Each data center includes a physical machine manager (PMM), and a PMM manages physical computing nodes in a data center. All PMMs monitor physical computing nodes to evaluate average response time of a data center to the consumer, and SLA management component selects a data center and specific a physical computing node by evaluated average response times. In conclusion, a service provider and a consumer can not only establish SLA about service price, time slot, and response time, but also the service provider can guarantee established SLA with a consumer through the SLA management component.

2.2 Automated SLA negotiation mechanism

In general a negotiation mechanism consists of negotiation protocol, negotiation strategy, and utility functions. Negotiation protocol is a set of rules in a communication (e.g., possible actions, language, and utterance turn) for a negotiation among negotiation parties. As a negotiation protocol, the negotiation mechanism in this work follows Rubinstein's alternating offers protocol [12] which lets agents make counter-offers to their opponents in alternate rounds. Both agents generate counter-offers and evaluate their opponent's offers until either an agreement is made or one of the agents' negotiation deadlines is reached. Counter-proposals are generated according to a negotiation strategy that consists of a concession algorithm and a tradeoff algorithm. When an agent generates a counter-proposal, the agent needs to concede a proposal since it is hard to reach an agreement without a concession. A concession algorithm determines the amount of concession for each negotiation round [13]. Also, a tradeoff algorithm is required to generate a proposal in multi-attributes negotiation. In a multi- attributes negotiation, there are multiple issues to negotiate, and a tradeoff algorithm generates a proposal by combining proposals of individual issues; the mechanism adopted a tradeoff algorithm in [14].

The utility function U(x) represents an agent's level of satisfaction of a negotiation outcome x. A negotiator (i.e., a cloud participant) can specifies utility functions. To define a price utility function, the negotiator needs to specify the most preferred price (IP, initial price) and the least preferred price (RP, reserve price). In general, the range of utility function is $\{0\} \cup [u_{\min},1]$, and U(P)= $u_{\min}$ represents the least preferred price (RP) and U(P)=1 represents the most preferred price (IP). If price is outside of IP and RP, then U(P) is 0.

To support cloud users negotiation for service price, time slot, and response time in the proposed framework, it is necessary to define utility functions of the negotiable SLA issues. In this paper, utility functions defined in [14] are adopted which are price utility function $U_P(\mathrm{P})$ and time slot utility function $U_{TS}(TS)$. Especially, the time slot utility function defined in [4] supports cloud participants to represent temporal preferences in cloud services. In addition to price and time slot issues considered in [14], this paper considers service response time as a SLA negotiation issue. The service response time represents the minimum response time that a provider provides. Let IRT (Initial response time) and RRT (Reserve response time) be the most preferred response time and the lease preferred response time respectively. A RT (Response time) given to a consumer can be evaluated by the response time utility function of a consumer $U_{RT}^{C}(RT)$ as follows,

$$U_{RT}^{C}(RT) = \begin{cases} u_{min} + (1-u_{min}) \cdot \left| \dfrac{RRT_C - RT}{RRT_C - IRT_C} \right|, & IRT_C \le RT \le RRT_C \\ 0, & \text{otherwise.} \end{cases} \quad (1)$$

Contrarily, a RT given to a provider can be evaluated by the response time utility function of a provider $U_{RT}^{P}(RT)$ as follows,

$$U_{RT}^{P}(RT) = \begin{cases} u_{\min} + (1-u_{\min}) \cdot \left| \dfrac{RT - RRT_P}{IRT_P - RRT_P} \right|, & RRT_P \le RT \le IRT_P \\ 0, & \text{otherwise.} \end{cases} \quad (2)$$

$u_{\min}$ is the minimum utility that a consumer and a provider receive for reaching a deal at their reserve prices. To differentiate between not reaching an agreement and reaching an agreement at the reserve price, $u_{\min}$ is defined as 0.01. Finally, the aggregated total utility function $U_{Total}(P,TS,RT)$ that includes price, time slot, and response time is as follows,

$$U_{Total}(P,TS,RT) = \begin{cases} 0, & \text{if either } U_P = 0,\ U_{TS} = 0,\ U_{RT} = 0 \\ w_P \cdot U_P + w_{TS} \cdot U_{TS} + w_{RT} \cdot U_{RT}, & \text{otherwise.} \end{cases} \quad (3)$$

w_P, w_{TS}, and w_{RT} are the preference weights for price, time slot, and response time, respectively. A negotiator can adjust the importance among the issues by differentiating the weights

where the weights satisfy $w_P + w_{TS} + w_{RT} = 1$. A consumer who cares price only, the consumer can assign 1 to w_P and 0 to the other weights. According to the (3), $U_{Total} = U_P$. The consumer can have a high chance to use a service in a low cost.

So, with the SLA negotiation mechanism, cloud participants can narrow preference differences (i.e., service price, time slot, and response time) so that the parties successfully reach an agreement for SLA.

2.3 Workload and location aware resource allocation

A cloud provider needs to properly allocate the provider's resources to a data center for a service provisioning so that the provider can guarantee the SLA agreed with a consumer. The response time for users depends on the utilization level of physical nodes in the data center and the location of the data center. The performance of VM depends on the allocated PM (Physical machine). If the allocated PM is under heavy workload, the performance of VM will be degraded. In addition, cloud computing services are delivered over the Internet that does not guarantee reliable delivery. Also, the response time may depend on network delay in service delivery. If the distance between a user and a data center is far, the response time of VM will be slow. So, both workload and geographical location are important factors to guarantee the SLA in terms of response time. WLARA selects a data center according to a utility function to evaluate the appropriateness in VM placement to data centers.

2.3.1 Utility function

To find an appropriate physical computing resource which fits user's SLA, this paper suggests an allocation model considering 1) the geographical location of users and provider and 2) the workload of computing resources. The proposed model uses utility function to measure an appropriateness of each data center. The utility function is described as follows:

$$U_m = \alpha \cdot U_m^{UL} + \beta \cdot U_m^{RT} \quad (4)$$

In (4), there are two terms in the utility function: 1) machine workload utility U_m^{UL}, and 2) expected response time U_m^{RT}. Each term is multiplied by the preference weight ($\alpha + \beta = 1.0$) respectively. The weight of each value can indicates that a provider's preference for placing user VM. If $\alpha \rightarrow 1.0$ and $\beta \rightarrow 0$, the provider emphasizes workload of data center in placing VM. Likewise, if $\beta \rightarrow 1.0$ and $\alpha \rightarrow 0$, the provider emphasizes finding a more close data center.

The utility function (5) for machine workload represents level of workload of a data center when the data center accepts VM placement. Let $W\tau$ be the upper bound of workload value, and W_θ and W_c be the expected workload in the data center including requested VM placement and current workload of the data center respectively. (5) shows higher utility if the placement does not affect increasing the workload of the data center. When W_θ is higher than $W\tau$ than the utility function returns the minimum utility 0.

$$U_m^{UL} = \begin{cases} 1 - \dfrac{W_\theta - W_C}{W_\tau - W_C} & , \quad W_C \le W_\theta < W_\tau \\ 0 & , \text{ otherwise.} \end{cases} \quad (5)$$

(6) describes utility function for expected response time U_m^{RT}. Let T_{SLA} be the threshold of response time in SLA, and T_e and T_c be the expected response time when a user's VM is placed in a data center and current average response time by the workload and location of the data center. This utility function returns values when T_e is in between T_c and T_{SLA}. Otherwise, the utility returns the minimum utility 0.

$$U_m^{RT} = \begin{cases} 1 - \dfrac{T_e - T_C}{T_{SLA} - T_C} & , \quad T_C \le T_e < T_{SLA} \\ 0 & , \text{ otherwise.} \end{cases} \quad (6)$$

By utility function (4), the provider can find appropriate data center for user's VM in terms of the workload and the location between user and data center.

2.3.2 Resource allocation strategy

When a provider receives the request from user, the provider asks to a reservation manager, who is in charge of managing resources to allocation and reservation, for evaluating appropriateness of each data centers. To find proper datacenter, the proposed allocation model uses utility function (4). When the reservation manager finds appropriate datacenters by the evaluation, the reservation manger asks to allocate the request of user to coordinator agent, who is in charge of managing numbers of PMs in the datacenter. Then, the coordinator receives resource allocation request, the coordinator also finds a proper PM that has light workload because we assumes that data center consists of number of PMs. Consequently, the request of user is allocated in the PM that closes to user with light workload. Therefore, when the provider uses the proposed allocation model, the request of user is allocating in the PM that guarantees reasonable response time under SLA.

3 Simulation and empical results

3.1 Simulation test bed

A simulation test bed for the proposed cloud computing framework has been implemented based on JAVA and JADE (Java Agent Development Environment) [15]. JADE is a software framework implemented by JAVA, and it is efficient to implement multi-agent systems with JADE since the implementation of JADE concretely follows FIPA (Foundation for Intelligent Physical Agents) [16] standard. The components of the proposed cloud framework were implemented as agents in the simulation test bed, and the agents communicate each other by exchanging messages needed among components by using message types defined in FIFA. The agents for the framework are as follows: 1) Service broker, 2) Service registry, 3) Reservation manager, 4) Data center coordinator, 5) PMM, and 6) PM.

3.2 Experimental settings

To show performance of the proposed framework, this experiment is focused on evaluating the number consumers who experience any SLA violation (i.e., slower response time than the response time limit descried in SLA). Also, we show 1) SLA negotiation outcomes in terms of price and response time (time slot is omitted to focus on the performance of the resource allocation in this evaluation), 2) load distribution to data centers, and 3) distance between user and data center.

Table 1 Experimant settings

SLA Negotiation Options		*Consumer*	*Provider*
SLA Preference range for price		IP:0.1($/hour) RP:1.0($/hour)	IP:1.0($/hour) RP:0.1($/hour)
SLA Preference range for response time		IRT:100(ms) RRT:250(ms)	IRT:250(ms) RRT:100(ms)
Consumer's Resources		*Range of Values*	
Number of virtual CPUs		[1, 32]	
Size of Storage		[10.0, 1000.0]	
Response time of SLA		[100, 250]	
Location		{zone 0, …, zone 9}	
Physical Machine Resources		*Values*	
Number of CPUs		{4}	
Number of Threads per CPU		{8}	
Data Center Specification		*Values*	
Number Of Physical Machines		{100}	
Storage Capacity		{1000000.0}	
Number of Monitoring Agents		{10}	
Number of Coordinator Agents		{1}	
Location		{zone 0, …, zone 9}	
Experimental Constraints		*Values*	
Allocation Model	*Reservation Manager*	{Greedy, Random, RR, IM, NIM, WLARA}	
	Coordinator and Monitoring agent	{Adaptive}	
Number of User Requests		{1000}	
Number of Data Centers		{10}	
Limitation of Workload in Physical Machines		{2.0}	

Table 1 shows input data source which is assigned to components in the test bed. Using the SLA negotiation options in Table 1, all consumers and provider select preference range for price and response time so that negotiation agents negotiate price and response time. The negotiation outcome regarding response time is then subjected to the limit of response time that the provider guarantees. At the end of each experiment, the response time of each user was calculated and checks whether the provider violated consumers' SLA or not. Also, consumer agent can have three different types of resources: 1) the number of vCPUs (virtual CPUs of a VM); 2) size of storage and 3) the VM location (Table 1). The test bed generates random value to assign types of resources as consumer's service request according to the input data range. Since the workload is depended how many virtual CPUs are waiting for allocate to physical CPU in this test bed, the number of vCPUs affects workload, and the limit of workload to a data center is bounded by 2.0. We assumed all datacenters are homogenous (i.e. same amount of resources).

In Table 1, as we described in Section 2.3, the geographical location between a data center and a consumer is an important factor that affects response time. For simulation purpose, we design ten different zones (i.e. zone 0 to 9) that represent geographical distance. In this experiment, a network delay is increasing gradually according to increasing differences between zones (20ms per each hop in the experiments). Each datacenter has a corresponding zone, and consumers can be in different zones as their locations. For each simulation, 1000 consumers, who request different amount of resources and are located in different locations, have been simulated. When a consumer agent is generated, a location is given to the consumer agent. For more realistic simulation, the distribution of locations to the ten zones follows a normal distribution (i.e. mean is 4.5, standard deviation is 2.0) so that some data centers face swamped situation with high demand while in the experiments.

The proposed framework especially the resource allocation model (i.e. Workload and Location Aware Resource Allocation, WLARA) is compared with related allocation models, which are widely used in resource allocation (i.e., VM placement) : 1) Greedy, 2) Random, 3) Round Robin (RR), and 4) Manual Zone Selection. According to the survey in [4], 1) Greedy, 2) Random, 3) RR have been used by Nimbus and Eucalyptus for placing VM to a PM in a data center. In addition, 4) the manual zone selection is a load placement scheme which is similar to current providers such as Amazon EC2. So, with the manual zone selection, consumers themselves manually select a data center to place their virtual machines. Since the manual zone selection assumes a human is aware and selects the closest data center, the manual zone selection used in this simulation makes all consumers' VM be placed to a data center deployed in the same location (i.e., zone) with each consumer. Manual zone selection is classified into ideal case and non-ideal case for a simulation purpose. With the ideal case (i.e., ideal manual selection, IM), a consumer's VM is placed to the closest data center. With the non-ideal case (i.e., non-ideal manual selection, NIM), a consumer's VM is placed to a close data center by applying random values that follow normal distribution so that we can simulate situations where users sometimes make a mistake in selecting the closest data center.

(b)

Figure 4. Performance results of WLARA with varing weights ({α, β}={0.7, 0.3}, {0.5, 0.5}, {0.3, 0.7}).

3.3 Empirical results and observations

Fig. 2 shows SLA negotiation outcomes in terms of service price and response time. According to Fig. 2, SLA negotiation mechanism properly worked since threshold of response time is low (fast, respectively) when the price is low (high, respectively). Also, the response times and the prices for SLAs are well distributed (100<Agreed Response Time<250; 0.1<Agreed Price<1.0) according to the given preference range in Table 1. In addition, Fig. 3 shows the performances of all resource allocation models. According to the experiments, the proposed allocation model shows the best performance in terms of the number of SLA violations and allocation failures; 2) a balanced resource loads distribution and distance of data center. The detailed observation is described as follows.

Fig. 3 (a) shows the number of SLA violations and allocation failures. The consumers have different threshold of response time according to the outcomes of negotiated SLA. At the final stage of an experiment, the response time of each consumer's VM is aggregated to check whether it violate given response time threshold or not. In Fig. 3 (a), when the provider uses the proposed model WLARA, it guarantees the least number of SLA violations (170) and no allocation failure (0) whereas Greedy, Random, RR, NIM, and IM occurred 753, 637, 624 342, 288 SLA violations, respectively. This is because WLARA is considering both workload and response time including network delay by the utility function (4). Hence, WLARA can allocate consumer's request to a PM in a data center that has less workload and is in a close location to guarantee the threshold of response time in SLA.

Fig. 3 (b) shows load distribution in data centers. Each allocation model shows different trends of load distribution in data centers. To represent the trends, we indicated standard deviations for each model. WLARA shows less biased and smoothly distributes loads in data centers. Since the user's request is distributed to follow the random normal distribution (i.e. mean is 4.5, standard deviation is 2.0), the provider may be requested more for allocating user's VM at certain location of data center. Hence, the load distribution trend has basically in a triangle shape like WLARA and IM. The worst case is greedy model. It allocated user requests by order of data centers. Therefore, the load distribution is biased. In Fig. 3 (b), random and RR allocation model shows slight uniform distribution of load and less standard deviation. But, as shown in Fig. 3 (a), since these allocation models are not considering workload and location, the models violated SLAs too frequently.

Fig. 3 (c) shows the average geographical distance between users and allocated data centers. When the provider uses IM

selection, the average distance is zero because the IM model always places VM to the data center which has the same location with each user. IM selection is slightly better than the NIM in SLA violations. However, considering standard deviation of load distribution to data centers in Fig. 3 (b), both NIM and IM show bad performances. This may lead low performances in SLA violations and the number of allocation failures. When user request is not acceptable to selected data center due to the capacity limit, the data center may deny to allocation. The average distance with WLARA was 0 to 1. Although WLARA sometimes does not allocate user's VM to exactly same location, WLARA shows less number of SLA violations because WLARA considers both workload and response time together.

Fig. 4 represents the performance among WLARA with different experimental settings (the weights α and β in (4)). WLARA uses the utility function (4) that allows provider to adjust each weight of preference (i.e. considering workload more or location more). Hence, the results are slightly different by the weight. In Fig. 4, when the provider uses load-prefer allocation (i.e. load weight α is 0.7, and location weight β is 0.3), the distribution of load shows also best results in Fig. 4 (a). However, Fig. 4 (b) shows WLARA (α =0.7) gives relatively longer distance than with other preferences.

4 Conclusion and future work

This paper proposed a SLA-based Cloud computing framework to facilitate temporal and locational load-aware resource allocation in which a cloud provider has several data centers geographically deployed., and we implement a test bed of the proposed cloud framework to verify the usefulness of the proposed framework in a case study.

The main functionalities of the proposed cloud computing framework include a SLA negotiation mechanism and a resource allocation mechanism. Hence, by using the proposed framework, we expect cloud computing providers can facilitate distributing resource load (i.e., resource demand) in temporal and locational perspectives. In summary the contributions of this paper are as follows: 1) Design of a cloud computing framework to facilitate temporal and locational load aware resource allocation in a cloud computing environment which is similar to Amazon EC2 that has multiple data centers geographically distributed. 2) Implementation of an agent-based cloud computing test bed according to the proposed cloud computing framework. The evaluation in this paper was focused on the performance of the resource allocation algorithm. The empirical result shows WLARA performs better than other related schemes such as greedy, random, round robin, and manual selection like Amazon EC2 in terms of the number of SLA violations.

Using the proposed system, a cloud consumer can establish SLA about service price, time slot, and response time by an automated SLA negotiation scheme, and a cloud provider can facilitate load balancing by a pricing strategy. As future works, the proposed framework requires a thorough evaluation that includes cost effectiveness, resource load, average resource utilization, and so on. In addition, we need to research and classify negotiable cloud SLA issues to be included in the framework considerations.

Abstract—*An effective workflow application scheduling on shared resources largely contributes to achieving a high performance in Utility Grids. Users share resources and these resources are autonomously managed in these environments. Users submit application-tasks to the resources, in turn, the resources eventually schedule the application-tasks due to their own allocation policy. Obviously, there is no explicit control on allocating resources to application-tasks on the part of users, the fact that results make users fail in optimizing the application makespan and allocation cost. The application scheduling problem is, in general, proven to be NP-complete. In the current paper, firstly, a Workflow Scheduling Cost-based (WSC) model is developed in order to effectively schedule an application in Utility Grids so that the application makespan and allocation-cost can be minimized. Secondly, a Minimum First-fit Cost-Makespan Trade-off (MinFCMT) heuristic algorithm is introduced to solve the WSC model. Based on the existing application scheduling algorithm, widespread simulation of the real parallel workload models as well as the synthetic workflow is exploited to evaluate the MinFCMT heuristic algorithm. The results show that the MinFCMT algorithm is more effective than the present algorithms due to optimizing the application makespan and allocation-cost in a very low runtime.*

Keywords*:* Utility Grids; Performance Optimization; Resource Provisioning; Workflow Scheduling.

1 Introduction

Grid computing can control many heterogeneous distributed resources for executing the computations and data intensive applications. Grid computing has recently been oriented towards pay-as-you-go models. In these models, the resource providers receive fees from the users for presenting computing and data services. That is why, the industry pioneers such as IBM, HP, Intel and SUN which have a large share in this business are more inclined toward the grid computing. IBM, for instance exploits "e-business on demand" model, HP exploits "Adaptive enterprise" model and Sun Microsystems apply to "pay-as-you-go" model [1].

The shared distributed infrastructures supply the grid environment software and hardware resources, in order to conduct large-scale computations. These infrastructures turned out to be efficient for executing applications in sciences such as astronomy [2], high energy physics [3], earthquake [4]. The challenge faced by the scientists in these fields is how to use cyber-infrastructure for transferring knowledge from the scientific environments to the distributed computing environments. The workflow is the most common approach to describe an application in a high level form regardless of the distributed computing environment. The workflow is represented in a "Direct Acyclic Graph" (DAG) with nodes and edges representing the tasks and data dependencies between the tasks, respectively. Once an application is transformed into the workflow structure, a workflow management system will be ready to control and manage the execution of workflow on the distributed infrastructure. In these environments, indeed, access to the shared computational resources is carried out through the queue-based Local Resource Management (LRM) system including Portable Batch System (PBS) [5] and Local Sharing Facility (LSF) [6].

In an interactive Grid computing environment the users are expecting to receive services whereas the resource providers are ready to offer services to them. The resource providers advertise the available resources planned by the application-level schedulers who receive fees upon providing services. An environment characterized with the above-mentioned users and service providers is known as Utility Grids. A competition develops among users caused by the resources-pricing policies so that users begin being involved in a competition with one another only to gain a resource with an affordable cost and an efficient processing capability. Hence, the resource providers are driven into a competition with one another to sell their idle resources to the users for more profits as well as to enhance the resource utilization. The scheduling problem becomes highly complicated and NP-complete [7] in such an environment due to the different resource consumers and providers so that each side pursues its own profits. It is worth noting that the resource consumers and providers are acting independently with conflicting aims. The resource consumers seek the minimum makespan and allocation-cost

for scheduling application, whereas the resource providers seek the resource utilization gains. Thus, the main challenge confronted by the users in this environment, will be scheduling an application on the heterogeneous resources in which the users have no explicit control so that both makespan and allocation-cost can be minimized.

The present paper deals with developing a Workflow Scheduling Cost-based (WSC) model in order to effectively schedule an application in the Utility Grids so that the application makespan and allocation-cost can be minimized. In fact, the WSC model allows the users to make a trade-off between an application makespan and allocation-cost. Next, a Minimum First-fit Cost-Makespan Trade-off (MinFCMT) heuristic algorithm is employed to solve the WSC model. The MinFCMT is a heuristic algorithm scheduling an application in a form that both makespan and allocation-cost can be optimized due to a trade-off factor. The trade-off factor shows the preference of the allocation-cost optimization to the turnaround-time. Finally, to study and evaluate the efficiency of the proposed algorithm on the proposed model, a handful of experiments have been conducted and simulated. The simulation results show that the MinFCMT algorithm is very effective in a workflow-application scheduling. The main contributions of the present paper are as follows:

- Developing a WSC model based on provisioning the resources for the workflow scheduling so that the task-execution dependencies are satisfied and its application makespan and allocation-cost can be minimized.
- Developing a MinFCMT heuristic algorithm based on the WSC model so that it is an algorithm scheduling an application in a form that both makespan and allocation-cost can be optimized due to the trade-off factor.

The rest of this paper is organized as follows: Section 2 introduces an execution environment. A proposed detailed model and heuristic algorithm is described in section 3. Section 4 involves a simulation setup and an analysis of the results and its relevant experiments in order to evaluate the efficiency of the proposed algorithm. Section 5 discusses the related works. Finally, section 6 ends with a conclusion and future work.

2 Execution environment

The agreement-based resource management allows an application-level scheduler to attain the resources in the desired time. The workflow management system, therefore, ensures access to the desired resources within the agreed time and cost. In the most resources, an agreed structure is reached between the provider and consumer in terms of available time slots. In clusters, for instance a slot indicates the availability of a number of the related processors, start time, duration and cost. Once a slot is obtained, it can subsequently be used without an extra interaction between the provider and consumer.

A workflow-application is represented in a DAG. A DAG is defined as $G = (V, E)$, where V is a set of nodes, each node representing a task, and E is a set of links, each link representing the execution precedence order between two tasks. For example, a link $(i, j) \in E$ represents the precedence constraint that task v_i needs to be completed before task v_j starts. The data is a $V*V$ matrix of the communication data, where d_{ij} is the amount of the data required to be transmitted from the task v_i to the task v_j. As a workflow may consist of sub-workflows with multiple entries and exits so the first thing to be done is to add two pseudo-tasks, a top task and a bottom task, with zero execution time indicated by 0 and $n + 1$, respectively. The top task spawns all actual entry tasks of the workflow to be linked to a single node, while the bottom task joins all actual exit tasks to a single node.

The user submits the application characteristics to the application-level scheduler only to be executed on the grid environment. The user expects to have his application executed with the minimal makespan and allocation-cost. Certainly, the users exploit trade-off factor in order to show a preference for cost to makespan. In cases where this factor is not specified by the users, the default trade-off factor is considered as equal.

In fact, the application-level scheduler acts as a mediator between the resource providers and users. Due to the reports of the available slots obtained from the resource providers, the application-level scheduler plans the application. The entire slots exploited in planning the application, will be submitted to LRM in order to provision the resources. All of the computational resources can act as a service-provider (site) for time-slots.

We suppose that the application-task performance models are clear on each resource. The execution time of a certain task, therefore, may be obtained from a certain resource due to application performance models. Also, the execution of a single task consists of three phases: (a) the input data retrieval from the resource executing the immediate predecessors of the task (b) the task execution and (c) the output data communication from the current resources to the resources presumed to execute successors of the task.

To transfer the data between the application-tasks, three data-management strategies have been proposed by Deelman et al. [8] known as the regular, dynamic cleanup and the remote I/O (on demand). In this paper, the remote I/O (on demand) strategy has been used, so that the output data are submitted to the resource that is seeking to execute immediate the successor-tasks from the immediate predecessor-tasks using the existing high-speed network among the resources.

3 The proposed model and algorithm

In general, the users are in need of two QoS: the deadline and budget of their applications on the pay-per-use services [9]. The users normally tend to run their applications in as the lowest makespan and cost as possible. Thus, a trade-off factor indicating the significance of the cost to time will be used. In this section, the issue of application scheduling will be stated and the WSC model will be presented and then solved in order to optimize the application cost-makespan. Finally, a heuristic algorithm will be developed to conduct the application scheduling with the aim of optimizing the cost and makespan.

3.1 The proposed cost-based model

The model consists of a set of heterogeneous consumers and resource providers where the consumers seek to schedule their workflow applications with the minimum cost and makespan. In the WSC model, R stands for a set of available heterogeneous resources. Each resource consists of a set of slots.

The application model is defined in section 2. If task v_i is executed on the slots available to resource r_j, then, the Task Execution Time (TET) will be TET_{ij} and the Task Allocation Cost (TAC) is obtained by

$$TAC_{ij} = TET_{ij} \times C_j \times RNP_i, \ \forall v_i \in V, r_j \in R, \quad (1)$$

where C_j is the allocation cost of r_j resource slots and RNP_i is the Required Number of Processors (RNP) of the task v_i. To make sure that each task is executed only on the slots of the same resource, binary decision variable x_{ij} is to be defined by

$$x_{ij} = \begin{cases} 1 & \text{if the resource slot of } r_j \text{ is selected for executing task } v_i \\ 0 & \text{otherwise} \end{cases}, \quad (2)$$

to achieve that, it is essential to satisfy

$$\sum_{\forall r_j \in R} x_{ij} = 1, \ \forall v_i \in V. \quad (3)$$

Now, the execution time and allocation-cost of each task v_i can be obtained, provided that the task is executed only on the slots of the same resource according to

$$TET_i = \sum_{\forall r_j \in R} TET_{ij} x_{ij}, \ \forall v_i \in V, \quad (4)$$

$$TAC_i = \sum_{\forall r_j \in R} TAC_{ij} x_{ij}, \ \forall v_i \in V. \quad (5)$$

The data transfer rates of the resources are stored in the matrix B and d_{ij} is the amount of the data supposed to be transmitted from the task v_i to the task v_j. L stands for the average latency cost of the resources. The Data Communication Cost (DCC) from the task v_i (scheduled onto the resource r_m) to the task v_j (scheduled onto the resource r_n) is defined by

$$DCC_{ij} = L + \frac{d_{ij}}{B_{mn}}, \ \forall v_i, v_j \in V, \forall r_m, r_n \in R. \quad (6)$$

The Total Data Communication Cost (TDCC) between the tasks v_i and v_j is obtained by

$$TDCC_{ij} = DCC_{ij} \left(1 - \sum_{\forall r_k \in R} x_{ik} x_{jk}\right), \ \forall v_i, v_j \in V, \quad (7)$$

in case, both tasks v_i and v_j are scheduled on the slots of the same resource, the acquired summation in (7) becomes one, as a result $TDCC_{ij}$ will be zeroed.

The Earliest Start Time (EST) of the task v_i on the resource r_j is known as EST_{ij}. The EST of the entry task is to be initialized with the Simulation Current Time (SCT) by

$$EST_{0j} = SCT, \ \forall r_j \in R. \quad (8)$$

For the rest of the workflow tasks, the EST value is computed by

$$EST_{ij} = \max_{\forall r_j \in R} \left\{ AV_j, \max_{\forall v_m \in pred(v_i)} \{SFT_m + TDCC_{mi}\} \right\}, \quad (9)$$

so that their computations recursively start with the entry task, where AV_j is the earliest start time of the slots of the resource r_j which is capable of executing the task v_i. The secondary max block in (9) computes the starting ready time of the execution of task v_i. To obtain a task ready time, firstly, execution time of the entire immediate predecessor tasks is computed. Secondly, all required data of the task v_i need to have reached the resource r_j. The Earliest Finish Time (EFT) of the task v_i on the resource r_j is known as EFT_{ij} which is computed by

$$EFT_{ij} = TET_i + EST_{ij}, \ \forall v_i \in V, \forall r_j \in R, \quad (10)$$

to compute the EFT of the task v_i, the entire immediate predecessor tasks need to be scheduled beforehand. After a task v_i is selected to be scheduled on the resource r_j (due to (11)) the EFT of the task v_i on the resource r_j is equal to the Selected Finish Time (SFT) of the task v_i.

Supposing α as a trade-off factor indicating the preference of the allocation-cost to the execution time, the trade-off cost metric of the execution of the task v_i on the resource r_j is obtained by

$$\varphi_{ij} = \alpha NTAC_{ij} + (1-\alpha) NEFT_{ij}, \ \forall v_i \in V, \forall r_j \in R, \quad (11)$$

where $NTAC_{ij}$ and $NEFT_{ij}$ are the normalized TAC_{ij} and EFT_{ij}, respectively, so that they are computed by

$$NTAC_{ij} = \frac{TAC_{ij} - \min_{\forall r_j \in R}\{TAC_{ij}\}}{\max_{\forall r_j \in R}\{TAC_{ij}\} - \min_{\forall r_j \in R}\{TAC_{ij}\}}, \quad (12)$$

$$NEFT_{ij} = \frac{EFT_{ij} - \min_{\forall r_j \in R}\{EFT_{ij}\}}{\max_{\forall r_j \in R}\{EFT_{ij}\} - \min_{\forall r_j \in R}\{EFT_{ij}\}}, \quad (13)$$

respectively. The normalization is important because we do not know what the range of values the allocation-cost and finish time will take, are for a given solution.

Thus, the objective function of the application scheduling problem is obtained by the minimization of the sum of the trade-off cost metrics for the whole application-tasks reached by

$$\min\left(\sum_{\forall v_i \in V} \min_{\forall r_j \in R} \varphi_{ij}\right). \quad (14)$$

The application scheduling problem involves mapping each task v_i onto the suitable resource r_j, so that the application makespan and allocation-cost can be minimized.

Upon the completion of the whole application tasks, makespan and allocation-cost will be computed by

$$makespan = \sum_{\forall r_j \in R} EFT_{(n+1)j} x_{(n+1)j} - \sum_{\forall r_j \in R} EST_{0j} x_{0j}, \quad (15)$$

$$allocation\ \cos t = \sum_{\forall v_i \in V} \sum_{\forall r_j \in R} TAC_{ij} x_{ij}. \quad (16)$$

In the following section, a heuristic algorithm is presented to solve the WSC model as a whole.

3.2 The proposed MinFCMT heuristic algorithm

The MinFCMT is a heuristic algorithm which is employed to solve the WSC model. This algorithm schedules an application in a form that both makespan and allocation-cost can be optimized due to the trade-off factor.

There is a handful of choices for each task, among which the choice capable of minimizing the cost metric of (11) will be selected as the best solution. According to the best solution, the *EST* needs to be computed to execute immediate successor tasks and this procedure will be carried on so long as the execution of the whole application tasks will be finished.

The MinFCMT pseudo-code is presented in algorithm 1 which operates according to the WSC model. The algorithm obtains the available slot lists to all resources and the unscheduled tasks as an input parameter (lines 1, 2). Moreover, the *EST* is initialized with simulation current time (line 3). The application-level scheduler carries out the planning of each application task due to available slots list characteristics with an eye on the cost metric presented in (11), (lines 4 to 14). Initially, a list of unplanned tasks which are eligible to be executed is selected (line 5). Next, the eligible tasks are defined as the ones whose parents' tasks execution is completed, though the very same tasks have not been executed yet. The available slots list of each resource is obtained by line 7. In line 8, the *EST* of the task *T* is computed recursively due to (9). Eventually, the *EFT* of the task *T* is computed by (10), (line 9).

The *EST* is computed on the basis of the completion-time of the latest parents tasks *T*. Next, the best slot capable of executing the task is selected for each task *T* on each resource. In cases, the selected resource does not match with the resource which executes the parents' tasks, the data-transfer time needs to be added to the *EST* due to (7) and (9).

Once the best slot for executing task *T* is obtained on each resource, the resource which minimizes the cost metric in (11) will be selected as the best resource (line 10). Now, it comes to allocating the task *T* to a selected resource (line 11) as well as updating the slots list of the selected resource (line 12). This procedure needs to be continued as long as there still exists an eligible task (lines 4 to 14). Finally, when the entire application tasks are planned, the makespan and allocation-cost need to be computed according to (15) and (16), respectively. At the end of the completion of the whole application tasks, the slots assigned to the application tasks will be released.

4 The simulation setup and the results

To conduct an experimental evaluation of the efficiency of algorithm 1, the GridSim [10] is used to simulate the application-level scheduler in the Utility Grids environment. The Grids environment which is modeled in this simulation consists of ten sites belonging to a subset of the European Data Grid (EDG) spread across five countries which are interconnected via a high-speed network [1, 11]. The workload simulated on these sites follows the workload model generated by Lublin [12]. The main purpose of the use of this model is to create a realistic simulation environment where the tasks compete with one another. Table 1 shows the workload parameters values applied to in the Lublin model. Table 2 shows the configuration of the resources on the Grids test-bed. The configuration of the resources is used in order to show the heterogeneity of the execution environment.

Table 1: Lublin workload model parameter values.

Workload parameter	Value
JobType	Batch JOBS
Maximum number of CPUs required by a job(p)	1000 $Log_2(p)$
uHi	uHi-2.5
uMed	As created by Lublin
Other parameters	model

Algorithm 1: The pseudo-code for the MinFCMT heuristic algorithm

Input: An application characteristics with an instruction length for each task and the required CPUs
The resource characteristics and the available slots to each resource

Output: The workflow scheduling

```
1   Get the list of the available time slots for all resources.
2   UnScheduledTask = get the list of the tasks which have not
    been scheduled yet.
3   Assign the simulation current time to the EST.
4   While UnScheduledTask is not empty do
5       EligibleTasks = select all tasks which executions of their
        parents have been completed.
6       for each T in the EligibleTasks do
7           Acquire the available slots of each resource.
8           Compute the EST of the task T on each resource by
            (9).
9           Compute the EFT of the task T due to (10).
10          Find a time slot (TS) which is feasible for the task T
            while minimizing the cost metrics as defined in (11).
11          Allocate the TS on the resource r to the task T
12          Update the list of available slots to the resource r.
13      end for
14  end while
15  Compute the makespan and allocation-cost of the application
    respectively, as defined in (15) and (16).
```

Bologna(Italy)	100	1140	0.0069

To conduct experiments, a parameterized graph generator is used to create a synthetic workflow application [13]. The application characteristics contain n=100 tasks with an average execution time of 1000 *s* [14]. The workflow on the average consists of $\sqrt{n}$ levels (the workflow graph depths) and $\sqrt{n}$ tasks at each level. Each task on the average needs 25 CPUs for executing. The mean value of the data transfer among the tasks is 1000 *Gb*. The mean bandwidth value among resources is 10 *Gb/s* with a mean latency time of 150 *s*.

At this stage, the scheduling algorithm that uses the best-effort QoS for scheduling, is simulated and tagged as the BE. In BE, the exploited heuristic method selects a resource with the minimum number of tasks in the waiting and running queues.

An application scheduling algorithm that uses a cost model, is presented by Singh et al. [14, 15]. This cost-modeled algorithm makes a trade-off between scheduling and allocation-cost based on trade-off factor. The scheduling takes place using a multi-objective genetic algorithm, as well as simulating the algorithm. It is tagged as the MOGA for brevity [14, 15].

The MinFCMT, the MOGA and the BE algorithms are simulated and their performance is evaluated through conducting a number of experiments. Finally, the results from the algorithms are compared with one another where *"trade-off factor=0.5"*. Due to the considerable discrepancy among the experiments' results, the scales of the y-axis of the diagram are shown in the logarithmic scales which are based on 10.

Fig. 1 reveals the simulation experiment results from the allocation-cost of the three algorithms. The MinFCMT algorithm allocation-cost declines nearly 40% compared to the MOGA algorithm as well as almost one order of magnitude compared to the BE algorithm.

Fig. 2 reveals the simulation experiment results from the makespan of the three algorithms. The makespan of the MinFCMT algorithm declines nearly 14% compared to the MOGA algorithm and almost one order of magnitude compared to the BE algorithm.

To obtain the slots for planning, the MOGA algorithm uses a genetic algorithm whose genes of each single chromosome correspond with a slot from a specified resource. Due to the Grids environment which is a dynamic one, the MOGA algorithms decision-making takes place based on the static information of the slots. That is why, it cannot effectively optimize the performance. In addition, the user has no explicit control on allocating the resources to the tasks, thus this model cannot optimize the performance either. As a result, the allocation-cost and makespan of the proposed algorithm is less than both above-mentioned algorithms.

Fig. 3 reveals a comparison of runtimes of the three algorithms: the MinFCMT, the MOGA and the BE. The MinFCMT algorithm runtime shows an outstanding decrease, approximately three orders of magnitude relative to both the MOGA and the BE algorithms runtimes. The very low runtime of the MinFCMT algorithm is explained by the fact that the MinFCMT selects the best resource just once for each task, so its runtime will be very low. Whereas the MOGA algorithm uses genetic algorithm, that is, it needs to repetitively test a handful of the solutions in order

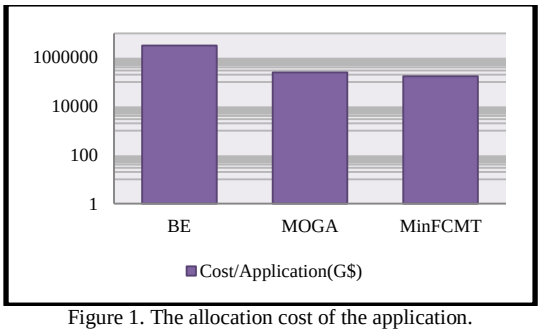

Figure 1. The allocation cost of the application.

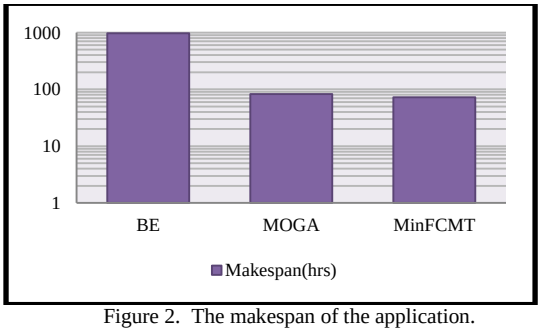

Figure 2. The makespan of the application.

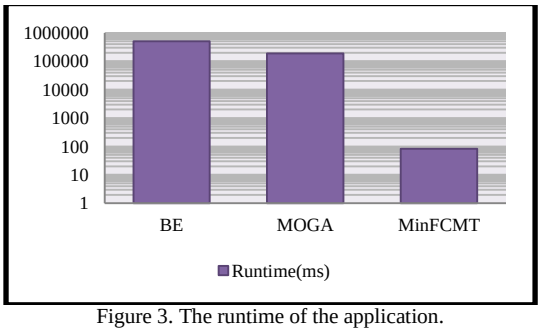

Figure 3. The runtime of the application.

to make decisions at each stage for planning the entire tasks. Therefore, this approach requires a high time-complexity to obtain the best solution. Compared to both the MinFCMT and the MOGA algorithms, the best-effort service has the highest runtime, because this approach does not supply the resources in advance. As a result, the proposed algorithm reveals a better performance compared to both algorithms.

5 Related works

As shared multiprocessing systems advance, the issue of the application scheduling has been the main concern. There is a comprehensive introduction on the job scheduling strategies [16, 17]. Moreover, in [18], the computational models are surveyed for Grid scheduling problems.

In the queue-based systems, the delivered quality of service to the users is the best effort QoS. However, the alternative approach is one of the planning-based systems [19]. In these systems, according to agreements the start time of the task can be established in advance instead of the task waits in queue in order to get access to the resource [20]. The above-mentioned agreements are based on an abstract description, so-called "slot".

In [21], a resource model is adopted similar to the proposed model. This model differs from the proposed model so that in this model, the resource provisioning takes place just for one task on a single resource, whereas in the proposed model, the resources are provisioned for the entire application tasks.

In [1], a heuristic algorithm is presented for scheduling many parallel applications on the Utility Grids that optimizes the cost-to-time trade-off. This approach is close to the studies conducted for this paper and its main difference from that of the proposed approach lies scheduling the parallel applications, whereas the approach adopted by present paper is based on scheduling the workflow application.

In [8], the Cloud computing for scheduling the scientific workflow is shown that uses the cost performance trade-off of the resource provisioning plans. This approach differs from the proposed approach, in that, it examines cost performance trade-offs disregarding the minimization of the multi-objective allocation-cost and makespan.

In [22], similar to the current paper, a genetic algorithm is proposed to find an optimized mapping of the tasks to the resources which minimizes both financial cost and makespan. This approach is developed in [14, 15], that is a multi-objective genetic algorithm. In [14, 15], the entire resources possess identical CPU ratings and cost processing whereas in the proposed model, all resources are constituted of the heterogeneous clusters with different processing cost and CPU ratings, that is the main difference between the proposed model and those models. Hence, removing this resource homogeneity complicates the identification of an appropriate resource selection.

Since, in [14, 15], the algorithms are genetic-based ones, the runtime takes a longer time. In case, the slots' characteristics undergo a change during scheduling, the slots' characteristics are to be updated and a rescheduled resulting in a far longer runtime. Hence, these approaches do not serve the purpose in the dynamic environments such as the Grids. In contrast, in the proposed approach, the WSC model is presented for the workflow scheduling problem which is highly adaptive to the dynamic environments. Also, this model is solved by the MinFCMT heuristic algorithm in an effective runtime.

6 Conclusion and future work

The present paper deals with designing, implementation and evaluation of the MinFCMT heuristic algorithm in order to schedule the applications. The paper seeks to optimize the cost-makespan based on the proposed WSC model. To develop a real distributed environment, the resources workload is simulated based on the Lublin model. Due to many experiments conducted on the generated syntactic workflow, it was shown that the MinFCMT heuristic algorithm is far more effective than the existing algorithms. The results indicate that the runtime of the MinFCMT algorithm decreases more than three orders of magnitude compared to the existing algorithms.

In future, we intend to develop an architecture by which the expected application performance can be determined with certainty and enhance our proposed algorithm.

Abstract *-The distributed Computation world is becoming complex and very large; Cloud Computing has emerged as a popular computing model to support large data processing using commodity hardware. In this context, the number of physical units (dedicated servers) may suffer shortage problem at peak time due to the increasing needs of using resources. In this paper we introduce a solution for resolving this problem by adopting the use of idle general purpose machines that exist within homes, universities or enterprises to be part of the cloud computing environment. The proposed solution is implemented and tested through the provision of the modified IaaS by using CPU cycles denoted by public and OpenStack Cloud Computing platform. On experimenting the proposed model ,the performance of the cloud has improve significantly ,which confirm that this mixing of generic and dedicated resources allocation leads to the provision of inexpensive resources with the guarantees of the quality of services.*

Keywords:Cloud Computing, CPU Cycle-Harvesting, Cloud Computing Infrastructure, Architecture

I. INTRODUCTION

The rapid growth in the distributed computing environment technologies has led away from the in-house Public Resources Computing to Grid computing and now to Cloud Computing paradigm. In this paradigm, Cloud resources are delivered in a flexible and service-oriented manner to consumers on an on-demand pay-as-you-go manner. This differs from common practice in IT whereby resources are procured and used in a more coarse-grained and less flexible manner. Cloud Computing is not a completely new concept for development and operations of the web application [3,12] .In the cloud we have to address a set of Cloud Computing fundamentals like virtualization management, scalability, interoperability, fail over mechanism and elasticity which represent one of the major attractions of the cloud. In Cloud Computing there are different delivery or deployment models such as Public, private, and Hybrid Clouds [13]. These models focus on the cloud architecture, and services as well. In Private Cloud, Data and processes are managed within organization boundaries without any restrictions on the network bandwidth, security exposures, or legal requirement for using service like these on public services. In Public Cloud, it describes the cloud computing in the traditional mainstream sense, whereby resources are dynamically provisioned on a fine grained, self-serviced basis over web services from an off-site third parity provider. Finally, in Hybrid Cloud, the environment is consists of two or private and public cloud computing providers.

Although private Cloud Computing is more secure than Public Cloud Computing, its elasticity is limited depending on the maximum hardware capacity and at the peak time it is bound to fall short of demand which is known as Cloud burst. As the needs for computational and storage resources increase the technology needs to develop to fulfil this increasing needs of using resources. We propose a new architecture to ad-hoc additional computational resources with reliable computing power using CPU cycles denoted by public (Organization PC.s) through the use of OpenStack Cloud computing software platform for on-premises Infrastructure as a Service (IaaS).

The availability of volunteer desktop machines as a part of the cloud leads to various benefits to individual organizations. It could reduce the numbers of dedicated machines needed to be purchased. Also it reduces the need for specialized infrastructure for resilience, such as redundant power and cooling systems, battery backup,… etc., which represents 25% of datacentre costs [8].Rather than ensuring resilience of a small number of physical buildings, the grain of resilience could be expanded by using more widely distributed machines and tolerating individual building failures [7]. As well as it reduces overall power consumption through the reduction in the total number of machines since the energy cost of manufacture for a computer has been estimated as four times that used during its lifetime [9].

The paper is organized as follows. Section 2 presents the related works on Cloud Computing IaaS implementations, Desktop Grid and public resources computing. The proposed Architecture is described in section 3. The architecture implementation and results is described in section 4. Finally, section 5 presents the conclusion.

II. RELATED WORK

The work presented in [14], explains an opportunistic cloud computing IaaS model implementation.It provides service at lower cost than dedicated cloud infrastructures based on basic computing resources (processing, storage and networking) through the opportunistic use of idle computing resources available in a university campus. UnaCloud uses a commodity and non-dedicated underlying infrastructure to implement the opportunistic design concepts which broadly has effect on; 1) the cloud services availability as the computing resources is dependent on the behavioural pattern of their currently owners, as the availability of the service represent an effective term to ensure any type of QoS or SLA. 2) Service scalability will always depend on the available resources on the opportunistic idle desktop machine which will limit the service scalability. 3) The architecture doesn't support integration with any of the currently used Cloud Computing platform APIs which limitsits use at peak times or at cloud burst.
Private cloud would provide flexible service availability and scalability while addition of hybrid clouds will providenot only elasticity but also would provideself-managing in terms of resilience, performance and balancing potentially.

In [25],an architecture is proposed to integrate grid and private cloud such that grid resource requirements are fulfilled by fetching resources from cloud when needed and vice versa with additional storage clusters to enhance the performance as Grid Computing resources are not utilized optimally most of the times.

In [7], an outline of the major implementation challenges has been introduced on how underused computing resources within an enterprise may be harnessed to improve utilization and create an elastic computing infrastructure, In contrast to the datacentre cloud model. This model is analogous to volunteer computing as exemplified by Condor [18] and BOINC [16, 17], although it poses considerable additional implementation challenges.

Volunteer computing (VC), Public Resources Computing (PRC) sometimes described as a paradigm of a large number of computers, on which individual users' machines are used to perform computationally tasks. SETI@home, Climateprediction.net, and LHC@home are the most popular projects based on the BOINC (Berkeley Open Infrastructure for Network Computing) framework [16, 17] or based on Condor [18]. Volunteer computing is being used in high-energy physics, molecular biology, medicine, astrophysics, climate study, and other areas.

In the context of IaaS models, OpenStack Cloud Computing platform [19, 20] is a collection of open source software projects that service providers can use to run their cloud compute and storage infrastructure. It is backed by Rackspace, NASA, Dell, Citrix, Cisco, and Canonical and over a hundred other organizations but it uses only dedicated servers to setup such Cloud Computing platform like that platform which created using Eucalyptus [21]

Our proposed approach focuses on extending the available Cloud Computing platform infrastructure which ensures service availability with the opportunistic use of idle resources which will provide services elasticity and service scalability through the using of both of the dedicated and non-dedicated infrastructures. It uses the same idea behind the building methodology of OpenStack Cloud Computing platform extending the infrastructure used by harvesting the idle computing resources donated by the public desktop machines.

III. PROPOSED ARCHITECTURE

In this approach we use the same idea behind the methodology of building the OpenStack Cloud Computing platform but with extending the used infrastructure by harvesting the idle computing resources donated by the public.
The architecture has three major components; Cloud Computing platform, Harvesting Middleware, and Resources allocation desktop agent.

1) ***Cloud computing platform:***The Cloud Computing platform consists of Cloud Controller which receives submitted user requests and passes them to the underlying components. It represents the interaction between computing nodes, block storage volumes, the networking controllers (software which controls network infrastructure), and API endpoints.

This interaction is represented in terms of managing and scheduling resources between different mentioned components. Since computing nodes have different operating systems running, there is virtualization machine manager called Hypervisor that mediates between the guest operating systems (Virtual machine or the Cloud Service) and the native hardware. The hypervisor is responsible to bring up virtualization by handling a set of certain protected instructions.

In our implementation we use Kernel Based Virtual Machine (KVM). KVM is a full virtualization solution that is unique in that it turns a Linux kernel into a hypervisor using a kernel module. This module allows other guest operating systems to then run in user-space of the host Linux kernel.

Each time a request for a new cloud computing services is submitted, the cloud controllers checks-up the available resources such as cores, memory, and storage to deploy the virtual machine. If there is a provisioning for deploying such virtual machine,the cloud controller will process the request by deploying the requested service. But if the virtual machine

can't be deployed on the current cloud infrastructure due to lack of resources, the cloud controller will ask the harvesting middleware local resources manager to free up resources. This is done by moving one of the currently running cloud services to the most suitable registered desktop machine.

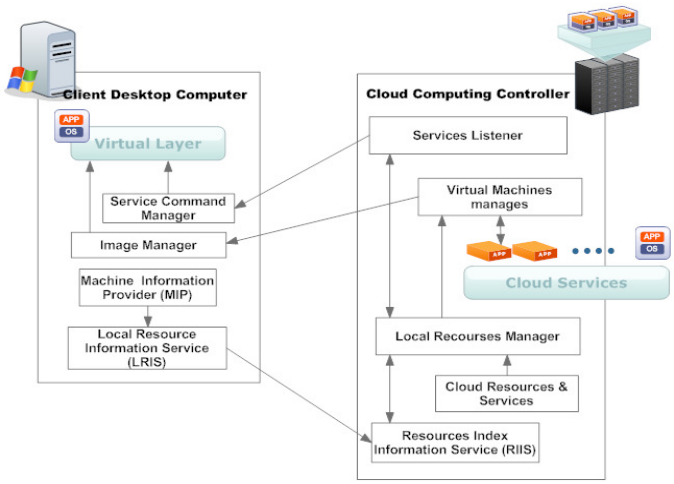

Figure 1 Harvesting Middleware Architecture

2) ***Harvesting Middleware:***The harvesting middleware consists of five daemons. Each one of these daemons plays a vital role in running any of the desktop machines included within the cloud computing. The five daemons are Resources index information service (RIIS), Cloud Resources and Service, Local Resources manager (LRM), Virtual machine manager (VMM), and Services Listener (SL) figure 1.

   a. Resources index information service (RIIS): RIIS represents a lightweight directory of the attached desktop machines, containing the basic information about local desktop resources and its aliveness status. This is done through a periodically heart beat message received from each registered desktop machine. RIIS collects information from several LRIS to allow searching the information to find the most suitable resources. The Desktop machine local resources information offered by the RIIS includes cores, memory, load status, desk storage and cloud service (Virtual machine) running on it if any.

   b. Cloud Resources and Service (CRS): it contains a complete list of Cloud platform resources e.g. computing node, network nodes, and storage. For each computing node there is a list of different running services associated with service information. This list may include, instance name, memory, virtualization type, kernel, desk source, interface type, service IP, DHCP server and all other information contained with a libvirt XML generated files.

   c. Local Resources manager (LRM): LRM is responsible for managing the execution of any cloud computing services on a desktop machine. It keeps track of all cloud computing services running on desktop machines, It also periodically query the status desktop running tasks from RIIS. If the Cloud Controller request the LRM to free up certain cloud resources, the LRM select the most suitable desktop machine from information provided by RIIS and CRS. Finally, it takes a snapshot of the running virtual machine to be deployed on the selected desktop machine.

   d. Virtual machine manager (VMM): VMM works in conjunction with the LRM to manage virtual machines in both the cloud environment and the desktop machines. It is responsible for creating image snapshots, suspending and starting running cloud services. Also, it can issue a deployment commends for starting , stopping , and monitoring cloud computing virtual machines on desktop PCs.

   e. Services Listener (SL): All users requests (Start, Terminate, Snapshot …etc.) are submitted to the cloud controller with the associated service identification. SL listen to all requests passed to the cloud controller and redirect basic requests to LRM registered cloud service running on desktop machines instead of passing it to either the compute nodes running these services or these that have a suspended image to guarantee service availability in case that desktop service failure.

3) ***Resources allocation desktop agent (RAD):***RAD consists of a simple four module, if we start from the bottom both of the Machine Information Providers (MIP) and Local Resources Information Service (LRIS) represent the resources discovery system which is responsible for publishing, and queuing the state of resources and their configurations. Up on installing the RAD agent on any desktop machine the MIP start by capturing information about the local resources which in turn passed to LRIS which represents the interface for RIIS on each desktop machine. Image Manager (IM) is responsible for issuing a simple virtualization commands for starting new virtual machine, terminating or monitoring. Also, it manages desktop virtual machine networking. The last module is the service command manager. It is used to execute basic requests redirect form SL Daemon on the running desktop cloud services.

IV. ARCHITECTURE IMPLEMENTATION AND RESULTS

In our implementation, the Cloud computing environment is established with the OpenStack [19,20] as a Cloud Computing middleware, KVM virtualization [6] as a hypervisor to

provide scalability and user isolation on OpenStack Cloud, and Libvirt [23] for hypervisor communication with cloud middleware.

The desktop Cloud services deployment includes the provisioning of the necessary data for its remote access using:

1) standard SSH [24] mechanisms
2) QEMUas a desktop virtualization tool [26]
3) Libvirt for virtualization interfaces.

Through the implementation we measure the values of the following parameters:

1) CPU utilization %: which depends on the software programs runningon this virtual machine, such as MySQL server or Apache server,… etc.
2) System Operation %: refers to the kernel's internal workings
3) IO requests wait%: is time spent waiting for I/O, such as a disk read or write as an important measurement parameter for the data intensive applications.
4) Memory used %: refers to the percentage of RAM used in performing tasks.

To test the previous parameters get results, we apply the following scenario:

1) Create Cloud computing services for monitoring various ways that CPUs spent on system performing different operations.
2) Monitor the system after the creation of cloud services without performing any user tasks whether it is by administration or by cloud client.
3) Load cloud services using a stress workload generator with half load and monitor system components performance.
4) Monitor cloud on peak load (peak usage time).
5) Suspend services on the cloud working node and monitor server performance.
6) Monitor number non-dedicated machined running windows 7 and display the average performance of all machines.
7) Move cloud service to desktop machine and record the machine performance.

By applying the previous scenario we recorded the following effects:

1) Effect on resources usages when creating N IaaS Cloud computing services.

From the client point of view, providing IaaS (Infrastructure as a service) is no more than creating a set of virtual machine by selecting the appropriate OS system required for the cloud client from those offered by the cloud provider. Upon creating service the client will have a virtual machine with a specific hardware specs running the chosen OS like any physical machines. IaaS Services/virtual machine creation consume almost all resources of the computing node host. The created virtual machine, effects on the performance of other VMs/services running on this host. Creating concurrent N service put the computing node under great stress as shown in fig 2. The Great stress effect is shown especially for the CPU and Memory utilization curves.

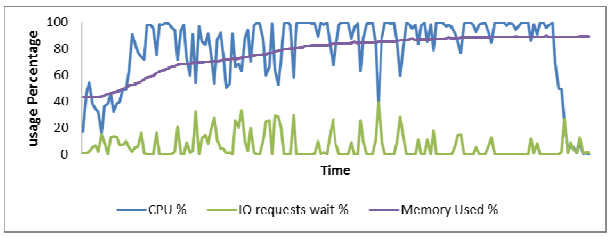

Figure 2 N Services (VM) Creation

2) Effect on resources usage rate after the time of creating N IaaS services and without loading any cloud services.

By monitoring different system parameters after IaaS services creation is done. We can see that about 90%of the computing node memory still used or reserved even through these services isn't using these resources in any useful work. The reason behind is that each virtual machine lock its own memory, which make it so difficult (consume longer time) to create another service on the same machine.

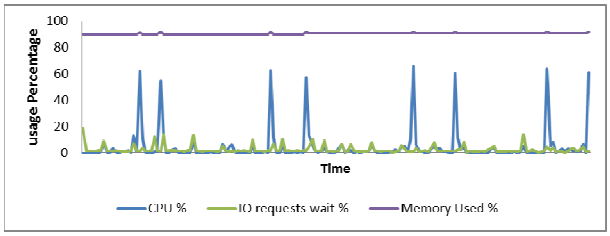

Figure 3 Cloud working node load after service creation without loading a cloud service

3) Effect on the resources percentage rate when half load running services occupied the system.

Upon putting the services under half load stress, , we can see that memory reach its maximum values and the CPU reach 90% at some points. System is fully utilized however the full load services are not reached yet.

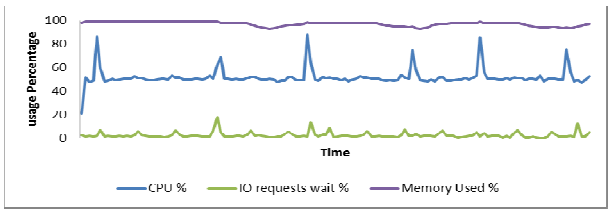

Figure 4Effect of Loading (N/2) of the running cloud services

4) Effect on the resources percentage rate when full load running services occupied the system.

Now, on full loading the cloud services, the computing node memory and CPU reach it maximum values which cause the system to reset a lot of tasks as we can see on fig 5. Not only but also the IO requests will wait for a significant amount of time. All these cause bad effect of the system throughput for the requested services.

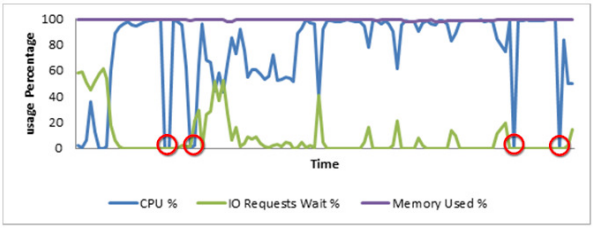

Figure 5 Effect of Loading N Cloud Service

5) Effect on computing node performance after suspending and moving service to a public desktop machine.

Now we apply our proposed solution by moving Cloud services (or part of the cloud load) to any available desktop machines (non-dedicated windows machines) with the same load. This movement is expected to increase the computing node performance due to decreasing its load and helping it to act well for the remaining part of the cloud services.

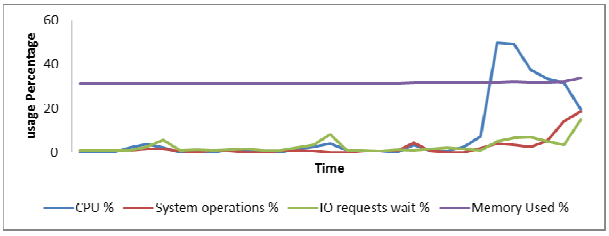

Figure 6 Cloud Computing node performances after suspending and moving service to desktop machine

6) Effect on desktop machine after completing the services movement process.

In normal cases we consume small part of our desktop machine computing power capabilities, as we can see on the following fig 7. Loading all services will have normal effect on desktop machine performance. As show in figure, over than 55% of machine memory is free to be used. Also, 80 % of CPU utilization is free to be used by desktop normal user. This indicates the good performance that we get when harvesting any available non-dedicated machines and use for freeing up the dedicated cloud computing nodes.

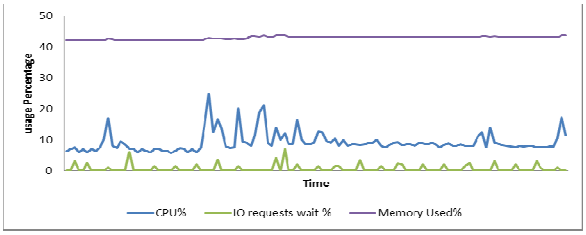

Figure 7 Regular usage desktop machine performances

7) Effect on performance when desktop and cloud computing users occupy the desktop machine,

The following two figures show the performance effect due to two cases. The first, when running IaaS service on the desktop (windows) machine while not running any other tasks need by the cloud computing our the desktop machine users. It still show the good performances showed in both memory and processor underutilization level. Memory is about 55% underutilized.

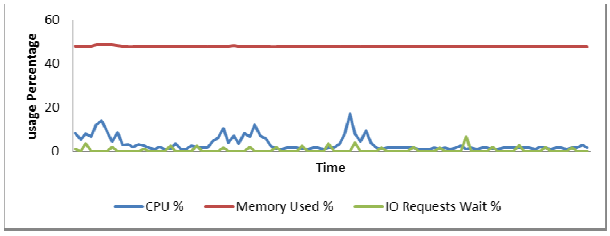

Figure 8 Run Cloud Service on windows machine (Both of the Client and service not loaded)

In the other hand, when user load services (whether it's by cloud user or desktop machine owner), the system is still working in the safe mode range. This mode will allow both users perform their tasks without affecting each other.

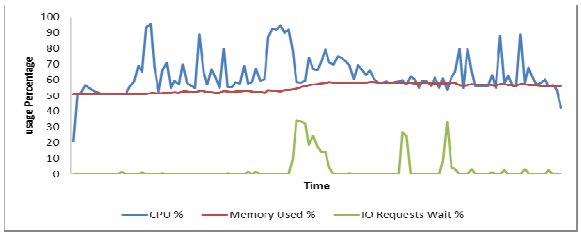

Figure 9 Run Cloud service on windows machine (Both of the Client and service loaded)

V. CONCLUSIONS

In this paper we presented a new approach which focus on extending the available Cloud Computing platform infrastructure to ensure service availability with the opportunistic use of idle resources which will provide services elasticity and service scalability through the using of both of the dedicated and non-dedicated infrastructure. Based on our implementation results, the action of moving cloud computing services to generic resources such as public desktop machines

easily available in homes, universities or enterprises will not affect the provided cloud services. On contrary it will help in improving the services and doesn't affect the public desktop machines performance at the same time.

CDAC Scientific Cloud: On Demand Provisioning of Resources for Scientific Applications

A. Payal Saluja, B. Prahlada Rao B.B, C. Ankit Mittal and D. Rameez Ahmad
SSDH, Centre for Development of Advanced Computing
C-DAC Knowledge Park, Bangalore, Karnataka, India

Abstract - Scientific applications have special requirements of availability of a massive computational power for performing large scale experiments and huge storage capacity to storage terabyte or petabyte range of outputs. Scientific Cloud provides scientists computational, storage and network resources with a inbuilt capability of utilizing the infrastructure. The scientific applications can be dynamically provisioned with the required cloud solutions that are tailored to the application needs. Centre for Development of Advanced Computing (CDAC) under Department of IT, is the pioneer in HPC in India with ~70TF compute power. The authors of this paper have discussed the need and benefits of scientific cloud. Authors have explained the model, architecture and components of CDAC scientific cloud. CDAC HPC resources can be provisioned on-demand to the scientific research community and released when they are not required. For Indian researchers and scientists, CDAC scientific cloud model will provide convenient access to reliable, high performance clusters and storage, without the need to purchase and maintain sophisticated hardware.

Keywords: HPC, HPC as a Service, Map Reduce, Cloud Vault

1 Introduction

High Performance Computing (HPC) allows scientists and engineers to solve complex science, engineering and business problems using applications that require high bandwidth, low latency networking, very high compute and storage capabilities. Scientists in the areas of high-energy physics [13], astronomy [14], climate modeling [15], chemo informatics [16] and other scientific fields, require massive computing power to run experiments and huge data centers to store data. Typically, scientists and engineers must wait in long queues to access shared clusters or acquire expensive hardware systems.

Cloud computing [17] is a model for on-demand access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, services, and software) that can be easily provisioned as and when needed. Cloud computing aggregates the resources to gain efficient resource utilization and allows scientists to scale up to solve larger science problems. It also enables the system software to be configured as needed for individual application requirements.For research groups, cloud computing will provide convenient access to reliable, high performance clusters and storage, without the need to purchase and maintain sophisticated hardware. It has been said by Pete Beckman, director of Argonne's Leadership Computing Facility that "Cloud computing has the potential to accelerate discoveries and enhance collaborations in everything from providing optimized computing environment for scientific applications to analyzing data from climate research, while conserving energy and lowering operational costs". However, there are various challenges of HPC on demand [29] like performance, power consumption and collaborative work environments. In this approach paper, we present the concept of scientific clouds, HPC as a service and its benefits to the scientific research community. The authors also propose a prototype for CDAC scientific cloud that will provide the following offerings

I. Infrastructure as a Service(IaaS)[18] by providing traditional MPI enabled HPC with parallel file system like GlusterFS[19] and by provisioning Hadoop[20] clusters with map reduce[21] with the support of Hadoop distributed file system(HDFS)[20].
II. Storage as a service (StaaS) [22] to provide petabytes of data storage to the scientific communities.

The rest of the sections of this paper are organized as follows: Section 2 describes the concept of HPC as a Service, the challenges of HPC on cloud and how cloud computing benefits the scientific community. Section 3 talks about the other scientific cloud projects and their objective and the relevant work. Section 4 details about the CDAC scientific cloud and its offerings. Section 5 details the proposed model and architecture for the CDAC scientific cloud. Section 6 talks about the applications that will be enabled on CDAC scientific cloud. Section 7 concludes and tells about the future plan of the work.

2 HPC as a Service on Cloud

Bringing HPC facilities to cloud will provision the scientists and researchers with a crucial set of resources and enable them to solve large-scale, data-intensive, advanced computation problems on research topics across the disciplinary spectrum. HPC as a service is an on-demand provisioning of high-performance, scalable HPC environment with high-density compute nodes and huge storage on high performance interconnects like Infiniband [4] and Myrinet [5]. HPC as a service is provisioned to meet the HPC application demands, whether one server (Virtual machine) or a large cluster (Virtual cluster). A Virtual cluster is a collection of Virtual Machines configured to interact with each other as a traditional Linux cluster. Scientific cloud or HPC as a Service enables greater systems flexibility and eliminates the need for dedicated hardware resources per applications and would help researchers cope with exploding volumes of data that need to be analyzed to yield meaningful results. It also simplifies usage models and enables dynamic allocation per given task.

[6] Described a demonstration of a low-order coupled atmosphere-ocean simulation running in parallel on an EC2 system. It highlights the significant way in which cloud computing could impact traditional HPC computing paradigms. The results show that the performance is below the level seen at dedicated, supercomputer centers, however, performance is comparable with low-cost cluster systems. Also it has been concluded that it is possible to envisage cloud systems more closely targeted to HPC applications, that feature a specialized interconnect such as Myrinet or Infiniband.

Scientific Cloud benefits to the Scientists & research Community:

- **Dynamic Provisioning of HPC Clusters**: Access to on-demand cloud resources enables automatic provisioning of additional resources from the HPC service to process peak application workloads, reducing the need to provision data center capacity according to peak demand. Hence, scientists will benefit from the ability to scale up and down the computing infrastructure according to the application requirements and the budget of users.
- **Virtual ownership of resources** : Virtual ownership of cloud resources will reduce uncertainty concerning access to those resources when you need to use them
- **Ease of deployment and access**: The use of virtual machine images offers the ability to package the exact OS, libraries, patches, and application codes together for deployment. Scientists can have easy access to large distributed infrastructures and completely customize their execution environment, thus providing the perfect setup for their experiments.
- **Reduction in overall Job execution time**: Jobs will be scheduled using intelligent data aware job scheduling algorithms.

Figure 1 depicts the layered architecture of scientific cloud. The lowest layer of the stack is the physical resources (compute, storage and network) that will be connected through a high speed link. The first software layer above the physical hardware is the host operating system. Since scientific cloud will be catering HPC applications, performance of such applications on such infrastructure will be of prime importance. Hence, Type 1 or bare-metal hypervisor should be preferred for virtualization that will run directly on the host's hardware to control the hardware and to manage the guest operating systems.

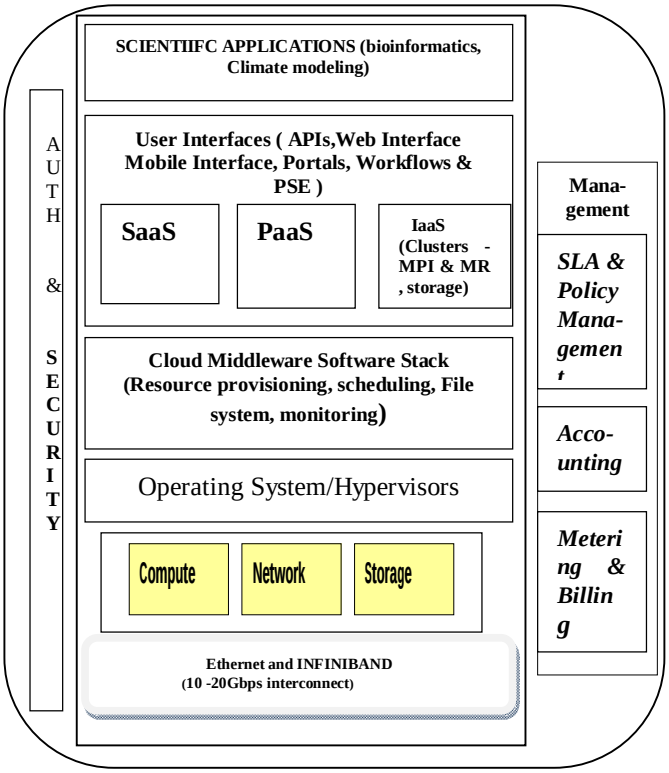

Figure 1 Scientific Cloud Architecture

A guest operating system will run on another level above the hypervisor. Hypervisor actually controls the host processor and resources, allocating what are needed to each operating system in turn and making sure that the guest operating systems (called virtual machines) cannot disrupt each other. The virtualized resources include the basic cloud computing services such as processing power, storage, and network. The Cloud middleware software stack is the key component that handles resource provisioning and scheduling, volume management, system monitoring for all the higher-level components and services.

Cloud management is a crucial component as it monitors and manages all the cloud resources at physical and virtual level. The various management components that will be part of scientific cloud are : Resource Inventory search, Hardware monitoring & Management , Storage maps and reports, Alerts & notifications with automated rectification, accounting and billing(to recover costs, capacity planning to ensure that consumer demands will be met) , policy management & SLA(Service level Agreements- management to ensure that the terms of service agreed to by the provider and consumer are adhered to, and reporting for administrators).

3 Science Cloud Projects

The following are some of the science cloud projects have been executed in the direction to achieve HPC as a Service:

3.1 Cumulus

Cumulus [2] is a project to build a Scientific Cloud for a Data Center. It is a storage cloud system that adapts existing storage implementations to provide efficient upload/download interfaces compatible with S3.It provides features such as quota support, fair sharing among clients, and an easy to- use, easy-to-install approach for maintenance. The most important feature of Cumulus is its well-articulated back-end extensibility module. It allows storage providers to configure Cumulus with existing systems such as GPFS [9], PVFS [10], and HDFS [11], in order to provide the desired reliability, availability or performance trade-offs. Cumulus is part of the open source Nimbus toolkit [12]. Cumulus is implemented in the python programming language as a REST service. The Cumulus API is a set of python objects that are responsible for handling specific user requests.

3.2 OpenCirrus

Open Cirrus [3] tested is a collection of federated datacenters for open-source systems and services research. It is designed to support research into the design, provisioning, and management of services at a global, multi-datacenter scale. It is designed to encourage research into all aspects of service and datacenter management.

3.3 GridGain

GridGain[30] is Java based open source middleware for real time big data processing and analytics that scales up from one server to thousands of machines. It enables the development of compute and data intensive High Performance Distributed Applications. Applications developed with Gridgain can scale up on any infrastructure - from a single Android device to a large cloud. Gridgain provides two major functionalities of Compute Grids and In-Memory Data Grids

3.4 StratusLab

Stratus Lab [31] is developing a complete, open-source cloud distribution that allows grid and non-grid resource centers to offer and to exploit an Infrastructure as a Service cloud. It basically enhances the grid infrastructure with virtualization and cloud technologies. It is particularly focused on enhancing distributed computing infrastructures such as the European Grid Infrastructure (EGI).

Each of the above mentioned projects focuses either on provisioning data centers on cloud or compute power on cloud. **Amazon Web Services** alone provisions the various services required for variety of HPC applications like Amazon Elastic Compute cloud EC2, Amazon Elastic Map Reduce (EMR), Amazon Simple Storage Service (S3) [32]. **CDAC Scientific cloud** is an effort to provide the services like compute and storage for the HPC community along with the software technologies like map reduce, MPI , mobile applications that will accelerate discoveries and enhance collaborations in science.

4 CDAC Scientific Cloud (CSC)

C-DAC [7] is the pioneer in HPC in India and its HPC facilities on cloud can be linked by a 1 Gbps National Knowledge Network (NKN) [8], developed by NIC. The bandwidth offered by NKN will facilitate rapid transfer of data between geographically dispersed clouds and enable scientists to use available computing resources regardless of location. In addition, CDAC Scientific cloud will provide data storage resources that will be used to address the challenge of analyzing the massive amounts of data being produced by scientific applications and instruments. Storage as a service is of particular importance to scientific research, where volumes of data produced by one community can reach the scale of terabytes per day .CDAC will make the Scientific cloud storage available to science communities by aggregating a set of storage servers .It will make use of advanced technologies to provide fast random access storage to support more data-intensive problems. The test bed will be a mix of virtual clusters and storage options, traditional HPC cluster, Hadoop cluster, distributed and global disk storage, archival storage. The system provides both a high-bandwidth, low-latency InfiniBand network as well as a commodity Gigabit Ethernet network. This configuration is different from a typical cloud infrastructure but is more suitable for the needs of scientific applications.

Using CDAC Scientific cloud instances, users can expedite their HPC workloads on elastic resources as needed .Users can choose from Cluster Compute or Cluster Hadoop instances within a full-bisection high bandwidth network for tightly-coupled and IO-intensive workloads or scale out across thousands of cores for throughput-oriented

applications. This will let scientists focus on running their applications and crunching or analyzing the data generated by applications without having to worry about time-consuming set-up, management or tuning of clusters or storage capacity upon which they sit. Users will be able to run HPC applications on these instances including molecular modeling, genome sequencing & analysis, and numerical modeling across many industries including Biopharma, Oil and Gas, Financial Services and Manufacturing. In addition, academic researchers will be able to perform research in physics, chemistry, biology, computer science, and materials science.

Following will be the supported features of CDAC High Performance Computing as a service (HPCaaS):

- ✓ **Dynamic Provisioning of clusters** :On demand Provisioning MPI and Map reduce clusters to support compute intensive and data intensive applications
- ✓ **On-demand dynamic provisioning of storage volumes**: Dynamic provisioning of clusters and storage will be handled by the Cloud Resource Broker (CRB) or cloud metaschedular.
- ✓ **Security** : Simple , Secure and quick access to HPC clusters
- ✓ **Provisioning of customized libraries, softwares** workflows ,etc on HPC clusters as per the applications requirement Users will be provided with an option of selecting the specific MPI versions or compiler versions to suffice the application requirements
- ✓ **Performance:** To reduce the hypervisor overhead type-1 kind of hypervisor will be used. The distributed locations will be connected with 1Gbps link and within the site nodes will be connected with infiniband interconnect to reduce the latencies.VM allocation to form a cluster will be done by the cloud scheduler based on nearness to storage nodes to minimize the data movement on cloud.

Following are the services that will be provisioned on the CDAC Scientific Cloud

4.1 Infrastructure as a Service (IaaS)

C-DAC has its HPC facilities at various CDAC locations like Bangalore, Pune, Chennai, and Hyderabad with approximately 70TF. Figure 2 depicts the prototype model for dynamic provisioning of the computational resources when requested by the user. Users will be able to access the CDAC scientific cloud services through cloud portal. First time users will have to register with their required details and also the details about the kind of applications they want to run on the cluster. Based on the type of the application mentioned by the user resources will be allocated by the cloud broker and the cluster instance will be created on the fly. Immediately user will be intimated online and through mail about their login credentials and the IP address for the ssh access to the compute cluster. The allocation of the cluster and its nodes (master & worker nodes) will depend upon the CPU, memory, IO requirements of the application. The applications that will need more of data processing and less of communications will provided with the best suited map reduce cluster. The applications that are more compute and memory intensive will be provisioned by the MPI enabled clusters with parallel IO facility.

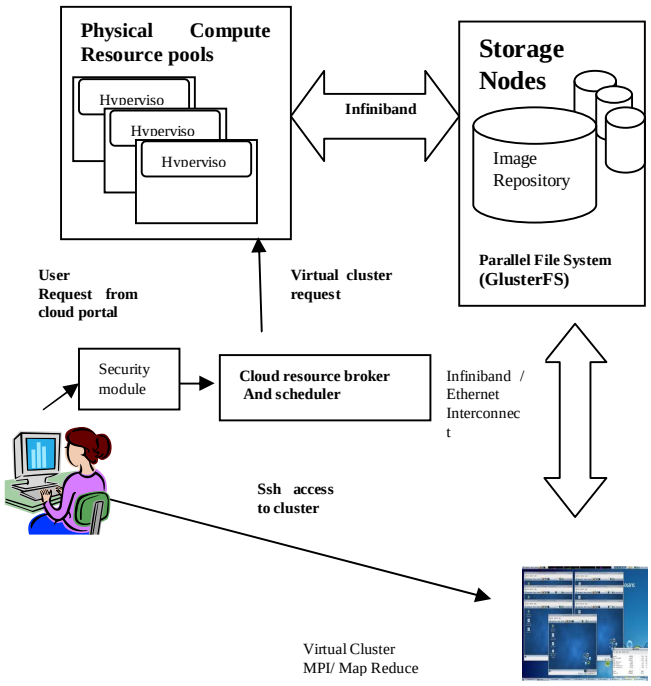

Figure 2 Infrastructure as a Service (IaaS)

4.2 Storage As a Service (StaaS)

A service of supplying data storage capacity over Internet is Storage as a Service. In context of scientific cloud, StaaS provisions petabytes of data storage to the scientific communities. CDAC's Cloud Vault based on OpenStack Swift Object Storage software will provide scientists and researchers partners with a convenient and affordable way to store, share, and archive data, including extremely large data sets. CDAC Cloud Vault is an object based storage system and multiple interface methods make the Cloud Vault easy to use for the average user. It also provides a flexible, configurable, and expandable solution to meet the needs of more demanding applications. In this, files (also known as objects) are written to multiple physical storage arrays simultaneously, ensuring at least two verified copies exist on different servers at all times. Figure 3 depicts the flow of the Storage as a service (StaaS).The user registers himself by

providing the required details and the required amount of storage. After the users request gets validated and approved, user is sent the access details of the storage through email. The various interfaces through which user can access Cloud Vault are as follows:

4.2.1 Web Interface

Web interface will allow access to the cloud vault files through browser. User will be able to list, create containers, Upload/Download files, and Delete files using this interface. There will not be any need of installation of any clients to access cloud files.

4.2.2 Desktop GUI Application

Cloud Vault files will be accessible using open source desktop application called cyberduck. It is an FTP-like stand alone GUI application for accessing files. It supports file/ directory listing, upload, download, synchronize, editing, etc. Cyberduck is a open source desktop application available for MAC and Windows system

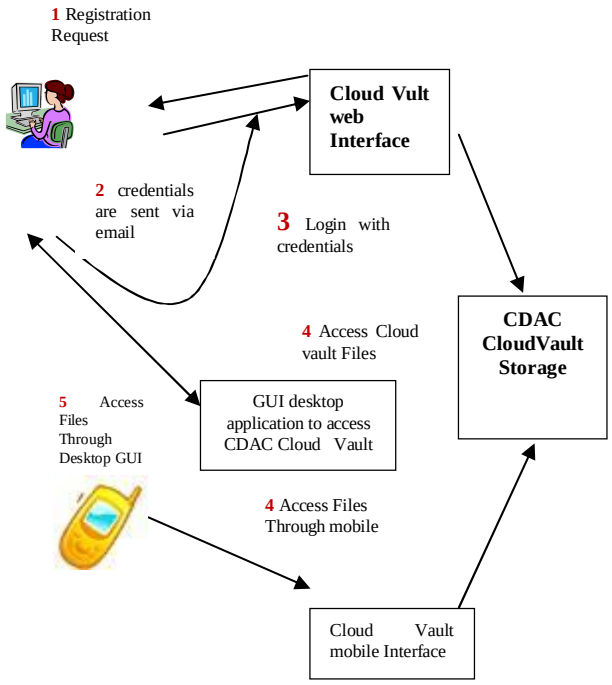

Figure 3 Storage as a Service (StaaS)

4.2.3 Command Line

Command line access will allow the access to cloud vault files with the UNIX shell. Client installation of the scripts needs to be done on the user machine or laptop.

4.2.4 Mobile Interface

Cloud Vault will also be accessed by mobiles using mobile application for the basic file operations like list, upload, download, and synchronize. There will also be a facility to auto synchronize users mobile with his cloud vault files so that he can keep his mobile backup on cloud vault.

4.2.5 APIs

Files of any size can be stored in the Cloud Vault, from small personal document collections to multi-terabyte backup sets routed directly to the cloud using Rack space or S3 API in applications.

5 CSC Architecture and Components

Figure 4 depicts the components of CDAC scientific cloud. The various components of CDAC scientific cloud are as follows:

5.1 Hypervisor

A hypervisor, also known as a virtual machine manager/monitor (VMM), is computer hardware platform virtualization software that allows several operating systems to share a single hardware host. The hypervisor controls the host processor and resources so that systems/virtual machines are unable to disrupt each other. As virtualization adds overheads to the cluster performance, we choose to use type-1 or bare-metal hypervisors for virtualization. Type-1 hypervisors run directly on the host's hardware to control the hardware and to manage guest operating systems. Some of the examples of type-1 hypervisors are Citrix XenServer [24], VMware ESX/ESXi [25], and Microsoft Hyper-V hypervisor. CDAC scientific cloud will be using Xen hypervisor for the same.

5.2 Cloud middleware

Cloud Middleware or Cloud OS: Cloud middleware is the software stack for provisioning the large networks of virtual machines on demand. It also handles scalability & reliability of the resources provided to the users. There are various open source & commercial cloud middleware available like Nimbus [12], Open Nebula [26], and vCentre [27], Eucalyptus [28].

5.3 Cloud resource broker

Cloud Resource Broker and Meta scheduler: Cloud resource broker is a common gateway to provision access to the HPC resources like compute clusters, storage on cloud .It is an intelligent scheduler that will provision the best pool of available resources to the users by using policy based decision. The various components that will build up a cloud resource broker are as follows:

5.3.1 Resource Discovery

Resource discovery of the available resources based on the kind of user application that can be Compute intensive or Data intensive or Memory Intensive

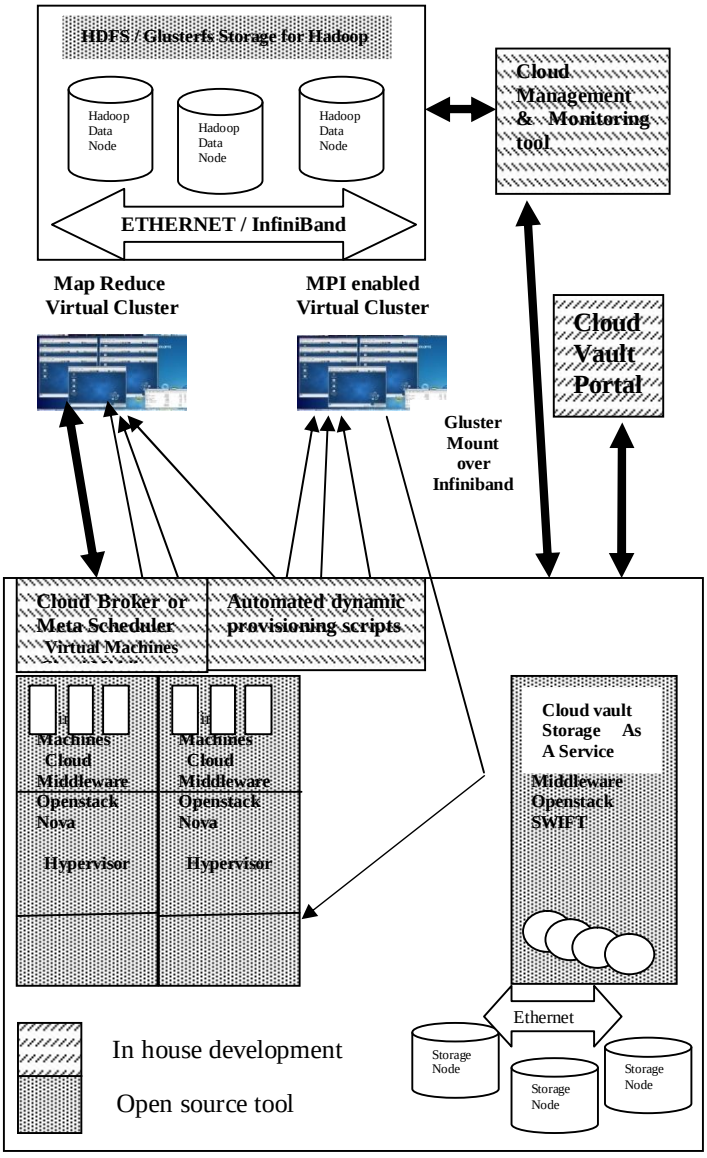

Figure 4 Components of CDAC Scientific Cloud (CSC)

5.3.2 Policy based resource selection

Resource selection and provisioning will be done considering the various aspects like Load balancing, resources utilization, power aware.

5.3.3 Data aware Job scheduling

Data aware scheduling enables computation to be done nearest to the location of the data .In this case, the cloud resource broker will talk to the cloud file system components to find out the nearest storage nodes where data resides

5.4 Cloud Management and Monitoring

Cloud Infrastructure monitoring & management tool is the control point for the virtual environment in cloud. This tool will provide a single point access for administrators to monitor & manage the resources of cloud. The following features that will be supported :

- Resource Inventory search: inventory including virtual machines, hosts, data stores, and networks at the administrators fingertips from anywhere
- Hardware monitoring & Management
- Storage maps and reports: Provides storage usage, connectivity and configuration. Customizable topology views give you visibility into storage infrastructure and assist in diagnosis and troubleshooting of storage issues.
- Alerts & notifications with automated rectification
- Utilisation, Performance & Energy Consumption Trends
- Accounting and billing (to recover costs, capacity planning to ensure that consumer demands will be met), Policy management & SLA.

5.5 Cloud Portal

5.5.1 Portal for IaaS Provisioning and Problem Solving Environments (PSE)

The scientific cloud portal will be the access point for the users for requesting & accessing the on demand HPC clusters. There will also be customized PSEs for bioinformatics & climate modeling domains that will provide the complete environment and workflow for the domain specific applications.

5.5.2 Portal for Storage as a Service

The portal for storage as a service will an access point for the cloud storage through which user can register himself and ask for the required amount of storage .Also user will be allowed to request for expanding the allocated storage on the fly

6 Target Applications on CDAC Scientific Cloud

On-demand cloud computing can add new dimension to HPC, in which virtualized resources can be sequestered, in a form customized to target a specific application requirement, at any point of time. [6] Described the feasibility of running Coupled Atmosphere-Ocean Climate Models on an EC2 computing cloud and found that the performance is below the level seen at dedicated clusters. However, cloud systems that feature a specialized

interconnect such as Myrinet or Infiniband and support MPI or Map reduce are more closely targeted to HPC applications.[23] states that Life Sciences are very good candidates for Map Reduce on cloud including sequence assembly and the use of BLAST and similar algorithms for sequence alignment. On the other hand partial differential equation solvers, particle dynamics and linear algebra require the full MPI model for high performance parallel implementation on cloud. The two application domains that have been identified as pilot applications for CDAC scientific cloud are Bioinformatics applications like Blast, Climate Modeling like Seasonal Forecast model (SFM). Seasonal Forecast Model (SFM) is an atmosphere general circulation model used for predicting the Indian summer monsoon rainfall in advance of a season. It involves the single operation on multiple data sets that makes it a suitable case for using map reduce in this particular application

7 Conclusions and Future Plans

Scientific applications require the availability of massive compute and storage resources. Cloud computing can be of great help in on demand provisioning of the HPC resources. The applications can scale up heavily using HPC as a service on cloud. However, the performance related challenges have to be addressed by fine tuning the cloud middleware stack and the software libraries. The proposed model of CDAC scientific cloud is an attempt to address the requirements and challenges of HPC as a service on cloud. Currently, the test bed setup for the same is in progress and in future we plan to develop the cloud system software components like Cloud Resource Broker and Meta scheduler, management and monitoring tools, portal & PSEs

Exploiting Instruction Level Parallelism for REPLICA – A Configurable VLIW Architecture with Chained Functional Units

Martin Keßler[1], Erik Hansson[1], Daniel Åkesson[1], and Christoph Kessler[1]
[1]Dept. of Computer and Information Science, Linköping University, Sweden

Abstract— *In this paper we present a scheduling algorithm for VLIW architectures with* chained functional units. *We show how our algorithm can help speed up programs at the instruction level, for an architecture called REPLICA, a configurable emulated shared memory (CESM) architecture whose computation model is based on the PRAM model. Since our LLVM based compiler is parameterizable in the number of different functional units, read and write ports to register file etc. we can generate code for different REPLICA architectures that have different functional unit configurations. We show for a set of different configurations how our implementation can produce high quality code; and we argue that the high parametrization of the compiler makes it, together with the simulator, useful for hardware/software co-design.*

Keywords: Scheduling, VLIW, Compiler, LLVM, instruction-level parallelism

1. Introduction

The REPLICA architecture, which is currently under development, is a chip multiprocessor with configurable emulated shared memory (CESM) architecture [1]. Its computation model is based on the PRAM (Parallel Random Access Machine) model [2]. The PRAM model gives a simple deterministic synchronous and predictable model of programming, where parallelism is homogeneous and explicit. The REPLICA core architecture is a VLIW architecture that supports chained functional units so that the result of one VLIW sub-instruction can be used as input to another sub-instruction in the same (PRAM) execution step. The architecture has support for parallel multi-(prefix)operations on the hardware level [3]. It enables the user to access the same memory location from a multitude of parallel threads. There is no need for explicit locking as it would be in conventional parallel programming. By running a high number of threads in parallel, latency at memory accesses is effectively hidden by the architecture. Shared (physically distributed across on-chip memory modules) memory is in PRAM mode accessed in a UMA (Uniform Memory Access) fashion as if it was local memory.

REPLICA also has support for NUMA mode execution, for being able to run sequential and parallel legacy (NUMA) programs.

At the moment a high-level programming language for REPLICA is under development and should be transformed to the REPLICA baseline language using a source-to-source transformer which is currently under development using ANTLRv3 and written in Scala [1].

The baseline language is based on C with some built-in variables to support parallelism, at the moment these are for example `_thread_id`, `_number_of_threads` and `_private_space_start`.

Programs written in the baseline language can be compiled using Clang to LLVM IR and then compiled to REPLICA target code and tested and evaluated on the REPLICA simulator. The key feature of the compiler is the parametrization of the scheduling algorithm. In an earlier version of the compiler [4] there was only support for one basic architecture configuration.

The focus in this paper is to show how the compiler actually utilizes instruction level parallelism for different configurations of the REPLICA architecture in which we have different combinations of chained functional units.

As a proof of concept we have written, in the baseline language, some test programs such as thread parallel blur and threshold filter as well as sequential programs such as multiply & move, discrete wavelet and inverse discrete cosine transformation. We compiled them for different configurations using our parametrized back-end. The compiled programs are run on the simulator. They all show speed-ups from instruction level parallelism.

The rest of the paper is organized as follows. We introduce the REPLICA assembly programming model in section 2. We give an overview of how the dependency graphs of basic blocks are created in section 3, and in section 4 a method of reducing register use is shown. In section 5 we present our scheduling algorithm, and how the compiler is parametrized is shown in section 6. We compare our scheduling algorithm to previous work in section 8. Results can be found in section 7. Finally the conclusion and future work are in section 9.

2. REPLICA assembly programming model

We refer to a single chained VLIW word as a *line*. Sub-instructions on the same line are to be issued at the same time. In contrast to traditional VLIW architectures, the sub-instructions can be dependent due to chained functional units. Different types of sub-instructions are executed in different functional units, in REPLICA we distinguish between the following sub-instruction types[4]:

- Memory unit sub-instructions: Load, store and multi-prefix instructions.
- ALU sub-instructions: add and subtract etc.
- Compare unit: Compare sub-instructions which, set status register flags.
- Sequencer: branch instructions, jump etc.
- Operand: sub-instruction for loading constants, labels etc. into an operand slot
- Writeback: sub-instruction for copying register contents.

In Table 1 different configurations are shown. The simplest configuration, T5, has one ALU before the memory unit and then a compare unit and a sequencer after each other.

When programming on assembly level for the architecture, one has to distinguish between two types of register storage for intermediate results:

- *general purpose registers* `R1` to `R30` can store values persistently;
- *output buffers* `O0` to `Ox` [1], `A0` to `Ax`, `M0` to `Mx` are transient and only valid inside the line.

Both types, however, can be used in the same way:

```
ADD0 R1,R2
ADD1 O2,A0
```

Listing 1: Using registers and output buffers as operands

As shown in Listing 1, every functional unit is bound to one output buffer, denoted by the number following the instruction mnemonic. Only one dedicated functional unit type, the write-back stage, can write values to the register file.

By using the output buffers inside the super-instruction different operations can be chained and the output of one functional unit is fed as an input to another one. This saves a lot of cycles compared to a way where every intermediate result first would have to be written back to the register file. A slight drawback is that results can only be used from the left to the right. Memory operations are an exception. They cannot be chained as latency hiding would not work any longer.

```
OP0 16     ADD0 O0,R1 LD0 A0     WB1 A0     WB2 M0
OP0 2      MUL0 O0,R2 ST0 A0,R0
```

Listing 2: REPLICA assembly example [4]

The example in Listing 2 computes at line 1 an address by adding 16 to `R1` using the first ALU, `ADD0`, the result will be available in `A0` and used to load a word. The result (available in `M0`) is copied to `R2` using the writeback instruction `WB2`, at the same time `A0` is copied to `R1`. In the second line (next execution step) `R2` is multiplied with 2; the intermediate result is in `A0` and will be stored at the address contained in `R0`.

3. Dependency Graph

In both this version and the earlier version [4] of the compiler, the support of VLIW is implemented by matching a set of pre-defined combinations of sub-instructions which we call super-instructions. Of course the instruction scheduling and register allocation will not be optimal. We try to solve this problem by splitting each super-instruction into its respective sub-instructions. User-written inline assembly code is also split up. After splitting, any dependency graph between the instructions previously built is no longer valid. We therefore need to build a new one, suited to the requirements given by both the register compression (see section 4) and the ILP scheduling pass (see section 5).

A new graph is constructed by adding one instruction after another in the existing order and determining dependencies to all previous instructions. Two classes are used to store and structure the acquired information, as shown in Listing 3.

```
class MINode {
public:
  MachineBasicBlock::iterator I;
  list<MIEdge> edges;
  unsigned predecessors;
  bool scheduled;
  // [...]
};

class MIEdge {
public:
  int latency;
  MINode* to;
  // [...]
};
```

Listing 3: Definition of the `MIEdge` and `MINode` class

The first one, `class MINode`, is used to encapsulate the `MachineBasicBlock::iterator` to one instruction. Furthermore it stores, among other attributes used later on, a list of edges to other nodes which depend on this

[1]Here, `x` denotes the number of functional units of that type minus 1. For example the T7 configuration has 3 ALUs, and thus the ALU output buffers are named `A0` to `A2`. The Oi buffers are for result of OPerand instr., the Ai of ALU instr. and the Mi of memory unit instr., respectively

Name	operands	pre ALU	memory	post ALU	compare unit	sequencer unit
T5	2	1	1	0	1	1
T7	3	2	1	1	1	1
T11	7	5	1	2	1	1
T14	7	5	4	2	1	1

Table 1: list of available standard configurations

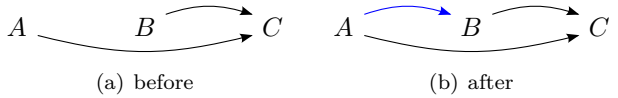
instruction. These edges are formed by instances of the `class MIEdge`.

The attribute `latency`[2] of an edge represents whether the two instructions:

- must stay within the same super-instruction, e.g. `OP0 42` $\xrightarrow{=0}$ `LD0 O0`: The operand `O0` is only valid within a line.
- the depending one *has* to be scheduled in a later super-instruction, e.g. `TRAP R0` $\xrightarrow{>0}$ `ADD0 R1,R2`: We cannot mess with the order before and after a trap.
- or it does not matter ($\xrightarrow{\geq 0}$).

The information what was previously part of one super-instruction is only important to such a degree as to determine how long transient registers are alive. Between the instruction defining the output buffer and the one using it will be an edge with latency constraint $= 0$.

In order to simplify the scheduling pass later on, additional edges are inserted between instructions that are not directly depending on each other.



(a) before (b) after

Fig. 1: Additional edges

This is only necessary for instructions that have to go into the same super-instruction. As shown in Figure 1(b), an additional edge is inserted between nodes A and B. This is required because node A would otherwise only force C into the same super-instruction and leave out B as the edges only provide a forward reference.

Compared to the dependency graph construction in the previous version of the compiler, the methods determining the dependencies have been optimized to report fewer unnecessary conflicts which results directly in fewer edges between the nodes. This in turn enables the scheduling algorithm later on to change the order of the instructions more freely and give a better result.

[2]Latency k of a data dependence edge *(i,j)* is usually defined as if $i \xrightarrow{\geq k} j$ then $t_j \geq t_i + k$ must hold for a correct schedule.

4. Register Compression

The number of slots provided for each functional unit type is limited per super-instruction. Therefore it is quite self explanatory that replacing instructions with shorter versions that do the same job. renders the resulting code more compact. As a result scheduling can pack the same code in fewer super-instructions and thereby speed up its execution. Up to now, the following substitutions are implemented:

- If the constant number 0 is required, use the register `R0` (which is there for that very purpose) instead of defining an operand with `OP 0` and then using the operand. Hence one operand slot is saved and can be used for something else. This is applicable whenever a variable is initialized or reset to zero.
- If an addition at which one operand is a constant zero (`R0`) is performed, the operation can be omitted and instead of the result the non-zero operand can be used. The same holds true for subtractions where the subtrahend is constant zero. This saves one slot in the ALU.
- With the last substitution we might end up with a situation where a register is written back to itself. Such a constellation can of course be removed entirely.
- If a constant zero (`R0`) is written back to a general purpose register, all upcoming usages of that register can be replaced with `R0` up to the next redefinition of that register.

To enforce the compiler to use register compression a flag, `-enable-replica-register-compression`, can be used. While at this point the compiler and simulator still operate under the assumption that we have unlimited write-back slots, this will not hold true in future versions. At that point saving `WB` operations will pay off.

5. ILP scheduling

5.1 Motivation

As REPLICA is a VLIW architecture, the compiler should identify operations that can be executed in parallel when there are no dependencies and resource conflicts between them, and put them in one super-instruction. Additionally the REPLICA architecture offers the possibility to chain instructions. That means that we can

use the output of one functional unit inside a super-instruction as an input to the next one. Thereby we don't have to wait until the result is written back to the register file.

When the LLVM intermediate representation is lowered to the REPLICA instruction set, the created VLIW super-instructions do represent the correct semantics, but they utilize the available functionality quite poorly. An addition operation, for example, will only make use of one ALU and one write-back slot in a super-instruction. All other slots are idling at that time. To make better usage of both the available ILP and the possibility to chain instructions, we have provided an optimization pass that reschedules the instructions, at basic block level, into new super-instructions.

Another important advantage is that this also helps us to generate code for different REPLICA configurations, i.e. providing different amounts of available slots per functional unit type.

Before we start with a description of the scheduling algorithm, some naming conventions that we will use should be introduced. The scheduler is written in a way that we support an arbitrary number of slots per functional unit type. The available slots per functional unit type as a whole will be referred to as a *bucket* (operand bucket, pre-memory-ALU bucket, memory bucket, ...). A *chain* of instructions is a list of instructions that must be scheduled in the same super-instruction. A chain is characterized by edges with latency constraint = 0. We call an instruction *ready* if all its predecessors in the dependency graph are scheduled. We call an instruction *schedulable* when it is ready and all the instructions in the chain are ready as well as there is enough space in the respective buckets to schedule the whole chain. An instruction is *emitted* when it is finally moved from its respective bucket to the output. Instructions that are scheduled but not emitted yet have a special influence during the scheduling.

5.2 Algorithm

As Figure 2 shows we start the scheduling by creating a dependency graph as described in Section 3. By implementation, this directly provides us with a list of instructions that are ready. These instructions are put into the `ready` set.

The main part of the work is split between two major steps "find next schedulable instruction" and "schedule instruction", and a third step "emit instructions" which are explained in the following.

5.2.1 Find next schedulable instruction

In this first step, we try to determine the next instruction that is schedulable. Naturally, this instruction has to be picked from the `ready` set. Hence, `isSchedulable` is called on one element (instruction) after another until we find a result. The challenge here is, that we not only have to consider the instruction itself, but the entire chain; so there has to be enough space in the respective buckets for all the instructions involved.

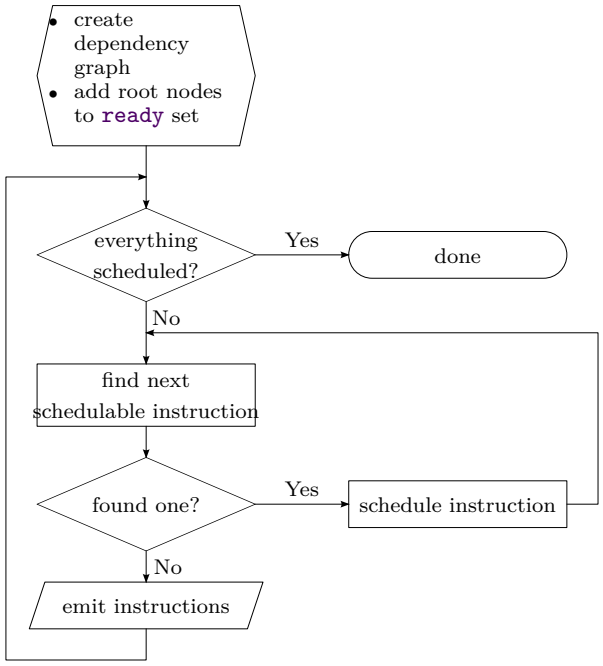


Fig. 2: Flowchart of the scheduling algorithm

A goal was to implement this in an efficient way such that we can start with an arbitrary instruction but if find at some point halfway through the chain that there is not enough space, we don't have to do a complicated roll-back of the involved data structures.

Our greedy approach does this by starting with a resource vector of type `struct RemainingSlots` that holds the amount of slots left in each bucket. This resource vector is passed by reference to recursive `isSchedulable` calls.

Every instance of `isSchedulable` now does the following steps:

- It is checked if the instruction has to be stalled because of an instruction that is already scheduled but not yet emitted. This can happen because of sequencing or memory instructions.
- The resource vector is checked if there is enough space in the respective bucket. If so, the corresponding counter is decremented by one.
- `isSchedulable` is called recursively on all depending instructions with latency = 0.

If one of these tests fails the entire attempt on the chain fails and the next ready instruction is tested.

One of the important features of the REPLICA ar-

chitecture is the chaining of instructions. Therefore `isSchedulable` checks if the current instruction is depending on a write-back (`WB`) that is scheduled but not emitted yet. If this is the case and all other prerequisites are met, we save a note that we bypass the write-back and use the output of the functional unit directly that the write-back would otherwise have to save first. Thereby we save one step. If this instruction is the only one that uses the register until it is redefined, the write-back is marked for removal altogether. At the same time we have to be aware of the order inside the super-instruction: E.g. a post-memory-ALU output cannot be used as an operand to a store instruction.

As an example, see the code in Listing 4:

```
OP0 1337        WB2 O0
OP0 42          LD0 R2,O0       WB2 M0
```

This will be rearranged to:

```
OP0 1337        OP1 42          LD0 O0,O1       WB2 M0
```

Listing 4: Skipping a writeback instruction

5.2.2 Schedule instruction

Now that we determined that an instruction plus all recursively dependent ones are schedulable, the instructions are all put in their respective buckets.

Two types of register modifications now have to be applied. Both can be observed in Listing 4.

1) The replacements that were earlier noted because we skip a writeback. `LD0` now uses `O0` instead of `R2`.
2) If we have more than one slot in a bucket, we replace the output buffer that is used. `OP0 42` was moved from slot 0 to slot 1.

All instructions that are pulled in by a latency = 0 constraint are scheduled as well. This goes fine as it was part of the `isSchedulable` check earlier.

All instructions depending on this one have now one predecessor less. Those that have reached zero predecessors are ready. Hence they are put in the `ready` set.

5.2.3 Emit instructions

If "get next schedulable instruction" can't find a suitable instruction, there are apparently not enough slots left. In this case the instructions are emitted as a VLIW and the buckets are emptied. This way of picking the next instruction will eventually cover all instructions because the initial packing into superinstructions derived by the LLVM IR sub-tree matching only imposes minimal requirements (i.e. only one slot per functional unit) and the algorithm will terminate.

6. Parametrization

In order to enforce the compiler to generate target code for a specific configuration we have introduced a set of compiler flags that we will explain briefly. Since the flags are quite many, the compiler is actually run from a script. The first parameter is `-enable-replica-ilp` which tells that the rescheduling should be applied in order to increase instruction level parallelism (ILP); for debugging purposes it can be switched off. The concept of having buckets is mentioned in the previous section, where the idea is to collect instructions that go into the same functional unit. This is intentionally built in a way that there is no restriction as to how many slots there are per bucket. The limitation of the number of slots is only imposed by passing a resource vector from an instance of `isSchedulable` to another. The initial amount (how many slots are there per bucket in a new super-instruction) is not defined in advance but rather given as a command line parameter to the compiler; `-num-ops` tells the number of integer or floating point constants available per super-instruction, `-num-alus` tells how many ALUs are available before the memory unit, `-num-mus` tells number of memory units, finally `-num-alus-post` tells the number of ALUs available after the memory access is done. All these parameters can be shown by calling `llc -help-hidden`.

As explained extensively, rescheduling tries to use the output of one functional unit as an input to another one and thereby bypass write-back operations. Furthermore, the PRAM model implementation by REPLICA requires to hide the latency to memory with different access times. Due to internal matters, this only succeeds when memory accesses are executed in parallel and not sequentially. Therefore chaining data going to and coming from memory is not possible:`-chained-mus` is therefore set to `false` by default. `-enable-replica-inline-integration` tells if an inline assembly string be split up into separate instructions and be subject to following optimization passes. The option to not split and reschedule inline assembly can be useful for debugging purposes. It is important to notice that the dependencies of inline assembly are actually taken care of. For evaluation purposes we have the parameter `-num-reg-read` and `-num-reg-write` to limit the number of general purpose registers that can be read and written respectively in each super instruction, the default is 32 (number of general purpose registers per thread).

7. Evaluation

In order to measure the improvement achieved through the different optimization passes, several test programs were written in REPLICA baseline language. Even though the focus was on instruction level parallelism

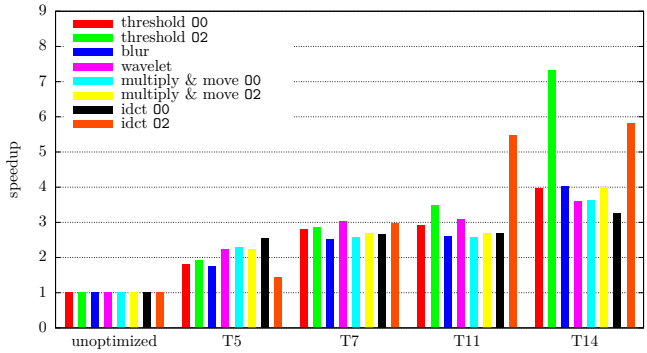

Fig. 3: Instruction level speed-up comparison with different configurations, no constraints on number of read and write ports to reg. file

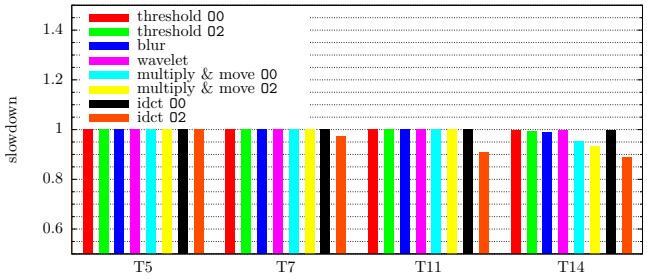

Fig. 4: Relative slowdown when limiting the number of read and write ports to four

we have also used some thread parallel programs as benchmark, to see their characteristics for instruction level parallelism. We have benchmark programs *threshold image filtering* and *blur filtering* which are both thread parallel, moreover a single threaded *discrete wavelet transform* (DWT), where our implementation is based on [5], and one simple test *multiply & move* where elements in an array are multiplied and then moved to another array. We also tested an *inverse discrete cosine transform* (IDCT), this computation kernel was extracted from the Mediabench [6] mpeg2 package.

The baseline case with unoptimized code means that no rescheduling is done, which means that unsplitted super-instructions are used directly from the mapping of the LLVM IR. For each configuration (T5, T7, T11 and T14) we did two test series for each benchmark program. One puts no constraints on the number of register read and writes, which can be seen in Figure 3. In the second test series we limited the number of both read and write ports to the register file to a maximum of four. Figure 4 displays a relative comparison with respect to performance between the two cases. It shows the expected behavior: When we increase the number of functional units without also increasing the number of available registers, speed-up will suffer. For the benchmarks multiply & move and image blur with limited register read and write ports, we will still get almost the same speed-up as in the unlimited case, this is because the functional units can be utilized well since the data dependencies allow us to make use of the buffers in the chained functional units.

8. Comparison to Previous Work

There has been a lot of work done in instruction scheduling, see e.g. [8], [9], [10], [11].

It is well-known that the time-optimal instruction scheduling problem for basic blocks is for most target architectures NP-complete [12]. While smaller scheduling problems can, today, be solved to optimality using integer linear programming and similar techniques, the general case is typically solved by heuristic algorithms.

One classical heuristic solution of the scheduling problem is Graham's greedy algorithm for scheduling tasks [13], known as "list scheduling". It maps tasks to a set of processors, where the tasks can be dependent on each other. The tasks are kept in a list ordered by their dependencies and other priorities so to assign a task to an idle processor it goes through the list and picks the next ready task. If no runnable task is found the processor will idle. Another scheduling algorithm is critical path scheduling [12].

Finlayson et al. [14] show how compiler support can help reducing power consumption without adversely affecting performance when introducing internal registers, that are read and written explicitly, instead of pipeline register. These internal registers reminds a lot of REPLICAs explicit functional unit result registers.

When it comes to VLIW scheduling for architectures with chained functional units we are only aware of the following two, which we compare in detail.

8.1 Original virtual ILP algorithm

Scheduling for a more generalized version of this type of architecture has been proposed by [7]. The algorithm proposed there proceeds in a different way than we do. It is more focused on filling the available memory slots. It sees the next free slot (both memory slots and other ones) and then tries to find a suitable instruction that is independent of all the remaining unscheduled instructions. From our point of view, this has some disadvantages:

- a lot of instructions are inspected which then turn out to have the wrong type.
- it is only taken into account that this instruction depends on other ones, not that other instructions (in this chain) might depend on this one and therefore have to fit into the same super-instruction/ VLIW.

Our algorithm, on the other hand, scans through the set of ready instructions and checks if they can be scheduled.

This seems to be more flexible if dependencies in both directions have to be considered.

8.2 Earlier ILP scheduler for the REPLICA compiler

Together with the general compiler back-end, Åkesson [4] also implemented an optimization pass that aims at exploiting more ILP. The implemented algorithm is based on [7] but looks for the next instruction (as we do) instead of the next slot. As the necessity to manage instructions in a different stage was recognized, different containers exist for holding instructions:

- those that have to be scheduled immediately (within the same super-instruction)
- those that have to be scheduled whenever there is enough space
- those that have to be scheduled at the earliest in the next super-instruction.

One can see that this corresponds to the different latency constraints defined in the dependency graph. This design, however, turns out to be rather cumbersome when we try to use short-cuts and skip write-backs. In order to do this scheduling, a dependency graph was required as well in [4]. The implementation however took in many cases a too conservative approach (e.g., it ignored the fact that output buffers are only valid inside a super-instruction) which resulted in too many unnecessary dependencies that rendered rescheduling more difficult or even impossible. [4] only support one basic REPLICA configuration.

9. Conclusion and future work

We have shown that our implementation of a parametrizable instruction scheduling algorithm for a VLIW processor with chained functional units produces high quality code for different hardware configurations. The high parametrization of the compiler makes it, together with the simulator, useful for evaluating different hardware configurations.

Future work includes the extension of scheduling beyond basic blocks, for example for loops using software pipelining techniques. It can be interesting to evaluate it for the REPLICA architecture since the case of chained functional units is a different one compared to standard VLIW architectures.

Another interesting idea would be to try to formulate and solve the scheduling problem as an integrated code generation problem of instruction selection, scheduling and register allocation together, for instance using *integer linear programming* both at basic block level and beyond. In earlier work Eriksson [15],[16] models integrated code generation for clustered VLIW DSPs using this technique. One example of similarity is that clustered VLIW DSPs have different register files which give constraints on which registers can be used by the different functional units; in our case we have the transient functional registers which are exposed to the programmer and can only be used from left to right and are only valid during one super-instruction step. Both lead to strong coupling between register allocation and instruction scheduling, for which integrated code generation provides higher code quality, see Eriksson [15].

New Advances in Asynchronous Agent-based Scheduling

Jack Harris[1] **and Matthias Scheutz**[2]

Abstract— *Traditional discrete event simulations enumerate the event-space in a sequential manner to guarantee the consistency of the simulation. Rrecent asynchronous agent-based scheduling work has demonstrated that it is also possible to achieve consistent simulations under certain constraints even when all agents are at different time steps. This paper extends asynchronous event-based scheduling for agent-based simulation by introducing a scheduling policy based on the notion of* Dynamic Goal-based Agent Prioritization *(D-GAP) which provides the opportunity for evaluating a simulation signifcantly faster and with fewer computational steps.*

Keywords: parallel scheduling, discrete event simulation, asynchronous scheduling policies, scheduler efficiency

1. Introduction

Scheduling in traditional discrete event simulation enumerates the event-space sequentially by updating all entities at time t before evaluating any entity at the next time step t+1. This serial temporal updating limits the utility of large-scale computational resources by requiring parallel processes to synchronize at every time step in order to maintain a consistent state configuration. Scheutz and Schemerhorn defined a methodology to identify entity sets that are "update-independent" and could temporally advance in the simulation without requiring synchronization updates, thereby maximizing parallel processing for discrete event simulations [1]. Scheutz and Harris, utilizing the notion of asynchronous discrete event scheduling, published a set of policies explicitly aimed at minimizing the runtime of distributed agent-based simulations [2]. This paper builds upon that prior work. First, we introduce an important performance optimization to the previously published general asynchronous scheduling algorithm. This improvement identifies the minimum set of agent state updates required by simulations to asynchronously advance a given agent to the next time step. Secondly, we introduce a novel scheduling policy, *Dynamic Goal-based Agent Prioritization* (D-GAP). This method utilizes a directed search technique to explore a simulation's discrete event-space targeting the events that will lead to simulation completion as defined by the modeler. Together, these two advances further optimize discrete event simulations for both serial and parallel execution environments by evaluating a simulation faster and with fewer computational steps.

2. Background and Related Work

The study of discrete event simulation has been driven by the need to efficiently model complex system interactions. To facilitate the development and execution of these models, formalisms such as the Discrete Event System Specification (DEVS) have been created [3]. Parallel and distributed resources are commonly leveraged to increase the performance of model execution runtime environments for DEVS and other discrete event simulators. (See [4] for an example of an agent-based simulation modeled using DEVS methodology and executed in parallel using the High Level Architecture (HLA) distributed simulation protocol.)

Though these discrete event systems utilize parallel resources, their efficiency is reduced by the need to continuously synchronize the distributed resources and update each agent in the simulation at each time step. It is sometimes interesting (or required) to evaluate the state of every element in a simulation at simulation termination, but it is often common for a modeler to only be interested in a small set of critical simulation elements (e.g., whether one agent reaches a particular location in the environment)..

In 2006, Scheutz and Schermerhorn introduced the notion of "update-independence" for segregating groups of agents across distributed resource pools and for determining how long they could operate in isolation without sharing agent state information. Formally, an agent A_1 is update-independent from A_2 if A_1 will advance from configuration state C at time t to C' at t+1 regardless of the existence of A_2 in the simulation. Fortunately, it is possible to identify some forms of update-independency without actually advancing a simulation from t to t+1 provided that there is some a priori constraints on agent interactions (e.g., for spatial agent-based simulation: maximum velocities, sensory ranges and effector ranges of agents). For example, if an agent A_1 is outside of agent A_2's maximum interaction range and A_2 is outside of A_1's maximum sensor range then A_1 is update-independent of A_2. However, the reciprocal relation must also exist for A_2 to be independent of A_1. Both A_1 and A_2 must be mutually update-independent for either to update without causing a misconfiguration in the simulation. Clearly, it is possible that A_1 would not be affected by A_2 even if it was not outside of these ranges, but this cannot be known for certain without executing the simulation. A conservative estimation of dependence in a simulation will always ensure consistent configurations are produced.

The notion of an agent's "event-horizon" was introduced to facilitate update-independence determination. An "event-horizon" defines the spatial region containing all possible positions for that agent in a future time step. This region is determined by assuming an agent traveled at its maximum velocity from current simulation time to the projected future time in all directions simultaneously. This assumption allows "event-horizons" to be calculated using only simple geometry. Using "event-horizons", it is possible to identify agents that must be update-independent from other agents even when they exist at different simulation times.

When determining update-independence and projecting "event-horizons" of an agent, a subset of interdependent agents are identified for a given time step. This subset of agents defines a local world that could function independently from the rest of the agents in the simulation. This local world is essentially a "transitive closure" of dependency, where dependency is recursively identified for a given agent and time. Scheutz and Schemerhorn exploited this characteristic of local world independence and used it to aid the parallelization of agent-based simulations. By distributing these sets of agents across different computational resources, performance gains were achieved. These parallel units could update asynchronously until the "event-horizons" of agents inside and outside the closure intersect. When such an intersection occurs the independence of the sets is removed and the agents at the future time step become blocked and unable to continue to advance asynchronously without additional information. Therefore, to maintain a consistent simulation, the asynchronous scheduler must never run an agent asynchronously beyond the point of being blocked [1].

The formalism and correctness proofs of Scheutz and Schermerhorn provided the foundation for future agent-based asynchronous discrete event scheduler research. Subsequent research by Scheutz and Harris explored new update scheduling algorithms to optimize the discrete-event scheduler and minimize the runtime of simulations [2]. From that work novel asynchronous agent-based scheduling policies were presented; each optimizing different heuristics. For example, the $Remote - Event - First$ policy attempted to minimize simulation runtimes by minimizing the occurrences of blocked agents in a distributed context. This was accomplished by preemptively advancing agents whose projected "event-horizons" would first interact with agents on other parallel systems.

3. Improving Asynchronous Scheduling

This section outlines efficiency improvements made to the general asynchronous scheduling algorithm originally proposed by Scheutz and Harris [2]. These advancements focus on minimizing the number of dependent agent updates required to advance a given agent asynchronously in the simulation. Before the new algorithm is proposed, the original methodology is discussed as a counterpoint. Following the description of the new algorithm, a proof for correctness is presented.

Algorithm 3.1: ORIGINAL METHOD(W)

procedure ISCOMPLETE(W)
return (has terminating criterion been met)

procedure PICK(W)
comment: select and return an agent to update

procedure GETTRANSITIVECLOSUREFOR(a, t, W, S)
comment: gets a's recursively dependent set at time t
for each $d \in senseOrAffectAt(a, t, W)$ **and** $d \notin S$
do $S \leftarrow S \cup \{d\} \cup$ GETTRANSITIVECLOSUREFOR(d, t, W, S)
return (S)

procedure ISOLATEDEPENDENTSUBSET(a, W)
$Ta \leftarrow$ GETTRANSITIVECLOSUREFOR($a, time(a), W, \emptyset$)
return (Ta)

procedure UPDATESET(S)
comment: advance agents youngest to oldest
$St \leftarrow sortByLocalTime$(S)
for $i \leftarrow 0$ **to** $size(St) - 1$
do if $i < size(St) - 1$

then { **if** $time(St[i]) <= time(St[i+1]$
  then { UPDATEAGENT($St[i], S$); $i \leftarrow 0$
  else UPDATEAGENT($St[i], S$)

procedure UPDATEAGENT($a, transitiveClosureForA$)
comment: transitions a's state from time(a) to time(a)+1

main
repeat
$a \leftarrow Pick(W)$
$S \leftarrow IsolateDependentSubset(a, W)$
UPDATESET(S)
until ISCOMPLETE(W)

3.1 Full Transitive Closure Update

The original algorithm, *Full Transitive Closure Update*, ensured consistency in simulations by fully synchronizing a set of agents when a dependency relationship was identified. For example, suppose agent A_1 is at time t and agent A_2 is at time t_0 | if agent A_1's sensory range intersects with the projected "event-horizon" of agent A_2 then agent A_2 would have to advance to time t before agent A_1 could update. Furthermore, this update requirement for agent A_2 is recursively required for any agents that agent A_2 could potentially have interacted with when projected to time t. Essentially, the sum of all A_1's recursive dependencies when projected to time t would have to be updated to time t before A_1 could advance. (See Algorithm 3.1 above for the abstracted pseudocode description.)

To maintain a consistent simulation configuration, the original method updates the entire transitive closure to the same time step; however, this level of synchronization is not necessary. When utilizing a *Full Transitive*

Closure Update, notice that an agent returned in the $IsolateDependentSubset$ calculation will be updated to t+1 even if the agent's actions removes the possibility of any future interactions with other agents after a single time step. For example, if the agent travels in the opposite direction its projected "event-horizon" would look very different after just a single update.

Algorithm 3.2: NEW METHOD(W)

procedure ISCOMPLETE(W)
 return (has terminating criterion been met)

procedure PICK(W)
 comment: select and return an agent to update

procedure INCREMENTALDEPENDENTSET(a, t, W, S)
 comment: gets a's incrementally dependent set
 for each $d \in senseOrAffectAt(a, t, W)$ **and** $d \notin S$
 do $\begin{cases} i \leftarrow time(d) \\ S \leftarrow S \cup d \\ S \leftarrow S \cup \text{INCREMENTALDEPENDENTSET}(d, i, W, S) \end{cases}$
 return (S)

procedure ISOLATEDEPENDENTSUBSET(a, W)
 comment: isolate youngest dependent subset
 $D \leftarrow \text{INCREMENTALDEPENDENTSET}(a, time(a), W, \emptyset)$
 if for all $b : b \in D$ **and** $time(a) = time(b)$
 then return (D)
 $Y \leftarrow getYoungestElementsInSet(D)$
 return (Y)

procedure UPDATESET(S)
 comment: advance agents in the temporally synchronized set
 for $i \leftarrow 0$ **to** $size(S) - 1$
 do UPDATEAGENT($St[i], S$)

procedure UPDATEAGENT($a, transitiveClosureForA$)
 comment: transitions a's state from time(a) to time(a)+1

main
 repeat
 $a \leftarrow Pick(W)$
 $S \leftarrow IsolateDependentSubset(a, W)$
 UPDATESET(S)
 until ISCOMPLETE(W)

3.2 Incremental Dependency Removal

The new algorithm, *Incremental Dependency Removal*, 'loosens' the constraints on an agent's update-independence by updating only a subset of the agents identified by the original *Full Transitive Closure Update* method a single time step on each scheduler iteration. This allows for the possibility that dependencies between agents will be removed with the additional state information provided by the incremental update. Like the previous algorithm, an agent is identified to update asynchronously at the beginning of each scheduling loop; however, unlike the previous algorithm, that agent will not update unless every agent in its transitive closure is at the same time step as that agent; otherwise, only a subset of that transitive closure will run (see Algorithm 3.2).

This means that after picking an agent to advance (A), we first identify the youngest agents within agent A's $IncrementalDependentSet$. The $IncrementalDependentSet$ is generated by recursively identifying partial agent dependencies starting with agent A. This is different from at transitive closure calculation only in that the transitive closure calculates all dependencies projected to agent A's time, while $IncrementalDependentSet$ calculates the recursive dependency relative to the local time of each agent. From this $IncrementalDependentSet$, we then obtain the set of youngest dependent agents (Y). Note that Y is update-independent, since all agents in the transitive closure for any agent in Y is also contained in Y. (A proof sketch is provided below.) The agents in Y are then advanced one time step in the simulation. For agent A to advance, it would have to be selected by the scheduler's $Pick$ method until it no longer has dependencies remaining in the past and, therefore, would advance as a member of set Y.

To prove correctness of *Incremental Dependency Removal* we must show that the agents returned from $IsolateDependentSubset$ are update-independent of all other agents in the simulation. Note that $IsolateDependentSubset$ selects the youngest members (Y) returned from $IncrementalDependentSet$; therefore these members must all be at the same time step $t = time(youngest)$. Since dependency calculations were made for each of these agents in Y (because $IncrementalDependentSet$ calls $senseOrAffectAt$ for each of them and their dependents), it follows that these dependents must all be at the same time step. Now observe that $IncrementalDependentSet$ is the same algorithm as $GetTransitiveClosureFor$ when the time of each agent is the same, since each recursive call will pass in the same value (t) for the time parameter. Therefore, $IncrementalDependentSet$ contains a transitive closure for each of the youngest agents in that set and no member of these transitive closures exist at a time step other than t. Furthermore, selecting all the youngest agents at time t results in a set with no external dependencies (i.e., an update-independent set).

3.3 New Dynamic Goal-based Agent Prioritization (D-GAP) Policy

Past asynchronous scheduling policies were designed to optimize system resources and minimize simulation runtimes in parallel environments. However, often times the schedulers would pick suboptimal agents to advance asynchronously through the simulation due to the fact that they had no knowledge of the simulation goals or an agent's likelihood of achieving those goals. This issue motivated the idea of biasing the scheduler's agent selection process by

dynamically prioritizing agents based on their probability of achieving a desired goal for the simulation. While still maintaining all the constraints required for ensuring consistent simulation configurations, the *Dynamic Goal-based Agent Prioritization Policy* (D-GAP) allows agent priorities to be adjusted during a simulation execution thereby influencing which agent will advance sooner.

The D-GAP policy, like any other asynchronous scheduling policy, will not speed up every simulation. For example, if a modeler wants to know the cause of death for all agents in a simulation, the D-GAP policy would have to make the same number of updates as a traditional discrete event scheduler. However, in a distributed context it may still be beneficial to run different asynchronous policies for maximizing parallel resources and ultimately reaching simulation completion faster. However, there are many scenarios when simulations are carried out with a more refined termination condition or goal for a simulation. For example, suppose a modeler designed a simulation experiment with the intent to understand what the cause of death will be for a particular agent. The modeller would set the terminating condition for the simulation to be when that partial agent is no longer alive. For this event to occur it is quite likely that not all agents need to be updated to the same simulation cycle, but instead only the agents required for the particular event to occur. The ideal scheduling policy for this example would be to utilize the D-GAP policy.

In situations involving a subset of agents from the simulation, where a particular event or phenomenon is being studied the D-GAP policy can greatly improve a scheduler's efficiency and lead to much faster runtimes. Setting the agent of interest to a higher priority will let the scheduler identify the agents to update that will push the agent of interest through the simulation event-space fastest. This will ultimately lead to any phenomena relating to those higher priority agents to also take place sooner since less superfluous updating of other agents would occur. The agents of interest do not exist separate of their environment and other agents; therefore, other agents with lower priority would still need to be updated. These lower priority agents would update when the agents of interest progress far enough into the simulation timeline that they required additional updated state information from agents at lower priority levels.

4. Evaluation Method

The performances of the D-GAP policy and the new asynchronous scheduler optimizations were measured using a new standard metric for evaluating asynchronous agent-based schedulers. Scheduling efficiency is determined by comparing the number of agent updates conducted in the new methods with what would have been required using a traditional sequential discrete event scheduler. The number of agent updates can be calculated by incrementing a counter each time an agent's update function is called or by summing the local simulation times of each agent in the simulation. This method of comparing the entity's *update count* is preferable to simply comparing runtimes because the former efficiency metric is more general in that it is not dependent on confounding factors such as simulation-unique agent computational costs or communication delays of a particular distributed context. Therefore the evaluation of the D-GAP policy and new asynchronous scheduler updates focused on comparing the three different configurations running a simulation using: (1) a traditional sequential discrete event scheduler, (2) the D-GAP policy with the original asynchronous scheduler, and (3) the D-GAP policy with the improved asynchronous scheduler.

To evaluate the scheduling policies, an a-life simulation was constructed within the SimWorld agent-based simulation framework [12]. The SimWorld system provides an extensible framework for authoring agent-based simulations complete with an integrated reusable asynchronous scheduling system. This scheduler was modified to include the new agent-based prioritization policy as well as the ability to use the incremental dependency removal method. The Alife simulation consisted of a modified version of Scheutz, Harris and Boyd's computational agent-based model of biological model organism *Hyla versicolor* ("gray treefrog") that was originally used to identify the dominant mating strategy of these animals [13].

In the model, each male calls at a given rate and females select the closest mate that exceeds some threshold of call quality. The distribution of the agents can be observed in Figure 1. In this modified configuration the simulations were run until a particular agent of interest (i.e., male2) mated. After each scheduler iteration, the SimWorld scheduler checks if the simulation should terminate (i.e., if male2 has mated). Also at this time the agent update priorities were dynamically modified to bias the scheduler towards updating agents that would bring about the terminating condition.

5. Case Study: Results

This section contains the results of the three different run conditions discussed in the previous section. Results consist of an image for the final state of each simulation configuration as well as an efficiency metric, *update count*, presented for each simulation. Finally, an efficiency comparison is made between the three conditions.

a) Traditional Sequential Discrete Event Simulation.: The base case for this comparison was to execute the simulation using a traditional sequential discrete event system. This provides a total picture of all agent updates in the simulation, including those of interest and those that are irrelevant to the phenomenon of study. After running the initial base case of the simulation (see top image in Figure 1) we see that the simulation terminates after 49 time steps with female9 mating with the agent of interest, male2. To reach

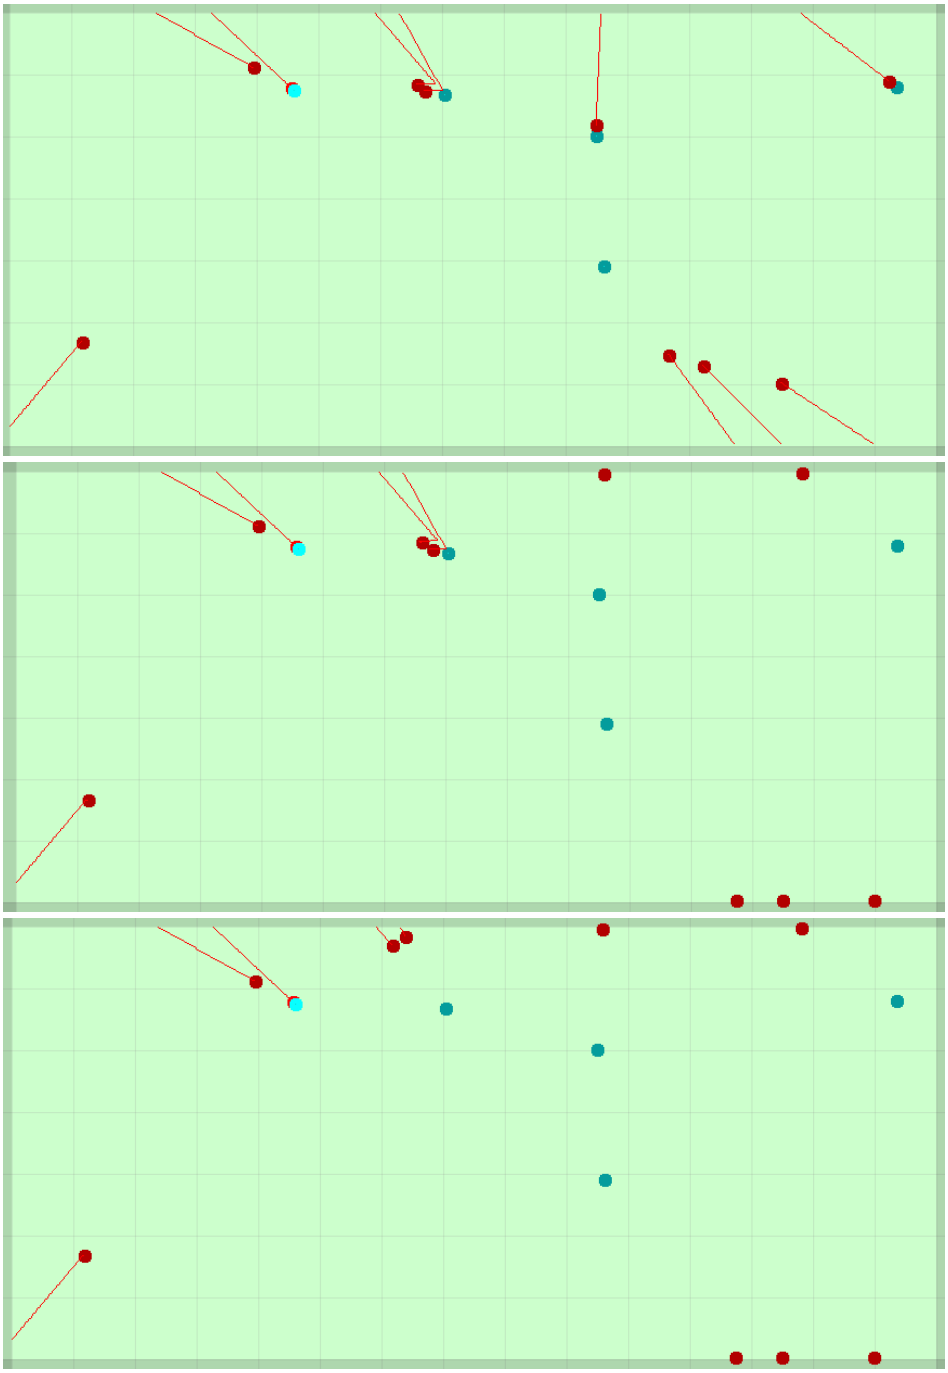

Fig. 1: *Top:* Traditional Sequential Discrete Event Simulation; the final configuration of the Alife tree-frog mating simulation. Female tree frogs (red) approach male tree frogs (blue) based on proximity and male call quality. Ultimately male2 mates with female9 (light blue) at time step 49 after executing **735** agent updates. *Middle:* D-GAP policy + Original *Full Transitive Closure Update* Asynchronous Scheduler. *Bottom:* D-GAP policy + New *Incremental Dependency Removal* Asynchronous Scheduler

the simulation's terminating condition (i.e. male2 finding a mate), **735** *agent updates* had to be calculated. From this image we see that a total of 3 females set out to attempt to mate with male2 at the beginning. By the time that the mating occured at time step 49, we can see that 2 other females had also chosen and began to pursue male2 for a

mate, however we also can notice that most of the other agents in the simulation have no bearing on male2.

b) D-GAP policy + Original 'Full Transitive Closure Update' Asynchronous Scheduler.: The simulation was then reinitialized using the exact same conditions and terminating criteria using the D-GAP policy with the originally published asynchronous scheduling algorithm. Since the simulation only updated agents in a way to ensure no inconsistent simulation states could emerge, the predictions of the simulation were identical to that of the base case; that is, male2 mated at cycle 49 with female9. However, in this case it only took **347** *agent updates* to generate this mating prediction. This algorithm, therefore, produced a scheduling efficiency gain of almost 53% for this scenario $[(735-347)/735*100]$. This a massive speed up given that the same number of processors were used in both cases and the predictive models of the simulation were not changed in anyway. When studying the middle image of Figure 1, we notice that most of the agents in the simulation did not advance far into the simulation's timeline. We will now walk through the logic by which some agents were updated and others were not. Upon simulation initialization all agents had the same priority level (unset) and all agents therefore were allowed to advance synchronously one time step. Following this initial step the *isComplete* check ran, returned false, and set the priority of the 3 leftmost females to have a higher priority since they had chosen to pursue the agent of interest Since females in this simulation do not interact with each other, these agents were *update-independent* until they could interact with a male. Therefore, the following simulation iterations allowed these three females to update asynchronously until female9 entered the interaction range of male2. Since male2 was in the past, he would need to be updated before female9 could advance and mating could take place. However, male2 could not advance independently to the female9's local time step since the "event-horizons" of two other females when extrapolated to female9's time could have potentially caused an earlier interaction with male2. Furthermore, these additional females could also have interacted with an another male when projected to female9's local time step, and, therefore, this male would also have to be included into the group that defined female9's transitive closure which would need to be updated before female9 could advance. From the simulation graphic we see that these additional female agents chose to travel in the opposite direction from male2 and essentially removed themselves from blocking female9's *update-independence*. Unfortunately the original general asynchronous scheduling algorithm still updated these agents to the female9's time. Following these updates female9 was free to proceed to mate with male2 at time step 49.

c) D-GAP policy + New Incremental Dependency Removal Asynchronous Scheduler.: Like the previous condition, the final condition utilized the D-GAP policy for selecting agents to run. However, in this case the new *Incremental Dependency Removal* optimization to the general asynchronous scheduling algorithm was also implemented resulting in the calculation of even fewer *agent updates*. Notice from the bottom image of Figure 1 that the two middle females only progressed a few time steps into the simulation's timeline as compared with the previous simulation (middle image of Figure 1). In this condition only **221** *agent updates* had to be calculated to produce the same predictions as the previous 2 cases. This results in a scheduling efficiency gain of almost 70% $[(735-221)/735*100]$.

The logical event trace for this simulation starts out similarly to the previous case. All agents update one cycle since no agent priority is initially set. Following that, the 3 females that chose to pursue the agent of interest (male2) receive higher priority in the system. The 3 female agents can all update independently until female9 becomes dependent on male2's state prior to attempting to mate. Male2 was then required to update to the same time step as female9. However, unlike the previous case, male2 was allowed to update by only one time step per scheduler cycle. At each scheduler cycle the high priority agents including female9 were selected. This again resulted in a male2 update and this continued until male2 was no longer update-independent with respect to the top middle females. The additional females were incrementally run for one step. The process continued with female9 requiring male2 to update, but in some cases male2 was able to update independently through the timeline since the top middle females actually move away from the agent of interest. The result of this incremental update strategy was that the two top middle females did not have to progress through the simulation timeline nearly as far and did not require the additional male to update at all (see bottom image of Figure 1).

5.1 Efficiency Comparison

Ultimately this case study illustrates a large performance gain from using the D-GAP algorithm and addition efficiency gain as a result of the optimization added to the general asynchronous scheduling algorithm (see Figure 2).

The D-GAP policy when coupled with the original asynchronous algorithm drastically outperforms the traditional synchronous discrete event simulator for this scenario. This improvement comes from the ability of the policy to prune unnecessary computations from the timeline based on prioritizing agents that are most likely to accomplish the research goals of the simulation. Essentially the timeline is expanded in a greedy manner such that the important events occur sooner and with less updating of agent configurations.

The additional efficiency gain achieved from using the *Incremental Dependency Removal* stems from the way this algorithm handles updating dependent agents. Instead of blindly updating agents to the point of projected possible

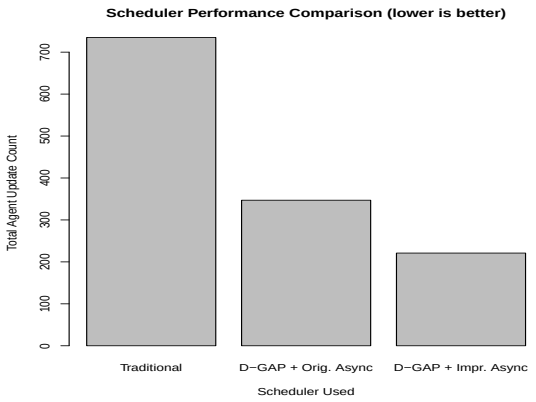

Fig. 2: Comparison of the efficiency of the 3 scheduling methods in terms of the number of *agent updates* that had to be accomplished before reaching simulation completion. The D-GAP policy with the improved asynchronous scheduling algorithm produced the most efficient runs.

interaction, dependent agents are updated only as far as necessary. Instead of updating all the agents in female9's *original* transitive closure, only the most dependent agents had to be updated incrementally. This allowed them the possibility of removing themselves from future dependencies and the need to update as much.

6. Discussion and Conclusion

The power of the D-GAP policy, like any greedy heuristic search, is only as strong as the heuristic used. In the case study, the priority assignment was clearly connected to the agent that could bring about the terminating condition. However, if priority was assigned to agents in an unrelated way to the goals of the simulation or even in an opposite way, the simulation could potentially take longer than traditional sequential scheduling. In the extreme case, it is possible for agent prioritization to be assigned such that the simulation never terminates. For example, if agent was given the highest priority in the simulation and that agent moved at maximum velocity away from the rest of the agents, it is possible that it would not interact with any other agent's projected "event-horizons" and maintain update independence indefinitely. This would lead to an agent being updated each simulation cycle that would never bring about simulation termination.

Therefore, the assignment of priority to agents must be done in an admissible way that guarantees simulation termination. There are many ways that this can be implemented. For example, adding stochasticity to the priority assignment will guarantee simulation termination even in the worst-case scenario when agent prioritization is completely assigned backwards. Another method would be to progressively penalize agents too far in the future so that there is a maximum time gap between the oldest and youngest agents in the simulation. The latter provides a bounded level of asynchrony and greedy search while maintaining the assurance of simulation termination.

Asynchronous discrete event scheduling is an extremely new concept. There have only been a handful of algorithms and policies developed to exploit the advantages of asynchronous scheduling. Policies developed so far have either optimized the characteristics of the distributed environment in which they were implemented (e.g. $Remote - Event - First$ or $Youngest - Unblocked - First$ [2]) or have attempted to optimize the scheduling using some heuristic to bias local scheduling of agents (e.g., the D-GAP policy described in this paper). Interesting future work would include policies that consider both the goals of the simulation and the distributed environment in which they are executed when making decisions on which agent to asynchronously guide through the simulation space first.

A Multi-criteria Class-based Job Scheduler for Large Computing Farms

R. Baraglia[1], **P. Dazzi**[1], **and R. Ferrini**[1]
[1]ISTI "A. Faedo", CNR, Pisa, Italy

Abstract— *In this paper we propose a new multi-criteria class-based job scheduler able to dynamically schedule a stream of batch jobs on large-scale computing farms. It is driven by several configuration parameters allowing the scheduler customization with respect to the goals of an installation. The proposed scheduling policies allow to maximize the resource usage and to guarantee the applications QoS requirements. The proposed solution has been evaluated by simulations using different streams of synthetically generated jobs. To analyze the quality of our solution we propose a new methodology to estimate whether at a given time the resources in the system are really sufficient to meet the service level requested by the submitted jobs. Moreover, the proposed solution was also evaluated comparing it with the Backfilling and Flexible backfilling algorithms. Our scheduler demonstrated to be able to carry out good scheduling choices.*

Keywords: Job scheduling; Deadline Scheduling; Software License Scheduling; Computing Farm.

1. Introduction

In large computing farms providing utility computing for a large number of users, with different functional and non-functional requirements, a scheduler plays a basic role in order to efficiently and effectively schedule submitted jobs on the available resources. The objective of the scheduling is to assign tasks to specific resources maximizing the overall resource utilization and guaranteeing the QoS required by applications. The scheduling problem has shown to be NP-complete in its general as well as in some restricted forms [3]. The scheduling on utility computing environments is multi-criteria in nature [8]. In fact, these environments generally manage computational requests dynamically time varying, and with different computational requirements and constraints that compete to access shared resources. Even if in the past research efforts has been devoted to develop multi-criteria job scheduling algorithms [7], [6], [1], [2], there is still the need to improve the scheduling techniques able to manage an increasing number of jobs and to address all the application and installation requirements as well as sets of constraints for the afore mentioned computational environment. In this paper, we propose a scheduler able to schedule a continuos stream of batch jobs on large-scale computing farms. As typical scenario we consider a computing farm made up of heterogeneous, single-processor or SMP machines, linked by a low-latency, high-bandwidth network. Some characteristics of the computing nodes (e.g. processor type, memory size, number of CPUs, link bandwidth) are static and known whereas some others are dynamic (e.g. floating sw licenses). The adopted scheduling policies permit us to optimize the scheduling with respect to different objectives, even contrasting, such as maximize the resource usage and to guarantee the non-functional applications requirements. The rest of this paper is organized as follows. Section 2 describes some of the most common job scheduling algorithms. Section 3 gives a description of the problem. Section 4 describes our solution. Section 5 outlines and evaluates our job scheduler. Finally, conclusions and future work are described in Section 6.

2. Related work

Batch jobs scheduling are mainly divided in two main classes: on-line and offline. On-line algorithms are those that do not have any knowledge about the whole input job stream. They take decisions for each arriving job without knowing future inputs. Conversely, offline algorithms know all the jobs before taking scheduling decisions. Many of these algorithms are exploited into commercial and open source job schedulers [4]. The Backfilling algorithm [9] is a widely adopted scheduling approach, it is an optimization of the FCFS algorithm [10]. It requires each job specifies its execution time, so that the scheduler can estimate when jobs finish and other ones can be started. The main goal of Backfilling is to exploit a resource reservation approach to improve the FCFS policy by increasing the system resource usage and by decreasing the average job waiting time in the scheduler's queue. In order to improve performance, some backfilling variants, such as Flexible backfilling [5] have been proposed. The Flexible backfilling algorithm is obtained by exploiting a different order of queued jobs. Jobs prioritized according to scheduler goals are queued according to their priority value, and selected for scheduling. Even if the multi-criteria approach seems to be the most viable one to solve the resource management and scheduling problem in heterogeneous and distributed computational environments, only a few research efforts have been done in such direction [1], [7], [2], [11]. In [1] a multi-criteria job scheduler for scheduling a continuous stream of batch jobs on large scale computing

farms is proposed. It exploits a set of heuristics that drive the scheduler in taking decisions. Each heuristics manages a specific constraint, and contributes to compute the measurement of the matching degree between a job and a machine. The scheduler allows its extensions to manage a wide set of requirements and constraints. In [7] K. Kurowski *et al.* propose a two-level hierarchy multi-criteria scheduling approach for Grid environments. All participants of a scheduling process, i.e. endusers, Grid administrators and resource providers, express their requirements and preferences by using two sets of parameters: hard constraints and soft constraints. A Grid broker at higher level exploits the hard constraints to compute a set of feasible solutions, which can be optimized by using soft constraints describing preferences regarding multiple criteria, such as various performance factors, QoS-based parameters, and characteristics of local schedulers. In [2] a bi-criteria algorithm for scheduling moldable jobs on cluster computing platforms is proposed. It exploits two pre-existing algorithms to simultaneously optimize two criteria: job makespan and weighted minimal average completion time. Such criteria are complementarity, and well represent the objectives of both users and system administrators. The algorithm was evaluated by simulations using two different synthetic workloads. In [11] a solution based on advanced resource reservation that optimizes resource utilization and user QoS constraints for Grid environments is proposed. It supports advanced reservations to deal with the dynamic of Grids and provides a solution for agreement enforcement. The proposed advanced reservation solution is structured according to a 3-layered negotiation protocol. Preferences of end-users are taken into account to start a negotiation to select resources to reserve. The user can select the best suitable offer or can decide to re-negotiate by changing some of the constraints. End-users preferences are modeled as utility functions for which end users have to specify required values and negotiation levels. In [6] is proposed a schedule-based solution for scheduling a continuous stream of batch jobs on computational Grids. The solution is based on Earliest Deadline First (EG-EDF) rule and Tabu search technique. The EG-EDF rule incrementally builds the schedule for all jobs by applying technique which fills earliest existing gaps in the schedule with newly arriving jobs. If no gap for a coming job is available EG-EDF rule uses Earliest Deadline First (EDF) strategy for including a new job into the existing schedule. The schedule is then optimized by using a Tabu search algorithm to move jobs into earliest gaps. Scheduling choices are taken to meet the QoS requested by the submitted jobs, and to optimize the hardware resource usage.

3. Problem Description

We consider jobs and machines annotated with information describing their requirements and features, respectively. Jobs in a stream can be sequential or multi-thread, and all the jobs are independent one from each other. To each job is attached a description containing both an identifier and a set of functional and non-functional requirements. Functional requirements include the number of processors, the RAM size and the software licenses a job needs to be executed. Non-functional requirements (also referred as QoS) are job slowdown equal to one, job deadline and job advanced resource reservation. The description also includes an estimation of the time required to compute the job and the features describing the processor exploited to perform such estimation (benchmark score). Each job is executed on a single machine, and all jobs are preemptable. Job preemption can be performed when either a job submission or a job ending event takes place. The machines composing the farm are described by a benchmark score, the number and type of CPUs, the size of the RAM installed and the non-floating (i.e. bound to a machine) and floating (i.e. not bound to any specific machine) software licenses they can run. Processors installed on each machine has associated a weight. Every machine can execute multiple jobs at the same time in a space-sharing fashion. All the machines support two basic forms of job preemption: stop/restart and suspend/resume. The checkpoint/restart form is possible only if the running job is properly instrumented. Machines are assigned to jobs in the shape of sub-machines, namely a subset of a machine's processors. A submachine is managed by the scheduler as an instance of the machine from which it is originated. Floating sw licenses can be assigned to any machine able to run them. The only limit is that the total number of licenses in use can not be greater than their availability. In our study, we consider the association of licenses to machines. As a consequence if a set of jobs requiring the same license can be executed on the same machine, only one license copy is accounted.

4. The scheduler achitecture

The proposed scheduler is based on multiple job classes. Each job is assigned to a class on the basis of its functional and/or non-functional requirements. Figure 1 depicts the architecture of our scheduler. Three main components are represented: *Job-Dispatcher*, *Class-Scheduler* and *Control-Scheduler*. The *Job-Dispatcher* receives, classifies, and dispatches each job to the proper class. A class is an entity characterized by a set of dynamically assigned computational resources, a job queue and a Class Scheduler. The classes are ranked according to a priority value assigned statically by the installation on the basis of the functional and non-functional requirements managed. To each class is associated a *Class-Scheduler* (CLS). This component is specialized for managing a specific class of job requirements. To each CLS is associated a job queue and a set of resources. The CLS extracts jobs from its queue and allocates them resources to be run. In case of resource shortage, it issues a request for additional resources to the Control Scheduler. A class releases the assigned resources when they have not been used

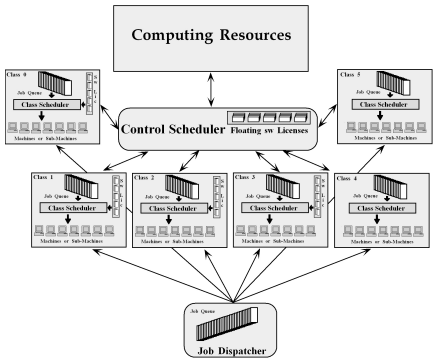

Fig. 1: The scheduler architecture.

for a predefined quantum of time, fixed by the installation. The *Control-Scheduler* (CNS) is devoted to manage requests issued by CLSs. CNS allocates resources to CLSs in the form of sub-machines or floating sw licenses. As an example, consider a job asking for four processors in a computing farm composed by only eight-processors machines. The CNS assigns four free processors from an available suitable machine to the requesting class. That class becomes the temporary owner of the assigned resources until it will not release them. Requests issued by higher ranked classes are scheduled first than the other ones, and requests issued by the same CLS are managed according to the FCFS order. CNS defines new sub-machines according to two alternatives: 1) The sub-machine is defined on a machine already assigned to the requesting class, 2) The sub-machine is defined on a machine not assigned to any class, i.e. a free machine. If no machine is available, the CNS can decide to enact a resource stealing process. The definition of a new sub-machine is performed by exploiting the principle of the least privilege, namely, from all the available machines is chosen the one with the least amount of resources that is sufficient to satisfy the requested assignment. Sub-machines are managed using a data structure consisting in a vector VFM which length equals to the number of processors P of the largest machine in the computing farm. Each element in the vector contains a list in which each elements represents a farm's machine. A machine belongs to list at index i if its actual availability of processors equals to i. The lists are arranged in increasing order with respect to machine memory size, and then the number of floating sw licenses the machine can run. In order to find a machine with p processors, a RAM of size r and l licenses, CNS starts its search from the $VFM[p]$ element and continues until it finds a machine addressing the assignment requirements or the vector ends. When a proper machine is found and a new sub-machine is created the number of available processors in that machine decreases correspondently. The data structure is updated consequently. The idea behind this data structure is to keep lager machines available for subsequent requests and to reduce machines fragmentation. Floating sw licenses are managed using a specific data structure consisting in a vector which length equals to the number of available floating sw licenses S. Each vector entry addresses a list storing the number of currently usable copies for a specific license. Such lists are structured according to three sublists storing respectively the number of available copies, the number of copies assigned to a class but not used, and the number of copies assigned to a class and in use. Floating licenses belonging to the first two sublists are available for assignment to classes, whereas the copies in the third list are already assigned. When a free copy of a floating sw license is assigned to a class, it is removed from the first sublist and assigned to the third sublist. When a job using a floating sw license finishes its execution the license copy is moved to the second sublist. After an installation-defined quantum of time licenses in the second sublist are released and moved to the first sublist. In our study we considered six job classes ($0 \div 5$) The first three classes (0, 1 and 2) manage jobs with both functional and non-functional requirements whereas the other three ones (3, 4 and 5) manage jobs with only functional requirements. Jobs are assigned to the classes according to the following criteria:

- *Class 0*: Jobs requiring a slowdown equal to 1. Jobs are managed by the related CLS according to the First Come First Served (FCFS) order.
- *Class 1*: Jobs requiring advanced resource reservation. Jobs are scheduled according their closeness to the reservation. Jobs for which the resource reservation fails are discarded. Alternatively, but not in our study, they could be moved to Class 3, 4 or 5 depending on their functional requirements.
- *Class 2*: Jobs with deadline. Jobs are scheduled according to the expected time they have to start to meet their deadline. The queue position of a job is determined exploiting the solution proposed in [6]. According to such solution, the closer the deadline of a job is, the higher its position in the job queue is.
- *Class 3*: Sequential or parallel jobs requiring floating sw licenses.
- *Class 4*: Parallel jobs not requiring any floating sw license.
- *Class 5*: Sequential jobs not asking for floating sw licenses.

Jobs within classes 3, 4 and 5 are selected by the related CLS according to the FCFS order. If a job has requirements to be assigned to two different classes, it will be assigned to the class having a higher priority. The assignment of resources to classes permits to exploit the locality in job requirements. In fact, after a initial time, it is highly probable that a class managing jobs with similar requirements owns in advance the resources to run the jobs to it assigned.

Resource stealing: When a class is experiencing a lack of free resources to satisfy a request its CLS issues a request to CNS. As a consequence, the execution of jobs belonging to classes with a lower priority have to be interrupted to release the needed resources. However, the interruption of a job has a cost for the computing farm. Actually, interrupting a job is convenient only if the gain resulting from the use of the released resources overcomes this cost. To evaluate this cost several parameters should be considered, e.g. the time elapsed in execution by the job candidate to be interrupted, the number of sw assigned to that job, etc. In our model a resource r can be moved from a class A to a class B if the following expression is verified: $Rank^A > Cost^B(r)$, where $Rank^A$ is the rank value of Class A and $Cost^B(r)$ is the cost associated to the interruption of jobs running on resource r and belongs to B. Considering a generic class C, a resource r, and the number k of jobs running on r such cost can be computed as: $Cost^C(r) = Rank^C + \sum_{i=1}^{k} P^C(i)$, where $P^C(i) = W_i \cdot (\frac{T_{ex}(i)}{T_{tot}(i)}) \cdot W_{dead} + (W_{pr} \cdot Pr(i)) + (W_l \cdot L(i))$. $T_{ex}(i)$ is the time spent executing the job i and $T_{tot}(i)$ is the total estimated execution time of the job i. W_i is the weight associated to the form of preemption adopted to interrupt the execution of the job i. This is small if the job supports checkpoint/restart, it increases in case of suspend/resume and it is maximum if the only option is stop/restart. W_{dead} is the weight associated to jobs having a deadline. It equals to 1 for jobs without deadline. W_{pr} is the weight associated to a processor and $Pr(i)$ is the number of processors assigned to i. W_l is the weight associated to a floating sw license and $L(i)$ is the number of floating sw licenses used by i. The idea of this approach is to allow an installation to tune W_i, W_{pr}, W_l and W_{dead} values and class ranks according to its objectives. As an example, suppose that an installation goal is to respect in a very strict way the prioritization given by the jobs classes.To this end, the *Rank* associated to two consecutive classes have to differ by a value greater than the maximum value that $P^C(i)$ can assume. Such value is obtained when a job i (it makes no difference to have just one or several jobs if the overall resource usage is the same) is using all the processors of the largest farm's machine, all the available floating sw licenses, and is approaching the end of its execution. Let's assume that the largest farm's machine has 1024 processors, and that the total number of floating sw licenses is 20. Moreover, consider weights assuming these values: $W_i = 200$, $W_{pr} = 1$, $W_l = 0.5$ and $W_{dead} = 2$. Hence, the maximum value $P^C(i)$ can assume is: $P^C_{max} = 200 * 1 * 2 + 1 * 1024 + 0.5 * 20 = 1434$. As a consequence, the rank values of the six classes have to be fixed as follows: $Rank\_Class5 = 0$, $Rank\_Class4 = 1500$, $Rank\_Class3 = 3000$, $Rank\_Class2 = 4500$, $Rank\_Class1 = 6000$, and $Rank\_Class0 = 7500$[1].

[1]These rank values are the ones exploited in the conducted tests

Resource search: Considering a job i belonging to a class A and requiring $Pr_x \leq P$ processors and $L_x \subseteq S$ floating sw licenses the resource search algorithm is structured according to the following steps:

1) Starting from the entry Pr_x, the VFM data structure is analyzed to find jobs to be interrupted.
2) For every machine m suitable for executing i indexed by Pr_x, a list of jobs that could be interrupted is created. The list also includes free processors.
3) The first N_x jobs, which interruption permits us to obtain the required Pr_x processors are selected.
4) If selecting the first N_x jobs a number of processors greater than Pr_x is obtained, a refined step is conducted to fix the number of selected processors. The list of selected jobs is visited in reverse order to remove exceeding processors.
5) The cost $Cost_r$ is computed as the sum of the costs related to the jobs being interrupted on m. If $Cost_r$ is smaller than the costs computed for the other analyzed machines, the machine m is selected, and the jobs on it executing are selected to be interrupted.
6) Steps from 2 to 5 are repeated from $Pr_x + 1$ to P to find machines suitable for executing i.
7) At the end of step 6, the list of jobs that cloud be interrupted (i.e. jobs running on the machines with associated the lowest costs) is carried out.

The interruption of the selected jobs may lead to free some required licenses. In this case, the found licenses are removed from L_x and the following steps are executed:

1) The floating sw licenses search starts from the queue $l \in L_x$ of the floating sw license data structure.
2) The cost $Cost_r$ due to the interruption of a job using l is computed. The job corresponding to the smallest $Cost_r$ is selected and its execution interrupted.
3) Steps 1 and 2 are repeated until all the licenses needed to run the job i are found.
4) At the end of step 3, the set of jobs to interrupt is found.

This phase is the most computation expensive one. In fact, the search of free processors requires in the worst case to analyze all the available machines and floating sw licenses. The search of processors needs to sort the N jobs running on each of the M machines in the farm. Since the sort operation has complexity $NlogN$, in the worst case, the resource search algorithm has complexity $C = M \cdot NlogN$. To search a floating sw licenses in the worst case has complexity $|L|$.

5. Performance Evaluation

The evaluation of the proposed scheduler was conducted by simulations using different streams of jobs and farms of different size. Job and machine parameters have been randomly generated from a uniform distribution in the ranges shown in Table 1. Moreover, we compared our solution

with Backfilling and Flexible backfilling algorithms. The job priorities of the Flexible backfilling algorithm are updated at each job submission or ending event and the reservation for the first queued job is maintained through events.

Table 1: Parameters used to generate jobs and machines.

Description	Range
Processor Type	$1 \div 5$
Number of processors	$1 \div 128$
Benchmark score	$0.5 \div 2$
RAM	$500Mb \div 5Gb$
Job estimated execution time (secs)	$16000 \div 20000$
Number of licenses copies	$50 \div 70$
Number of different licenses	20

For each simulations the percentages of jobs requiring specific functional and non-functional requirements have been generated according to the values shown in Table 2.

Table 2: Percentages used to generate the job steams.

Percentage	Description
5%	requires a slowdown equal to 1
30%	has a deadline
5%	needs of advanced resource reservation
60%	needs a software license
30%	needs a floating software license
10%	needs a specific hardware
2%	supports checkpointing
40%	needs 1 processor
40%	needs 2 processors
10%	needs 4 processors
0.8%	needs 8 processors
0.08%	needs 16 processors
0.06%	needs 32 processors
0.04%	needs 64 processors
0.02%	needs 128 processors

The duration of each simulation was set at 43200 time units (i.e. the number of seconds in 12 hours). For each simulation unit the system: (1) Generate a job and put it in the Dispatcher's job queue, (2) Update of the running jobs status (3) Update of the status of the resources (4) Execute the CLSs, (5) Execute the CNS, (6) Store the simulation statistics. In the conducted experiments the number of generated machines varied from 1000 to 1200, and to obtain stable values each simulation was repeated 50 times with different farm configurations and job streams. The performance metrics have been evaluated versus the system contention. Usually, this value is roughly computed as: $ResourceR/ResourceA$, where $ResourceR$ is the amount of a specific resource requested by the jobs in the system, and $ResourcesA$ is the available amount of such resource. This ratio does not provide an accurate information on resource availability because it ignores the jobs allocation implied constraints. In fact, all the requirements of a job must be satisfied to allocate it, so the variables describing the available resources cannot be considered independently. To clarify this point, let us suppose that the value computed by using the above expression is less than 1. In principle, it indicates an availability of the considered resource. As a consequence, a scheduler should be able to properly allocate the jobs on the available resource. However, this is not always true. As an example consider an availability of 20 processors in the system and a job to schedule requiring 16 processors. Clearly, if at least 16 of the 20 free processors are not available on the same machine the job can not be scheduled even if a rough analysis would suggest enough processors availability. Unfortunately, in general can be hard to understand if the resource shortage is caused by the ineffectiveness of the adopted scheduler or by an insufficient number of available resources. To overcome this problem we introduce the RRI index. Its aim is to exploit a simple allocator to measure, with a certain degree of approximation, if at a certain time, the resources in the system are sufficient to meet all the jobs requirements. In particular, in this paper we only consider the resource processor for computing the RRI index. To this end, we considered the following four job scheduling algorithms (but in principle others can be also considered), each one basing its strategy on a different job allocation policy: 1) *Largest Machine*, which allocates a job on the machine with the largest number of free processors, 2) *Smallest Machine*, which allocates a job on the machine with the smallest number of free processors, 3) *Smallest Residue*, which allocates a job on the machine where remains, after the allocation of a job, the lowest number of free processors, 4) *Largest Residue*, which allocates a job on the machine where remains, after the allocation of a job, the largest number of free processors. These algorithms were evaluated to find the one leading to the best processor usage in the simulated environment. To this end, a workload able to use all the available processors of the simulated farm was designed according to the following four steps: 1) A random generation of a set of machines, 2) For each machine a proper set of jobs were generated, 3) A random distribution of all the processors belonging to each machine to the generated set of jobs, 4) Assignment of the generated jobs to a free computation slot in such a way that they finish their execution on the target machine all at a fixed time. RRI is computed as: $(Processors_r + Processors_q)/Processors_a$, where $Processors_r$ are the processors request by the allocated jobs, $Processors_q$ are the processors request by the not allocated jobs, and $Processors_a$ are the available processors. The higher the RRI value is, the higher the system contention is. Smallest Residue is the method that obtained the best results in 500 simulations we conducting varying the number and the type of the machines inside the simulated farm. This is the allocator we used for computing the RRI index. It behaves as a sort of probe to measure the processors availability throughout a simulation. It is executed each time a job execution is started. To evaluate the scheduler efficiency, we analyzed the algorithms exploited by CNS

to handle sub-machines. Figure 2 shows the percentages of new sub-machines definition and expansion we obtained by the simulations. When the RRI value is low ($RRI < 0.4$) there is a high rate of new sub-machines definition because the classes have only a few resources assigned. When the value of RRI is between 0.4 and 0.8 there is a higher sub-machines expansion rate because the classes already have a large number of sub-machines and at the same time there are enough available processors on the farm machines. When the value of RRI is greater than 0.8 the percentages of the expanding and new definition processes tend to stabilize at values of 30% and 40%, respectively. This result means that, when the system is heavily loaded, for example, when RRI is equal to 2 the classes in about 35% of cases already have a submachine able to execute a submitted job. While, in the other 65% of cases, CLSs require to CNS to extend a sub-machine (25%) or to define a new sub-machine (40%).

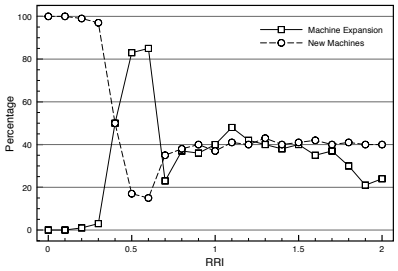

Fig. 2: New sub-machines definition or expansion.

The graph of Figure 3 shows the percentage of processors used by the running jobs. When the RRI index is greater than 1, i.e. when the requested resources begin to be unavailable, the processor utilization approaches to 100%. But the shape of the curve clearly shows that in some cases there are free processors even if the values of RRI are greater than 1. In fact, also when the value of RRI is greater than 1.2 (i.e. when the estimated number of requested resources go over in the available ones) the figure shows that some processors are not used. This happens because, also when the number of requests is much greater than the available resources, the last are not able to run any one of the waiting requests. However, it is worth to point out that our scheduler is able to schedule jobs in a way that keeps low the number of unused resources.

We also investigated the degree of satisfaction of non-functional job requirements. We evaluated the *quality of service* provided by the Control-Scheduler on the basis of decisions it has made to allocate resources to the classes. This analysis has been conducted to assess the choices made in the following areas: (1) Job classification policies and rank values assigned to classes; (2) Resource stealing technique. Bad choices can cause long queuing times for some types of jobs, in particular the ones belonging to low ranked classes.

To evaluate the satisfaction level of the resource demands

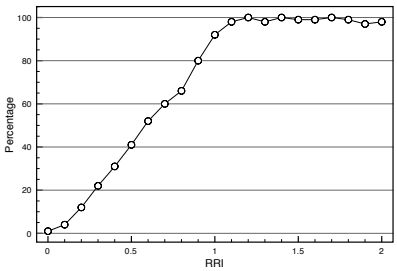

Fig. 3: Processor usage.

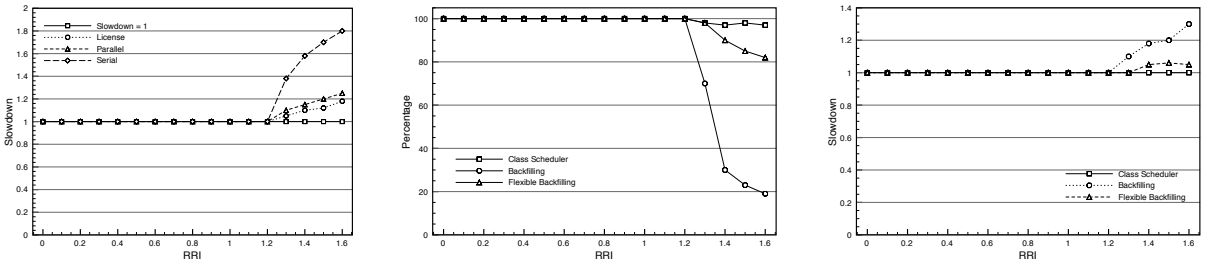
we used the *slowdown* metric. This measures the ratio between the response time of a job (i.e. the time elapsed between its submission and its termination) and its execution time. It is computed as: $(Tw + Te)/Te$, with Tw the time that a job spends waiting to start and/or restart its execution, and Te the job execution time [9]. Figure 4(a) shows the average slowdown obtained executing job belonging to the following job classes: Class 0, i.e. jobs requiring a slowdown equal to 1; Class 3, i.e sequential or parallel jobs requiring floating license, Class 4, i.e. parallel jobs do not requiring floating license, and Class 5, i.e. sequential jobs do not asking for floating license. In this evaluation jobs requesting advanced reservation or a deadLine were not considered because for such jobs the slowdown is not indicative. In fact, depending on their characteristics, such jobs can spend some time enqueued before to be executed without affecting their performances. In our tests all the requests of advanced resource reservation were satisfied. Figure 4(a) shows that, when the resources are available (i.e. $RRI < 1$) all the jobs obtain a slowdown equal to 1. When $RRI > 1$, i.e. the job competition to access the available computational resources increases, jobs are forced to spend some time in the queues resulting in an increase of the job average slowdown. It can be seen that in the conducted tests the job requirement *slowdown=1* is satisfied also when the value of RRI reaches 1.6 (i.e. high system contention). The slowdown value of jobs asking floating software licenses remain under 1.2 also with high system contention, while the slowdown increases only up to a 20% for parallel jobs. Instead, the value of the slowdown of the serial jobs is the worst, their completion time can increase up to 80%. Figure 4(b) shows the percentage of jobs executed respecting their deadline. The results obtained by the proposed scheduler were compared with those obtained by running a Backfilling and Flexible backfilling algorithms with the same simulation conditions, i.e. with both the same machines and the same job streams, used to evaluate the proposed scheduler. As expected, the lower the system contention is ($RRI \leq 1$), the higher the percentage of the jobs meeting their deadline is, and all the schedulers are able to satisfy all deadline requests. The proposed scheduler is able to obtain better results than the other algorithms. It obtains a percentage of



(a) Job slowdown (b) Job deadline (c) Slowdown of jobs requiring slowdown = 1

Fig. 4: Slowdown

jobs that respect their deadline very close to 100% also with a high system contention ($RRI \geq 1.5$). As the system contention increases the Flexible backfilling algorithm reaches a performance that is 16% lower than the one obtained by the proposed scheduler, while the Backfilling algorithm obtains a performance significantly lower than the one obtained by our scheduler. In Figure 4(c) we show the results obtained from the execution of jobs requiring a $slowdown$ value equal to 1. It can be seen that when the resources are not longer available the Backfilling and Flexible backfilling algorithms are not able to guarantee this QoS. The proposed class scheduler, by using the technique of resource stealing, makes available the resources needed also when the system contention is high ($RRI \geq 1.5$). It is worth to point out that the Flexible backfilling algorithm maintains the slowdown value within an acceptable level, offering in this test a performance comparable to the one obtained by the proposed scheduler.

6. Conclusion

In this paper, we propose a new multi-criteria scheduler to dynamically schedule a continuous stream of batch jobs on large-scale non-dedicated computing farm made of heterogeneous, single-processor or SMP machines, linked by a low-latency, high-bandwidth network. The proposed solution aims at scheduling arriving jobs respecting several functional and non-functional job requirements and optimizing the hardware and software resource usage. Several configuration parameters allow the scheduler customization with respect to the goals of an installation. The scheduler was evaluated by simulations using different job streams synthetically generated. To conduct the evaluation a technique to measure the system contention throughout a simulation was adopted. The scheduler has been evaluated comparing it with Backfilling and Flexible backfilling schedulers. In the conducted tests, the proposed scheduler demonstrated to be able to carry out good scheduling choices As future work, we plan: (1) to enhance the current scheduler refining the adopted advanced resource reservation technique, and to manage jobs requiring co-allocation to be executed on more than one machine, (2) to introduce energy efficiency policies dispatching workloads to more energy-efficient machines, (3) to evaluate the scheduler when applied to computing platforms made of distributed computing farm, (4) to investigate the feasibility of different scheduling criteria to estimate the RRI index.

Load Balancing Approach Based on Limitations and Bottlenecks of Multi-core Architectures on a Beowulf Cluster Compute-Node

Damian Valles, David H. Williams, and Patricia A. Nava
Electrical and Computer Engineering, University of Texas at El Paso, El Paso, Texas, USA

Abstract - *This paper studies the improvement of performance and execution time of a single compute-node in a Beowulf cluster. We want to implement a load balancing approach through the Linux scheduler which improves the performance and execution time of High Performance Linpack (HPL) benchmark. We compare the performance and execution time when spawning processes for two processing cores in a local processor up to all eight cores in two processors. The results showed that this approach helped to improve performance throughput since the load balancing approach created a higher L2-cache awareness, with increased hit rate, while reducing the number of times processes accessed the Front-side Bus (FSB) and Memory Controller Hub (MCH) during execution. Performance and execution time peaked with block sizes of 64 and 128 for different HPL matrix size and problem sizes; however, the performance throughput decreased for other sizes due to hardware contentions in the FSBes and MCH.*

Keywords: cluster, performance, quad-core, benchmark[1]

1 Introduction

Beowulf clusters are scalable performance clusters constructed with off-the-shelf hardware components, communicating on a private system network, with an open source software infrastructure [1]. A Beowulf cluster consists of a front-end machine that communicates with the outside world, and manages and distributes jobs to identical compute-nodes. The compute-nodes are connected to the front-end via a private network that normally uses a commonly available communication protocol such as Ethernet or InfiniBand for communication. Together, the compute-nodes and associated private network form a homogenous environment that make-up the structure of the cluster. The compute nodes are servers that are always listening for incoming requests and provide the necessary processing computational power to the assigned tasks coming from the front-end machine.

Virgo 2.0 is a Beowulf cluster system that consists of a front-end machine, twenty-one compute nodes and two memory nodes [2]. Throughout Virgo 2.0, the processing architecture is constant in all compute-nodes that consist of two Intel Quad-core Xeon processors [4]. Both processors can communicate with each other and to the rest of the system by their perspective Front-side Bus (FSB) into the Memory Controller Hub (MCH). The focus is to analyze the architecture of the two processors in this type of cluster environment in order to prevent performance bottlenecks that might be present during execution.

Benchmarking was utilized to measure the performance and execution time of the system in order to come understand the architecture [3]. High Performance Linpack (HPL) 2.0 was utilized in order to perform the benchmark on a single compute-node and spawn the desired number of processes to the cores. For the subprogram support of HPL, the Automatically Tuned Linear Algebra Software (ATLAS) 3.8.2 was installed which carries the Basic Linear Algebra Subprograms (BLAS) for the HPL algorithm to execute properly. And MPICH 2.0 was installed in order to carry the Message Passing Interface (MPI) standard libraries for proper communication between the processors and cores.

Assuming that the Linux Scheduler is applied to all compute-nodes in the cluster system, it is developed for its specific instruction set for the hardware, and it is the only mechanism that schedules all of the tasks that are executed for all users and applications. We hypothesize that the scheduler can be modified to further take advantage of the hardware configuration, in being more aware of the pre-existing limitations to the load balancing caused by specific hardware limitations, and by redefined the decision-making when performing load balancing of tasks. An average of double digit percentage improvement in performance and execution time for large computational jobs executed on Virgo 2.0 can be obtained.

2 Virgo 2.0 Overview

Virgo 2.0 is a Beowulf cluster that consists of a front-end machine, twenty-one dedicated compute-nodes and two memory-nodes. All compute-nodes consist of homogenous architecture parts which include two Intel Quad-core Xeon processors without hyper-threading capabilities. In effect, the

cluster can have up to one hundred and eighty-four processing cores working on a single application not including the front-end machine. Therefore, it gives the opportunity to explore the possibilities of improving the load balancing of tasks on Virgo 2.0 through reprogramming of the Operating System (OS) kernel to improve performance and execution time.

Virgo 2.0 is a cluster system in which a user has access to all compute-nodes once the user accesses the front-end machine. The user is able to launch individual and/or concurrent applications on each compute-node. If distributed applications are needed, the user must employ a communication protocol to spawn the processing to all needed compute-nodes. Such protocols include sockets; Remote Procedure Calls (RPCs) and the Message Passing Interface (MPI). All scheduling and job creation is interactive. This cluster system does not contain an internal batch queue program that launches and distributes jobs to its compute-nodes. However, the configuration of the cluster system provides an opportunity to improve performance of a single compute-node and replicate to all others.

Two Harpertown processors [4] is the architecture implemented on each compute-node with a total of eight processing cores. Each of the processing cores has their own Level 1 (L1) cache memory and each pair shares a 6MB Level 2 (L2) cache memory. The pair of processing cores also shares a FSB which provides the communication path for data and address buses.

Each of the Intel Quad-core Xeons is labeled with a physical identification number as shown in Figure 1. The physical identification given to the processor helps the system to identify the processing cores with even numbers assigned to processor physical id zero and odd numbers assigned to processor physical id one.

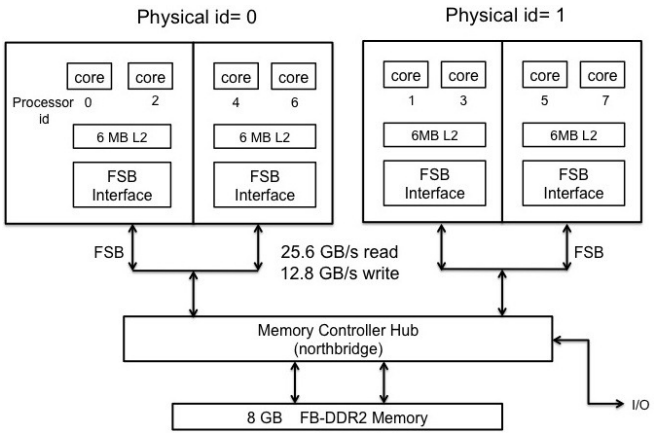

Figure 1. Harpertown Block Diagram Configuration in a Computer-Node

Each processor combines the signals from the two FSBs into a single dedicated FSB bidirectional interface to the Memory Controller Hub (MCH). Each of the FSBs has a 38-bit address bus, a 64-bit data bus, and associated control signals. The setup time for actually requesting the address/data buses is four FBS-clock cycles and the request of the busses can last up to a maximum of twenty FBS-clock cycles for that one single request [4], if the four clock cycles are not enough for the task to complete before another request must be issued.

As we try to improve the performance and management of tasks within the compute-node, we must consider the functionality and design of the FSBs. The merger of data from the two FSBs within each Harpertown and the merger of data of the FSB interfaces from the two processors within the MCH must be considered as tasks normally access the addresses and data from memory many times. What we can expect is that the larger the tasks become and the more memory accesses are needed, bottlenecks will start to occur as more and more data is moved through the FSBs and the MCH to each pair of processing cores within the Harpertown processor.

The Memory Controller Hub (MCH) is the main chipset that bridges both of the Harpertown processors together and is the pathway to the I/O Controller Hub. The MCH provides two FSB processor interfaces, four fully buffered DIMM (Dual In-line Memory Module) memory channels, nine x4 PCIe (Peripheral Component Interconnect Express) bus interfaces configurable with x8 or x16 ports, an Enterprise South Bridge Interface (ESI), six SM Bus interfaces for system management, and DIMM Serial Presence Detect (SPD) [4]. Figure 2 show a block diagram of the MCH with all of its interfaces.

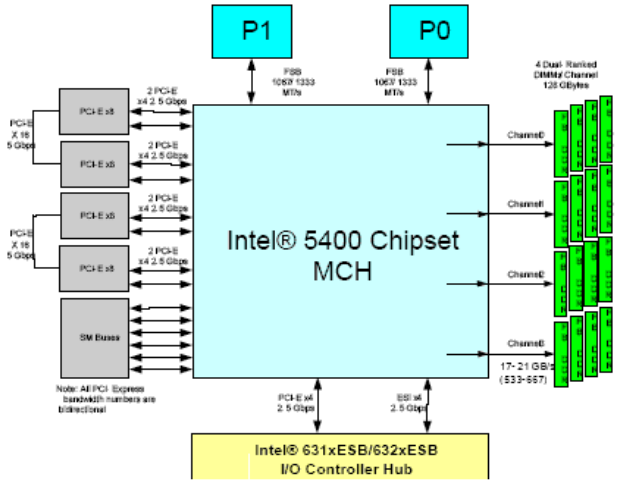

Figure 2. Intel's 5400 Chipset Memory Controller Hub Block Diagram

The MCH can play a big role when developing a load balancing mechanism of processes. One of the main decisions of the scheduler is to know when it is appropriate to migrate tasks from one core to another. It may not be a problem to

move the task to a neighboring core within the same die since all of the resources of the task are located in the same area. However, the decision can be expensive if the migration occurs from one core to another core in a different processor. This is because the task and all of its resources are too big to migrate completely within a single request and therefore forces a context switch. The migration can occur but the new destination might not have all the necessary space to accommodate all the migrating resources. That is why there must be an understanding in how the MCH can treat this scenario of task migration between two processing cores on different die.

Completely Fair Scheduler (CFS) is a scheduling algorithm that will run each process for some amount of time in round-robin order, then context switch, selecting next the process for execution that has run the least. Rather than assign each process a timeslice, CFS calculates how long a process should run as a function of the total number of runnable processes. And instead of using the nice value to calculate a time slice, CFS uses the nice value to weight the proportion of processor time a process is to receive: Higher valued (lower priority) processes receive a fractional weight relative to the default nice value, whereas lower valued (high priority) processes receive a larger weight [6].

The O(1) Scheduling algorithm is the current scheduler on the Linux 2.6.18 kernel. The big-O notation is used to denote the growth rate of an algorithm's execution time based on the amount of input [7]. Previous schedulers contained O(n) algorithms which indicated that the algorithm increases linearly or more as the input grows in size n. For example - the running time of $O(n^2)$ grows quadratically. Therefore, an O(1) algorithm is one that guarantees to operate at a constant time independently of the load size coming in to the input. The Linux 2.6.18 O(1) Scheduler includes per-core structures called run-queues, which contain the set of runnable threads assigned to each core in the MCA environment [8].

This becomes ideal for the Virgo 2.0 system because as the number of tasks increases for execution, the scheduler will be able to handle more tasks to be scheduled without additional system overhead. The idea of implementing a CFS Scheduler for the kernel would be unnecessary since none of the compute-nodes have any interaction processes to execute at any time. Therefore in combining the O(1) Scheduler algorithm and the SCHED_FIFO policy of each of the tasks executing on each compute-node, will help to improve system performance. SCHED_FIFO tasks do not have time slices and they may run indefinitely, which is desirable by avoiding preemption and increase processing core utilization. A SCHED_FIFO task can only be interrupted or preempted by other FIFO tasks that have higher priority or by system interrupts [7].

3 Procedure

The load balancing modification of the Scheduler deals with how the processes will be balanced and affinity assignments is made to match tasks with the processing cores. Assigning affinity of processing cores to each of the tasks immediately starts. The manner in which each task is assigned to a processing core is implemented using the load_aff() function.

The load_aff() function is a modification that load balances the tasks that are ready to execute and assigns the task's affinity to a processing core. The load_aff() function is as follows:

• It first determines if the previous modification was able to group single or multiple tasks for execution, if not, the function returns control as shown in the code below.

```
if(arraypid[0][0]==NULL)
  return;
```

• Next, the load_aff() function performs an availability test of the processing cores through the idle cpu(int cpu) function. The processing cores that are idle and ready for execution are saved in a vector array in order to use the list during the load balancing part of the function.

```
for(go through processing cores)
  ready[] = idle_cpu(order[]);
```

• The ready[] array keeps the information of the available processing cores that are available for execution.

• The order[] array is a defined array which holds the sequence of processing core identification numbers.

• The order[] array is ordered by pairs of processing cores that share the L2 cache memory.

After initial checks, the load_aff() function begins load balancing the tasks that were grouped in the previous modification and begins assigning affinity to processing cores. The simplest form of load balancing is when the number of tasks equals or is greater than the number of processing cores available for execution. In this case the load_aff() function will:

• Check that the order[] array and the ready[] array have the same number of elements and value of each element in order.

• For each element, the function begins to assign affinity to each task by their PID and the order of the processing cores.

• The pseudo-code below demonstrates in how tasks are assigned in this scenario.

```
if(check readyarray == orderarray)
 for(arraypid[][])
  if(tskcore=
    sched setaffinity(p->arraypid[][],
    cpumask of cpu(ready[])) == 0)
    if(ready[indx++]!= NULL)
     indx++;
    else return;
  else return -1;
```

• tskcore is an int-type variable which checks the return value of the sched_setaffinity() function.

• The sched_setaffinity() function is a defined function in the Scheduler which is used to set any task to a CPU. Each time the sched_setaffinity() function is called, it must also have the two parameters: the PID of the task and the mask-type value of the CPU.

• Each PID of tasks in the group is obtained from the arraypid[][] array used in the grouping of tasks modification.

• For the second parameter, each processing core ID that is in the ready[] array must be changed to cpumask_t type.

• The function cpumask of cpu(int cpu) is used to do this conversion correctly. The cpumask of cpu(int cpu) is a defined function in the Scheduler. The int cpu value is obtained from the ready[] array.

• If the sched_setaffinity() function returns a zero, the task affinity will be set to the indicated processing core.

• Also, it needs to keep track of the indexing of the ready[] array. It will check if it is at the end of the array.

This keeps repeating, setting affinity to each task, until all are assigned. However, many other scenarios of processing core availability can be presented when trying to execute a program with eight tasks. The load balancing would need to decide where the tasks in the group need to execute and assign affinity to all. Therefore, the load balancing must take into account the number of processes each instance of the HPL benchmark is asked to execute and decide the best affinity assignment accordantly when the number of tasks is greater than the available processing cores.

Once the number of concurrent threads continues to increase, the IPC performance and the L2 hit rate begin to decrease. Therefore, the load_aff() function must consider performance decreases that can occur by assigning affinity to all the processing cores. The way the load balancing is modified is by setting affinity in pairs of two processing cores that share L2 cache memory. The main reason to pair the processing cores in this manner is to take advantage of the L2 cache share capabilities. Secondly if any process communication is needed, the tasks will have minimal latency. Finally, as the processes share L2 cache memory to execute the same instance of the benchmark, it reduces the number of L2 miss rates which in effect reduces the number of main memory accesses and creates less contention in the FSB and MCH.

The load balancing decision making is shown in Figure 3. The decision making begins with finding the number of available processing cores and servicing the number of tasks that are ready to execute. If the number of processing cores is greater than or equal to the number of tasks, the function will set affinity for all tasks and then continue scheduling. However if the number of processing cores are less than the number of tasks that are ready to execute, then the function must check the number of available processing cores and begin deciding the course of action that can be taken as follows:

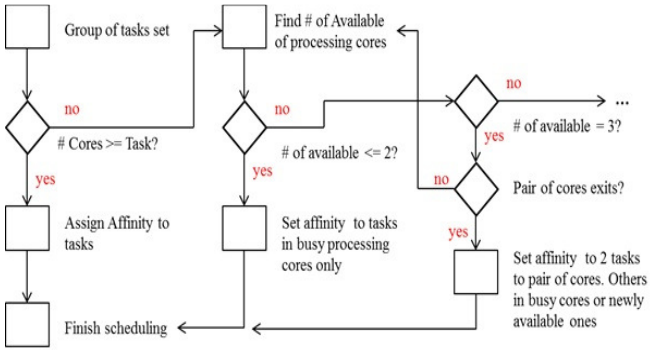

Figure 3. Low Balancing Flowchart

• Once the number of available of processing cores is less than the number of tasks, the function checks if the number of available processing cores is less than or equal to two.

• If the number of processing cores available is less than or equal to two, the decision is to not set affinity to the available processing cores in order to:

- Avoid using all of the processing cores which causes a decrease of IPC performance.
- Lowers the overall L2 hit rate for all processing cores.
- Avoid increase of traffic through the FSBuses and MCH.

• Instead, the function will set affinity to processing cores that are currently busy in order to schedule them next.

• This keeps the available processing core free and next group of tasks out of the way of the currently execution of tasks.

When checking that the number of available of processing core exceeds two, then the number can be either an odd or even number of available processing cores. The decision of the load balancing will need to consider the availability of processing cores in pairs and if no pair exits, then continue to wait for processing cores to become available.

The configurations of the HPL benchmark used for current test are similar to previous work [3] but each run contained a

heavier load. In where, N – The number of problems sizes that will be used for execution of the benchmark. Ns – This specifies the exact value(s) of the problem size. NBs – It specifies the values of each block size to be executed for each problem size defined in Ns. Ps – Specifies the number of processes row value. Qs – Specifies the number of processes column value.

Eight different problem sizes Ns = {6000, 7000, 8000, 9000, 11000, 12500, 15000, 17500} were used for each instance of the benchmark. From [3], it could be seen that the benchmark provided better data with problem sizes higher than 5000. The matrix dimensions were varied for different Ps and Qs values and also depended on the scenario that needed to be tested (i.e. all eight cores, seven cores, down to just two cores). Block sizes NBs = {64, 128, 256, 512, 1024, 2048} were used for each of the problem sizes.

Different instances of the HPL benchmark are necessary since it introduces an environment that tests the modifications made to the Scheduler. Each instance of the benchmark can spawn other processes that will test the grouping of the processes with the parent process. After each instance of the benchmark finished execution, process termination and the dead state of the parent process was tested to determine if revising the state of the processing core was possible in order to assign affinity to the next group of tasks that are ready to execute.

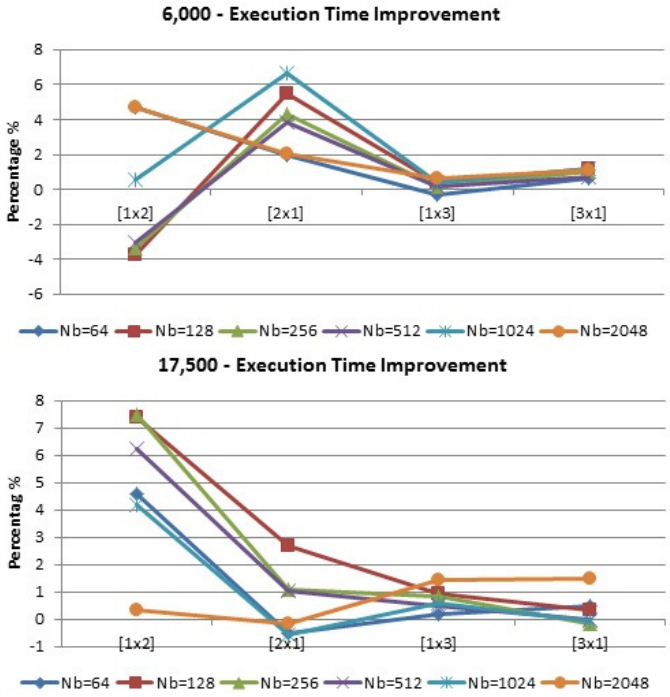

Figure 4. Execution Time Percentage Improvement in a Four Process Execution

4 Results

The low concurrency case was expanded to include up to and including four processes. This qualifies as a low concurrency case because it provides enough concurrent processes to create small contentions in the FSB and MCH and test the Scheduling modifications. This number of concurrent processes also illustrates higher number of HPL benchmark instances that were launched to test low concurrency scenarios. Figure 4 summarize the percentage improvements of execution time for this scenario for problem sizes 6000 (smallest problem size) and 175000 (largest problem size). The improvements are listed by different matrix dimensions and different block sizes during execution.

Figure 5 shows the improvement percentage of performance throughput in GFLOPS of the same problem sizes shown in Figure 4. The percentage improvements from Figures 4 and 5 indicate it is hard to improve the performance and execution time when the processing core executes small loads. This is due to several factors:

1. When the computational load does not employ all of the available processing cores, the performance of the overall compute-node does not reach its maximum performance. This is true even with customized load balancing and affinity task allocation.

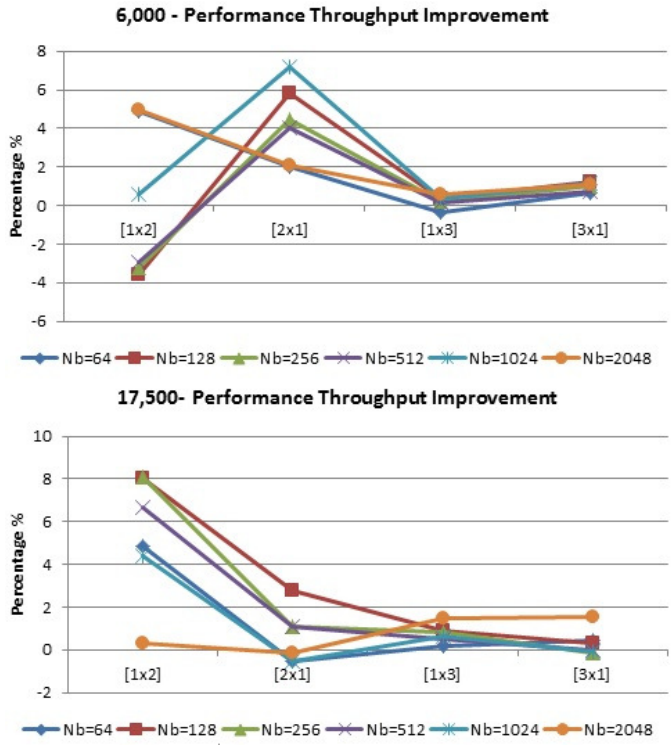

Figure 5. Performance Throughput Percentage Improvement in a Four Process Execution

2. The small improvements that were attained are due to the load balancing modification, which provided task affinity, which allowed the processing cores to share L2-more efficiently. This is achieved by the decision making of having tasks allocated with processing cores

Spreading out the tasks between the two processors alleviates traffic in both FSBs; and each task has an increase amount of L2-cache since not all cores are in use. The following case shown in Figures 6 and 7 is of high concurrency with eight concurrent processes occupying all the processing cores. The configuration consists of having two or more instances of the HPL benchmark running in which the total of processes equal to the number of all the processing cores. More than one instance of the benchmark is needed to make the Scheduler group and load balance all processes.

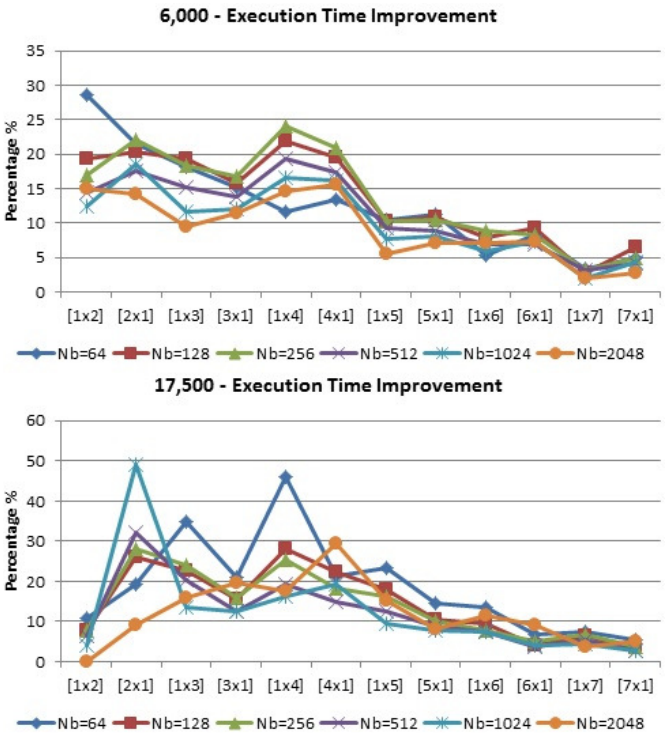

Figure 6. Execution Time Percentage Improvement in an Eight Process Execution

In order to summarize the percentage improvements of the eight concurrency execution scenario, Figure 6 shows the improvement in execution time of problem sizes 6000 (smallest problem size) and 175000 (largest problem size). The improvements are showed by different Nb block sizes, each using different PxQ matrix dimensions during execution. Figure 7 shows the improvement percentage of performance throughput, in GFLOPs, for the same problem sizes shown in Figure 6. The improvements are showed by different matrix dimensions each through different block sizes during execution. The percentage improvements from Figures 6 and 7 indicate that for low PxQ matrix dimensions, there is greater improvement in performance and execution time. However, it is much harder to improve the performance and execution time when executing with all of the processing cores. This is due to several factors:

1. The other instances of the benchmark concurrently executing increases the traffic in the FSB and MCH.

2. As the problem size increases, the limitations of the hardware (bus sizes, cache sizes) begin to decrease processing core utilization.

3. As the bottlenecks and limitations become more apparent during execution, the modifications made to the Scheduler converge to very low to no improvement regardless of the affinity set to all tasks.

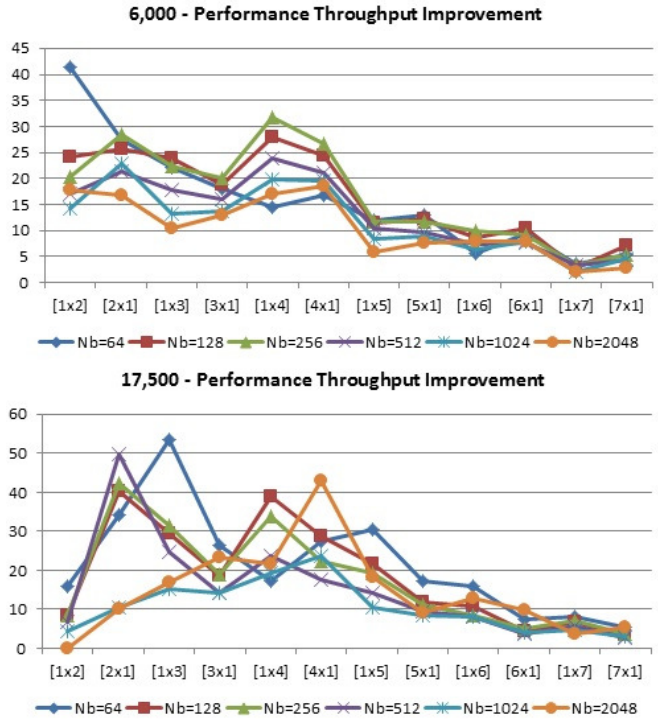

Figure 7. Performance Throughput Percentage Improvement in an Eight Process Execution

5 Conclusions

Overall, the results for low concurrency show that the improvements in both GFLOPS and execution times were less than 10% for low numbers of processing cores. Regardless of the block sizes, the small improvements are due to the affinity assignment which help increase the L2 cache hit rates. However, the affinity assignments can sometimes create contention to the FSB when load balancing other instances of the benchmark which can be seen by the negative percentage numbers at different problem sizes in Figures 4 and 5. With larger numbers of processes (dimensions) performance cannot be improved since FSB and MCH contention increases; in fact, the GFLOPS decreases and execution times increases.

Overall the results for medium to high concurrency show that the larger improvements were obtained by these common factors:

• Small block sizes of 64-128 show the highest improvements than other block sizes due to the width of the data line that exists in the hardware.

• The larger the block sizes, the harder it is to improve GFLOPS and execution time due to the time to transmit information; although improvements were still achieved with smaller percentages from the smaller block sizes.

• Small numbers of processes (dimensions) are easier to allocate affinity to processing core pairs. In this case the load balance modification helps increase the processing core utilization which yields a higher improvement of GFLOPS.

• Larger number of processes (dimensions) are difficult to speed up as contention on the FSB and MCH increases; therefore, the GFLOPS decrease and execution time increases.

• All of the benchmark runs and instances were executed in row-major format. This means that the elements of the matrix are placed in a contiguous form in memory. Therefore, single row dimensions of the benchmark show higher peaks in GFLOPS and execution time.

A few cases of large peaks indicate high percentage improvements in GFLOPS and execution time, such as in the bottom figure in Figure 7 where matrix size dimensions are [1x3] at block size 64 or similar dimensions. This is due to a non-modified run under-performed in this instance of the benchmark which causes the modified run to show higher increases in percentage in GFLOPS and execution times. Also, the matrix dimensions are favorable for the row-major execution of the matrix during each run. Furthermore, the small block size that is able to use the full bandwidth of data lines and the L2 cache awareness which helped improved hit rates for the instance of the benchmark.

Other cases of large peaks that indicate high percentage improvements in GFLOPS and execution time, such as in the bottom figure in Figure 7 where matrix size dimensions [4x1] at block size 2048 or similar dimensions are attributed to the non-modified run under-performing which causes the modified run to show higher increases in percentage in GFLOPS and execution times. Also, the load balancing modification helped increase the percentages due to the affinity assignments of the instance of the benchmark.

Abstract - *Load balancing is very important for achieving high performance in distributed computer systems which often consist of heterogeneous computing and communications resources. In this paper, we study a cooperative load balancing scheme for central-server node distributed systems (CCOOP-IO) and evaluate its performance using simulations. The objective of CCOOP-IO is to minimize the mean response time of jobs in a heterogeneous distributed computing system and also to provide fairness to all the jobs in the system. We consider a heterogeneous computing system model connected by a single-channel communications network. A central-server model is used to model the computers in the system. The performance of CCOOP-IO is evaluated using simulations with various system loads and configurations.*

Key words: Load balancing, Resource Allocation, Distributed Systems, Fairness.

1. Introduction

The computing resources (computers or nodes) in distributed computing systems are often heterogeneous. Jobs may arrive with different job arrival rates to these nodes. Also, the communications networks that connect the computing resources may have different bandwidths. The above factors may degrade the performance of distributed systems if load is not properly balanced among the computers. Hence, load balancing is very important for achieving high performance in distributed computer systems.

The problem of load balancing in distributed systems has been studied extensively. For example, in [4, 11, 15, 16, 10], static load balancing schemes for single-class and multi-class job distributed systems were proposed and analyzed by considering various network topologies. Various models for dynamic load balancing were studied in [1, 6, 14]. A macroeconomic model for resource allocation in distributed systems was studied in [12]. Most of the past work on load balancing in distributed systems considered the minimization of the overall system expected (mean or average) response time (job execution time) as their main objective. However, some jobs might experience much longer response time than the others in such allocations. Providing *fairness* to all the jobs in the system is to find an allocation of jobs to computers that yields an approximately equal expected response time for all the jobs of approximately the same size. Fairness is a major issue in many modern computing systems.

Load balancing in distributed systems based on game theory with the objective of providing fairness has been studied ([2, 5, 7, 17] and references there-in). However, in most of the above studies, the computer model considered has only a processor. Game-theoretic scheduling in cognitive radio systems has been studied in [13] and references there-in. Here, we consider a central-server computer model which is very common in modern computer systems. A central-server computer model consists of a CPU (processor) and one or more input/output (I/O) devices. A central-server node model for static job allocation in E-commerce systems and utility-computing systems has been studied in [8, 9] and for dynamic job allocation in [6].

In this paper, we study a cooperative load balancing scheme for central-server node distributed systems (CCOOP-IO). CCOOP-IO is derived from the cooperative scheme studied in [7]. The objective of CCOOP-IO is to minimize the mean response time of jobs in a heterogeneous distributed computing system and also to provide fairness to all the jobs in the system. We consider a heterogeneous computing

system model connected by a single-channel communications network. Jobs arrive at each computer according to a time-invariant exponential process. We achieve load balancing by transferring some jobs from the heavily loaded nodes to the nodes that are idle or lightly loaded.

The performance of CCOOP-IO is evaluated using simulations with various system loads and configurations. *Expected response time* (execution time) and *fairness index* are used as the performance metrics. For comparison, we also implemented two representative load balancing schemes. These schemes are: OPTIM-IO (which minimizes the expected response time of all the jobs in a system) and PROP-IO (which allocates the jobs to the computers in proportion to their processing speeds in the system).

2. Cooperative Load Balancing

A distributed computing system model having *n* nodes connected by a single channel communications network is considered. The nodes in the system are typically heterogeneous having different processing speeds. Each node is modeled as a central-server model as shown in Figure 1 similar to [6]. The terminology and notations used similar to [3, 6, 7] are as follows:

- t_{IO}: The service time of an input/output (I/O) device.
- μ_i: The service rate of node *i*.
- ϕ_i: The external job arrival rate at node *i*.
- $\boldsymbol{\Phi}$: The total external job arrival rate of the system. So, $\boldsymbol{\Phi} = \sum_{i=1}^{n} \phi_i$.
- βi : The job processing rate (or load) allocated by the load balancing algorithm for node *i*.
- x_{ij}: The job flow rate from node *i* to node *j* (i.e. the number of jobs sent from *i* to *j* per unit time).
- *t*: Mean communication time for sending or receiving a job from one node to another.
- P_0: Probability that a job after departing from the processor finishes.
- P_1: Probability that a job after departing from the processor requests I/O service.
- P_1/P_0: Average number of I/O requests per job.

Each node is assumed to have a single computing resource (processor) with a round-robin service discipline and jobs arrive in a single queue. The nodes and the communications network have an exponential service-time distribution [3] and the external jobs arriving at each node and jobs being transferred by the communications network follow a Poisson distribution [3].

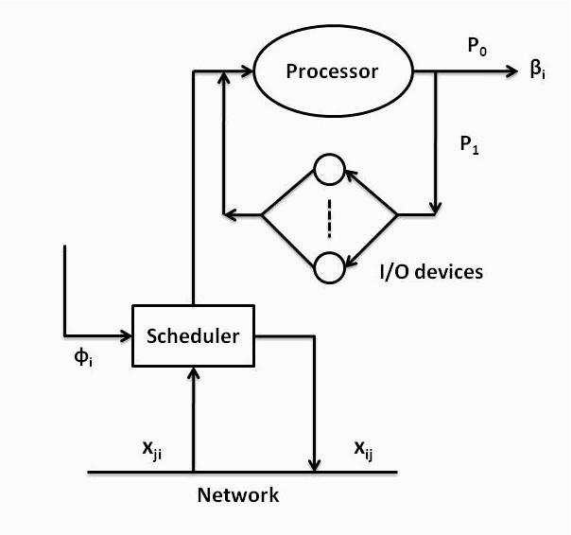

Figure 1. Node Model

A job arriving at node *i* may either be processed at node *i* or transferred to node *j* through the communications network for remote processing. The mean communication delay from node *i* to node *j* is independent of the source destination pair (*i*, *j*) but depends on the total traffic through the network denoted by λ where $\lambda = \sum_{i=1}^{n} \sum_{j=1}^{n} x_{ij}$. Based on the above assumptions and assumptions similar to [7], the mean node delay (mean response time or total execution time) of a job at node *i* is given by:

$$d_i(\beta_i) = \frac{1}{\mu_i - \beta_i} + \frac{P_1}{P_0} t_{IO}, \quad i = 1, \ldots, n.$$

The mean communication delay for a job is given by:

$$g(\lambda) = \frac{t}{1 - t\lambda}, \ \lambda < \frac{1}{t}.$$

The inverse of the node delay is given by:

$$d^{-1}(x) = \mu_i - \frac{1}{(x - \frac{P_1}{P_0} t_{IO})} \quad if \ x > \frac{1}{\mu_1} + \frac{P_1}{P_0} t_{IO}$$

$$d^{-1}(x) = 0 \quad if \ x \leq \frac{1}{\mu_1} + \frac{P_1}{P_0} t_{IO}$$

We also assume that the communication delay incurred as a result of sending a job directly from node *i* to node *j* is less than or equal to the sum of the delays from node *i* to node *k* and from node *k* to node

j. Based on this assumption, nodes are classified into Sinks (S), Idle Sources (R_d), Active Sources (R_a), and Neutrals (N) similar to [7].

The load balancing problem for providing fairness to all the jobs in the system is formulated as a cooperative game among the computers and the communications subsystem similar to [7]. Based on the Nash Bargaining Solution (NBS) which provides a *pareto* optimal and fair solution, we provide an algorithm (CCOOP-IO) for computing the NBS for our cooperative load balancing game.

In the following, we present the CCOOP-IO algorithm. The cooperative load balancing game among the computers and the communication subsystem, theorems, and properties which are the basis for the below algorithm are similar to the ones described in [7] by replacing *d*, *g*, and d^{-1} in [7] by *d*, *g*, and d^{-1} presented in the previous section.

CCOOP-IO Algorithm:

Input: Node job service rates: $\mu_1, \mu_2, \ldots, \mu_n$
Node job arrival rates: $\emptyset_1, \emptyset_2, \ldots, \emptyset_n$
Mean communication time: t
Service time of an I/O device: t_{IO}
Probabilities: P_0, P_1

Output: Load allocation to the nodes: $\beta_1, \beta_2, \ldots, \beta_n$

1. Initialize the loads of all the nodes to their job arrival rates and label all the nodes as *Neutrals*.
2. Sort the computers in increasing order of their node delays.
3. Categorize the nodes into Sinks (S), Idle Sources (R_d), Active Sources (R_a), and Neutrals (N) using a binary search (for finding an optimal point (say, α) that categorizes) similar to Step 3 of the CCOOP algorithm in [7].
4. Determine the loads on the computers as follows:
   - $\beta_i \leftarrow 0$, if node *i* is an Idle Source.
   - $\beta_i \leftarrow d^{-1}(\alpha + g(\lambda))$, if node *i* is an Active Source.
   - $\beta_i \leftarrow d^{-1}(\alpha)$, if node *i* is a Sink.
   - $\beta_i \leftarrow \emptyset_i$, if node *i* is a Neutral.

3. Experimental Results

In this section, we evaluate the performance of the CCOOP-IO scheme. The performance metrics that are used in the experiments are the *expected response time* and the *fairness index*. The fairness index [7] is used to quantify the fairness of load balancing schemes. We also implemented the Overall optimal load balancing scheme (OPTIM-IO) [4] and the Proportional load balancing scheme (PROP-IO) [1] for comparison purposes.

System utilization represents the amount of load on the system and is defined as the ratio of the total arrival rate to the aggregate service rate of the system. A heterogeneous distributed system consisting of 16 computers was simulated (as shown in Table 1) to study the effect of system utilization. The system has computers with four different service rates. For each experiment, the total job arrival rate in the system is determined by the system utilization and the aggregate service rate of the system. We had chosen fixed values for the system utilization and determined the total job arrival rates. The mean communication time is assumed to be 0.001 sec. We assumed that I/O operations were evenly spread throughout the execution of each job (similar to [6]) and that each disk I/O request took 0.06 milliseconds. The number of I/O requests for each job was chosen from a normal distribution with a mean of 12 and a standard deviation of 10 and was assumed to be greater than 0.

Table 1. System Configuration.

Relative service rate	1	2	5	10
Number of computers	6	5	3	2
Service rate (jobs/sec)	10	20	50	100

In Figure 2, we present the expected response time of the system for different values of system utilization ranging from 10% to 90%. The performance of CCOOP-IO is very similar to OPTIM-IO for system utilizations ranging from 10% to 40% and is around 50% better than PROP-IO for system utilizations ranging from 50% to 60%. CCOOP-IO approaches PROP-IO for high system utilizations.

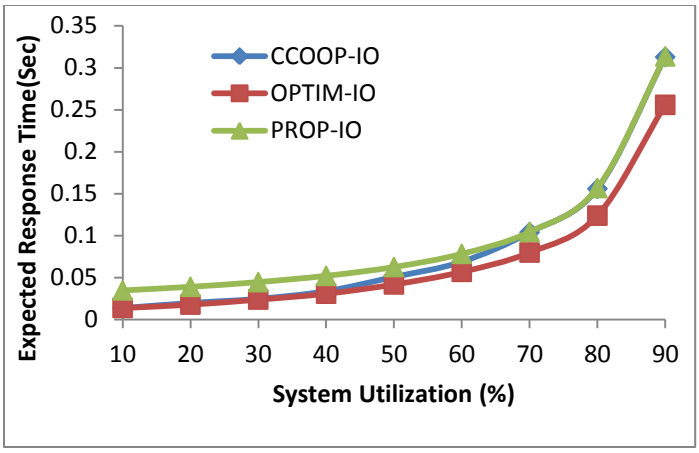

Figure 2. Expected Response Time v/s System Utilization

The effect of the system utilization on the fairness index of the various schemes is presented in Figure 3. It can be observed that the fairness index of CCOOP-IO is almost 1 for any system utilization and the fairness index of OPTIM-IO drops from 1 to around 0.85. PROP-IO has a constant fairness index which is around 0.72. This shows that CCOOP-IO provides fairness to all the jobs in the system independent of the computers to which they are allocated.

Figure 4 presents the expected response time at each computer for all the schemes at a system utilization of 70%. It can be observed that CCOOP-IO guarantees almost equal expected response times for all the computers. This means that all the jobs will have almost the same expected response time independent of the allocated computers. In the case of OPTIM-IO and PROP-IO, the expected response times are less balanced than CCOOP-IO.

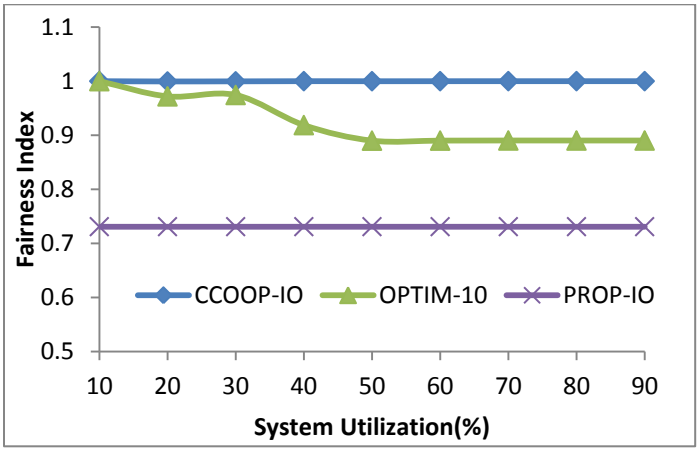

Figure 3. Fairness Index v/s System Utilization

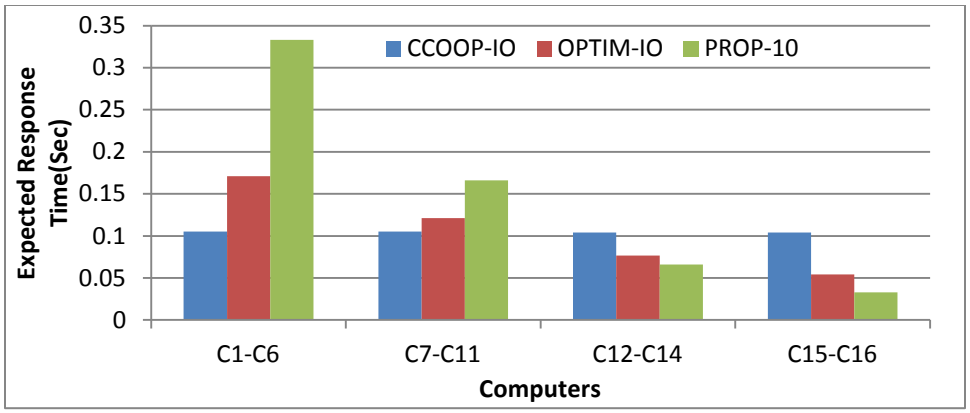

Figure 4. Expected Response Time at each Computer (System Utilization = 70%)

In the following, we study the effect of heterogeneity (speed skewness) [7] on the performance of CCOOP-IO. Speed skewness is defined as the ratio of maximum service rate to the minimum service rate of the computers in the system. A heterogeneous distributed system of 16 computers (2 fast and 14 slow) was simulated to study the effect of heterogeneity. Slow computers have a relative processing rate of 1 and the relative processing rate of the fast computers is varied from 1 (homogenous system) to 20 (highly heterogeneous system).

Figure 5 presents the effect of speed skewness on the performance of CCOOP-IO. For low skewness, the performance of CCOOP-IO is similar to PROP-IO. However, as the skewness increases, the performance of CCOOP-IO approaches to that of OPTIM-IO. Figure 6 presents the effect of speed skewness on the fairness index of CCOOP-IO. It can be observed that CCOOP-IO has a fairness index of almost 1 over all range of speed skewness. The fairness index of OPTIM-IO and PROP-IO falls from 1 at low skewness to 0.95 and 0.9 respectively at high skewness. This shows that CCOOP-IO provides fairness in highly heterogeneous systems for all the jobs in the system.

Figures 7 and 8 present the expected response time at each computer for all the schemes at medium system utilization for a skewness of 8 and 12. CCOOP-IO guarantees almost equal expected response times for all the computers. This means that CCOOP-IO provides a fair and load balanced allocation compared to OPTIM-IO and PROP-IO where the jobs are treated unfairly.

4. Conclusions

In this paper, a cooperative load balancing scheme (CCOOP-IO) for heterogeneous distributed systems was studied and evaluated. A distributed system with central-server nodes was considered. The performance of CCOOP-IO is evaluated by varying the system utilization and heterogeneity. Experimental results showed that CCOOP-IO is not only fair but also is comparable with that of the system optimal scheme in terms of the mean response time.

Performance Evaluation of a Dynamic Single Round Scheduling Algorithm for Divisible Load Applications

Leila Ismail, Liren Zhang, Khaled Shuaib, and Sameer Bataineh
Faculty of Information Technology, UAE University, 17551 Al-Maqam, Al-Ain, United Arab Emirates

Abstract— *Divisible load applications occur in many scientific and engineering applications and can easily be mapped to a distributed environment, such as computational grids or clouds, using a master-worker pattern. However, dividing an application and deploying it on a set of heterogeneous computing resources pose challenges to obtain an optimal performance due to the underlying system processing and networking capacities. We provide a dynamic scheduling algorithm for allocating divisible loads on a set of heterogeneous resources to decrease the overall application execution time. The algorithm uses a single-round strategy which is a known approach adopted by the majority of the developers as it is simple to design and implement. Our algorithm computes the chunk size that should be distributed to each worker. We analyze the performance of the algorithm in different scenarios of heterogeneous computing and networking capacities.*

Keywords: Distributed Systems, Divisible Load Application, Dynamic Scheduling, Performance

1. INTRODUCTION

The capacity of today's infrastructures, the ubiquity of network resources, and the low storage cost has led to the emergence of heterogeneous distributed memory systems such as Grid and Cloud computing. These platforms are promising technologies to run parallel applications in a low cost [1] [2] [3] [4] [5].

In this work, we propose a dynamic scheduling algorithm to obtain an optimal performance when distributing divisible load applications [6] to a set of heterogeneous resources in a computational platform, such as a Grid or a Cloud. Divisible load model represents a class of applications, where an application can be divided into a number of tasks that can be processed independently in parallel ([6], [7]) with no or negligeable inter-tasks communication. Many scientific and engineering applications fall into this category, such as search for a pattern, compression, join and graph coloring and generic search applications [8], multimedia and video processing [9], [10], convolution [11], and image processing [12] [13].

The tasks of a divisible load application are amenable to a master-worker model [14] that can be easily implemented and deployed on computing platforms, such as clusters, computational Grids, or computational Clouds. The master is a processor which divides an application load into tasks and assigns each task to a separate worker. In this work, we compute the chunk sizes of an application that should be distributed to a set of computing workers to obtain an optimal performance. The algorithm takes into consideration the communication and the computation capacities of the underlying platform. It also accounts for computing delays and communications latencies. In our scenarios, our algorithm shows a maximum of 1.29 of relative makespan to the *ideal* algorithm in the heterogeneous environments we have set, and with no specific selection policy. The *ideal* algorithm determines a chunk size in an ideal situation in which all computing workers are homogeneous, and that networking and computing overheads are negligeable.

Several works have been done to find an optimal scheduling algorithm to schedule a divisible load application [15] [16] [17] [18] [19]. The multi-installment algorithm, studied in [15], proposed a model of scheduling tasks in a single round, but communication time and computation time are assumed to be proportional. A multiround algorithm [16] was built based on [15] by adding communication and computation latencies to the model. The algorithm aims at optimizing the number of rounds to obtain an optimal makespan of the application. Consequently some computing workers will be waiting, while others are working within a single round. [20] studies the complexity of multi-round divisible load schedule, and concluded that the selection process of computing workers, their ordering and the distribution of the adequate chunk sizes remain an open problem. [17] has built up a scheduling model with the assumptions that computations are suspended by communications. Other works have been done on specialized infrastructure, such as in [21] for distributed bus network.

The rest of the paper is structured as follows. Section 2 describes the system model we consider. Our dynamic scheduling algorithm is described in section 3. In section 4, we evaluate the proposed model and discuss the obtained results. Section 5 concludes the work.

2. SYSTEM MODEL

The computing platforms that we are targeting are Grids and Clouds of computing resources. As shown in Figure 1, a computing platform consists of nodes which are connected via a network link whose speed dictates the speed of the

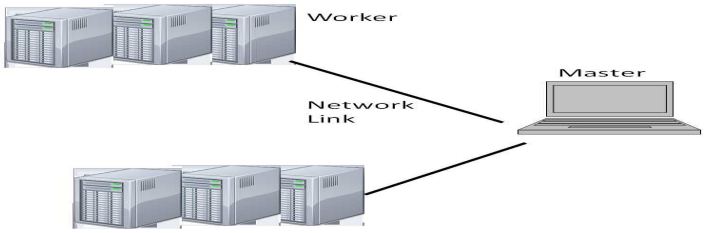

Fig. 1: Computing Platform Model

communication processing when data is transmitted among the nodes. A node consists of multiple cores. A core is the smallest processing unit available in the system. A core can be a context, a processor or a physical core.

Upon receiving of an application or a user's request, the master divides the whole application, of a total load of W_{total}, into different tasks and schedules these tasks to the selected computing workers based on their individual capability in terms of: the conditions of the communication link between the master and each computing worker, and the existing computing power of each computing worker. Each computing worker in the system has a computing capacity, μ_i, where $i = 1, ..., N$, and N is the number of computing workers in the system. In the rest of the paper, we use the terms task and chunk interchangeably.

Consider a portion of the total load, $chunk_i \leq W_{total}$, which is to be processed on worker i. We model the time required for a computing worker to perform the computation, TP_i, as:

$$TP_i = \theta_i + \frac{chunk_i}{\mu_i} \quad (1)$$

where θ_i, is a fixed latency, in seconds, for starting the computation at the computing worker r.

We model the time for sending $chunk_i$ units of load to computing worker i, TC_i, as:

$$TC_i = \lambda_i + \frac{chunk_i}{C_i} \quad (2)$$

where the component λ_i in TC_i, is a latency, in seconds, incurred by the master to initiate data transfer to worker r. C_i is the data transfer rate in terms of units of computing loads per second that can be provided by the communication link from the master to the worker i. The λ_i component may caused by the delay when initiating communicating from the master to the worker i by using SSH or any Grid or Cloud software which is used to access the worker i.

3. SCHEDULING ALGORITHM

To obtain an optimal performance for a single round, our main objective is to determine the chunk size that is to be assigned to each computing worker so that all computing

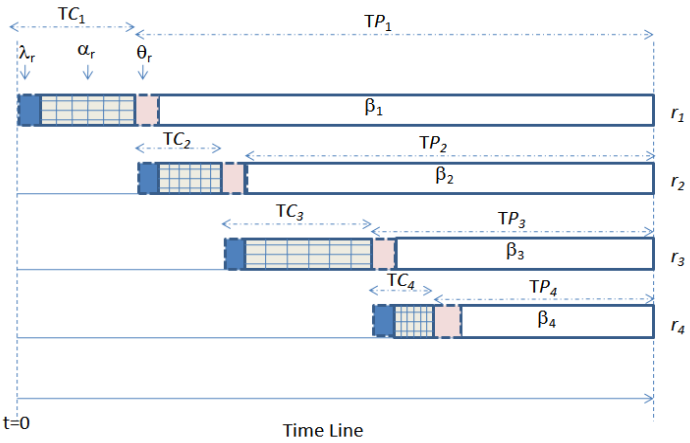

Fig. 2: Distribution of Chunk Sizes to Computing Workers in a Single Round

workers complete their computations at the same time. The total load W_{total} computation units is divided into N computing worker. We assume that the master starts to send chunks to N available computing workers in a sequential fashion. Consequently, every computing worker i will get its chunk size $chunk_i$ to process. Figure 2 shows an example, in which four computing workers are used.

Let us define $\alpha_i = \frac{chunk_i}{C_i}$, is the time required to transfer $chunk_i$ form the master to the worker i by using the communication link between the master and the computing worker C_i, and $\beta_i = \frac{chunk_i}{\mu_i}$ is the time required to compute the chunk $chunk_i$ by the computing worker i with computing processing capacity of μ_i. The time required by the first computing worker to complete the assigned task, $chunk_1$, is given by the following formula:

$$\begin{aligned} T_1 &= TC_1 + TP_1 \\ &= \lambda_1 + \frac{chunk_1}{C_1} + \theta_1 + \frac{chunk_1}{\mu_1} \\ &= \lambda_1 + \theta_1 + chunk_1 \left(\frac{1}{C_1} + \frac{1}{\mu_1} \right) \end{aligned} \quad (3)$$

The time required by the second computing worker to complete its task, $chunk_2$, is given by the following formula:

$$\begin{aligned} T_2 &= TC_1 + TC_2 + TP_2 \quad (4)\\ &= \lambda_1 + \frac{chunk_1}{C_1} + \lambda_2 \\ &\quad + \frac{chunk_2}{C_2} + \theta_2 + \frac{chunk_2}{\mu_2} \\ &= \lambda_1 + \frac{chunk_1}{C_1} + \lambda_2 + \theta_2 + chunk_2\left(\frac{1}{C_2} + \frac{1}{\mu_2}\right) \end{aligned}$$

In general, the time required by the computing worker i to complete its task, $chunk_i$, is given by:

$$\begin{aligned} T_i &= \sum_{j=1}^{j=i-1} TC_j + TC_i + TP_i \qquad i = 1, ..., N \quad (5)\\ &= \sum_{j=1}^{j=i-1} (\lambda_j + \frac{chunk_j}{C_j}) + \theta_i + chunk_i\left(\frac{1}{C_i} + \frac{1}{\mu_i}\right) \end{aligned}$$

The time required by the last computing worker N to complete the task, $chunk_N$, is given by:

$$\begin{aligned} T_N &= \sum_{j=1}^{j=N-1} TC_j + TC_N + TP_N \quad (6)\\ &= \sum_{j=1}^{j=N-1} (\lambda_j + \frac{chunk_j}{C_j}) + \theta_N + chunk_N\left(\frac{1}{C_N} + \frac{1}{\mu_N}\right) \end{aligned}$$

To achieve the goal that all workers complete the computation of their assigned chunks at the same time, it is required that:

$$T_1 = T_2 = ... = T_N = T \quad (7)$$

To simplify the formulas, we assume that:

$$\lambda_1 = \lambda_2 = ... = \lambda_N \quad (8)$$

and

$$\theta_1 = \theta_2 = ... = \theta_N \quad (9)$$

Then based on the Equation 7 and the Equations 3, 4, 5, and 6, we obtain:

$$\begin{aligned} \frac{chunk_1}{\mu_1} &= \lambda + chunk_2\left(\frac{1}{C_2} + \frac{1}{\mu_2}\right) \quad (10)\\ \frac{chunk_2}{\mu_2} &= \lambda + chunk_3\left(\frac{1}{C_3} + \frac{1}{\mu_3}\right) \quad (11)\\ &... \\ \frac{chunk_{i-1}}{\mu_{i-1}} &= \lambda + chunk_i\left(\frac{1}{C_i} + \frac{1}{\mu_i}\right) \quad (12)\\ &... \\ \frac{chunk_{N-1}}{\mu_{N-1}} &= \lambda + chunk_N\left(\frac{1}{C_N} + \frac{1}{\mu_N}\right) \quad (13) \end{aligned}$$

Based on Equation 10, we obtain the following equation:

$$chunk_2 = \frac{C_2\mu_2 chunk_1}{\mu_1(C_2+\mu_2)} - \frac{C_2\mu_2\lambda}{C_2+\mu_2} \quad (14)$$

Based on Equations 11 and 14, we obtain the following formula:

$$\begin{aligned} chunk_3 &= \frac{C_3\mu_3 chunk_2}{\mu_2(C_3+\mu_3)} - \frac{C_3\mu_3\lambda}{C_3+\mu_3} \quad (15)\\ &= \frac{C_2C_3\mu_3 chunk_1}{\mu_1(C_2+\mu_2)(C_3+\mu_3)} \\ &\quad - \frac{C_2C_3\mu_3\lambda(1+\frac{C_2+\mu_2}{C_2})}{(C_2+\mu_2)(C_3+\mu_3)} \quad (16) \end{aligned}$$

Based on Equation 12, and by substitutions, for a computing worker i, we obtain the following formula:

$$\begin{aligned} chunk_i &= \frac{\prod_{j=2}^{j=i} C_j\mu_i chunk1}{\mu_1\prod_{j=2}^{j=i}(C_j+\mu_j)} \\ &\quad - \lambda\frac{\prod_{j=2}^{j=i} C_j\mu_i(1+\sum_{k=2}^{k=j}\frac{\prod_{k=2}^{k=j}(C_k+\mu_k)}{\prod_{k=2}^{k=j} C_k})}{\prod_{j=2}^{j=i}(C_j+\mu_j)} \quad (17) \end{aligned}$$

As $W_{total} = \sum_{i=1}^{i=N} chunk_i$, and based on Equation 17, then we obtain the value of $chunk_1$ as follows:

$$\begin{aligned} chunk1 &= \\ &\frac{W_{total} + \lambda(\sum_{i=2}^{i=N}\frac{\prod_{i=2}^{i=N} C_j\mu_i(1+\sum_{k=2}^{k=i-1}\frac{\prod_{k=2}^{k=i}(C_k+\mu_k)}{\prod_{k=2}^{k=i} C_k})}{\prod_{j=2}^{j=i}(C_j+\mu_j)})}{1+\sum_{i=2}^{i=N}\frac{\prod_{j=2}^{j=i} C_j\mu_i}{\mu_1\prod_{j=2}^{j=i}(C_j+\mu_j)}} \quad (18) \end{aligned}$$

Based on Equation 17, the remaining chunks, $chunk_i$, $i = 2, ..., N$, can be obtained by substituting the value of $chunk_1$ obtained by Equation 18.

4. PERFORMANCE EVALUATION

In this section, we evaluate the efficiency of our scheduling algorithm in different scenario. The efficiency of the algorithm is measured and compared to the *ideal* makespan. The best makespan is calculated by dividing the total workload over the summation of the computing powers of the individual workers($\frac{W_{total}}{\sum_{i=1}^{i=N}\mu_i}, i = 1, ..., N$). In particular, we analyze the impact of the system parameters (μ_i, C_i) on the performance of our scheduling algorithm.

4.1 Experimental Runs

The experiments use a set of 10 computing workers. We vary the heterogeneity degree of the workers and study the performance of the scheduling algorithm. In a first step, we study the performance of the algorithm running on homogeneous clusters with increasing network capacity.

Table 1 shows the experimental values in which all the computing workers of the cluster have similar computing powers and they are connected to the master via similar network capacity. In a second step, we run the experiments with heterogeneous processing powers and homogeneous network connecting the master to the computing workers. We study the performance of the algorithm with increasing network capacity. Table 2 shows computing processing powers which have been randomly generated. In these experiments, the network and the processing powers have been chosen in a way that the computation to communication ratio can represent realistic scenarios. To that purpose, we have run a parallel MPEG video compressor in our heterogeneous Lab cluster. An input video is composed of frames and each frame can be processed independently [22]. Table 4 shows the communication and the execution times of 600MByte of raw video and the ratio of communication time to execution time in our experimental environment.

In order to analyze the impact of the degree of heterogeneity of resources on the scheduling algorithm, experiments are conducted using clusters of different heterogeneity. We randomly generate computing and communication resources by variating the standard deviation and by using the same mean of 0.50 and 30 for computation and communication respectively. Table 3 shows the standard deviations for generating the different set of communication and computation respectively. For every run, we compute a normalized makespan relative to the *ideal* makespan. Every run is executed for 100 times and the average over the runs is taken.

Table 1: Experimental Runs using Homogeneous Resources ($N = 10, W_{total} = 2000, \mu_i = 1, \lambda = \theta = 1$)

26.375	578.9375	21.95023697

4.2 Performance Analysis

In devising a scheduling algorithm for a single-round-based applications, several requirements have to be considered. Those requirements considerations have an impact on the experimental results:

a) Minimize waiting time of processes. This waiting time can be generated in 2 cases:
   - Processes wait for other processes to complete: after being assigned their chunks, processes which complete their executions first will wait for other processes to complete their execution. Our scheduling algorithm imposes that all computing workers complete their executions at the same time.
   - Processes wait for other processes to start: as our algorithm distributes the chunks to the processes in a sequential fashion, processes wait to receive their chunks. A selection policy of resources can decrease the impact of this problem on the overall performance of the scheduler. Our algorithm does not impose a selection policy and any selection policy can be used.

Figure 3 shows the relative performance of our scheduling algorithm on a homogeneous environment. The makespan decreases when the network capacities increase to become close to the ideal makespan with large network capacities; i.e., C=60. Figure 4 shows the chunk sizes that are distributed to the computing workers according to the scheduling algorithm. It shows that as the network capacity increases between the master and the computing worker, the chunk size decreases. This is to accommodate quicker transfer time for a current process during which previous processes are being executed. The scheduling algorithm shows a good performance with heterogeneous computing powers as shown in Figure 5. Figure 6 shows the corresponding chunk sizes distribution. To know the performance of the

scheduling in a heterogeneous environment for both computing and networking resources, we calculate the relative makespan in different heterogeneous sets of computing and networking scenarios as shown in Figure 7. The scheduling algorithm achieves a relative makespan of 1.21 for low processing heterogeneity (standard deviation of 0.1) and medium networking heterogeneity (standard deviation of 6). The performance of the algorithm decrease with high computing heterogeneity (standard deviation of 0.35) and high network heterogeneity (standard deviation of 10).

At the performance level, while it looks intuitive that a selection policy by increasing of networking capacities will achieve a better performance than using no selection, as the waiting time of the remaining processes waiting for the chunk to be distributed to the previous processes will be less, yet our first experiments were to schedule loads without any selection policy. By sorting the resources based on their computing capacities of resources in an increasing order, the scheduling algorithm achieves a minimum makespan of 1.20 and a maximum is 1.31, as shown in Figure 8. When resources are sorted by network capacities the algorithm achieves a relative performance of a minimum of 1.19 and a maximum of 1.22, as shown in Figure 9; an improvement over the performance of the algorithm with no selection policy or with computing-based selection.

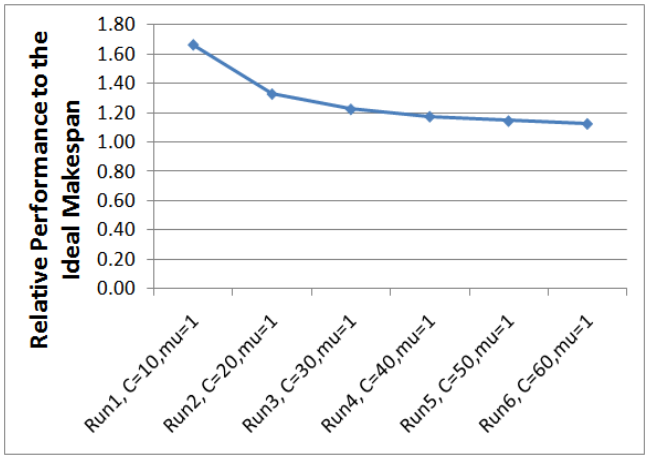

Fig. 3: Relative Performance of the Scheduling Algorithm on Homogeneous Clusters with Increasing Network Capacities.

5. CONCLUSION

In this paper, we presented a dynamic scheduling algorithm for divisible load applications to a set of heterogeneous computing workers to obtain an optimal performance. The algorithm uses single round, as this is the most used design algorithm by developers for its simplicity to program. Taking into consideration the processing and the networking capacities, our algorithm shows a good performance compared

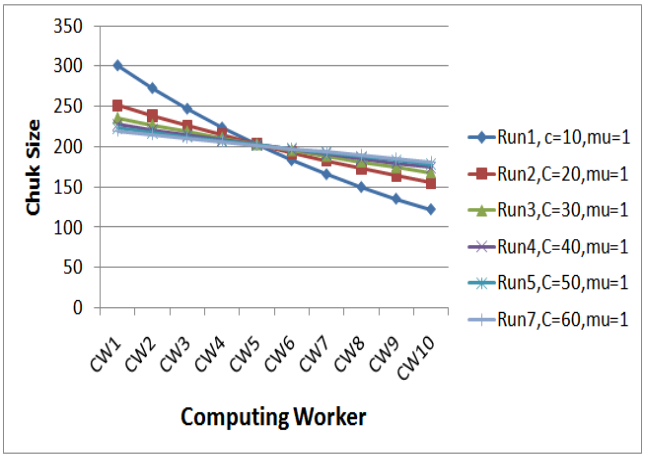

Fig. 4: Chunks Allocated to Computing Workers on Homogeneous Clusters with Increasing Network Capacity.

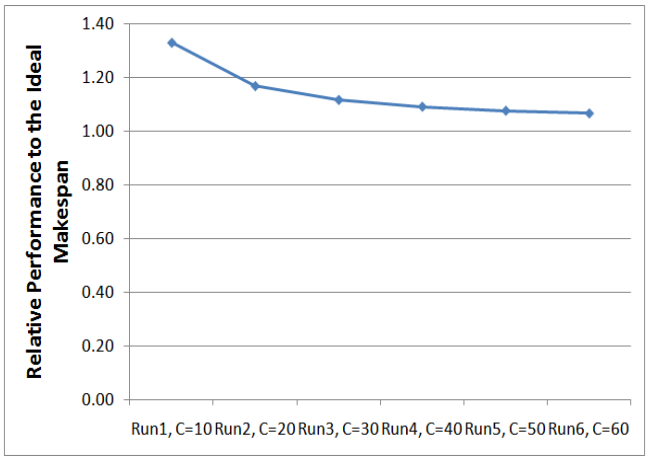

Fig. 5: Relative Performance of the Scheduling Algorithm with Heterogeneous Computing Powers and No Selection Policy versus Increasing Network Capacity.

to the ideal performance, in particular whenever a selection policy is applied. The performance results show that our algorithm has a relative makespan of 1.19 with increasing network and processing heterogeneity of of 9 and 0.3 respectively, by using a network-based selection with increasing order of network capacities.

Abstract. Effective job scheduling schemes play a critically important role in cluster-based parallel processing system for remote sensing image. However, the recent job scheduling strategies without accurate estimated run time of algorithms commonly treat various parallel algorithms as undifferentiated jobs, which could cause blindness in resource allocation, and always lead to low system utilization and long average weighted turnaround time of job. To properly settle the problems above, APKB an Adaptive Prior-Knowledge-Based parallel job scheduling strategy is proposed in this paper. The length (average run time of processing per unit data) of various parallel algorithms that recorded in the prior knowledge database with self-learning ability are used for estimating the accurate run time of parallel jobs. With the accurate estimates of job run time and system load that dynamically computed by fuzzy model, the optimized resource allocation policy will be used in APKB strategy to shorten the average weighted turnaround time of job, and finally to achieve the load balancing of the entire system. Through experimental and comparative analysis, its outstanding scheduling efficiency is showed in this paper.

Key words. Parallel Processing System for Remote Sensing Image; Dynamic Scheduling Strategy; Load Balancing

1 Introduction

Remote sensing image processing is a compute-intensive and time-consuming task. And the increasing image scales pose many computational challenges for cluster-based processing system for remote sensing image. A suitable parallel job scheduling strategy is the key to achieving high parallel efficiency [1-4]. Commonly, the Operation and Management sub System (OMS) which responsible for parallel job scheduling always uses some cluster scheduling strategies like FIFO, First-Fit, Greedy, Priority, Weighted round-robin, Backfilling and so on. Due to the lack of accurate estimated run time of jobs and real-time load of system, those scheduling approaches which simply assigned to different jobs with the same number of computing resources, always suffered from poor system utilization and long average weighted turnaround time of job.

To properly solve the issue above, APKB an Adaptive Prior-Knowledge-Based parallel job scheduling strategy is proposed in this article. In this strategy, the prior knowledge database is imposed for accurately estimating the run time of parallel jobs. And with the accurate estimates of job run time and system load gained dynamically, the system utilization and performance could be greatly improved through proper allocation of system resources during job scheduling.

2 Adaptive Prior-Knowledge-Based Scheduling Strategy

Adaptive Prior-Knowledge-Based scheduling strategy is a dynamic parallel job scheduling scheme for cluster-based parallel remote sensing image processing system. By using adaptive resource allocation policy, APKB strategy dynamically allocates the system resources to various parallel jobs that enter the system according to the accurate estimates of job run time and current system load. Rather than the simple even allocation policy used by other scheduling strategies, this adaptive resource allocation policy would automatically adapt to the changing system load conditions and randomly arrived jobs. The mechanism of APKB strategy is illustrated as follows.

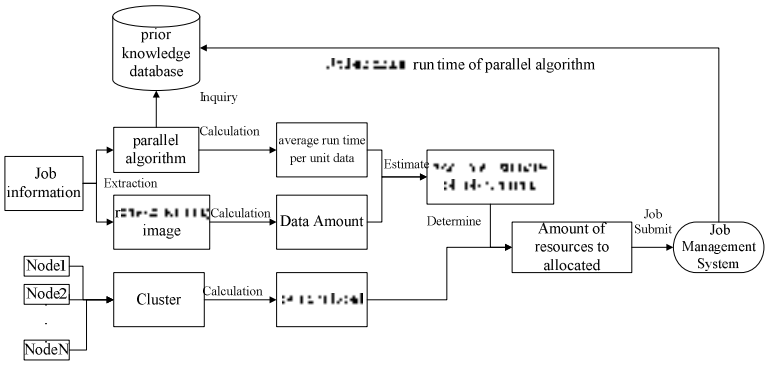

Fig. 1. The mechanism of APKB strategy

The mechanism of APKB strategy is implemented under following steps:

1) Estimates the accurate run time of job. By querying prior knowledge database with algorithm name of job, the relevant length (average run time of processing per unit data) of that parallel algorithm will be get to calculate the average run time per unit data with single node. Accordingly, this average run time together with the data amount of image to be processed are used for estimating the accurate run time of job.

2) Gain system load of the cluster. Through continuously monitoring of the load conditions of all nodes, like CPU utilization, Memory utilization, I/O speed of disk and response time, the load of each computing node would be dynamically gained. And the system load of the cluster is the weighted value of the node load.

3) Implement adaptive resource allocation policy. Dynamically allocates the system resources to the arriving parallel jobs according to the accurate estimates of job run time and current system load.

4) Job submission. Finally the jobs submit to cluster scheduler for execution. Update the actual run time of the algorithm into the prior knowledge database when finishing job execution.

2.1 The Accurate Estimation of Job Run Time

The accurate estimates of job run time is determined by T_{ave} which is the average run time of processing per unit data with single computing node and m which represented for the total data amount of remote sensing image to be processed. When arrives a new job request, the value of T_{ave} would be queried from prior knowledge database by the APKB strategy. And obviously the accurate estimates of job rum time would be equals to $T = T_{ave} \times m$.

The prior knowledge database is used for storing the basic information of various parallel algorithms, like T_{ave} and N_{tal} which is the total number of algorithm runs. Whenever the task is completed, the value of T_{ave} and N_{tal} in prior knowledge database should be updated.

The new value of T_{ave} is: $$T_{ave} = (T_{ave} \times N_{tal} + t_r / (n * m)) / (N_{tal} + 1) \quad (2.1)$$

Assume that the actual job run time is t_r when using m assigned computing nodes and dealing with image data of m MB.

2.2 Estimating System Load Using Fuzzy Membership Functions

The system load which considered as a synthesized metrics of whole cluster is closely related to CPU utilization, memory Utilization, disk I/O speed and system responding time. Usually, it is hard to exactly tell whether the utilization of CPU or memory is high or low, as the problem its self have some kind of uncertainties. Therefore, three simplified fuzzy membership functions fL(u), fM(u) and fH(u) depicted in figure 2 are put forward to respectively define three levels High, Middle and Low.

According to fuzzy statistical method, the expression of those three simplified fuzzy membership functions [5-7] put forward is as follows, where u is the utilization of CPU.

$$fL(u) = \begin{cases} 1 & 0 \le u \le 0.15 \\ 1.6 - 4u & 0.15 < u \le 0.4 \\ 0 & 0.4 < u \le 1 \end{cases} \qquad fH(u) = \begin{cases} 0 & 0 \le u \le 0.6 \\ 4u - 2.4 & 0.6 < u < 0.85 \\ 1 & 0.85 \le u \le 1 \end{cases} \quad (2.2)$$

$$fM(u)=\begin{cases}1 & 0\le u\le 0.3\\ \frac{20}{3}u-2 & 0.3<u<0.45\\ 1 & 0.45\le u\le 0.55\\ \frac{14}{3}-\frac{20}{3}u & 0.55\le u\le 0.7\\ 0 & 0.7\le u\le 1\end{cases} \tag{2.3}$$

When given the CPU utilization u of any time, the CPU utilization level could be pointed out as L, M or H according the above fuzzy membership functions. Similarly, when considering four factors CPU utilization u_1, memory utilization u_2, disk I/O Speed u_3 and responding time u_4, we will get four similar groups of fuzzy membership functions. While define a factor Set U={ u_1,u_2,u_3,u_4 } , then there exists a fuzzy relationship from factor set to decision-making set V={L,M,H}. This fuzzy relationship is expressed by $R_{3\times4}$, and r_{ij} indicates the level set that factor j belongs to.

Obviously, the larger $r_{1j}$is, the higher possibility that u_1 would belong to L set. Considering that the node with low CPU utilization leads to low CPU load, so the CPU load is like $r_{11}\times(-2)+r_{21}\times0+r_{31}\times2$. Similarly, the calculate method of each node load factor is showed in following table.

	CPU	Memory	I/O	Reponses
L	$r_{11}\times(-2)$	$r_{12}\times(-2)$	$r_{13}\times(-4)$	$r_{14}\times2$
M	$r_{21}\times0$	$r_{22}\times0$	$r_{23}\times0$	$r_{24}\times0$
H	$r_{31}\times2$	$r_{32}\times2$	$r_{33}\times4$	$r_{34}\times(-2)$

Table. 2.1. The calculate method of each load factor of node

It is indicated that the coefficients (2, 2, 4, 2) given in the above table can also be regarded as weight of each factor (0.2, 0.2, 0.4, 0.2) in calculating system load. Accordingly, the load of each computing node is:

$$\text{Load}=[r_{11}\times(-2)+r_{31}\times2+r_{12}\times(-2)+r_{32}\times2+r_{13}\times(-4)+r_{33}\times4+r_{14}\times2+r_{34}\times(-2)] \tag{2.4}$$

Finally, the system load of the entire cluster is Load_{ave}:

$$Load_{ave}=\sum_{i=1}^{N}\omega_i Load_i \tag{2.5}$$

Assume that there are N computing nodes in the cluster, and the load of the ith node is $Load_i$, ω_i is the weight of each node and $\sum_{i=1}^{N}\omega_i=1$. The nodes with high performance will have a high weight value ω_i.

2.2 Adaptive Resource Allocation Policy

The main ideal of the adaptive resource allocation policy is: the parallel algorithms are classified into four different categories according to T_{ave} the average run time when processing per unit data with single node. Also, the job queue is divided into four separated sub queue by the amount of resources to be allocated. The mapping relationship from algorithm categories to job queue is as follows.

$$N=\begin{cases}2, & (0<T\le800)\\ 4,(800<T\le1600)\\ 6,(1600<T\le2400)\\ 8,(2400<T)\end{cases} \tag{2.8}$$

Furthermore, Load_{ave} the real-time system loads of the whole cluster are classified to four levels, each level have its Corresponding index value λ, the mapping relationship between λ and Load_{ave} is expressed as follows.

$$\lambda=\begin{cases}0.5,(Load_{ave}>15)\\ 1,(10<Load_{ave}\le15)\\ 1.5,(5<Load_{ave}\le10)\\ 2,(0<Load_{ave}\le5)\end{cases} \tag{2.9}$$

Eventually, the amount of resource to be allocated is dynamically determined by the accurate estimates of job run time and the real-time system load of cluster. And the accurate estimates of job run time could be calculated by T_{ave} and data amount. Therefore, the amount of resources allocated to each job equals to $n=N\times\lambda$.

As a matter of fact, when more parallel jobs are processed in the system, the estimates of job run time will be more accurate due to the self-learning ability of prior knowledge database, and finally the resource allocation would be much more reasonable and adaptive. Just benefit from the proper resource allocation, the run time

gap between long parallel job and short parallel job is shorten, and also the time overhead caused by long parallel jobs and short parallel jobs waiting for each other is reduced. Accordingly the optimized performance of the whole system would be achieved.

3 Performance Evaluation and comparison

Through the quantitative evaluation of the average weighted turnaround time and system utilization of both APKB and FIFO strategy, their performances are comparatively analyzed.

3.1. Comparative Analysis of Average Weighted Turnaround Time

Suppose that n parallel jobs are requested randomly, $T_{process}$, T_{wait} and T_{weight} are respectively the actual run time, waiting time and average weighted turnaround time. And the $T_{\text{FIFO-process-i}}$ and $T_{\text{FIFO-wait-i}}$ are stands for the run time and waiting time of the ith jobs when using FIFO strategy, the $T_{\text{APKB-process-i}}$ and $T_{\text{APKB-wait-i}}$ are stands for the run time and waiting time of the jth jobs when using APKB strategy.

The average weighted turnaround time for FIFO strategy $T_{\text{FIFO\_average}}$ is:

$$T_{\text{FIFO\_ave}} = \sum_{i=0}^{n} \frac{(T_{FIFO\_process\_i} + T_{FIFO\_wait\_i})}{n * T_{FIFO\_process\_i}} \tag{3.1}$$

The average weighted turnaround time for APKB strategy $T_{\text{APKB\_average}}$ is:

$$T_{\text{APKB\_ave}} = \sum_{j=0}^{n} \frac{T_{\text{APKB}\_process\_j} + T_{\text{APKB}\_wait\_j}}{n * T_{\text{APKB}\_process\_j}} \tag{3.2}$$

The differences between $T_{\text{FIFO\_average}}$ and $T_{\text{APKB\_average}}$ is :

$$T_{\text{FIFO\_ave}} - T_{\text{APKB\_ave}} = \frac{1}{n}\left(\sum_{i=0}^{n} \frac{T_{FIFO\_wait\_i}}{T_{FIFO\_process\_i}} - \sum_{j=0}^{n} \frac{T_{\text{APKB}\_wait\_i}}{T_{\text{APKB}\_process\_i}}\right) \approx \frac{to}{n}\left(\sum_{i=0}^{n} \frac{1}{T_{FIFO\_process\_i}} - \sum_{j=0}^{n} \frac{1}{T_{\text{APKB}\_process\_i}}\right) \tag{3.3}$$

$$\sum_{i=0}^{n} T_{FIFO\_process\_i} = \sum_{j=0}^{n} T_{APKB\_process\_i} = Tp \tag{3.4}$$

$$\frac{1}{a} + \frac{1}{b} \geq \frac{1}{(a+b)/2} \tag{3.5}$$

As the waiting time of both two scheduling strategies $T_{FIFO\_wait\_i}$ and $T_{\text{APKB}\_wait\_i}$ are almost equivalent due to the random job requests, we assume that this waiting time equals to to. The difference between $T_{\text{FIFO\_average}}$ and $T_{\text{APKB\_average}}$ is estimated in equation 3.3. From the above formula we can infer that the when using FIFO strategy, there is a big gap between the run times of the long jobs and short jobs, but when using APKB strategy, the run time of each job is trend to be similar especially when lots of parallel jobs are requested. Suppose that the sums of processing time of each job when using these two scheduling strategies are nearly the same, which is showed in equation 3.4. And when there are lots of jobs requested, the time of $T_{\text{APKB}\_process\_i}$ will trend a mean value processing time Tp/n. So according to theory expressed in equation 3.5, the average weighted turnaround time for APKB strategy is much smaller. Obviously, when the gaps between the long parallel jobs and short parallel jobs are widen, the performance improvement will be more significant.

3.2. Comparative Analysis of System Utilization

The system utilization is the ratio of current system load and total ability of system load. When do job scheduling the load balancing between computing nodes is an effective way to raise system utilization.

The system utilization η is: $\eta = N_{busy} / N_{total} \times 100\%$ （3.6）

During a period time of T (T is big enough) which equals to $T = T_{\text{high}} + T_{\text{middle}} + T_{\text{low}}$, the system load could be divided into three phases as High load, middle load and low load.

So the system utilization when using FIFO strategy η_{T_FIFO} is:

$$\eta_{T\_FIFO} = \frac{T_{high}}{T} \times \eta_{high\_FIFO} + \frac{T_{middle}}{T} \times \eta_{middle\_FIFO} + \frac{T_{lowc}}{T} \times \eta_{low\_FIFO} \tag{3.7}$$

And the system utilization when using APKB strategy η_{T_APKB} is:

$$\eta_{T\_APKB} = \frac{T_{highc}}{T} \times \eta_{high\_APKB} + \frac{T_{middlec}}{T} \times \eta_{middle\_APKB} + \frac{T_{low}}{T} \times \eta_{low\_APKB} \quad (3.8)$$

While the system is high loaded, the FIFO strategy which allocated to each parallel job with same amount of nodes will finally leads to over loaded of some nodes, so the $\eta_{high\_FIFO} < \eta_{high\_APKB}$. When the system is phase of middle loaded, these two strategies will implement nearly the same resource allocation, so $\eta_{middle\_FIFO} \approx \eta_{middle\_APKB}$. But when system is poor loaded, the FIFO strategy will result in the idle of some nodes, thus $\eta_{low\_FIFO} < \eta_{low\_APKB}$. To draw the conclusion that APKB scheduling strategy would achieve a much better system utilization.

4 Experiment & Analysis

The experimental performance comparison of FIFO and APKB will be taken on Lenovo Deepcomp 6800 which composed of 18 nodes, each with dual Intel(R) 3.0Ghz processors. Network capability is 1000MBps. The resource amount allocated to each is 4 for FIFO.

(1) Comparative analysis of total time and average weighted turnaround time

As is showed in the figures the APKB scheduling strategy outperforms FIFO strategy with smaller total run time and average weighted turnaround time.

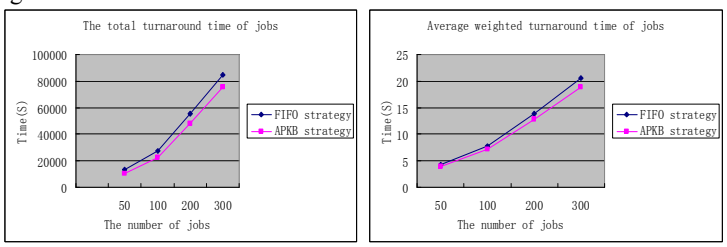

Fig. 2. Comparison of total time and average weighted turnaround time

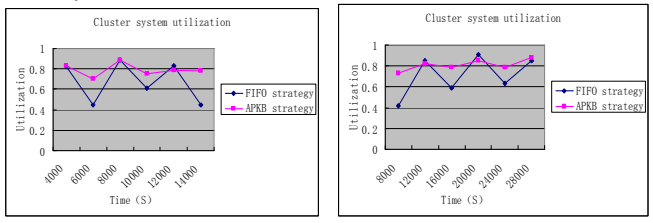
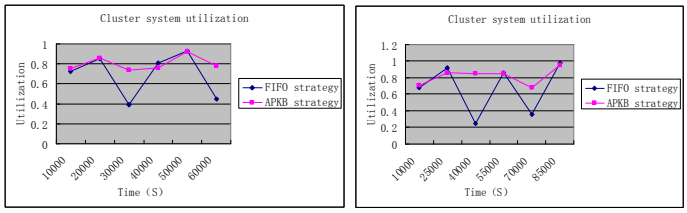
(2) Comparative analysis of system utilization



(a) 50 samples of jobs (b) 100 samples of jobs



(c) 200 samples of jobs (d) 300 samples of jobs

Fig. 3. Comparison of system utilization

As is demonstrated in figures above, the APKB strategy gains more system utilization than FIFO. And with increasing of job samples, the system utilization trends to be stable rather than FIFO.

5 Conclusions

In this paper introduced and implemented a practical and efficient adaptive prior-knowledge-based parallel job scheduling strategy for cluster-based parallel processing system of remote sensing image. Trough accurate estimation of job run time using a prior-knowledge data base and real-time system load of cluster, an adaptive resource allocation policy is used avoid the blindness in resource allocation. Experimental results have shown that

the average weighted turnaround time of jobs is greatly reduced by the proposed scheduling strategy, and also a better system utilization and performance enhancement is achieved.

Abstract— *Multicore-GPU platforms are now common and affordable, yet capitalising on their parallel processing capability is not straightforward. Existing sequential and parallel software must be tuned, or designed anew, to efficiently capitalise on these platforms.*

This paper presents the design of parallel data list processing in multicore-GPU platforms, wherein application data is organised into various lists, one list for each core and GPU device, for the purpose of balancing the workload through work (data items) stealing. A novel aspect of our design is the processing of **new data dynamically generated within GPUs***. We present experimental results for three applications with different granularities and access patterns. Overall the use of GPUs can significantly improve performance, but using them profitably may not be simple.*

Keywords: Parallel Computing, Multicores, GPUs, Load Balancing, Shared Memory

1. Introduction

Multicores and GPUs are now common in laptops, desktops and compute nodes in clusters, offering unprecedented compute power to improve application performance substantially in many cases. And the cost is rather reasonable. However, not all of this compute power is readily usable. Existing software must be tuned to be able to capitalise on the parallel processing capability of such platforms. Sequential applications must be redesigned anew and implemented into a parallel multi-threaded version with shared memory communication based on semaphores, locks and/or conditional variables [1].

Many parallel application were designed for cluster computing using the message passing interface (MPI). In clusters of uniprocessor nodes, they would run in parallel with a single process running on each node. In cluster of multicore nodes, they can capitalise on the parallel capacity of these platforms *unmodified*, running as many processes for each multicore node as cores available in each node. However, processes running in the same node will communicate through message passing which, in principle, is less efficient than shared memory communication between threads because of the need to prepare, send, receive and unpack messages. Also, MPI applications must be modified to capitalise on the parallel capacity of GPUs, as using GPUs involves shared memory communication between the host platform and the GPU device [2], [3].

The Data List Management Library (DLML) is a middleware to process data lists in parallel that has undergone the above tuning in order to run more efficiently on clusters of multicore nodes with GPUs attached to some nodes. The first version of DLML was based on multiprocess parallelism and communication based on MPI message passing. *MultiCore* (MC) DLML is based on multithreaded parallelism and shared memory communication for intra-node parallelism and message passing for inter-node parallelism; it has been reported in [4], [5].

This paper presents *MultiCore-GPU* (MCG) DLML, a version able to capitalise on the parallel capacity of multicore-GPU platforms. The main issues we addressed in the design of MCG-DLML were: i) communication between the multicore platform and the attached GPU, and ii) the processing of dynamically generated data within the GPU. The last aspect is novel in that most GPU applications involve some form static processing, wherein a GPU is allocated a fixed amount of work (e.g., a scalar-vector multiplication) that is processed until completion before the GPU is allocated more work. In contrast, one of our DLML applications, the Non-Attacking Queens (NAQ) problem [6], generates new data items dynamically, which is handled as follows in MCG-DLML. Application threads running on the multicore platform insert new items back into its list. Application threads running on the GPU share an input buffer from which they read items to process and an output buffer onto which they write new items dynamically generated. Once the input buffer is exhausted, the input buffer is turned into the output buffer and the previous output buffer is turned into the input buffer.

The paper continues as follows. Section 2 presents the motivation for parallel data list processing. Section 3 outlines the organisation of MC-DLML. Section 4 presents the design of MCG-DLML. Section 5 presents our experimental platform and applications to compare the performance of MC-DLML and MCG-DLML. Section 6 presents our results. We present results for three applications with different granular-

ities and data access patterns running on a single multicore with a GPU attached, as using two or more multicore nodes would involve message-passing overhead which will become dominant. Two of our applications show much improved performance on the multicore-GPU platform; the other application shows some performance loss due to communication between the host multicore and the GPU device, but we believe it can be tuned. We conclude in Section 7.

2. Parallel Data-List Processing

In designing DLML [7], our purpose was to simplify the parallel programming of some applications through providing users with a simpler interface than that provided by MPI or Pthreads, or both. Other middlewares for parallel computing that have the same purpose are Skeletons [8] and Mapreduce [9]. In DLML, users only need to organise their data into items to *insert* into and *get* from a list using DLML functions. DLML applications run under the Single Program Multiple Data (SPMD) model: all processors run the same program but operate on distinct data lists. When a list becomes empty, it is refilled through *stealing* data items from another list transparently to the programmer. Only when `DLML_get()` does not return a data item, the calling application thread knows that no more data items are available and it can terminate. DLML functions hide synchronisation communication from users, while automatic list refilling tends to balance the workload according to the processing capacity of each processor, which is essential for good performance.

The first version of DLML [10] was designed with clusters composed of uniprocessor nodes in mind, and thus was designed based on multiprocess parallelism and message-passing communication with MPI. In this version, an application process and a DLML process are run in each node. The former runs the application code while the latter is in charge of: i) making data requests to remote nodes when the *local* list becomes empty, and ii) serving data requests from remote nodes whose list has become empty. Both tasks follow a message-passing protocol. Message passing is also used between an application process and its *sibling* (*in-same-node*) DLML process to move list items between their address spaces.

Note that the first version of DLML can run *unmodified* in clusters of multicore nodes and yet capitalise on intra-node parallelism, i.e., running in parallel on the various cores available within each multicore node. We only need to run an application process and a DLML process for each core. However, message passing would be used between DLML processes running in the same multicore node. An obvious improvement was to reduce the communication overhead of message passing between the cores in the same node, through multithreaded parallelism and communication based on shared memory.

```
void application_thread( void *my_id ) {
  DLML_dataitem item;
  DLML_list *L = DLML_thread_list( my_id );

  if ( DLML_Iam_master_thread( my_id ) ) {
    insert_data_items();
  while ( DLML_get( L, &item ))
    process_data_item( &item );
}

int main(int argc, char *argv[]) {

  DLML_init( argc, argv );
  application_thread( (void *) 0 );
  DLML_finalise();
  return 0;
}
```

Fig. 1: General organisation of an application in MC-DLML.

3. MultiCore DLML

Multicore DLML, or MC-DLML, was designed based on multi-threaded parallelism and shared memory communication for intra-node parallelism [4], [5]. Figure 1 shows a typical application in MC-DLML. The code in the `main()` procedure in Figure 1 is run by the master thread (id=0) only. The call `DLML_init()` initialises the DLML lists for each application thread, and then creates as many applications threads as cores available (by default) or as many as the user indicates as a parameter in the command running the application. The master thread then itself runs the code corresponding to application threads, `application_thread()`, passing as parameter its id 0. Within the application thread, the user code must distinguish between the master thread and all other threads: the master thread typically inserts the data items to be processed, or just the initial data items if the application dynamically generates data items, and then loops while `DLML_get()` returns a data item to process it. The user code deals with a single list, while internally several lists are implemented.

The main issues addressed in designing MC-DLML were the following: i) the locking overhead for MPI calls to be thread safe, ii) cache locality and memory consumption, and iii) intra-node synchronisation cost.

i) MC-DLML uses various application threads, usually as many as the number of cores available in each multicore node, and only one thread to make requests to remote nodes and to serve requests from remote nodes using `MPI_THREAD_FUNNELED` support, which does not involve thread-safe locking. Using one thread to make requests and another thread to serve requests simplifies coding, but requires using `MPI_THREAD_MULTIPLE` or `...SERIALIZED` level support, which involves thread-safe locking whose overhead with fine-grain applications we found to be quite high.

ii) MC-DLML uses a list for each application thread, each thread getting items from, and inserting new items

dynamically generated at, the front of the list, i.e., using lists as stacks. Hence items that have just been placed on the list are sooner removed from the list and processed while still resident in the cache. Using other list organisations, we found we were losing cache locality. We also found that, one of our applications, the non-attacking Queens (NAQ) problem, consumes much less memory when we use lists as stacks (a problem similar to traversing a tree either depth-first or breadth-first). Thus our design of MC-DLML that outperforms DLML uses a single list for each application thread, with gets from and inserts at the front. This design decision has various points in common with the "data structures in the multicore age" described in [1].

iii) Application threads running in a multicore share a workload. Although each thread uses a list to get and insert the data items, when a list becomes empty, the owner thread *steals* data items from another list. Hence the workload gets balanced according to the processing capacity of each thread. The simplest work stealing synchronisation algorithm is for a thread to lock its list every time it inserts or gets a data item from its list, and for a work stealing thread to lock its list and the lists of other threads when attempting to refill its list.

To optimise performance, we identified two *operating modes* for each thread: *normal operation* and *stealing operation*. A thread is in normal operation when it is either inserting or getting a data item. A thread is in stealing operation when it is attempting to steal data items to refill its list, or when a thread stops using its list as a result of acknowledging the synchronisation required by a stealing thread. In one of our synchronisation algorithms [5], normal operation requires no synchronisation. Each thread that inserts or gets a data item only *reads* a flag to check if a stealing operation has been signalled in order to change its operating mode. Thus in normal operation no overhead but that read is incurred. Under a stealing operation, synchronisation is needed for threads to stop using their lists so that the stealing thread does not interfere with the normal operation of the other threads. This synchronisation requires all other threads to stop using their lists in order for the stealing thread to choose the largest list to refill its list. We call this algorithm *Global Locking* (GL). Choosing the largest list is in principle a good policy, as it should tend to reduce the number of work stealing operations and the corresponding overhead.

In another algorithm we designed [4], we identify safe phases to access the lists of other threads with no or little synchronisation, thereby reducing the overhead of stealing operations. The purpose was to avoid potentially long idle periods running coarse grain applications. We call this algorithm *Low-synchronisation Locking* (LSL). LSL requires each thread to lock its list every time it enters `DLML_get()` or `DLML_insert()`, and unlock it when it returns from those procedures. The locking and unlocking consists of turning on and off a flag with atomic operations — not a mutex lock which is more costly. Then, a stealing thread only attempts to steal data items from a list that is not currently locked.

```
01 int DLML_get( LIST *L, ITEM *item ) {
02   synchronise if needed      // SYNCHRONISE
03   if  L->size > 0
04     *item = L->first         // GET ITEM
05     return 1
06   else                       // REFILL LIST
07     signal synchronisation for
08       exclusive access to other
09       list/s
10     if data items available
11       steal some
12       return 1
13     else
14       return 0
15 }
```

Fig. 2: DLML_get() main phases.

For different workloads, each of the algorithms above can be superior. GL will tend to perform well with fine-grain applications, while LSL with coarse-grain applications. Figure 2 shows the main phases of DLML_get() under either GL or LSL.

4. MultiCore-GPU MCG-DLML

4.1 Introduction

Recall that MPI parallel applications can run unmodified on multicore-node clusters, although not as efficiently as they would run if they were tuned to use multithreaded parallelism and shared memory communication. On GPUs, however, an application cannot run unless it is adapted to capitalise on the parallelism that GPUs offer.

GPUs are designed to perform well in compute-intensive, highly parallel computation typical of graphics rendering and many scientific applications that model physical phenomena. Their design devotes more transistors to data processing than to data caching and flow control [11]; the opposite is the case in general purpose processors. GPUs can process many data elements in parallel using the same program. However, this *same program* is not quite the same as that in the term Single Program Multiple Data (SPMD). In GPUs, the *same program* is synchronised by hardware, while in SPMD it is synchronised through message passing and/or shared memory synchronisation primitives specified by the programmer.

In GPUs, the *same program* is scheduled as follows. First, a thread in the host platform (e.g., a multicore) copies the data to be processed from host memory onto GPU memory, and then *invokes* the GPU threads to run the *same program* to process the data. When the GPU finishes processing the data, it signals the host thread, which may again schedule new work. Below, we describe the main components of MCG-

DLML related to processing data items in GPUs: GPU work scheduling and GPU dynamic data processing.

4.2 GPU work scheduling

Scheduling work onto a GPU consists of first copying the data to be processed from host memory onto GPU memory, and then invoking the GPU threads. This is as follows in MCG-DLML. Recall that MC-DLML uses, in each multicore node, various application threads, usually as many as the number of cores available in each multicore node, and one thread to make data requests to remote nodes and to serve requests from remote nodes. In addition to those threads, MCG-DLML uses a Host-GPU (HG) thread to move data from host memory onto GPU memory and vice versa, and multiple GPU threads in charge of processing data in GPU memory.

The HG thread is similar to the application thread shown in Figure 1 in that it repeatedly calls DLML_get() to get items while items are available. The HG thread runs on the host and the items it gets it copies them to GPU memory as described shortly. As DLML_get() steals data items from other lists if need be, the workload gets balanced among the cores and the attached GPU/s.

Getting and copying items to GPU memory is different for each of our applications in order to improve performance. Our applications include the NAQs problem, a matrix multiplication (MM) algorithm, and an image segmentation (IS) algorithm. We describe each application in detail in Section 5, and here only the general aspects of their processing in cores and the GPU. For NAQs and MM, the HG thread calls DLML_get() a number of times, say N, storing the obtained data items contiguously in host memory without processing them. It then copies the N data items to GPU memory and invokes the GPU threads to process the items.

For IS, the HG thread gets and copies to GPU memory only one item which is an image. GPU threads are then invoked to process each a pixel of the image. Each image is a matrix of size 217 rows and 181 columns, and thus 39277 GPU threads are invoked at once. For MM and NAQ, the HG thread gets and copies to GPU memory 5000 and 500 items respectively; it then invokes that many GPU threads to process each an item. The items are described in Section 5.

Invoking GPU threads is asynchronous: the HG thread can do something else immediately after invoking the GPU threads, but in our current implementation of MCG-DLML we do not capitalise on this. Copying data from GPU memory to host memory (e.g., some totals) is synchronous, however; the HG thread must wait for its completion. Moreover, a copy from GPU memory to host memory can only take place until the GPU has finished processing the last scheduled work.

4.3 GPU dynamic data processing

The NAQs problem dynamically generates new data items that need GPU memory to hold them. Hence, not all of the GPU memory is used to hold items copied from host memory. A portion of GPU memory is reserved for new items dynamically generated. Thus GPU memory is logically divided into two portions. A portion is used as input buffer to hold items copied from host memory by the HG thread; the other portion is used to hold items dynamically generated (out of processing items in the input buffer). Reading items from the input buffer and writing new items to the output buffer occur concurrently. When the input buffer is exhausted, the input buffer is turned into the output buffer and the previous output buffer is turned into the input buffer without synchronising with the host thread.

(As MM does not generate new data, we copy as many items to GPU memory as possible. In the case of IS, we try to process each image as soon as possible.)

Recall that items to copy to GPU memory are first stored contiguously in host memory. When copied into the GPU input buffer, items are also stored contiguously. Also, a pointer variable is set to point to the beginning of the output buffer. Then, all items in the input buffer are processed simultaneously: as many GPU threads as the number of items in the input buffer are run concurrently, each GPU thread accessing and processing an item whose location in the input buffer is computed based on the GPU thread ID.

When processing an item, if a GPU thread generates a new item, such thread *atomically increases* the pointer variable pointing to the output buffer, and stores the new item in the address returned by the atomic operation (i.e., the address of the previous location).

Once the input buffer is processed, the number of new items generated, say NEW, is computed from the value of the pointer variable to the output buffer. The previous input buffer is turned into the output buffer, and the previous output buffer into the input buffer, and NEW GPU threads are run to process the new input buffer. Turning input/output buffers into the other continues until no new items are generated and control is given back to the HG thread in the host platform.

Note that the processing of an item can generate various new items, but only one for each processing of an input buffer. If an item can still potentially generate new items (not all queens have been placed), it is sent back to host memory, inserting it into the list of the HG thread with DLML_insert().

5. Experimental Platform and Applications

This section describes the experimental platform and applications we used to compare the performance of both MC-DLML and MCG-DLML. We will present results for a

single multicore with a GPU attached, as using two or more multicore nodes would involve message-passing overhead which will become dominant. ***MULTICORE specification***: Intel(R) Core(TM) 2 Quad CPU Q6600 (4 cores in total) at 2.40GHz, 4 x 32KB L1 instruction caches, 4 x 32KB L1 data caches, 2 x 4MB L2 caches (each cache shared between 2 cores), and 6GB DRAM. ***GPU specification***: GeForce GTX 460, 1.53 GHz 336 CUDA Cores (7 Multiprocessors x 48 CUDA Cores/MPK), 1023 MB, 512MB L2 cache.

SOFTWARE used: CentOS release 5.7, Open MPI 1.4.4, gcc version 4.1.2, NVIDIA Corporation Cuda compilation tools, release 4.0, V0.2.1221, CUDA Driver Version/Runtime Version 4.10/4.0, CUDA Capability Major/Minor version number: 2.1. The work stealing algorithm used by both MC-DLML and MCG-DLML is the Low-synchronisation algorithm reported in [4].

Our applications include: i) image segmentation (IS) using the Mean-Shift (MSH) method, ii) a matrix multiplication (MM) algorithm, and iii) the Non-Attacking N-Queens (NAQ) problem. Image segmentation (IS) with the Mean-Shift method (MSH) is used to reconstruct 3D brain images [12], [13], through applying such method to each pixel on several 2D images (cuts). The method is expensive for the large number of cuts and high resolution required. The number of cuts is fixed, but the processing cost of each cut varies according to MSH cost, which depends on the intensity of pixels of each cut. In the DLML version, each list item is an integer value that identifies an image cut; our experiments processed 165 image cuts.

Matrix multiplication (MM), $C = A \times B$, is a *static* application because all data is known in advance. In the DLML version, each list item contains all the data to compute an element in the results matrix C, i.e.: a full row of A, a full column of B, and the x, y position of the element in C. A, B and C are $N \times N$ matrices, and we experimented with $N = 500$ and 600.

The NAQ problem consists of finding all possible ways of placing N queens on an N×N chessboard, so that no queen attacks another queen [6]. The search space of NAQ can be modelled with an N-degree search tree. The solutions are found exploring the search tree for possible solutions, eliminating those that can not be solved. In the DLML version, each list item contains a possible solution to explore formed by the number of queens to be placed and an array of size N with the position of the queens placed so far. The list *dynamically* increases and decreases as new possible solutions are generated and failed solutions are eliminated. The cost of finding a solution is a function of the depth of the relevant item in the search tree.

6. Results

This section presents experimental results on the performance of MC-DLML and MCG-DLML running our applications. In the figures shown below, the Y axis shows response time and the X axis the number of (application) threads used to run an application code. The results corresponding to MCG-DLML are labelled with the prefix *gpu-*. In the results of gpu- runs, the number of application threads shown, say N, means that $N - 1$ application threads were run in a core in the host multicore platform, while 1 thread was the HG thread responsible for scheduling work to the GPU as described in Section 4. The HG thread does not process application data; it only schedules work to the GPU.

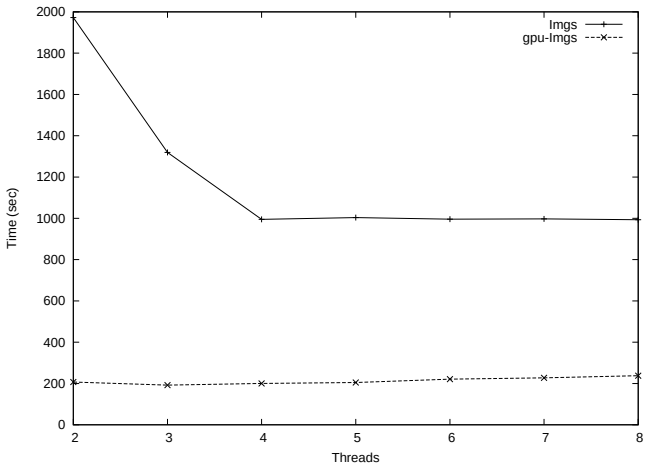

Fig. 3: MC-DLML vs MCG-DLML (gpu-) running IS.

6.1 Image Segmentation (IS)

Figure 3 shows the performance of MC-DLML and MCG-DLML (gpu-) running IS with 165 image cuts/files, using 2-8 application threads, one of which is the HG thread in MCG-DLML runs. IS is a static application: all the images to be processed are known at the start of each run (no new images are generated dynamically throughout each run). The master application thread inserts the id of each image into its list at the start of computation; then other application threads steal work from the master thread or other application threads that have stolen work.

The figure clearly shows MCG-DLML having much better performance than MC-DLML. This is because IS is an application that is both coarse-grain and compute-intensive. IS is a coarse-grain application in that processing each image is relatively expensive compared to getting its id from a list and reading the image file onto main memory to be processed; IS is compute intensive in that it involves relatively many floating point operations. The use of a GPU by MCG-DLML clearly helps in this kind of workload, since the GPU processes each image in parallel using many GPU threads (one for each pixel), while a core (in the host platform) processes each image sequentially, i.e., all the floating point operations involved in processing an image are carried out sequentially by each core.

The GPU processes most of the workload because it is much faster for this kind of workload than each core: the performance plot of MCG-DLML shows that using only 2 threads (one of which is the HG thread that only schedules work to the GPU) yields as good performance as using more threads. Using 3 threads shows only a marginal performance gain over using 2 threads; using more than 3 threads increasingly deteriorates performance due to synchronisation overhead, particularly the bottleneck of reading image files into main memory.

The performance plot of MC-DLML is typical in that it shows improved performance as more cores (processing elements of same capacity) are used. The best performance corresponds to using the same number of application threads as the number of cores available, 4.

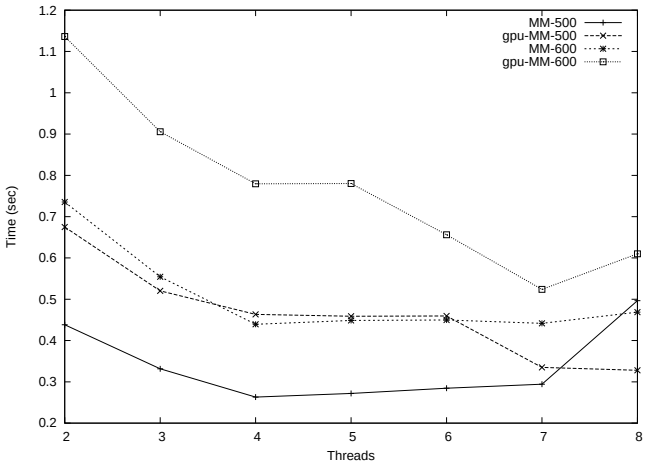

Fig. 4: MC-DLML and MCG-DLML (gpu-) running MM.

6.2 Matrix Multiplication (MM)

Figure 4 shows the performance of MC-DLML and MCG-DLML (gpu-) running MM with $N = 500$ and 600, using 2-8 application threads, one of which is the HG thread in MCG-DLML runs. MM is a static, medium-grain application. MM runs for a relatively short time (less than 1s for those values of N), and thus any of its threads that gets delayed significantly affects overall performance.

MC-DLML performs better than MCG-DLML, nearly twice as fast in most cases. The way we chose to use the GPU within MCG-DLML was not profitable for MM. Recall that each list item contains all the data to compute an element in the results matrix C, i.e.: a full row of matrix A, a full column of matrix B, and the x, y position of the element in C to compute. We decided to move a number of items to the GPU and process each item using only a GPU thread. This is conceptually simple, but it involves a wait to get that number of items to move to the GPU, and also that each GPU thread carries out sequentially all the operations to compute the corresponding element in matrix C.

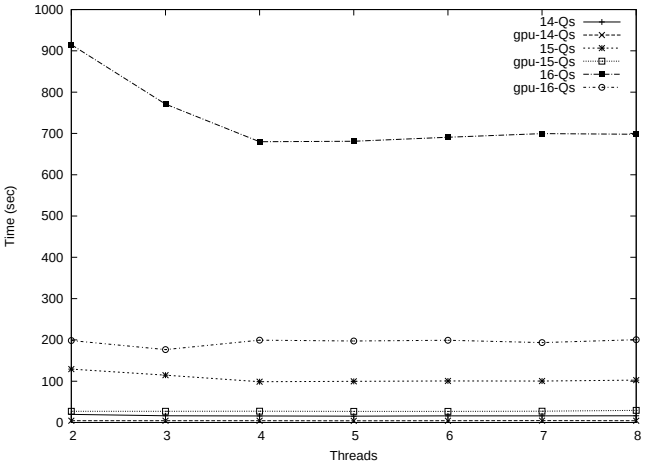

Fig. 5: MC-DLML and MCG-DLML (gpu-) running NAQ.

Such use involves a relatively high communication to computation ratio; the communication consists of that wait to get all the items to move to the GPU at once and the actual copying of the items from the host multicore memory to the GPU memory.

The number of items we are moving from host memory to GPU memory is 5000. The rationale behind this number was to use as many GPU threads as possible and thus make the most out of the GPU without modifying the multicore code substantially. However, this number apparently imposes a coarse granularity in the use of the GPU. We need to investigate further how to better use GPU threads for this kind of workload in the context of MC-DLML.

6.3 The Non-attacking Queens (NAQ) problem

Figure 5 shows the performance of MC-DLML and MCG-DLML running NAQ for $14 - 16$ queens, using 2-8 application threads, one of which is the HG thread in MCG-DLML runs. NAQ is a fine-grain application: processing an item (usually adding a queen) is very quick compared to getting or inserting an item. It is thus prone to high contention overhead. However, NAQ *dynamically* generates new items which each thread inserts into its own list and thus keeps busy doing work.

The figure shows that MCG-DLML significantly outperforms MC-DLML. Despite NAQ being a data-intensive symbolic application, the use of the GPU is very profitable. This is because the communication to computation ratio between (the host multicore and the GPU) is relatively low: the NAQ application generates data dynamically, and most of the data generated by the GPU is processed by the GPU itself. Note that MCG-DLML performs much better MC-DLML for all the problem sizes of the application shown in Figure 5; Figure 6 shows the same results (response times) in logarithmic scale.

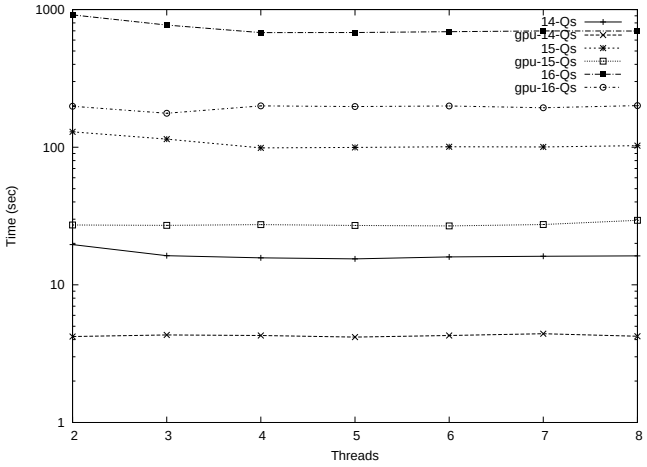

Fig. 6: MC-DLML and MCG-DLML (gpu-) running NAQ, logarithmic scale.

7. Conclusions

We have presented a design and an evaluation of parallel data list processing in multicore-GPU platforms. These platforms offer a very good price-to-computation ratio, and overall our work shows that they can be used profitably both in compute intensive applications (e.g., our IS application) and in symbolic intensive applications (e.g., NAQs application). However, performance may deteriorate substantially because of the communication cost of moving data between the host platform and the GPU device (MM application). Although this is to be expected (in retrospect), we initially thought our MM application would do better running on a mixed multicore-GPU platform (MCG-DLML) than on a single multicore platform (MC-DLML).

The rationale behind the design of (MC-MCG-) DLML is that an application workload gets balanced according to the processing capacity of the processors running an application. It obviously needs further tuning for a multicore-GPU platform. The way a GPU is used imposes a granularity for scheduling work into the GPU, and it can adversely affect performance. We will investigate further how to efficiently use GPUs within MCG-DLML.

ABSTRACT

The issue of static scheduling of tasks is of particular importance in multiprocessor systems due to optimal use of processors and taking less time. It is a NP-Hard problem and obtaining the optimal solution involves a high time complexity. Thus the heuristic method is used to solve this problem. The genetic algorithms and Automata are suitable method for scheduling of multiprocessor systems. In this paper a solution is introduced for algorithms of scheduling. The main idea in designing these algorithms is to obtain the least run time and the highest possible parallel with minimum critical path. By using of this solution the graphs with many tasks can be transformed in to fewer ones. We use a combination of both tasks merging technique and scheduling with genetic of algorithm to shorten the length of critical path.

A new genetic algorithm is introduced to schedule of multiprocessor systems in which the scheduling priority of performing the tasks is based on the number of child. The results show that the new proposed algorithm achieves the optimal scheduling solution in acceptable time compared to other common methods.

Keywords

Scheduling, tasks gragh, merging, Multiprocessors, genetic algorithm.

1. INTRODUCTION

The issue of scheduling in multiprocessor systems and heterogeneity distributed systems is a NP –Hard problem. In the classical method it is time-consuming to obtain of a complete optimal solution of a minimum scheduling and in many cases running the tasks randomly takes too much time. Thus the heuristic complete optimal solution is not necessarily obtained but within reasonable time span an answer will be obtained which almost close to optimal solution. Many heuristic methods have been introduced include: Duplex[14,12], OLB[14,12,4], GA[19,20,17,24,21], SA[1,2,19,13,3], LMT[11], MCT[14], A*[16,2,19,15], Min-min[14,12,10], Max-min[14,12,10], DLS[5], GSA[13], Tabu search[18,19]. One of the best heuristic method is to use the genetic algorithm. In this paper a new genetic algorithm based on earliest tasks run is simulated given their priority on the number of child.

In order to increase the program efficiencies in parallel systems an accurate scheduling of tasks is highly taken into consideration. The scheduling should be performed so that the total run time of the program with regard to tasks run time and the relation between processors can be minimized. Certainly the more the number of processors during running, the simpler the planning carries out. Today it is common to use a lot of processors in super computers, quick processing clusters, the distributed networks like grids. Hence it is important to optimize along the critical path. By using the tasks merging the length of this path can be decreased considerably.

Given being NP-Complete of the scheduling task the approaches based on uncertainty methods in this field will not ever efficient. In the past decades much works have been performed by this algorithm, however many of which had not the required efficiency. Therefore, use of uncertainly method and mainly the genetic algorithm is very effective for solving such problems.

In this paper, we use a combination of both task merging technique and scheduling in order to shorten the critical path. Accurately merging of the tasks before scheduling the task graphs have significant impact on scheduling result. The results obtained by applying our algorithm on the different graphs for evaluating the scheduling algorithm represents a positive impact of merging on scheduling.

2. RELATED WORKS

In order to improve the performance of scheduling algorithms of task graphs, before applying the algorithms, they can be prepared by using two solutions i.e. clustering [6]and tasks merging [22,26] for suitable scheduling. The results from multi processors scheduling algorithms can be greatly improved by using of both solutions. In the following, the two above solutions will be examined to solve multiprocessors scheduling problems.

A lot of works have been done on task scheduling in the multiprocessor systems by genetic algorithm [19,20,17],. Some of them have employed the random genetic algorithm and some others used genetic algorithm and prioritizing tasks based on height [20]. In this research a new genetic algorithm has been simulated based on earliest task run given their priority and also on the number of their child.

2.1. Clustering the tasks

A task clustering solves only a part of multiprocessor scheduling problem. A cluster of tasks is a set of tasks that together are run on a processor. In turn all the edges inside a cluster of a graph their relation cost equals to zero. Although the sequence of running tasks within a cluster is often determined by algorithms of clustering, the main aim of them is to increase granulating of tasks graph. However the tasks within clusters are not summed together. In the other word, the resulting data from each of tasks are sent as soon as provided. It is considered as a substantial difference between task clustering technique and task merging [2].

In order to cluster the tasks some optimal or nearly optimal processors are determine for task graph scheduler. In the other word, the more processors are needed from generated clusters by algorithm of task scheduling. Also it shows where the task clustering is performed prior to scheduling. The balancing (LB) for merged cluster is proffered because LB is fast and is easily implemented and yields better final scheduling. In short, two phase method of jobs scheduling and balancing have significant effect strategically for job graph scheduling on distributed parallel architecture.

2.2. Algorithm of Merging Task

In [4] a merging task algorithm is presented which its input is a graph with micro granulating. The main idea is iterative selection of a pair node for merging. If merging of these two nodes lead to decrease the length of critical path, then it select two new nodes.

2.3. Algorithm Based on Graph Rewriting System

Graph Rewriting System (GRS) Is an algorithm used for merging tasks[22]. It is employed as a way for reducing the length of critical path. The transformation is specified by several graph rewriting rules.

2.4. Prioritizing scheduling algorithm based on height or based on offspring (children)

The aim of scheduling in a multiprocessors system is to assign N job to M processor so that the finished run time of final job in this system is minimized. For simplicity, if two tasks are scheduled on two different processors, then the communication cost for sending data between two tasks is taken as zero. The algorithm of task scheduling generation in term of height or offspring is as follows:

a. Arrange the tasks in order of incremental in term of their height or offspring (children).

b. Repeat the stages 3,4 in the tasks.

c. Generate a random number r, so that 1<r<m (m is the number of processors)

d. Select the first task from arranged ones and allocate it to processor r^{th} then eliminate it.

By repeating the algorithm of scheduling generated, an initial population is generated from search nodes.The path from input node to output node is the longest critical path where we denote it by and length of path by representing the run time of the program in a state in which the maximum number of processors can be used. (Each existing task in task graph is sent to a processor) the value of upper bound of output node reflects the length of critical path of the graph.

3. PROPOSED ALGORITHM

This novel scheduling algorithm is a combined technique resulting from task merging as well as tasks scheduling. In order to manage large graph with micro granulating, the tasks are merged so that in addition to improve the graph specifications such as length of critical path, the amount of granulating is increased as well. It is done through graph rewriting system which consist the series of codes transforming graph on task graph.

It is NP-Complete. Therefore, the approaches based on conclusive methods are not so efficient in this field. Using of evolutionary processing algorithm and mainly genetic algorithm given their non-conclusive nature will be effective for solving problems. Genetic scheduling algorithm is ever seeking to find the closest answer. In order to find a closest answer, this paper presents a two-step algorithm as follows:

The first step is to receive a task graph with micro granulating. After receiving the task merging algorithm graph, it analyzes the graph and attempts to merge the tasks for modifying the parameters of qualitative program. The next one, the obtained graph from this merging is carried out by priority genetic scheduling algorithm based on child. The cost sending data between the tasks equals to L+n/B where n is the delivered data cost, (B) is the bandwidth an (L) is the delay time of the dispatched data. Similarity the scheduling problem can be considered as triple (G,B,L) in which G is the task graph, B is bandwidth and L is the delay time.

In the general state, the algorithm of rewriting graph system can be taken into account as three independent rules: 1: Merging single children, 2: Merging all parents, 3: Replicate Parent Merge .

The rule of Merging single children has the lowest cost since it does not involve any condition but a sub-graph pattern (figure 1).

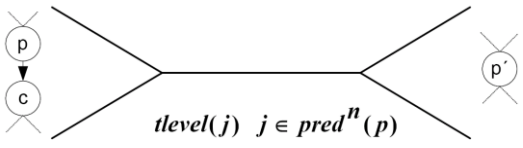

Figure 1. Merging single children

As shown in figure 1, by using this rule we can merge two nodes with each other if in the tasks graph a node has a single children and its children owing a single parent. In such conditions, the node C for running will wait the results

from node p. If this merging is failed these two nodes may be assigned to two distinct processors in a scheduling and it is obvious that a such action only will lead to delayed entering in to system as large as edge weight connecting between both nodes C and p. By merging two above mentioned nodes the possibility of wrong decisions will be removed when scheduling tasks graph.

At first glance, it seems that if using of an ideal scheduling algorithm taking such implications in to account it can be replaced by above method. However by now such algorithm is not introduced because of high complexity of scheduling. In this paper by distinguishing the problem of tasks graph quality improvement from scheduling one the complexity of the problem has reduced and the possibility of actual implementation has also provided.

The merging of propagated parent includes second merging all parent rule (figure2). In this rule a task of parent is divided in to a number of tasks based on the number of its child and each of these copies is merged by one of the child. The first row in the list of conditions will be decisive so that the upper bound for each children and their child is not increased by merging copy p.

In the other word if the greatest delay factor of running the nodes c_i is the node p, then by merging it this amount can be reduced (set of nodes C) for each of child having such situation.

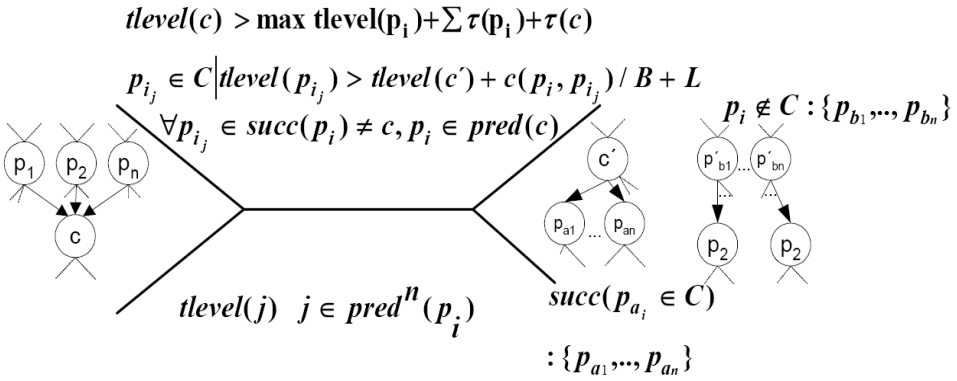

Figure 2. Merging all parents

As shown in figure 2, by using this rule we can If the node p is not the factor affecting the maximum delay of running child c_i, though by merging the node p with nodes c_i the upper bound of that node is not increased, but due to increased volume of running the negative impact of upper bound is transferred to child c_i. Thus, as shown in figure 2, the node p is propagated for the whole child existing within C set and merged in to them; if the node c_i does not exist in C set it will be left alone.

The last rule is the merging of the whole parents As shown in figure 3. Here all of the parents' child of C node denoted by p_{ij} are examined. If merging the whole parents with C causes the level of upper bound of these child is not increased the node of interest is added to C set.

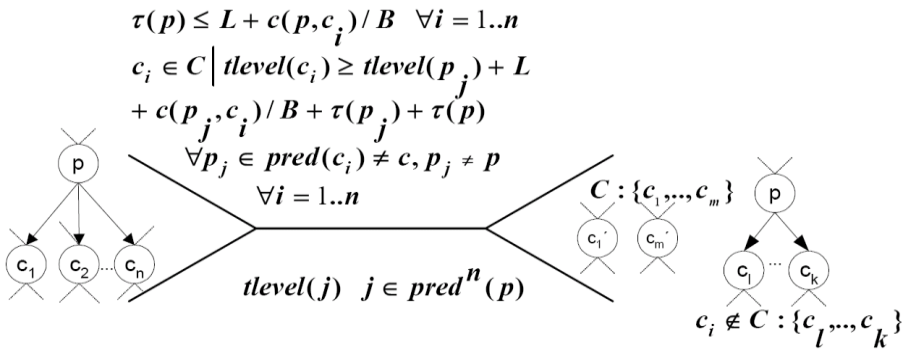

Figure 3. Replicate Parent Merge

The algorithm generating tasks scheduling for initial population in term of the number of offspring is as follows[25]:

a. Arrange the tasks in the order of descending in term of the number of their offspring.

b. Put separately the task with the same number of offspring.

c. Select a task from group of tasks randomly and eliminate it from group.

By using of this algorithm the degree of task graph parallelization will be increased due to decrease the length of critical path. It means that we can obtain a more suitable solution by increasing the number of processors. Having applied the above rules, the graph is prepared for applying the scheduling. The graph resulting from this technique is introduced as an input to prioritized genetic scheduling algorithm based on the number of offspring for scheduling. In the algorithm evaluation section it has shown that by using of this method a suitable scheduling will be established. The proposed method passes the tasks based on prioritizing the new offspring on processors in order to be run. It means that the more the tasks have offspring the sooner scheduling is done. Then that tasks are dedicated to processors P1 to Pm based on EST method in such a way that start time for that task on the processors became short for other processors.

4. SIMULATION AND EVALUATION

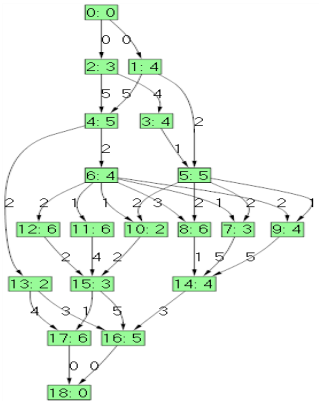

Figure 4. A standard task graph

Table 1. Comparison of the figure 4 graph with existing scheduling algorithm.

MCP	LAST	ETF	HLFET	EZ	LC	NOVIN
[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

In order to evaluate the proposed algorithm, a series of simulation has been performed by Visual Basic.net 2005 package on a computer Pentium IV equipped with processor AMD 2.8 MHZ with 512 megabyte memory. By using a formulated program for automatically generating graph, a set of task graphs including 57 graphs with the number of 30, 70, 90 tasks with tasks dependency percentage between 1 to 100 have been established in such a way that the task run time can be varied in the range of 1 to 1000. These graphs were scheduled on multiprocessors with the number 5,7,9 ones for genetic algorithm without applying any priority, genetic algorithm based on offspring

In order to evaluate the solution presented in this paper the priority genetic scheduling algorithm based on offspring is used and also the graph resulting from merging is assessed. The scheduling problem is NP-Hard and so far many algorithms have been suggested for it [27,6]. The above optimizing algorithm is applicable before any scheduling, and can be used in place of proposed genetic algorithm.

The solution of the problem or completed time of running the final task in the scheduling algorithm after averaging for any similar number of processors / number of work is shown in table 2. By over viewing the results it is seen that the proposed algorithm has a solution close to optimal one.

By running the proposed algorithms on graph in the figure4, a graph with 16% modification in parallel as well as 6% improvement in length of critical path will be obtained. Also 5% decrease is seen in number of task graph nodes. Figure 5 shows algorithm stability.

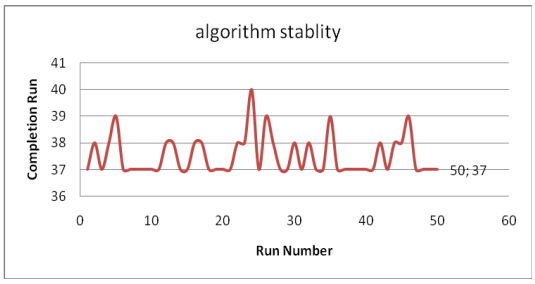

Figure 5. Algorithm stability

This graph is introduced into scheduling algorithm as an input. A run time 38 is obtained with six processors. In the table 1 and figure 6, we see the results of graph figure 4 with algorithms ETF [9], HLFET [7], MCP [8], EZ [16],LC [10].

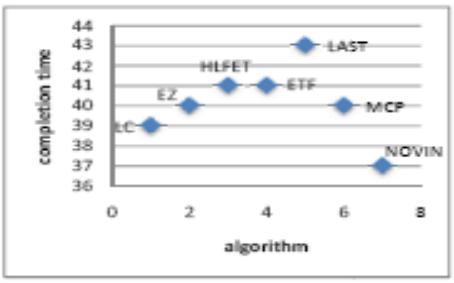

Figure 6. Comparison of the figure 4 graph with existing scheduling algorithm

as well as new proposed algorithms. In order to take other thing being equal, the experiment of all the running steps and operators have been considered the same for all the three algorithms except for prioritizing and establishing initial population. The values of parameters of initial population for algorithms are the number of tasks and replications (number of generations) respectively. Prioritizing based on the number of offspring is better than on the height because it is possible that a task has higher height than the other one and at the same time has more offspring. Logically, running the tasks with more offspring have a greater priority compared to the ones having lower height. It allows more tasks to be run, because its prior task has been done. On the other hand, it is impossible, that the task has more offspring to be the task with less offspring. Therefore, its running does not depend on finishing the task with less offspring.

The solution of the problem or completed time of running the final task in the scheduling algorithm after averaging for any similar number of processors / number of tasks is shown in table 2. By over viewing the results it is seen that the proposed algorithm improves the solution close to optimal one 39% and 24 % compared to priority based on height algorithm and 17 % compared to random genetic algorithm and priority genetic algorithm in term of number of offspring respectively. However, the computing time and implementation of the four algorithms are within the same place since only the parts of the four algorithms differ with each other; each is computed once and initially for generation of primary population.

Table 2. The schedules for last algorithms and proposed algorithm (Merge and Priority based on children)

Algorithms	Total Finish Time (TFT) (seconds)								
	Number of processors = 3			Number of processors = 5			Number of processors = 7		
	Number of tasks			Number of tasks			Number of tasks		
	30	50	70	30	50	70	30	50	70
Algorithm Genetic(A)	1066	2729	7223	2604	2135	3498	855	2314	2919
Priority based on height(B)	978	2440	6003	1882	2005	3222	850	2199	2888
Priority based on children(C)	918	2300	5792	2222	1981	3197	809	2065	2742
Merge and Priority based on children(D)	803	1947	4475	1491	1644	2588	736	1789	2251
Optimal percent (D) to (A)	32	40	61	74	30	35	16	29	30
Optimal percent (D) to (B)	21	25	34	26	21	24	15	22	28
Optimal percent (D) to (C)	14	18	29	5	20	23	10	15	21

Table 2 shows the schedules and TFT for four scheduling algorithms. The results indicate that our suggested new algorithm finds better schedule with minimum TFT compared to the other heuristics. While the computation time of the two above genetic algorithms is more than the other heuristics obviously, and is quite similar, as only their initial population producing step is different, the step is calculated once.As it is shown, while the number of tasks, the number of processors and task implementation within specified time are taken constant.

As the task dependency percentage increases, corresponding to proposed algorithm optimized percentage for obtaining the answer close to optimal one, it increases over the two other algorithms. The main reason of this feather is attributed to merge the tasks prior to prioritize the tasks based on the number of offspring. Since the higher task dependency percentage is taken into account, the more merging of tasks and offspring is and the scheduling became better.

5. CONCLUSION

In this paper, a method is presented for improvement of scheduling algorithm efficiency on graph through technique of merging tasks GRS. First the existing rules in GRS are applied on graph of interest then the output is given to genetic scheduling algorithm based on the number offspring (children). The results from applying the proposed solution on graphs show that after merging the task, the existing tasks within graph become small, the parallel increases and the length of critical path is shorten.

Locality-aware memory system for PRAM mode private data storage in the CESM architecture

Martti Forsell
Platform Architectures Team
VTT
Oulu, Finland

Abstract - *The Configurable Emulated Shared Memory (CESM) is a chip multiprocessor (CMP) architecture. It implements a dual computational model—the strong synchronous Parallel Random Access Machine (PRAM) and weaker but more conventional asynchronous Non-Uniform Memory Access (NUMA)—so that a programmer can make use of easy-to-use fine-grained parallel algorithmics of the PRAM paradigm for functionalities with enough parallelism and standard coarse-grained NUMA algorithms for low parallelism cases. In this paper we propose adding local memories to CESM processors for storing thread-private data in the PRAM mode for performance and safety reasons. While this kind of solutions typically introduce a partitioning problem, most parallel computing languages make use of the concepts of shared and private data that provide natural and orthogonal partitioning of data to global and local subspaces. Preliminary performance evaluation of the proposed solution on our CESM architecture along with programming/implementation considerations are provided.*

Keywords: Parallel computing, CESM, PRAM, memory system, local memories, private and shared data

1 Introduction

Although all the processor manufacturers have moved to multicore processors, programming of them has remained challenging. This is partially because the computational models defined by the underlying architectures are asynchronous and locality-sensitive, forcing a programmer to constantly orchestrate execution threads with barrier synchronizations and locks and play with functionality mapping schemes and data partitioning to obtain even decent performance. The rest of the challenge is due to the fact that by far the most programming-related education is given using the sequential computing paradigm. Instead of trying to incrementally refine the current tools and the architectures, we take a radical approach of studying new architectures that would provide stronger models of computation and make it possible to program multicore machines in a much simpler way.

The *Configurable Emulated Shared Memory* (CESM) is a *chip multiprocessor* (CMP) architecture [Forsell09]. It implements a dual computational model—the strong synchronous *Parallel Random Access Machine* (PRAM) [Fortune78] and weaker but more conventional asynchronous *Non-Uniform Memory Access* (NUMA) [Swan77] scheme—so that a programmer can make use of easy-to-use fine-grained parallel algorithmics of the PRAM paradigm for functionalities with enough parallelism and standard coarse-grained NUMA algorithms for low parallelism cases.

In this paper we propose adding/making use of local memories to CESM processors for storing thread-private data in the PRAM mode for performance and safety reasons. While this kind of solutions would typically introduce a partitioning problem, most parallel computing languages make use of the concepts of shared and private data that provide natural orthogonal partitioning of data to global and local subspaces. Preliminary performance evaluation of the proposed solution on our CESM architecture along with programming/implementation considerations are provided.

The rest of the article is organized so that in Section 2 we describe the basic concepts used in this paper, including the PRAM-NUMA and CESM, the way how local memories are employed in the PRAM mode is described in Section3, in Section 4 we discuss language and compiling support with practical examples, in Section 5 we evaluate the performance of the proposed solution on our CESM architecture, and finally in Section 6 we give our conclusions.

2. Basic concepts

In order to extend the success story of the sequential computing paradigm also to parallel computing, we have developed the CESM architecture. It realizes the PRAM-NUMA model of computation, which can be seen as a physically feasible extension of the model of sequential computation. In the following the basic concepts related to this attempt are explained.

2.1 PRAM-NUMA

The PRAM-NUMA model of computation is a configurable synchronous shared memory model developed by us [Forsell11a]. It consists of T processors grouped as P groups of T_p processors, a word-wise accessible global shared memory, P local memory blocks, a *metric* defining distance between the processor groups and target memory blocks, and distance-aware interconnection network (see Figure 1). Each processor is attached to the shared memory and each processor group is attached to its own local memory block. The interconnection network connects the local memory access paths of processor

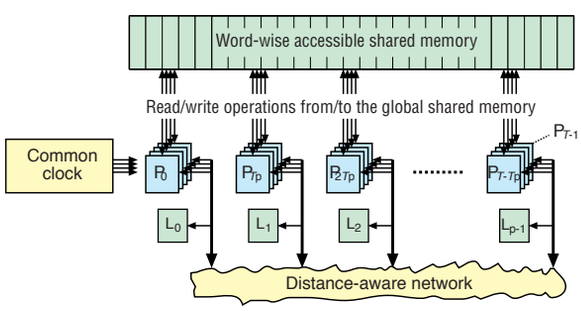

Figure 1. PRAM-NUMA model (P=processor, L=local memory).

groups together so that remote local memories can be accessed. This network is distance-aware in a sense that the latency of routing is proportional to the distance between the source processor and destination memory. The bandwidths from a group of processors to the shared memory and local memory are the same. Each processor can be *configured* to either the PRAM mode or NUMA mode. Along with configuration from the PRAM mode to the NUMA mode, one can set the state of the processor to point an arbitrary state within the group it belongs to. With this indirection of states, two or more processors belonging to the same group can be configured to form a NUMA bunch so that they execute a common instruction stream and share their state with each other, i.e. can be seen as executing code like a single processor would do.

Execution in the PRAM-NUMA model happens in synchronous *steps* during which every processor of each group executes exactly one instruction in the PRAM mode and every bunch executes exactly as many instructions for a single instruction stream as there are participating threads in the bunch.

The PRAM-NUMA model solves the low-TLP execution problem of standard *Emulated Shared Memory* (ESM) machines by providing a possibility to configure two or more processors of a group to use a common state like they were a single processor and to perform NUMA access to the local memories. In the case of low TLP portion of code, a programmer can just set up to T_p processors per group to run that portion as a NUMA bunch and gain more performance proportionally to the number of processors in the bunch.

2.2 CESM

The CESM architecture is a hybrid architecture implementing the PRAM-NUMA model of computation to support both high-speed execution of functionalities with sufficient parallelism and full utilization in low parallelism cases [Forsell09]. A CESM CMP consists of P T_p-threaded (in total constituting $T = PT_p$ threads) F-functional unit *MultiBunched/Threaded Architecture with Chaining* (MBTAC) processor cores [Forsell10] connected to a distributed memory system (see Figure 2). The memory system has P dedicated instruction memory modules, P local data memory modules, P T_p-line step caches and scratchpads attached to processors, P fast data memory modules with active memory units, and a high-bandwidth multimesh interconnection network. Step caches, scratchpads and active memory units are used to support concurrent memory access and multioperations in the PRAM mode [Forsell06]. A MBTAC processor features A ALUs, M memory units, compare unit, and sequencer organized as a chain for the PRAM mode and a single ALU, memory unit, and sequencer organized in parallel for the NUMA mode. In order to save in hardware costs and to provide as seamless configurability as possible between the PRAM and NUMA models, the execution pipelines for the modes are merged and share some units like fetcher, operand select, and the first ALU (see Figure 3). The effective length of the pipeline is T_p for the PRAM mode and 4 for the NUMA mode. The CESM architecture implements support for fast and synchronous switching between the PRAM and NUMA modes for groups of threads with dedicated machine language instructions JOIN and SPLIT [Forsell09]. Synchronous switching is necessary because a NUMA bunch may get switched back to the PRAM mode in the middle of a PRAM step.

3. Supporting PRAM mode local access

In order to increase the performance of processors, providing sufficient memory system bandwidth is often one of the most critical things. In the following we propose adding local memory access to the PRAM mode of the CESM architecture.

3.1 PRAM mode local access

At the first glance, adding local memories to a PRAM-based architecture may sound to be against the basic idea of the model. If we however take a more detailed look at the models at hand, we can observe that the PRAM-NUMA model features already local memories but they are dedicated for local/distance aware remote access in the NUMA mode only. Since also our PRAM-NUMA implementation architecture, CESM, implements local memories for the NUMA mode and connects them together with a help of the PRAM mode intercommunication network, it is quite straightforward to consider using these local memories also in the PRAM mode. This does not require extra hardware except for adding the local memory operation code field to the PRAM mode instruction word and adding logic that controls the local memory unit with this code in the PRAM mode (see Figure 3).

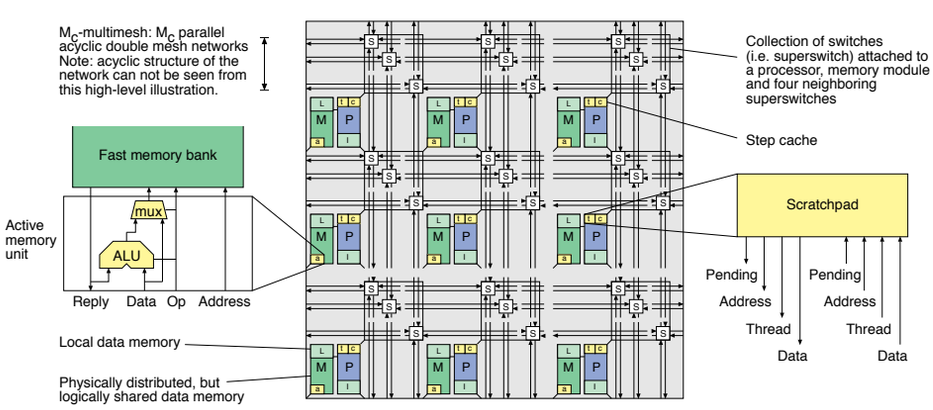

Figure 2. Block diagram of the CESM architecture (P=processor, M=shared data memory, L=local data memory, I=instruction memory, a=active memory unit, c=step cache, and t=scratchpad)..

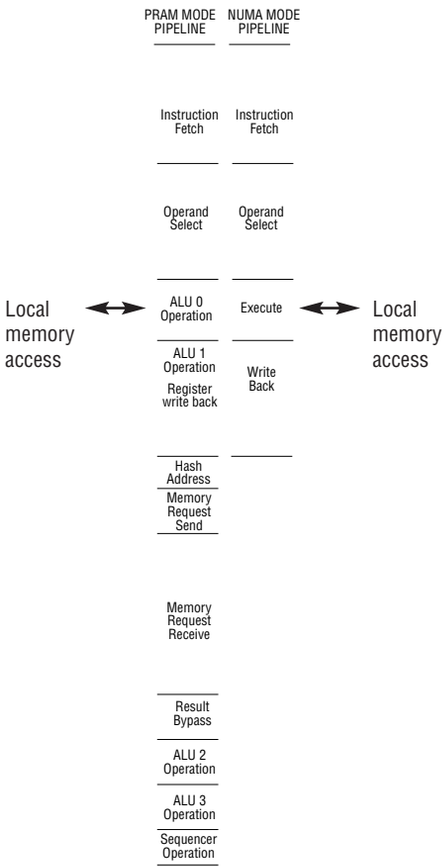

Figure 3. Pipeline for the local memory aware solution.

The local memory space of the CESM is easier to extend with techniques used in sequential computers than the shared memory. One can just provide each local memory with a standard memory hierarchy with multiple levels of caches like in the sequential machines. There will be no coherency problems since the local memories are distinct from each others assuming the standard NUMA model is used.

In theory it is possible to extend this technique to multiple local memory units per processor core but this would make the partitioning problem much worse.

3.2 Related work

To our best knowledge, this is the first attempt to add local memories to an ESM architecture. However, there exist some prior work for the ESM architectures as well as for the memory systems for them.

The shared memory emulation was first attempted in the late 70's soon after the PRAM model was introduced [Schwarz80, Gajski83, Pfister85]. These attempts, however left much room for improvements in performance, implementability and scalability. The second wave of attempts [Alverson90, Abolhassan03] included much more sophisticated techniques to address synchronicity and bandwidth constraints of existing parallel architectures. The current ESM projects include the TOTAL ECLIPSE [Forsell02a, Forsell10] and XMT [Vishkin11]. The former provides fully scalable sparse/multimesh interconnection network while the latter relies on low-latency mesh of trees network featuring link length proportional to square root of P divided by logarithm of P and thus having weaker scalability. They both aim to implement ESM as a *Chip MultiProcessor* (CMP) making use of the huge communication potential of on-chip networks.

The memory systems for ESM computers has been studied in the TOTAL ECLIPSE research line. Balancing the slow data memory access/cycle time with the processor clock rate is considered in [Forsell02b]. Providing sufficient bandwidth to the instruction memory in ESM is studied in [Forsell02c]. Active memory techniques supporting the partial and full multioperation support are considered in [Forsell05] and [Forsell06], respectively. Local memories are used in many commercial application-specific processors, e.g. DSPs, to improve the memory bandwidth.

Intercommunication belonging to essential parts of memory systems of ESM computers is considered in a wide variety of studies. For a summary of the work done before the year 1996, [Leppänen96] reviews communication solutions that can be used for PRAM realization. Our recent study [Forsell11b] evaluates the bandwidth, silicon area, and power consumption of various sparse networks, e.g. sparse meshes, making use of multidimensional embeddings. Various aspects of memory systems in ESMs making used of networks on chip are studied in [Forsell11c].

4. Methodological considerations

Widely used distinction between shared and thread-private data is the key mechanism for simple exploitation of the local memories in the PRAM mode. In the following we will take a look at needed language and compiler support.

4.1 Language support

Most parallel programming languages make use of the concept of sharity of a variable. The two most popular forms of sharity are shared and private. A *shared* variable is accessible by all the execution threads while a *private* variable can be accesses only by a single thread for which it is declared. The former raises the question of concurrent access models in synchronous architectures and exact timing and order of accesses in asynchronous architecture. In the synchronous PRAM mode of a CESM architecture a programming language could make use of this distinction to provide a natural partitioning of data to global and local memories. With these assumptions, programming the proposed CESM architecture with a high-level parallel language happens exactly in the same way as that of the baseline CESM machines. Explicit assembler programming is a bit more difficult than that of the baseline machine since one must assign data to corresponding global and local memory units explicitly.

Consider functionality computing the *prefix sum* of a vector of integers. With the high-level e-language, it can be easily implemented for the PRAM mode of CESM (see Figure 4a). The compiled version with explicit memory operation assignments is shown in Figures 4b and 4c. Since global and local memory accesses can be made during a single step for each thread, the number of the instructions in the inner loop (L5_LF0) is reduced by 20%. The speedup is not higher in this case since the local variable data is stored in a register making the data storage always private.

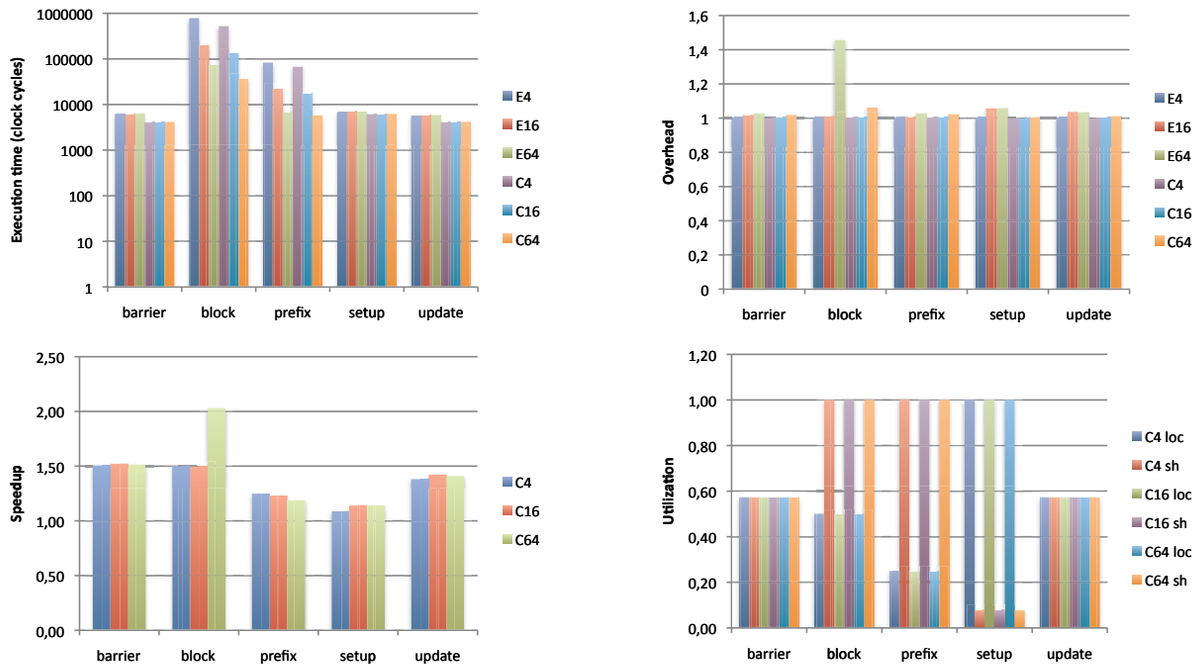

Figure 5. Execution time (top left), overhead with respect to ideal machine with the same instruction set (top right), achieved speedup (bottom left), and utilization of memory units (bottom right). Note that the problem size is proportional to the total number of threads in the architecture.

4.2 Compiling challenges

The compiling for the proposed architecture can be made similarly as for the baseline CESM. The challenge is to assign the correct memory operations to right memory units. This can be made similarly as in the virtual instruction-level optimization algorithm [Forsell03] but knowledge about the access space is needed. It should, however, be noted that this technique would provide only suboptimal results, since for the optimal reasons, full parallel alias analysis would be needed.

5. Evaluation

In order to evaluate the performance and utilization of the proposed local memory -aware technique, we applied it to the TOTAL ECLIPSE framework being developed at VTT [Forsell10].

5.1 Preliminary performance simulations

We measured the performance of the solutions outlined in Sections 2 and 3 by simulating execution of five benchmark problems representing important and widely used primitives of parallel computing and standard RTL (see Table 1) in six CESM CMP configurations having 4 to 64 512-threaded MBTAC processor cores featuring global memory only or both local and global memory aware memory systems in the PRAM mode (see Table 2).

The benchmark programs were compiled with the e-compiler, ec, with –O2 and –ilp optimizations on. The resulting programs were simulated with the IPSMSim tool modified for the proposed solution. The results of the simulations are shown in Figure 5.

5.2 Discussion

As expected, CMPs using the proposed memory system solution executed benchmark programs faster than the baseline CMPs assuming that both private and shared variables were used. The individual speedups ranged from 8.7% to 202% while the average speedups were 34%, 36% and 46% for C4, C16 and C64, respectively. The results are close to that of the 40% rule-of-thumb (characterizing typical benefit of an additional memory unit). The overheads with respect to a similar machine with ideal memory system were less than 1% in average in the proposed machine. This is only one fifth of that in the baseline machine. The main reason for this is reduced traffic in the inter-communication network since the private data accesses are targeted the local memories. The selected benchmark set showed quite different kinds of memory patterns, some providing equally high utilizations for both local and shared memory units, while two had more shared memory accesses than local memory accesses and one benchmark had more local memory accesses than shared memory accesses.

6. Conclusions

We have described adding/making use of local memories to CESM processors for storing thread-private data in the PRAM mode for performance and safety reasons. While this kind of solutions typically introduces a partitioning problem, most parallel computing languages make use of the concepts of shared and private data that provide natural orthogonal partitioning of data to global and local subspaces. According to our evaluation, the performance increases 40% in average while individual speedups range from 8.7% to 202%. The hardware implementation of the proposed solution is very simple since the CESM

architecture provides the local memories and memory units for the NUMA mode operation anyway.

Our future work includes implementing an FPGA prototype of the CESM making use of this technique. We will also study possibilities to implement compiler support for automatic assignment of right data to rights units/memories.

On Maximizing Resource Utilization for Simultaneous Multi-Threading (SMT) Processors by Instruction Recalling*

Yilin Zhang Caleb Douglas Wei-Ming Lin

The University of Texas at San Antonio
San Antonio, TX 78249-0669, USA

Abstract— *Simultaneous multi-threading (SMT) has been a very popular design in improving resource utilization by sharing key datapath components among multiple independent threads. When critical resources are shared by multiple threads, to effective use of these resources proves to be the most important factor in fully exploiting the system potential. Allowing any of the threads to overwhelm these shared resources not only leads to unfair thread processing but may also result in severely degraded overall performance. How to prevent idling threads from clogging the critical resources in the pipeline becomes a must in sustaining system performance. In this paper, we show that, if one can manage to recall instructions of idling threads from Issue Queue (IQ), a very important shared resource in the SMT pipeline, the system performance is easily enhanced by a significant margin. An even more noteworthy feature about this technique is that the ensuing hardware overhead is very insignificant and its effect in clock timing also is negligible. The feature proposed in this paper can also be easily coupled with other advanced techniques employed in other stages of the SMT pipeline.*

Keywords: SMT, Instruction Recalling

1. Introduction

Simultaneous Multi-Threading (SMT) offers an improved mechanism to enhance the overall performance by exploiting Thread-Level Parallelism (TLP) [1], [2] to overcome the limited of Instruction-Level Parallelism (ILP), based on the traditional superscalar processors. The most common characteristic of SMT processors is the sharing of key datapath components among multiple independent threads, which ensures improved resource utilization. Subsequently, due to the sharing of resources, the amount of hardware required in an SMT system is significantly less than employing multiple superscalar machines while achieving similar performance.

Due to the requirement in resource sharing (those resource that are cost-wise better to share such as Issue Queue, functional units, etc.), these hardware components tend to remain busy in order to accommodate more instructions from all threads. Although allowing these instructions to share these resources ensures the full performance potential afforded by SMT [13], it tends to induce extra control complexities in managing the critical timing path and the processors cycle. To retain the exploitation of both TLP and ILP, a necessary solution must be introduced in order to minimize the complexity among these shared resources without affecting the ILP exploitation significantly. At the same time, an appropriate level of intelligence has to be incorporated into the resource sharing mechanism to ensure that threads share these components in the most efficient and fair manner.

Recently there have been many research activities targeted in improving SMT performance through modifying various stages in the pipeline. These include: improvement of thread co-scheduling by using probabilistic modelling for prediction in [8], avoiding register allocation by predicting transient values from branch misprediction in [3], packing instructions in issue queue to reduce delay and power consumption in [14], improving SMT fetching with an estimation of outstanding work in the system for each thread in [18], early deallocation of registers in association with cache misses in [12], dynamically reconfigurable cache design for better IPC in [6], a modified fetch policy with adaptive resource partitioning in [19], and another fetch policy by considering memory-level parallelism in [7]. None of these techniques specifically addresses the contention in the issuing stage and most come with a significant requirement in extra hardware to implement the desired intelligence.

In this paper, we show that, if one can manage to recall instructions of idling threads from Issue Queue (IQ), a very important shared resource, potential clogging from threads that are temporarily idle can be drastically relieved, and the system performance is easily enhanced by a significant margin. An even more noteworthy feature about this technique is that the ensuing hardware overhead is very insignificant and its effect in clock timing also is negligible. This technique can also be paired with all the techniques aforementioned in the literature which emphasize on other stages of pipeline to further improvement the performance.

2. Instruction Dispatch

There have been many different terminologies adopted for instruction pipelining stages (e.g. issue, dispatch, etc.) in a superscalar system. Throughout this paper, we choose to adopt the terminologies used by most SMT articles, which is also showed in Figure 1.

In a typical single-thread superscalar system, instructions are "dispatched" from ROB into the reservation stations (either centralized or functional unit-specific) whenever space is available and then "issued" to the corresponding functional unit whenever the issuing conditions are met, i.e. operands are ready and the requested functional unit becomes available. However, in a basic SMT system, each thread has its own ROB and instructions from these thread-specific ROBs have to "compete" for a shared Issue Queue (IQ) through a dispatching scheduling algorithm. This IQ can be considered as Centralized Research Station not only shared among the functional units but also shared among the threads in real time. A basic functional block diagram of this basic design is depicted in Figure 1.

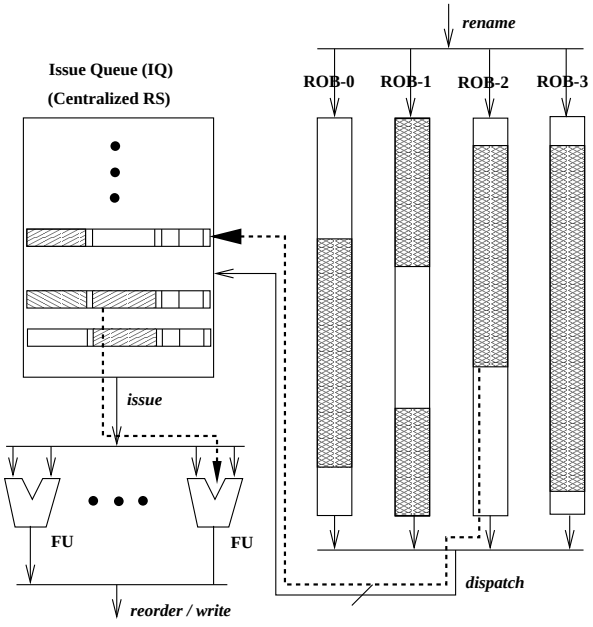

Fig. 1: A Simple Four-Thread SMT Instruction Processing Flow

Due to the significantly large size of each IQ entry, the number of entries in this shared resource usually is much smaller than the number of ROB entries. Having its output sent into a tightly shared resource, the instruction dispatch stage is considered one of the most critical stages that dearly affect the overall system performance.There have been many non-adaptive dispatching algorithms proposed, including simple round-robin, within-clock-cycle-round robin [5], and some other techniques intend to exploit ILP by scheduling instructions to be dispatched from ROB, which relies on simple instruction-level readiness to reduce the instructions' waiting time in IQ [15]. To better utilize the shared IQ entries, instructions from different threads should be given different priorities depending on the threads' "activeness" in real time. Threads have been shown to demonstrate various types of transient behaviors throughout their life span, including stretches of time durations with fluctuating ILP. Instructions from thread(s) of lower ILP (or simply "slower" in instruction issuing) would clog the IQ if they are allowed to continue to be dispatched into IQ. On the other hand, instructions from higher ILP (or simply "faster" in instruction issuing) should be given a higher priority in utilizing the IQ. There have not been many research results on how to share the IQ in a more time-adaptive manner allowing different threads to utilize (occupy) the IQ in an "on-demand" basis. In [11], an adaptive technique is proposed to allow each of the ROBs to be "partially" used to accommodate threads that are not as active, in which "activeness" of a thread is based on a ratio between number of issue-bound and commit-bound instructions in a thread's ROB. Other more advanced scheduling techniques, such as the one presented in [20], combine more information from different stages in the pipeline to optimize the scheduling/dispatching result, albeit requiring significantly more hardware and control logic.

Our analysis shows that the activeness of a thread can be fluctuating very unexpectedly in time due to cache misses, branch miss-predictions, write port latencies, etc. A thread that has been active can suddenly become "inactive" and stay "idle" in the pipeline for a long duration of time. To make it worse, these threads that have been just recently more active (than other threads) tend to occupy more shared resources (e.g, the IQ) than others. When these threads suddenly become inactive, the shared resources typically cannot be released for other threads to use, mainly due to various system or operating limitations inhibiting it from doing so and consequently limit the potential performance. Besides, to further improve the system resource utilization at this level of high-speed instruction processing, one cannot afford employing any design that involves too much intelligence for real-time implementation.

In this paper, we choose to retain the per-thread ROBs without any sharing among them, and rely on a simple scheduling algorithm in dispatching instructions from different threads. The basis for performance comparison in this paper will be with a more advanced round-robin dispatch scheduler in which all threads take turn dispatching at most one instruction in its own turn during a clock cycle until the bandwidth is consumed. The average and Harmonic mean of IPC will be compared to see the improvement.

3. Simulation Environment

The simulation environment including the simulator and the workloads used for our simulations are first described in this section.

3.1 Simulator

We used M-Sim [10], a multi-threaded micro architectural simulation environment model, to estimate the overall performance of the proposed scheme. M-sim includes accurate models of the pipeline structures such as explicit register renaming, concurrent execution of multiple threads, detailed power estimation using Wattch framework [16], separate Reorder Buffer, and Load-Store Queue (LSQ) which are necessary for an SMT model. The Issue Queue and execution functional units are shared among the threads, but register files and branch predictor is exclusive to each thread. The detailed processor's configuration is shown in Table 1.

Parameter	Configuration
Machine Width	8 wide fetch/dispatch/issue/commit
L/S Queue size	48-entry Load/Store queue
IFQ size	32-entry Instruction Fetch queue
ROB& IQ size	as mentioned
Function Units & Latency (total/issue)	8 Int Add (1/1) 4 Int Mult (3/1) / Div (20/19) 4 Load/Store (2/1), 8 FP Add (2) 4 FP Mult (4/1) / Div (12/12) / Sqrt (24/24)
Physical registers	256 integer and floating point
L1 I-cache	64KB, 2-way set-associative 128 byte line
L1 D-cache	32 KB, 4-way set-associative 256 byte line
L2 Cache unified	2 MB, 8-way set-associative 512 byte line
BTB	2048 entry, 2-way set-associative
Branch Predictor	2K entry gShare 10-bit global history per thread
Pipeline Structure	5-stage front-end (fetch-dispatch) scheduling (for register file access: 2 stages, execution, write back, commit)
Memory	64 bit wide, 200 cycles access latency

Table 1: Configuration of the Simulated Processor

3.2 Workloads

For multi-threaded workloads, we use the mixed SPEC CPU 2000 benchmark suite [4], [9], [16] based on ILP classification. Each of the benchmarks is initialized in accordance with the procedure mentioned in Simpoints tool [17] and then up to 100 million instructions are simulated in a simple scalar environment. As shown in Table 2, three types of ILPs - low ILP (memory bound), medium ILP and high ILP (execution bound) - are identified, and 12 mixes of multi-threaded workloads are used based on different combinations of ILP types.

Mix	Benchmarks	Classification (ILP)		
		Low	Med	High
Mix 1	swim, locus, galgel, twolf	0	0	4
Mix 2	locus, galgel, twolf, applu	0	0	4
Mix 3	equake, vpr, mesa, ammp	0	4	0
Mix 4	vpr, mesa, ammp, gap	0	4	0
Mix 5	gcc, perlbmk, crafty, mgrid	4	0	0
Mix 6	crafty, mgrid, apsi, bzip2	4	0	0
Mix 7	crafty, mgrid, lucas, galgel	2	0	2
Mix 8	gcc, perlbmk, twolf, applu	2	0	2
Mix 9	apsi, bzip2, equake, vpr	2	2	0
Mix 10	mgrid, apsi, ammp, gap	2	2	0
Mix 11	swim, lucas, vpr, mesa	0	2	2
Mix 12	twolf, applu, ammp, gap	0	2	2

Table 2: Simulated Multi-threaded Workload

4. Proposed Method

In a typical SMT system, a shared IQ (Issue Queue), which is used as a set of centralized reservation stations for all functional units, is required to hold all the necessary information for instructions. Thus, further increasing the number of entries in the shared IQ usually is hampered by the cost factor, and therefore the utilization of these limited resources becomes very critical to the overall system performance.

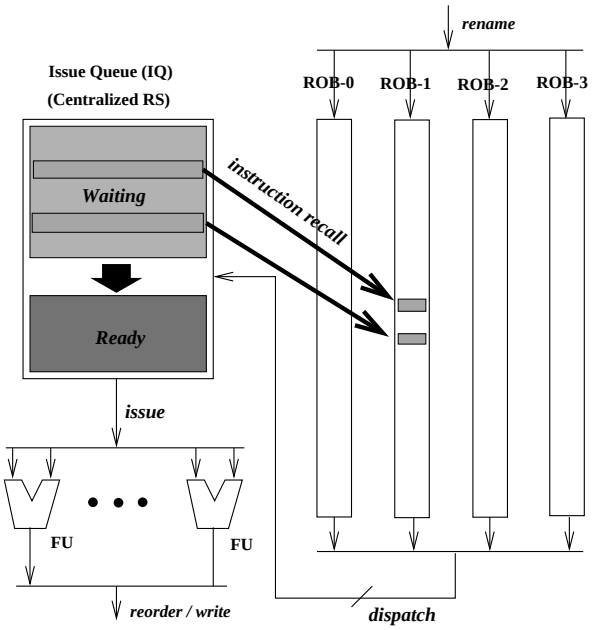

Fig. 2: Instruction Recalling

Once an IQ slot is allocated to an instruction, all known architectures will allow it to stay in IQ until it eventually becomes ready for execution, even it may take hundreds of clock cycles. Our proposed technique instead will recall such an instruction if the owning thread shows a sign of inactiveness. Figure 2 shows a simple illustration of such instruction recalling. Since a dispatched instruction recalled

is still in ROB, recalling it actually involves setting/resetting a flag in each of the two entities, one in the IQ entry and the other one in the original ROB entry. This process essentially re-declares the IQ slot to become available (empty) and resets the instruction in ROB to become "yet-to-dispatch". To determine whether a thread is "inactive" may require some extra intelligence incorporated into the system. Any of the operands that have become ready after the instruction was dispatched can be easily re-established (read) again when the instruction is dispatched again.

4.1 Motivation

The proposed technique is based on the conjectures that, if IQ is not properly managed, instructions do stall in IQ for a long period of time, its imbalanced occupancy scenario among threads does exist. This section will be devoted to the discussion to support these conjectures.

4.1.1 IQ Occupancy Latency Analysis

We first look into behavior of instructions after they are dispatched into the IQ; namely, how long they stay in IQ and how long it takes for them to become ready for issuing to the corresponding functional units. Figure 3 shows the cumulative percentage of instructions that spend in IQ for at least the given number of clock cycles, where R is used to denote the number of ROB entries and q is the size of IQ used. As Figure 3 shows, close of 30% of instructions

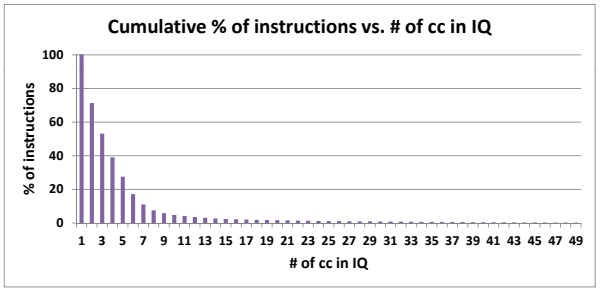

Fig. 3: IQ Latency Cumulative Distribution with $(R, q) = (96, 24)$

encounter an IQ latency of at least 5 clock cycles, and there are a significant number of instructions that get stuck in IQ for a long period of time, e.g., about 1% of instructions spend more than 30 clock cycles in the IQ. These IQ slots could have been better used if these instructions can be recalled after their latency exceeds a certain threshold.

4.1.2 Per-Thread IQ Occupancy Analysis

Another scenario we want to look into is how exactly the IQ may be dominated by a single thread among the threads in SMT processing. Figure 4 shows the average percentage of time (out of the 12 mixes used) that at least one thread is occupying at least the given number of IQ entries. This

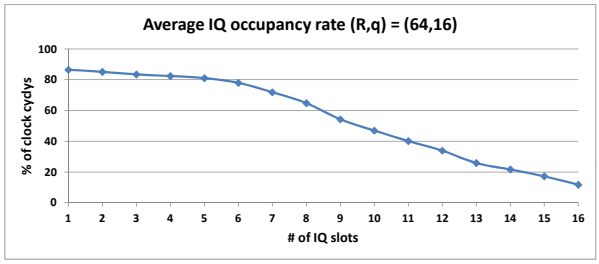

Fig. 4: Average IQ Occupancy Rate

clearly shows that on the average in over 60% of clock cycles there is at least one thread occupying more than 50% of IQ slots, and three quarters of resources are tied up by one thread in over one third of time. Once such a dominating thread somehow becomes "inactive", the consequence can be significant.

4.2 IQ Instruction Recalling

One straightforward method in effectively using the IQ is to allow the slots that have been occupied by stagnant instructions to be freed for other instructions. To "correctly" classify whether an instruction (or more specifically its owning thread) is considered "stagnant" may require an intelligence too expensive or too execution-time-critical to implement. We choose to simply set a time threshold for a thread to be considered "inactive" (or "blocked") when this thread has not (1) any of its instructions in IQ become "ready" and (2) any of its instructions committed during this time period. The complete algorithm is depicted in Figure 5. This threshold is referred to as "Cycles-of-Stall-to-Blocked" (CSB). Such a condition is chosen due to the consideration that a blocked thread usually displays one or both of the two symptoms. In our algorithm, once a thread reaches this threshold value, all its instructions in IQ that are not ready for issuing will be recalled. This condition-checking step is shown in the flowchart as "stall_cc==CSB?". As aforementioned, the recalling process of an instruction involves two simple logical operations: resetting the "free" flag of the IQ slot back to "1" (yes), and resetting the "dispatched" flag of the instruction in ROB to "0" (no). This thread, once recalled, will not be allowed to dispatch again until (1) it starts resuming instruction committing, or (2) a time-out is reached. If a thread so-declared "blocked" starts to commit instructions again, then most likely the condition that rendered this thread stagnant is resolved. On the other hand, there may exist situations that a thread simply does not have any instruction dispatched in the system after the recalling and thus will not be able to resume the active status by committing an instruction. In such a case, this time-out is a necessary mechanism for the thread to have a chance to become active again, even it may not be ready yet. Such a time-out value will be referred to as the "Cycles-of-Blocked-to-Reactivate" (CBR) value. In the flowchart this time-out is

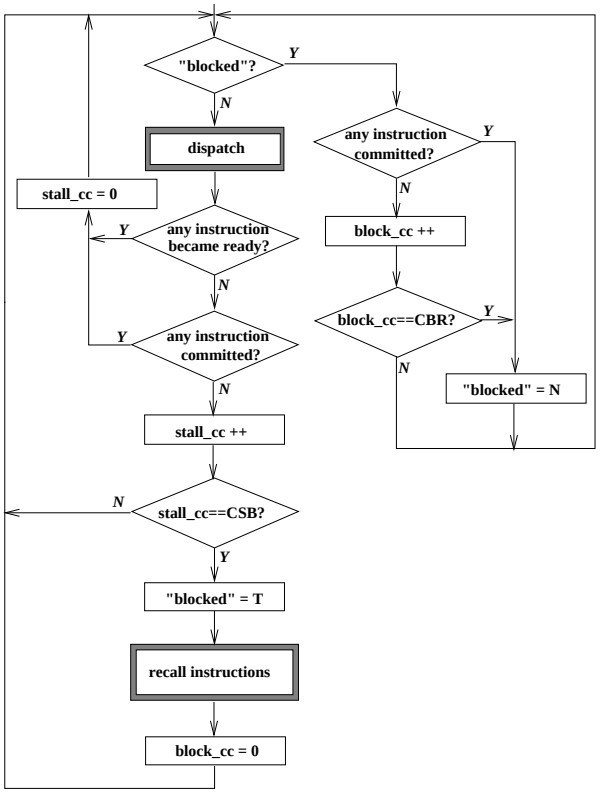

Fig. 5: Instruction Recalling Algorithm

checked with the "block_cc==CBR?" condition.

Note that the selection of CSB value and CBR value greatly influences the effect of this technique in improving the overall performance. A too small CSB value will lead to unnecessary recalling which will be a waste of resource, while a too large CSB value will diminish the effect of this technique. Similarly, the adoption of a proper CBR also may have a significant impact on the performance. A too small CBR will dampens the effect of recalling and a too large CBR will jeopardize specific thread from effectively using resource. One should suspect there should be a pattern of matching CBR and CSB leading to best resource utilization, which will be discussed in our simulation results.

5. Simulation Results

Based on the simulation environment and workloads described in Section 3, our proposed technique is tested compared to the default dispatching system. An average of overall performance from 12 mixes as described in Section 3.2 is used for presentations. Figure 6 shows the average IPC improvement percentage values when different CSB values are applied, with the reactivation delay CBR fixed at 20 clock cycles. Three different combinations of ROB size (R) and IQ size (q): $(R, q) = (128, 32)$, $(96, 24)$ and $(64, 16)$ are tested. From this chart, one can tell among the three (R, q) combinations the one with the smallest IQ

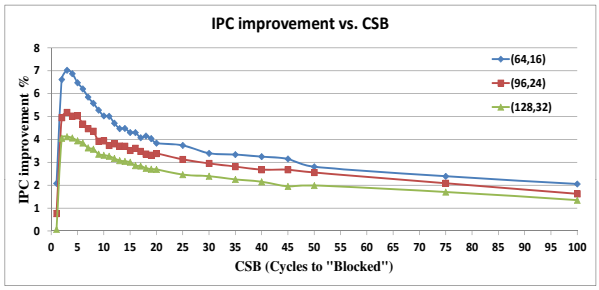

Fig. 6: IPC Performance Improvement by Using Instruction Recalling

size leads to the best improvement, up to 7% in average IPC. The larger the IQ size is the smaller the improvement is obtained. This scenario can be easily explained by the more critical effect of our instruction-recalling technique on a smaller IQ than on a larger one. Also note that no matter what combination of (R, q) is used, the best improvement in IPC happens when the CSB values is set to about 3 or 4. The fact that the "optimal" CSB value is so small indicates that the benefit from recalling more instructions (with a small CSB value), even though these instructions may not be exactly "blocked", may clearly outweigh the loss in dispatching capacity utilization due to the recalling. When the CSB value is set to an even smaller value, the effect of loss quickly diminishes the benefits.

Comparison of individual IPC values for each mix between the default and the proposed techniques is presented in Figure 7, with $(R, q) = (64, 16)$ and (CSB, CBR) =(4,20). From these results, the proposed technique consistently leads

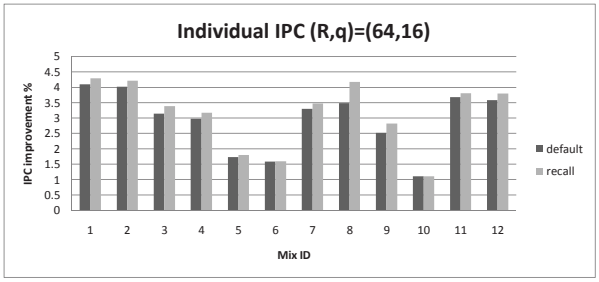

Fig. 7: IPC Performance Comparison for Each Mix

to improved IPC over the default technique throughout all mixes and all combinations of queue sizes, with improvement percentage up to 20% on some mixes.

To further demonstrate that overall IPC improvement achieved by the proposed technique does not jeopardize the fairness of threads' execution due to the recalling process, Figure 8 shows the harmonic mean IPC values for all mixes between the default and proposed techniques when $(R, q) = (64, 16)$. The formula used to calculate the harmonic mean follows the standard definition in $H = n / \sum_i^n \frac{1}{IPC_i}$, where n is the number of threads in this case. From these, one

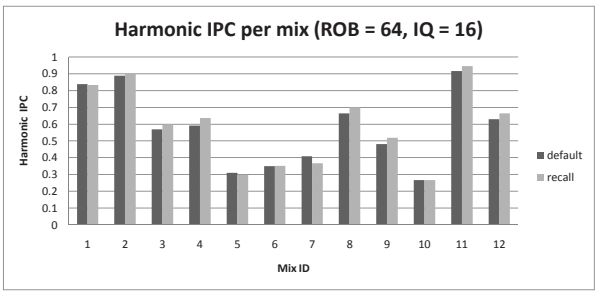

Fig. 8: Harmonic IPC Performance Comparison for Each Mix

can tell that the improvement on the overall IPC from the proposed recalling process not only does not lead to any imbalance among the threads but mostly incurs positive effect (up to 8% in improvement) in raising individual IPC for all threads.

From Figure 6 we can tell that the impact of setting a proper CSB value and it shows that the optimal CSB value stays very consistent throughout different combinations of buffer sizes, (R, q). Figure 9 shows the impact of CBR on overall performance when CSB is fixed. When the CSB

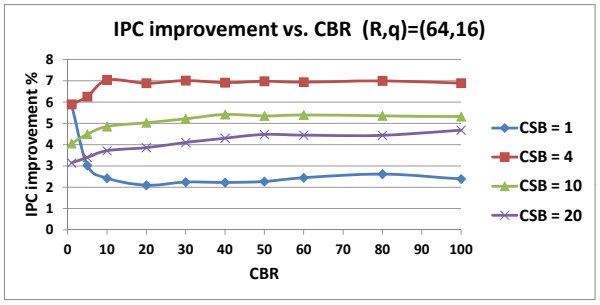

Fig. 9: IPC Performance versus CBR

value is set to the optimal value of 4, the IPC performance stays relatively unchanged once the CBR is set to be more than 10. It is reasonable because most threads can reactive themselves by resuming committing, thus a large CBR affects very little on the performance. However, if the CSB is set to a very small value, e.g., 1 as shown in the figure, the IPC drastically suffers once the CBR is set to a value higher than 1. This can be explained by the fact that with such a small CSB, a lot of instructions are unnecessarily recalled, and if these instructions are not re-dispatched soon again (under a larger CBR value), then the performance degrades easily. From this result, one can tell that the selection of CSB is much more critical than selecting CBR as long as the latter is not set to a value too small.

One analysis that can somewhat reveal the true impact of the proposed recalling technique is on the percentage of all executed instructions that have been recalled. Figure 10 shows this percentage value when a different CSB threshold is adopted. One can see that less than 3% of dispatched

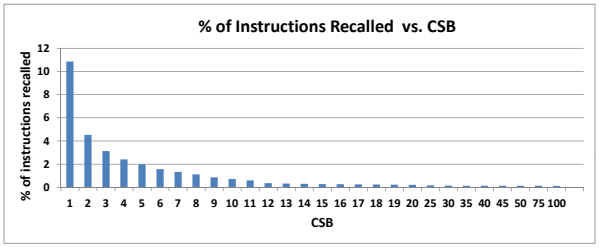

Fig. 10: Percentages of Instruction Recalled vs. CSB

instructions are recalled when the CSB value is set to at least 4, and only about 11% of instructions are recalled when CSB is set to 1.

Out of all the instructions dispatched that are recalled, some of them actually are of the same instructions that are recalled multiple times. The next analysis is to see, among all the instructions that are recalled, how often an instruction is recalled multiple times. Figure 11 shows the percentage of instructions that are recalled a given number of times with different (CSB,CBR) patterns. The figure

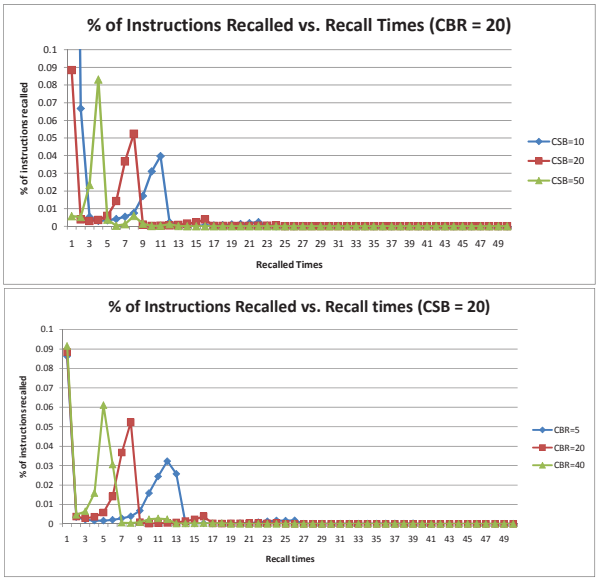

Fig. 11: Percentages of Instruction Recalled vs. Recalled Times under Different (CSB,CBR) Patterns

shows a very interesting pattern in having a clear spike indicating that some significant number of instructions are recalled a somewhat specific multiple times, and this specific number depends on both the CSB and CBR value. A close investigation into these patterns reveals that

$$p \times (\text{CSB} + \text{CBR}) \approx C \tag{1}$$

where p is where the peak appears at, when multiplied by the total cycles for each repeated recall, the product is

approximated by a constant C, in the range of 250 to 300 in all cases.This somewhat constant value corresponds very close to the cache miss penalty. This indicates that this peak corresponds to the group of instructions that were delayed by a cache miss situation. Based on this observation, extra intelligence can be further incorporated into the system to specifically detect the occurrence of a "blocked" situation due to cache miss and subsequently set a proper CBR value to prevent redundant repeated recalls of the same instructions from the thread.

To further analyze the effect of recalling on the IQ occupancy rate, the average per-thread IQ occupancy analysis is performed again when the recalling technique is applied, similar to the one shown in Figure 4. Figure 12 displays the comparison. Note that after the recalling technique is

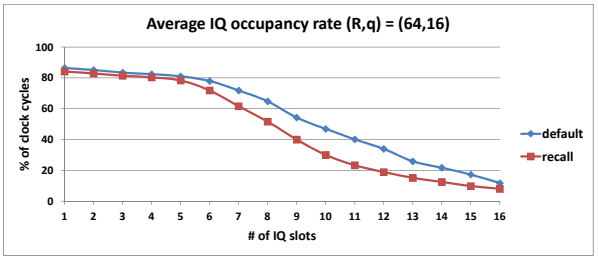

Fig. 12: IQ Occupancy Rate Comparison

applied, the "blocking" from a thread in IQ is not as severe – there was about 65% of clock cycles in the default case that at least one thread takes up more than half of the IQ slots, and, with the recalling, only about 51% of time such a situation happens. Three quarters of slots were occupied by a thread in 34% of time, while it is reduced to about 19% by the recalling method. This analysis clearly shows the effect of instruction recalling in relieving the IQ blocking.

6. Conclusion

This paper clearly demonstrated that utilization of resources shared among the threads in an SMT system could significantly affect the overall performance. By recalling idling instructions from the critically shared resources, overall performance can be vastly improved without sacrificing fairness of execution among the threads. In addition, such an improvement is achieved without having to invest much extra hardware or imposing extra constraints on the clock rate. Incorporating further intelligence into such a recalling process will likely improve the performance more while one would need to justify the potential in leading to excessive hardware requirement.

Abstract: *This paper reviews the history and current use of multi-threading in software development. Over the last decade, there has been a complete paradigm shift in computer hardware. Currently, increased computing power is supplied using an increasing number of core processors. This paradigm shift has led to the development of higher level programming constructs and frameworks in many popular languages. Therefore, it is clear that both the hardware and software of the future are going to be based heavily upon concurrency. Despite this, software developers are still resistant to embrace multi-threading. This resistance is understandable due to the complexity of coding concurrency. However, this paper proposes that Concurrency is no longer an option but a necessity. In conclusion, the paper presents a case study based on the visualization of large quantities of Neurophysiological data. This application was developed using the Java concurrency framework.*

1. Introduction

During the early days of Computing, there was a considerable difference between the operating speed of CPUs and the speed of connected peripherals. Back then, CPU time was expensive, thus it was highly inefficient to pause the execution of a program to enable the execution of a slower input/output peripheral.

The first attempt to address this problem was the LEO III (Lyons Electronic Office) developed in 1961. LEO III employed the first multiprogramming system [1] which enabled a batch of programs to be loaded into the CPU simultaneously thereby essentially queuing for CPU time. In this system, the first program would execute until it reached an instruction which required the use of a peripheral device. At this point, the context of the first program would be stored thereby enabling the next program to execute. Subsequently, the use of CPU time was maximised. The main limitation of this system was that it required multiple programs to maintain this level of CPU usage. Nowadays this would be recognised as a problem of granularity, the executing units were too large to maximise the CPU usage.

The limitations of multiprogramming became obvious as computer systems moved from batch processing to interactive use. Multiprogramming was not capable of delivering well designed systems. One of the key benchmarks for well-designed systems was the set of "Golden rules" defined by Shneiderman [2]. These rules were, and still are, widely adopted throughout the industry. They emphasise the importance of providing "informative feedback" to the user.

Initial attempts to provide interactive feedback to users involved the co-operation of software developers. This was known as co-operative multitasking. This relied on developers ensuring their applications yielded CPU time to other applications.

Initially, this approach was successful. The earlier versions of Windows (prior to Windows 95) and the Mac operating system (prior to MAC OS X) employed co-operative multitasking [3, 4]. Whilst co-operative multitasking was increasingly deployed as a multitasking solution, another option called pre-emptive multitasking evolved.

In contrast, pre-emptive multitasking paradigm provides slices of CPU time to each of the executing processes. Effectively, this enforces the sharing of the CPU time. This implicit guarantee of CPU time enables developers to provide user with well- designed systems capable of proving "informative feedback" quickly. In 1969, this approach was selected for use in the UNIX operating system. It is standard in UNIX and its derived operating systems [5].

By the mid 1990's, Microsoft Windows had adopted the pre-emptive multitasking system incorporating it into both Windows NT and Windows 95. Apple Inc. followed suit with the MAC OS 9.x, released in October 1999.

2. The Pre-emptive Model

In the pre-emptive model, processes are separated into two categories:

- I/O Bound processes where the total computation time to complete the process is limited by the speed at which data can be requested and delivered [6]. Typically processes that make long read / write operations to disk would be I/O Bound and
- CPU Bound processes where the total computation time to complete the process is limited by the operating speed of the CPU. Typically a process that primarily 'crunches numbers' will be CPU bound.

This blocking mechanism enables the CPU time being consumed by these "waiting" processes to be re-allocated to processes in the CPU bound category. This continues until an interrupt signals to the I/O bound process that the blocked process can proceed.

As this pre-emptive model evolved, programmers began to develop applications as a collection of interacting (co-operating) processes. In turn, this raised the issue of how to efficiently share data between multiple processes. As originally conceived, a process ran in its own protected memory space isolated from other processes. However, this was not conducive to data sharing. The solution was that co-operating processes should share the same memory space. This approach would become known as multi-threading with multiple 'threads of execution' sharing a single processes memory space.

2.1 The paradigm shift from Moore's Law to Amdahl's law

Moore's Law states that the power of computer processing would double approximately every two years. Since its formulation in 1965, this law has provided a reliable guide to the growth of computing power. This predictable growth in computing power has been quietly exploited by software engineers worldwide. Until now, developers have enjoyed ever faster performance from their software simply by updating to newer hardware. However, it is proposed [7] that Moore's Law cannot be sustained as physical limitations for miniaturisation are encountered. Conversely, it is argued that advancing technologies will enable the law to survive far into the future [8].

Regardless of these opposing opinions, developers must consider how current and future technologies will deliver computing power. It is clear that hardware manufacturers have moved to the idea of delivering computer power through multi-core systems. Almost all forms of computer now employ multi core hardware as standard. This ranges from the mobile phone through to desktop computers of major research projects. Whilst considering highly compute intensive operations such as weather forecasting, computing power is now delivered by massively parallel super computers, grid computing and the opening of graphics processing cores for general non-graphical use (for example using Nvidia's CUDA) is becoming more widespread in research. Yet, it is still not enough.

Consequently, another law is now dominating the current expansion of computer processing and throughput. This is Amdahl's law which describes the performance increases that can be achieved through the parallelisation of software. Essentially a program is divided into two portions, the parallelisable and the sequential components. Additional compute cores will improve the execution speed of the parallel component of the program but these will have no effect on the sequential component [9].

2.2 Recent developments in hardware

In the last decade computer power has expanded based on the development of multithreaded execution architectures as well as the delivery of additional power using multicore systems. However, this increased processing capability can only be realised when software developers change their programming styles to exploit this new paradigm. Fundamentally, the latest hardware advances are completely dependent on the understanding and adoption of these new techniques by software developers. David Stewart CEO of CriticalBlue and chairperson for the Multicore Programming Practices (MPP) working group comments on this situation stating that "There's capability in (multicore) platforms which is not being utilized or not being optimized by the software development community" [10].

Developers are often deterred due to the difficulty of using threads and locks to control access to shared memory. Goetz [11], a key developer of the Java languages Concurrency Framework, states "writing correct programs is hard; writing correct concurrent programs is harder." Indeed, this style of programming has "a well-deserved reputation for introducing bugs that are difficult to find and fix." [10]. Even Apple Inc. dismisses it stating that "the dominant model for concurrent programming - threads and locks - is too difficult to be worth the effort for most applications." [12]

Despite the difficulties Goetz notes that "threads are the easiest way to tap the computing power of multiprocessor systems". Furthermore, "as processor counts increase, exploiting concurrency effectively will only become more important" [11]. Therefore if the true power of multicore systems is to be realised, it is essential that the next generation of developers will have the tools and the training to address the difficulties of concurrent programming.

2.3 Recent developments in software

Over the last few years several mainstream programming languages have evolved to address the tools needed for concurrent programming. These tools provide

concurrency frameworks that allow developers to work with abstract concepts rather than the lower level threads and locks.

This trend is likely to continue. Intel is currently experimenting with the Intel Array Building Blocks (Intel® ArBB) framework that will integrate with standard C++ applications without any compiler specific extensions [13]. This would remove a major compatibility hurdle to developing C++ parallel code.

Table 1 shows a selection of the major coding languages that have released a concurrency framework over the last decade. Stack-less Python represents a significant fork of the language that has enjoyed commercial success and development support (via CCP Games Inc). The Java Concurrency Utilities merged a concurrency framework with cross platform support to produce a flexible and widely deployable solution. Microsoft's Task Parallel Library went a step further seeking the same goal for a whole range of languages supported by the .NET framework. While all of these were high level languages, Intel have addressed the lower level C++ language. Note that they too are now experimenting with a new more general solution than the existing Threading Building Blocks (TBB).

The development of frameworks to remove the complexity of task and thread management is essential to promote multi-threaded computation and ensure it is accessible to the software development community. This is very helpful. However, software engineers must also be able to able to design, debug, validate and optimise code. Tools to support all these area of software development are at an early stage of their development. Areas such as debugging and validation are challenging. Patterson [14] states that multi-threaded code is well known to be notoriously difficult to debug and validate. The non-deterministic behaviour of concurrent code and the dangers of deadlock as well as race conditions are well understood. Despite these challenges, the tools to detect such errors during development are only now beginning to emerge.

For example, it was 2008 when Intel announced the development of a dedicated package of software engineering tools called the Intel® Parallel Studio suite [15]. The package was released to the development community in May 2009 [16]. With such tools only just beginning to emerge most developers remain uncertain how to validate and debug parallel code beyond repeated testing and code inspections. Issues of code optimisation, identification of parallelisable code and its long term maintenance are seldom considered by most developers.

3. Future Trends

Over the next decade, parallelism in software development will become more important both in research and in commerce applications. Indeed, the development company, CCP based in Iceland, is already crediting its commercial success to Stackless Python [17]. With the preference for multicore architectures firmly entrenched with manufacturers, the demand for software to exploit its power is unavoidable. However, this raises one of the primary issues, namely that of training software developers to exploit the hardware capability. Many of the current generation of programmers seldom consider parallel execution of code. This is understandable as it has mirrored the underlying hardware (subject to processor time slicing providing an illusion of parallel execution).

However, the next generation of developers must embrace the harder task of parallel code development as 'standard practice'. To achieve this training programs both in universities and industry must to be updated to emphasize parallel coding principles and to introduce the software engineering tools that will support the design, implementation, validation and tuning of parallel programs.

3.1 Power and Environmental issues

Power has traditionally been seen as being in abundant supply, but this view is changing. The emergence of cloud computing has led to the formation of warehouse sized data centres that "are now consuming more energy than heavy manufacturing in the United States" [18]. Subsequently, this has led to political pressures (in light of carbon emission targets and taxes) to reduce energy consumption and waste.

Table 1: Concurrency Frameworks for major coding languages

Language	Frame-work	Re-lease Date	Source
Java	JSR 166: Concurrency Utilities	09/04	[19] Lea (2004)
.Net Frame-work (v4)	Task Parallel Library (available in all .Net languages)	04/10	[20] Microsoft (2010)
Python	Stack-less Python	01/00	[21] Tismer, (2000)
C++	Intel® Threading Building Blocks	08/06	[22] Reinders (2007)

One of the primary benefits of the multicore architecture is that such systems "feature more even power density and do not show dramatic temperature peaks" [23]; nevertheless "the power consumption of the basic multicore component is critical to its cost and operation" [18].

4. Case Study: Visualization of large Neurophysiological datasets

This case study of the VISA (Visualisation of Inter Spike Associations) software demonstrates that concurrent programming is already a necessity in current applications. This software is the main output of an established research VISA project at the Visualization Lab, University of Plymouth. The main aim of this research is to develop a new approach to the analysis of experimental data in neurophysiology based on the use of modern computer science techniques such as graphical engineering, visualization and virtual reality. This new approach will provide neuroscientists with an interactive environment within which to explore their data sets. The primary focus of this research is on the analysis of multi-dimensional spike train datasets.

4.1 VISA Project Goals

Due to increasing size of data, the VISA software was completely redeveloped to fully exploit the Java concurrency framework. It was essential for the software to maintain throughput in order to achieve three main project goals:

- To enable the Neurophysiologists to process exponentially larger datasets than earlier versions in order to manage current and future demand.
- To develop the software in a language that offered cross platform compatibility to enable easy distribution
- To target a "typical researchers computer" with the option to execute with increased efficiency and speed on more powerful systems.
- To introduce a workflow based interface loosely based on "visual programming languages". This workflow interface would enable users to control the ordering of data pre-processing operations. This would provide users with greater control over the types and ordering of pre-processing operations. Ultimately the goal is to enable users to create their own pre-processing code modules to fine-tune their workflows in the future

4.2 Spike train data

In general, a neuron accumulates electrical stimulus, from other neurons coupled to it, until some internal threshold is reached. Once its threshold is reached, the neuron initiates an action potential. When a neuron initiates action potentials over time, we say that the neuron is firing. Note that action potentials are more commonly referred to as spikes and a series of these spikes over time is known as a spike train. Spike train data is one of the main types of data collected during Neurophysiological experimentation.

Spike train datasets are records of the activity of a collection of neurons under investigation. It is well established that information is encoded in this data. In the VISA project, the spiking frequency and thus, inter-spike-intervals carry information. Therefore, research is focused on the analysis of multidimensional spike train data to uncover information about the synchronisation of spike trains and the connectivity of neurons.

4.3 Quantity of Data

VISA is currently in its third edition. The first two development cycles of the VISA project incorporated the development of a cross platform tool [24, 25].

When the project began, laboratories were typically recording from at most 64 electrodes simultaneously. This was deemed to be a very large amount of data and it was recorded using an 8 by 8 multi-electrode array. Currently, due to recent improvements in electrode hardware, Neurophysiologists are now able to routinely capture data using 4096 electrodes simultaneously. For example, the Plexon Array [26], can now record data for over 30 minutes at a sampling frequency of 7.702 kHz when matched with appropriate hardware.

With typical trials lasting anywhere from a few milliseconds to tens of minutes, datasets sizes have vastly increased. For example: During an experiment when recordings are taken from all 4096 electrodes sampling data every millisecond, a 30 minute trial would result in a data file of 10.43 MB with approximately 1 million data points.

4.4 Introduction to VISA

The VISA[3] interface is effectively a visual programming language which enables the user to create a workflow.

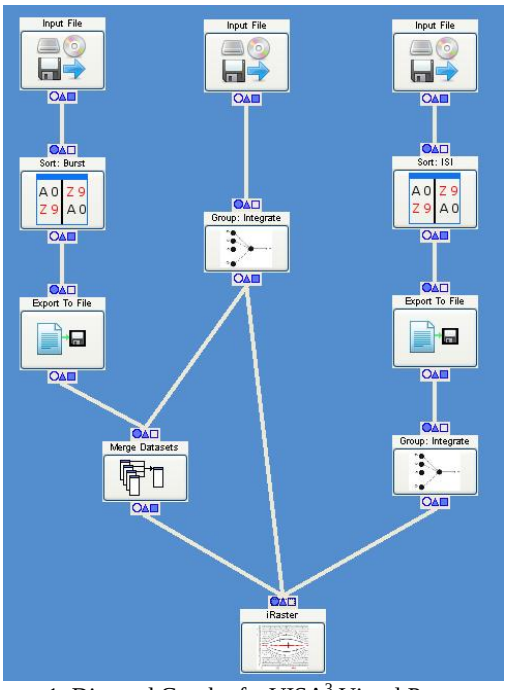

Figure 1: Directed Graph of a VISA[3] Visual Program

A workflow is a set of processes joined together. It is understood that such a programming model is naturally parallelisable; processes are able to execute as soon as all inputs are available.

A typical VISA[3] workflow is shown in Figure 1. This workflow shows 12 processes on the workflow interface. Note that these processes are selected by the user from a Toolbox and dragged on to the interface. These processes have parameters set by the user and they are connected together into the workflow as shown by dragging the mouse between process "ends". This workflow is dealing with three input files, two of which subsequently sorted and then exported to an external file. Eventually, all this data is visualised using the iRaster visualization.

The iRaster visualization enables the Neurophysiologists to investigate their data interactively using a traditionally-based raster plot representation. In addition to the functionality delivered by classical raster plot visualization, iRaster also provides the user with the following core functionality: data zooming methods, multiple views of data with view synchronization, and the contextual labelling of spike train identifiers and time points. iRaster also enables users to interactively and dynamically remove spike trains or time periods and to zoom in onto specific time periods to look at spike trains in greater detail. The software also provides an extensive list of spike train reordering functions. The majority of software tools currently available provide the usual static raster plots that are merely snapshots of the spike train data. In contrast, iRaster enables the user to interactively navigate through and directly manipulate spike train data, providing a dynamic experience of the data.

4.5 Concurrency in the VISA Interface

The key benefits of this interface are apparent. Scientists are not confronted with the need to learn a text based interface, the interface is designed to be intuitive.

The structure of the workflow, which may exploit parallel execution, is also apparent. If you refer to Figure 1, three sections of the workflow that could execute in parallel are obvious. Each process, such as the Import File process or the "Merge Datasets" process, represents a processing activity that may commence execution as soon as its inputs are available. The connections between various processes show the precise flow of data within the program.

Within the Java language, parallel execution is achieved through the concurrency framework. It operates as follows:

A 'pool' of threads each capable of executing a code module is created. Note this applies only to code modules that implement the concurrency frameworks 'Callable' interface. Pool size is dynamically determined based on the processors available on the executing machine but aims to optimise for CPU bound tasks. It is reasonable to assume that most tasks in VISA[3] will fall into this category.

At the beginning of execution the application determines all paths, through the directed graph, that comply with the requirements of the information processing cycle. Specifically this ensures that some input is received (usually from a data file), some processing is performed and finally some output is generated (typically a data visualisation module is triggered).

Each processing node of the directed graph is implemented as a "binary latch" [11]. This latch acts a synchroniser which simulates a gate that can only be opened once. Until the conditions for opening the gate are met, all threads reaching the latch will be unable to proceed. The latch will be converted into the terminal state once these conditions are met. In the case of VISA[3], the conversion requires all preceding operations to have completed and delivered a dataset to the waiting process. When the gate opens, all datasets from previous nodes are delivered to the next node and processing begins on that thread.

The datasets flowing through the directed graph are required to implement the VISA[3] interface IProcessingResult. Note that IProcessingResult is designed to wrap any data structure. Therefore, classes implementing this interface serve as the 'tokens' that drive the dataflow processing [27] and are placed onto the nodes input/output paths (triggering the 'latches' as required).

In addition to the development of a workflow interface, the Java Concurrency Framework was further leveraged to improve performance of the iRaster visualisation. As described in section 4.4, this visualisation provides an interactive raster plot of the spike trains.

The re-engineering of the visualisation was critical to maintain interactivity, due to the increase in dataset size. The original implementation typically worked with several hundred spike train recordings simultaneously whereas the new version works with thousands. Note that scientists are particularly keen to embrace this software as their traditional means of analysis do not scale.

4.5.1 Exploiting multiple-cores in VISA

Maintaining the responsiveness of an interactive application while filtering and processing this amount of data is challenging. Given this complexity, effective use of computing power in the rendering and display of the raster plot is essential. Recall that it has already been established that future increases in computer power will be delivered through multiple compute cores. The Java Concurrency Framework provides a natural means to access and manage this increased computing power in the future.

To exploit multiple cores, the VISA[3] data model was redesigned as a set of thread safe classes that could be shared across multiple executing tasks in the Concurrency Framework. The iRaster visualization process was designed using the model, view, controller design pattern with the synchronisation of shared data occurring in the model. Subsequently, the rendering could easily be adapted for parallel execution.

This required a concurrent task that accepted a screen area and spike train to render within the area. Therefore, rendering the display focuses on the individual components of the data model that are to be shown as well as generating a collection of concurrently executable tasks. A latch is again employed to ensure the various tasks complete before the final display is presented. The raster chart is then cached with re-rendering occurring only as data is filtered into/out of the display. Interactive components, such as selection highlights, scale sliders, are sequentially rendered over the cached chart.

4.6 Future VISA3 Development plans

The workflow interface and the iRaster visualisation have clearly demonstrated that parallel execution of data pre-processing and visualisation activities can scale the application to 2000+ data recordings each with thousands of data points while maintaining responsiveness. There are now two primary tasks. The first task is the conversion of the iGrid visualisation [24] to use the Java Concurrency Framework to enable the new larger datasets to be visualized in this way. This will enable the popular visualization iGrid to exploit multicore processors, thus enabling the visualization of new, larger datasets. This is challenging as iGrid is based on the production of numerous cross-correlograms. These calculations become so numerous that it is likely to be necessary to move to general-purpose computing on graphics processing units (GPGPU) model to ensure the user requirement for responsiveness are delivered.

The second task is to deploy the iRaster software more widely. The CARMEN Project is developing a 'workflow' system similar to the VISA interface [28] for processing neural recordings. In principle, this should be directly connectable to the iRaster visualisation. Whilst it requires conversion to a client-server model to support deployment on the CARMEN hardware, it will be offered as a downloadable client to view data stored in the CARMEN repository. The intention is to make this software freely available for all non-commercial use.

5. Conclusions

Multi-Threaded code originally arose from the need to manage long running tasks without the executing application becoming unresponsive to the user. However, over the last decade a new use of this technique has arisen. This is attributed to the fact that hardware manufacturers now deliver increased computing performance through multiple compute cores. Threads have been used as a natural way of writing applications that fully exploit delivery of computing power. Nevertheless, this application of threads falls outside their original purpose. Therefore, its use has been limited by a lack of software tools and developer training.

Now that hardware manufacturers have committed themselves to multi-core hardware systems, the software developer must acknowledge that to continue to benefit from ever faster hardware, the way in which they write programs must change.

Developers are beginning to accept this need to change and this is supported by the availability of development tools such as Intel® Parallel Studio suite and the addition of concurrency frameworks to major programming languages.

Despite the availability of these support tools, threading and concurrency continue to be seen as advanced concepts with training continues to lag behind the deployment of hardware capable of executing concurrent code.

In the next few years, this must change with the next generation of developers being trained to expect their code to execute in a concurrently on multi-core hardware. In many research fields multi-core hardware will be combined with clustering and grid technologies (cloud computing) to dramatically increase data processing throughput. In business, every employee can expect to be using multi-core devices as standard (from desktop PC to mobile phones and tablets). The developers of today graduate with a firm understanding of object orientated development; the developer of tomorrow will need to add concurrent programming and the experience of a concurrency framework to these skills if they are to meet the needs of business tomorrow!

The value of these skills has been demonstrated in the case study of the VISA^3 project. In VISA^3, the number and length of neural spike train recordings that need to be processed by the software has been scaled up by a factor of ten. Finally the application of a workflow based interface to the VISA^3 software demonstrates that visualising a concurrent application in this manner may offer a means to effectively design and debug concurrent software.

SKALA: Scalable Cooperative Caching Algorithm Based on Bloom Filters

Nodirjon Siddikov[1] **and Dr. Hans-Peter Bischof**[2]
[1] Enterprise IT Operation and Planning Unit, FE Coscom LLC, Tashkent, Uzbekistan
[2] Computer Science Department, Rochester Institute of Technology,
Rochester, New York, USA

Abstract - *This paper presents the design, implementation and evaluation of a novel cooperative caching algorithm, called SKALA, which is based on the bloom filter data structure. The algorithm is designed using decentralized architecture and offers highly scalable solution. It resolves the problems related to an inefficient use of the manager's resources. The scalability of the algorithm is maintained by distributing the global cache information among cooperating clients. Furthermore, the memory overhead is decreased due to a bloom filter data structure which reduces the global cache size. The correctness of the algorithm is evaluated by running experiments. The experiment results demonstrate that SKALA decreases the manager load by the factor of nine which implies that it is more scalable compared to existing algorithms. The results also show a significant reduction in the memory overhead which implies that SKALA uses manager's resources more efficiently.*

Keywords: bloom filter, global and local cache, scalability, decentralized architecture, memory hierarchy

1 Introduction

The distributed systems, such as distributed file systems (DFS) and content distribution networks (CDN), usually employ caching mechanism. The primary goal of this mechanism is to temporarily store the frequently or recently accessed data, so that future data requests can be served faster. The benefit of caching can be extended by implementing a cooperative caching mechanism in these systems. Cooperative caching is implemented using two layers of memory – local and global cache. The distributed systems based on client/server architecture usually use the local cache to provide data reusability at client side. While the local cache is dedicated to specific client, the global cache is shared among all clients. The global cache's primary goal is to help clients benefit from earlier accesses (to the same data) by other clients sharing the global cache. The content of the local and global caches are managed by special caching algorithms such as *N*-chance [4] and hint-based algorithms [5].

1.1 Research problems

The existing cooperative caching algorithms, such as *N*-chance and hint-based algorithms face several problems that prevent them from being applicable for wide variety of distributed systems. First, these algorithms do not scale when the number of clients or the local cache size is increased. The primary reason for such behavior is due to a centralized architecture implemented in these algorithms. This architecture uses single manager node which is responsible for the maintenance of the global cache. When the number of clients increases, the manager is required to handle more requests coming from clients and eventually becomes overloaded. Second, existing algorithms create a memory overhead on the manager side. As the number of clients increase, the global cache size at the manager also increases gradually which causes a memory overhead.

1.2 Proposed solution

This paper addresses the research problems by introducing a novel cooperative caching algorithm, called SKALA, which is based on a bloom filter data structure. SKALA uses decentralized architecture that relieves the manager from global cache maintenance and distributes the global cache among client nodes. Thus, clients would have their own copy of the global cache so that they avoid contacting the manager for the data. This feature reduces the load on the manager to maintain the scalability of the algorithm. Moreover, SKALA decreases memory overhead by incorporating the bloom filter into the global cache. The proposed solution is suitable for distributed systems that operate in client/server environment.

In order to evaluate the performance of the algorithm, a trace-driven software simulator has been developed. The experiment results demonstrate the effectiveness and correctness of the algorithm. According to the results, SKALA performs better compared to the existing algorithms when the number of clients or the local cache size increases. In particular, the bloom filter reduces the global cache overhead by factor of nine and maintains the algorithm's scalability over many client nodes.

1.3 Motivation

The primary motivation of this paper is to measure the scalability of the cooperative caching algorithms. Another motivation is to explore the relationship between cryptography and caching algorithms. The bloom filter data structure, for example, establishes this relationship, because it uses a cryptographic hash function to insert, lookup and delete its elements. Moreover, it was also claimed that bloom filter can be applied for caching algorithms to save memory space [2]. The bloom filters and hash functions are relatively new in the current research area, thus it is interesting to see how they help cooperative caching algorithms be scalable.

1.4 Organization of paper

The current paper is organized as follows: Section 2 describes the required background knowledge and concepts. Section 3 elaborates more into existing cooperative caching algorithms. Section 4 examines the research problem and introduces the novel caching algorithm. Section 5 describes the experiments and the metrics used to evaluate the algorithms. The limitations of this paper and the future works in this research field are discussed in Sections 6 and 7, respectively. Finally, Section 8 summarizes the paper by presenting the conclusions drawn from the experiment results.

2 Background

2.1 Cache memory

A cache memory transparently stores the data so that future data requests can be served faster [9]. It can be used to increase the performance of secondary storage devices, such as a hard disk, by saving the copies of frequently or recently accessed blocks. In a client/server environment, caching is used to reduce the request latency, service time (i.e. round trip time) and the network traffic. The data stored in the cache may either be a previously computed value or the block that has been requested before.

The cache memory is a part of the computer *memory hierarchy* ordered from the fastest memory at the top to the slowest one at the bottom. In such setting, cache filters out the data request directed toward the slower layers of the hierarchy. For example, when the client requests the data block, it first checks the cache. If the requested data is in the cache (i.e. a cache hit), it is served directly from the cache memory, which is relatively faster. Otherwise (i.e. a cache miss), the data has to be fetched from the slower memory layer such as a disk. Therefore, the performance of the system will be improved if more data is read from the cache [9]. The size of a cache depends on the requirements of the system, but it is usually kept small to maintain its efficiency.

2.2 Cooperative caching system

A typical cooperative caching system in client/server environment usually implements the local and global caches. The local cache is implemented in the client side as part of its memory hierarchy. The global cache is also considered as a layer in the hierarchy and it is positioned between a local cache and the server's storage [5]. Its content is managed by a cooperative caching algorithm using the logic of least recently used (LRU) and least frequently used (LFU) algorithms.

The architecture of cooperative caching system usually involves a manager, clients and a server. The manager implements and maintains the global cache; the server hosts the data blocks and the client sends the read requests to these blocks. The manager is responsible for the coordination of the clients' requests to the blocks. The extent of coordination is different among various cooperative caching algorithms and it is considered a major distinction between them [5]. Moreover, the clients have to cooperate with each other when accessing the blocks. Cooperation takes place when one client does not have the required block in its local cache and it probes caches of other clients for the required data.

Cooperative caching systems are usually designed using a centralized architecture. In this architecture, if client experiences local cache miss, then it contacts the manager to lookup the global cache. The manager usually knows which client's cache contains the required block through its global cache. If there is a global cache hit, the manager redirects the request to the appropriate client. Otherwise, the manager fetches the block from the server which may be a slow and an expensive process. Figure 1 illustrates an example of such centralized architecture.

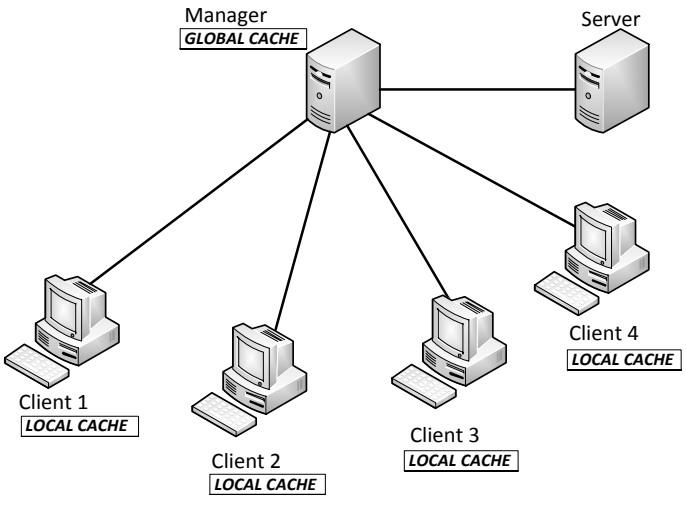

Figure 1: *A centralized cooperative caching system. In this system, a single manager is responsible to maintain the global cache.*

3 Existing algorithms

3.1 *N*-chance algorithm

The *N*-chance algorithm is one of the pioneers in the field of cooperative caching. It uses a centralized architecture which includes clients, the manager and the server. In this algorithm, the local cache is located in the clients' side. But the global cache is maintained by the manager and has the comprehensive view of the all local caches. Local cache content is managed by LRU cache replacement algorithm, but the global cache is coordinated using a more sophisticated policy. In this policy, the data block is either discarded or kept in the global cache based on its quantity in the cooperative caching system. If there is only one specific block in entire system, it is called a *singlet*; otherwise it is considered as a non-singlet. The singlet data blocks are forwarded to a randomly selected client to further retain them in the system; otherwise, they are discarded immediately. Each singlet block is given a recirculation count *N* such that every time the block is forwarded, the count is decremented. In other words, the block is given *N* chances to stay in the cooperative caching system. When the count reaches zero, the block is discarded regardless of its singlet status [4]. The central manager component plays an important role in the *N*-chance algorithm. It is responsible for global cache maintenance and lookup, and forwarding the block requests to the clients and the server. Every time client inserts or removes a block from its cache, it reports these changes to the manager. The manager uses this information about changes to maintain the consistency of the global cache [4].

3.2 Hint-based algorithm

In *N*-chance algorithm, the information contained in the global cache is considered as *facts*. This is because global cache reflects the factual data stored in the local caches of clients. However, maintenance of these factual data increases overhead on the manager. The hint-based cooperative caching algorithm attempts to solve this overhead problem by relaxing the centralized control of global cache. In particular, the algorithm distributes the portions of the global cache information among clients as *hints*, so that clients can make local caching decisions. Thus, the global cache is maintained by both clients and the manager [5]. In such setting, the manager still retains the control of the global cache, but it incurs much less overhead from clients.

Facts and hints are main components of the hint-based algorithm. They usually contain the information about the location of a *master* block, which is the original block fetched from the server. The hints reduce the client's dependence on the manager when performing caching operations. However, the hints are not always accurate, because they are local to the client and they do not reflect the changes taking place in the caches of other clients. For example, if a hint tells the client about the location of a particular master block, it is not guaranteed that the block is present at the remote client's cache. The chances are that the remote block might have been forwarded to another client or it has been discarded entirely. Also, the information about this change might not have been reflected in the client's hint. Thus, the hint gives client only a clue about the probable location of a block in the cooperative caching system. However, managing hints is less costly for a client than managing facts, because the accuracy of hints needs not to be maintained at all times [5].

4 New algorithm: SKALA

4.1 Problems with existing algorithms

There are several problems associated with existing cooperative caching algorithms. The first problem is related to their scalability – the algorithms do not scale when the number of clients increase in the cooperative caching system. Increased number of clients generate excessive amount of block requests towards the manager and causes it to get overloaded. For example, in the *N*-chance algorithm, the singlet block is relocated to the remote client through the manager. When the number of clients increases, such block relocation procedures happen more often which causes a communication overhead among the clients and the manager. In the case of hint-based algorithm, the local hints may become obsolete, thus clients will be required to contact the manager to obtain the fact. Such algorithm also produces a communication overhead as the number of clients increases. Also, it may take a while until hints are updated, so there is a risk for a client to perform an inaccurate caching operation based on the obsolete hint. The outcome of this operation is unfavorable since inaccurate decisions increase the cache miss rate [8].

Another problem of existing algorithms is associated with a memory overhead placed on the global cache. As more clients are added to the system, the manager has to allocate more memory space for the global cache. While the hint-based algorithm mitigates this problem by using hints, it still maintains facts in the global cache at the cost of manager's resource. This may result in a waste of memory resource when the number of obsolete facts becomes excessive.

4.2 Proposed solution

In order to overcome the problems with existing algorithms, current research paper proposes a solution to reorganize the components presented in Figure 1. In this solution, the global cache component is removed from the manager and distributed among the clients. Thus, each client maintains its own copy of the global cache besides its local cache. A client periodically updates the state of its global cache. Updating procedure involves calculation of bloom filter from local cache and broadcasting it among the other clients. Figure 2 shows the overall architecture of the proposed solution.

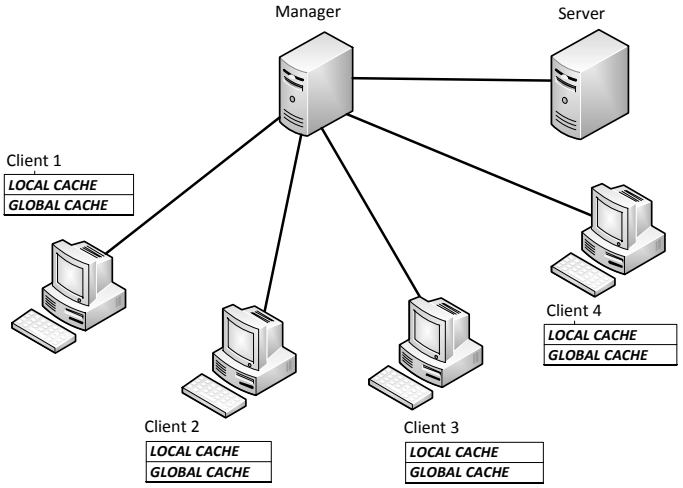

Figure 2: *The architecture of the proposed solution. In this architecture, the global cache component is removed from the manager and distributed to each client.*

The proposed solution is implemented by a novel cooperative caching algorithm called SKALA. It is designed using decentralized architecture and requires each client to maintain local and global cache components. The local cache stores the accurate state of the data block including its content. But, the global cache stores only approximate information about blocks. Due to such approximate information, the global cache lookup operation may return false positive (i.e. false cache hit) and false negative (i.e. false caches miss) results. However, in SKALA, the local cache is accessed more frequently than the global cache. Therefore, the algorithm does not keep the global cache up-to-date at all times and false positives and negatives happen occasionally within tolerable threshold. SKALA also reduces the global cache size by using bloom filter. This assures that global cache uses less space in client's memory which increases the local cache hit rate.

4.3 Data structures used in SKALA

SKALA uses traditional and novel data structures to implement the cache memory (Figure 3). The local cache is implemented using a hash table which keeps each data block as a key/value pair. The key represents the block's ID and the value denotes the block's content. Unlike a hash table, a bloom filter only stores the block's ID as a key, but the block contents are not stored [6]. Such design gives an advantage during caching operations. For example, a bloom filter spends less time to look up the block information compared to the hash table. But, the time to access the block contents stored in the local cache becomes significant because of the network latency [1].

The bloom filter data structure is considered as an exceptional feature of the SKALA. It is a probabilistic data structure which basically is an array. Similar to an array, it supports insert, delete and lookup operations. However, the result of the lookup operation is returned with some level of probability. For example, the lookup operation may result in false positives and negatives. The false negative happens when the particular block is stored in the cache, but the bloom filter says otherwise. On the other hand, the false positive occurs when the block is not stored in the client's cache, but the bloom filter says otherwise. Even though these errors affect the cache hit ratio, bloom filter keeps the logic of the cooperative caching algorithm intact. For example, a false cache hit does not result in a wrong block being served [2]. The probability of getting false positives and negatives can be controlled by proper choice of values for bloom filter parameters (such as its size and expected number of elements). One of the advantages of bloom filter is its fixed size so that the capacity of the global cache does not change over time. On the other hand, the bloom filter can only be used for cache lookup operation, and it cannot directly be used to store the block's other attributes such as its size [7].

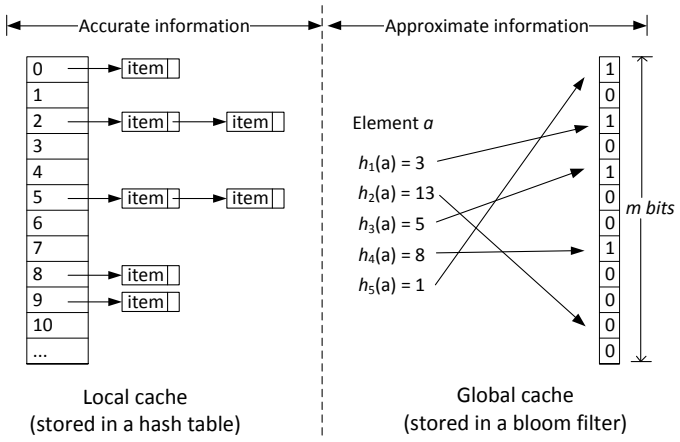

Figure 3: *The data structures used in the local and global cache.*

4.4 Algorithm limitations

Even though the SKALA has significant advantages over the existing algorithms, it exhibits some limitations. First, SKALA only works in block level granularity; thus, the algorithm requires the data to be split into blocks. Thus, SKALA accepts block ID as an input, but not a whole file name. Second, the performance of SKALA under large cooperative caching systems such as CDNs is not predictable. The algorithm is only tested with a cache memory which size is 64 – 2048 KB. Such test sizes are significantly small compared to the cache sizes of real-world distributed systems. Third, SKALA executes its operations sequentially and is not tailored to run in parallel. In order to develop a parallel version of the algorithm, a special parallel library has to be used. Also, applying parallelism into algorithm requires an external synchronization of internally used data structures.

5 Evaluation

5.1 Evaluation metrics

The following metrics are used to evaluate the performance of the cooperative caching algorithms:

- *Manager load* measures the overhead a client imposes on the manager. The overhead is expressed as a number of messages generated by the client to communicate with the manager. This metric is important because it represents the amount of work completed by the manager for cooperative caching operations.
- *Memory overhead* measures the overhead imposed on the manager's memory. The size of the global cache is used to determine the memory overhead. Such measurement is also an important factor in estimating the algorithm's scalability.

5.2 Experiment results

In order to conduct the experiments, a special software simulator is developed in Java which implements all cooperative caching algorithms under investigation. The simulator used a single Java Virtual Machine and its input parameters are adjusted through a configuration file. List of algorithms tested are provided below:

- *N*-chance algorithm;
- Hint-based algorithm;
- Non-bloom filter based algorithm;
- Bloom filter based algorithm (SKALA).

The input parameters of the simulator specific to caching algorithms (local cache size, the number of clients and the network latency) are adjusted regularly based on the requirement of the experiment.

5.2.1 Manager load

Figure 4 shows the measurement of the load imposed on the manager. The load is directly proportional to the amount of messages exchanged between clients and the manager. These messages are broken down to consistency, replacement and lookup messages. According to the figure 4, the *N*-chance algorithm imposes most load on the manager compared to the rest of the algorithms. Its centralized architecture requires clients to make frequent contacts to the manager to lookup the global cache. Another reason is because a client constantly updates the manager with the change in its local cache content for the purpose of global cache maintenance. Consistency messages put most of the load on the manager due their importance for the global cache. In the case of the hint-based algorithm, the manager load is three times less than that of *N*-chance. Despite using hints, the algorithm still requires clients to contact the manager in order to maintain the facts in the global cache. Finally, the decentralized architecture of SKALA imposes fewer loads on the manager making the algorithm scalable. Because the global cache is locally stored in each client, it does not contact the manager at all for lookup, insert and delete operations.

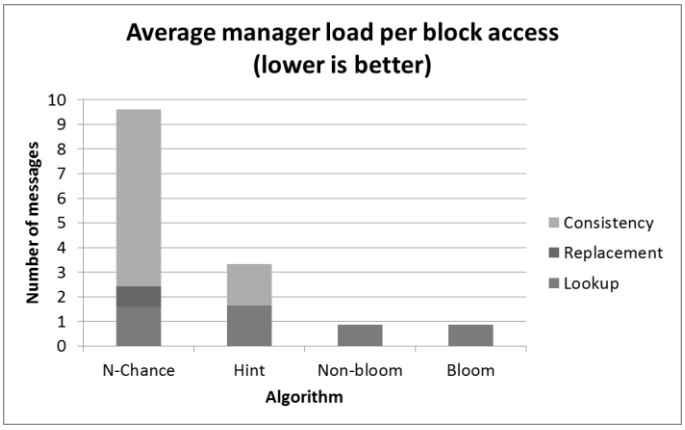

Figure 4: *The average load imposed on the manager by each algorithm. The load is defined as the number of messages sent and received by the manager. The manager load is broken down to consistency, replacement and lookup messages.*

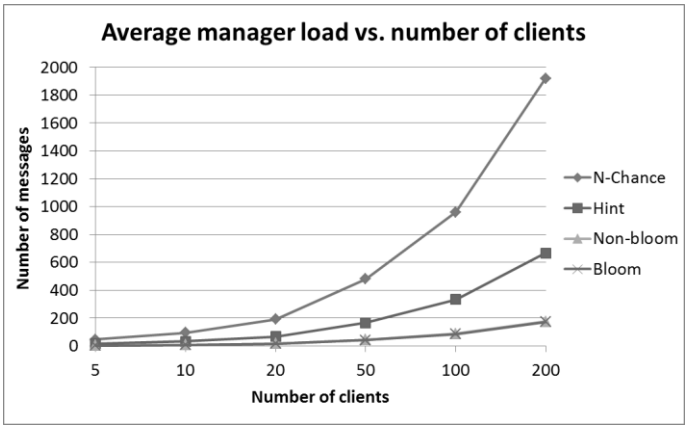

Figure 5: *The variation of the manager load as the number of clients increase.*

It is important to measure the scalability of the algorithms when number of clients increases in the cooperative caching system. If algorithm's load on the manager does not change as more clients join the system, then it is considered as a scalable. The outcome of the experiment for scalability is presented in Figure 5. According to the figure, the manager load on bloom and non-bloom filter based algorithms grows slower than the rest of the algorithms. The decentralized architecture of these algorithms keeps the communication among the clients and the manager to low regardless of the number of clients. However, the *N*-chance and hint-based algorithms demonstrate a gradual increase of the manager load under the same conditions. The reason is that algorithms require the clients to contact the manager to maintain the global cache consistency. Increased amount of messages degrade the manager's performance which eventually reduces the algorithm's scalability.

5.2.2 Memory overhead

Figure 6 shows the result of the experiment which evaluates the memory overhead of the algorithms. This research used the

value of the global cache size to estimate the memory overhead. This value is variable and depends on the aggregate sizes of local caches. According to figure 6, the memory overhead of SKALA is significantly low compared to that of other algorithms. SKALA uses a bloom filter to implement the global cache which keeps its size fixed regardless of number of blocks. On the other hand, the memory overhead is the highest in case of non-bloom filter based algorithm. Such huge difference is due to the method used to store the blocks in the global cache. This algorithm stores the exact copy of each block in the global cache. However, the rest of the algorithms use block's ID to populate the global cache and the actual block contents are stored in the local cache.

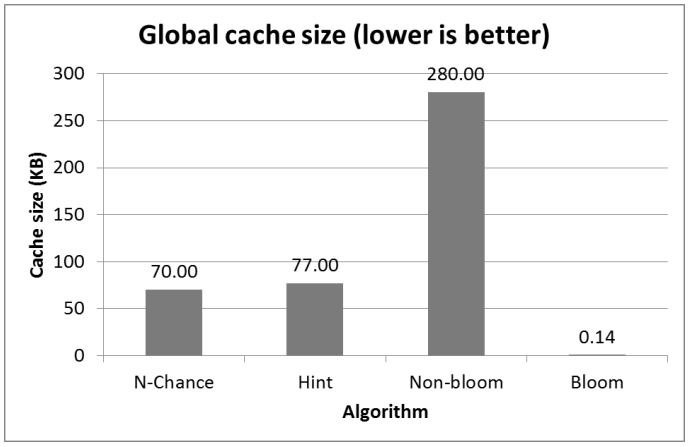

Figure 6: *The memory overhead in the cooperative caching algorithms.*

Another experiment evaluates the scalability of the algorithms when the local cache size varies between 64 – 1024 KB. The experiment assumes that the size of the global cache is proportional to size of the local caches in all algorithms. The result of experiment is shown in figure 7. In case of the non-bloom filter based algorithm, the global cache size increases exponentially as local cache size reaches the 1024 KB mark. This algorithm stores the block contents in the global cache, thus local cache content consumes more space in the global cache. *N*-chance algorithm shows similar behavior but at lesser extent due to allocation of global cache maintenance to the manager. The hint-based algorithm achieves the better result than *N*-chance through keeping merely master block information in the global cache. Finally, SKALA demonstrates immunity to the increase in the local cache size due to the fixed size of the bloom filter used in its global cache.

The final experiment uses the number of clients to evaluate the scalability of the algorithms (Figure 8). According to the figure 8, the number of clients in the system directly affects the memory overhead. *N*-chance and hint-based algorithms demonstrate that the overhead on the memory grows exponentially when number of clients increase. Such exponential growth indicates that these algorithms are not scalable due to increased block access time and increased load on the manager. Moreover, both of these algorithms use a variable size global cache which can grow infinitely. Thus, when the number of clients increases, the amount of cached block information consumes more space in the global cache. On the other hand, SKALA's global cache size remains relatively stable until the number of clients reaches 50. The global cache allocates one bloom filter for each client's local cache information, thus exceeding this threshold of 50 clients is sufficient for to increase the size of the global cache.

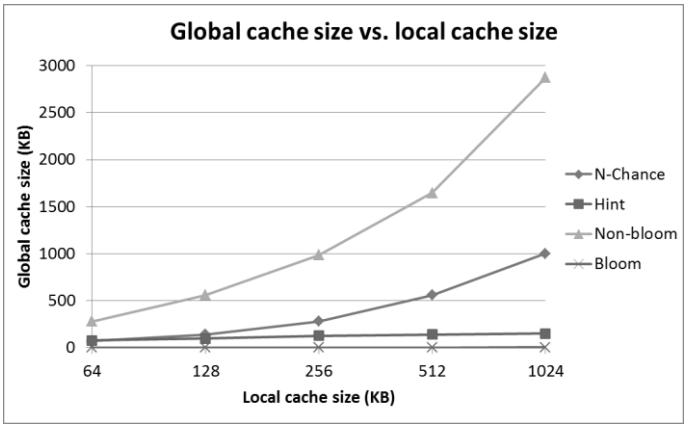

Figure 7: *The sensitivity of the memory overhead to the variation of the local cache size.*

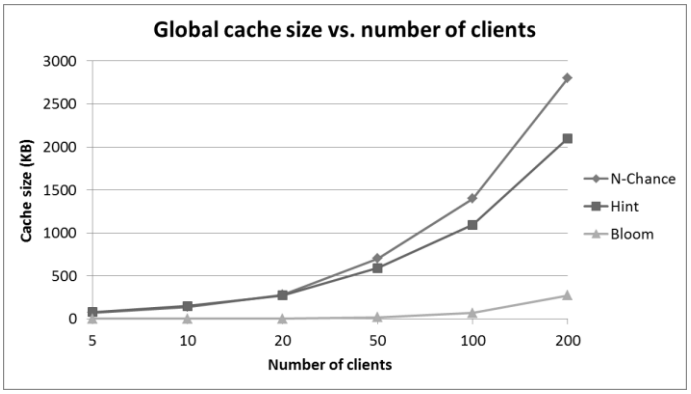

Figure 8: *The sensitivity of the memory overhead to the change in the number of clients.*

6 Limitations of proposed solution

The proposed solution faces some limitations that could affect its performance. For example, the bloom filter data structure only stores the approximate state of the global cache. This may result in false positives and negatives which means not all global cache lookup operations return accurate answer. Inaccurate answers are primary reasons for the local and global cache misses. Consequently, this increases the block access time and reduces the performance of SKALA. Therefore, the bloom filter has to be created with appropriate input parameters. Moreover, SKALA does not implement the cache

writing policy. However, integrating this policy into SKALA would make the contents of cache memory and server disk more consistent. On the other hand, such modification may not change the outcomes of the experiments, because cache writing and block reading policies are mutually exclusive and they do not affect the cache hit/miss rates. Another shortcoming of SKALA is associated with the input data used in the experiments. The input data (trace) is synthetic meaning that it is randomly generated which does not reflect the real world block access pattern. However, using real world traces would increase the credibility of the experiment results.

7 Future work

Even though SKALA proved itself as scalable caching algorithm, there are some enhancements that could be applied for the algorithm. One of them entails implementing a cache writing policy in SKALA. According to this policy, when the content of the cache is changed, the updated blocks are written back to the server's disk. Thus, the consistency of the cache memory and the disk is maintained. Another extension to SKALA is to implement an offline caching algorithm. All of the algorithms presented in this paper are all considered online algorithms. The offline algorithm can be used in the experiments to measure the upper performance bound of these online algorithms. Such measurement would help optimize the performance of the existing algorithms. Finally, implementing a multithreading would improve the performance of SKALA. For example, the computation of the bloom filter can be parallelized with multithreading so that each hash functions are calculated by separate thread.

8 Conclusion

A cooperative caching system usually implements two layers of cache memory: local and global caches. The system components usually consist of the manager, the clients and the server all of which works under the rule of the specific caching algorithm. The algorithm is also used to coordinate the contents of the local and global caches. The level of coordination is an important factor and is the main difference between various cooperative caching algorithms. The current paper introduces the bloom filter based decentralized caching algorithm, called SKALA, which focuses on the scalability and efficient use of global cache memory. SKALA achieves the scalability by removing the maintenance of the global cache from the manager. Instead, it distributes the entire global cache among the clients. The content of the global cache is composed of a set of bloom filters, one filter to represent each client's local cache. The bloom filter simplifies the implementation of the global cache replacement policy in SKALA which does not involve the manager. The experiments on SKALA show that the load on the manager is decreased due to algorithm's decentralized architecture. This assures the scalability of SKALA without reducing its performance. Moreover, the bloom filter reduces the memory overhead for the global cache. This signifies that SKALA is better at using the manager's resources efficiently compared existing solutions.

Evaluating Utilization of the I/O System on Computer Clusters

Sandra Méndez[1], **Dolores Rexachs**[1], **and Emilio Luque**[1]
[1] Computer Architecture and Operating Systems Department (CAOS)
Universitat Autònoma de Barcelona, Barcelona, Spain

Abstract— *The increase in computational power of processing units and the complexity of scientific applications which use high performance computing require more efficient Input/Output (I/O) systems. In order to efficiently use the I/O system it is necessary to know its performance capacity to determine if it fulfills applications I/O requirements. Evaluating the performance capacity of the I/O system is difficult due to the heterogeneity of its architecture and the complexity of I/O software stack. It is necessary to understand the application's access patterns, the architecture, the software stack and its interaction to evaluate the I/O system utilization.*

We propose a methodology to evaluate the I/O system utilization taking into account parallel applications behavior and the I/O system performance capacity. To analyze the I/O system we evaluate the I/O path of computer clusters. We use a hierarchical scheme of the I/O system with its performance capacity at I/O library level and at I/O device level.

We propose a method to identify I/O phases of parallel scientific applications depending on its temporal and spatial patterns. We have evaluated the I/O system utilization taking into account the I/O phases behavior of applications in I/O devices.

Keywords: Parallel I/O System, I/O Architecture, Mass Storage, I/O Configuration

1. Introduction

Due to the historical "gap" between the computing and Input/Output (I/O) performance, in many cases, the I/O system becomes the bottleneck of parallel systems. In order to hide this "gap", the I/O factors with the biggest effect on performance must be identified. Furthermore, the increased computational power of processing units and the complexity of scientific applications which use high performance computing require more efficient Input/Output Systems. The parallel I/O system is complex because it is composed of different components of hardware and several layers of software. Also these I/O components are heterogeneous in computer clusters. The designer or system administrator has the difficulty either to select components of the I/O subsystem (JBOD (Just a Bunch Of Disks), RAID (Redundant Array of Inexpensive Disks) level, filesystem, interconnection network, among other factors) or to choose from different connection models (DAS, SAN, NAS, NASD) with different parameters to configure (redundancy level, stripe, among others). Programmers can modify their programs to efficiently manage I/O operations, but they need to know the I/O system, especially the I/O software stack. The system administrators and programmers need information to answer the following questions, When is it convenient to use a parallel or distributed file system? When is it convenient to use I/O nodes for management the Input/Output? When is it convenient to use RAID or single disks? When is it convenient to use local storage or remote storage? We propose a methodology to evaluate the I/O system utilization taking into account the parallel I/O of the application and the I/O subsystem. To analyze the I/O subsystem we try to cover the I/O path of data on the subsystem of computer cluster. We use a hierarchical scheme of the subsystem with its performance capacity at I/O library level and at I/O devices level. Our methodology requires extracting access patterns of the application to identify the I/O phases from to which we define an I/O model of application. To do this, we have used a tool (PAS2P [1] library) developed by our research group. This tool traces parallel applications I/O operations at MPI-IO level.

We evaluate the utilization of two I/O configurations (where we have used parallel filesystem PVFS2 and network filesystem NFS). Furthermore, we show the I/O model for two I/O benchmark of scientific applications.

The rest of this article is organized as follows: in Section II we review the related work, Section III introduces our proposed methodology. In Section IV we review the experimental validation. Finally, we present our conclusions and future work.

2. Related Work

There are several works which present evaluation of the I/O configurations for improving the performance of the I/O subsystems. Since the I/O systems are complex to evaluate, generally, the studies are focused on specific supercomputers or computer cluster.

The I/O performance analysis developed in the Sandia National Laboratories over the Red Storm platform is presented in [2]. In order to arrive at a theoretical estimation for the Red Storm configuration, they started with a single end to end path definition, across which I/O operation travels. This study differs from our work since we evaluate the I/O path at I/O Library level and at devices level taking into account the different I/O configurations of the computer

cluster. Furthermore, we use these information to evaluate how much of the I/O system capacity is being used by the application.

Kunkul and Ludwig [3] presented an evaluation of performance for computer cluster on parallel filesystem PVFS2. They introduced a systematic approach for performance analysis for parallel filesystem's architecture for various request types. This study differs from our work since we have used the IOR benchmark at I/O library level to evaluate different patterns and the IOzone benchmark at level devices to obtain the peak values of the I/O architecture.

Carns et. al. [4] presented a multilevel application I/O study and a methodology for system wide, continuous, scalable I/O characterization that combines storage device instrumentation, static filesystem analysis, and a new mechanism for capturing detailed application-level behavior. Our work differs from his study because we evaluate the I/O system utilization taking into account I/O phases of application which are used to represent an I/O model of application.

Byna et. al. [5] defined the access patterns to identify the I/O signatures for parallel I/O prefetching. They presented a classification of I/O patterns for parallel application. We use her I/O pattern classification. Our work differs from his study because we define I/O phases of the application at I/O library level. The I/O model is independent from architecture allowing us to analyze the application behavior on different I/O system configurations.

3. Proposed Methodology

In order to evaluate the I/O system configuration utilization by scientific applications it is necessary to know its performance capacity and I/O patterns of the application. We characterize the behavior of the application at I/O library level and we also evaluate its behavior on I/O configuration at I/O devices level. Figure 1 shows our methodology. This is composed of three stages: Characterization, I/O analysis and Evaluation.

3.1 Characterization

The characterization of application is done with PAS2P tracing tool. Also, we define the I/O phases of application and show the I/O model for the application. We characterize the I/O subsystem of a computer cluster following the structure of the I/O system of Figure 1. The data travels along an I/O path from application to I/O devices in writing operations and from I/O devices to application for reading operations. Depending of I/O system, data can cross over interconnection networks to arrive to data storage.

3.1.1 Scientific Application

I/O patterns of parallel applications can be divided in local patterns and global patterns. Local patterns are determined per process, showing how a file is accessed by a process. Global patterns show how the file is accessed temporally

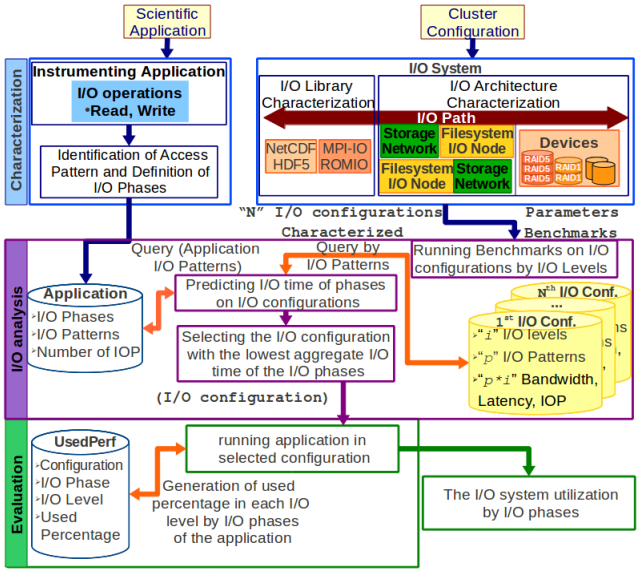

Fig. 1: Methodology to evaluate the I/O system utilization by parallel scientific applications

and spatially for processes of parallel application. We use the classification of local patterns of [5] and we define global patterns from analyzing local patterns. We define a I/O phase as a repetitive sequence of I/O patterns of a parallel application.

We represent the I/O model of an application by three major characteristics: i) the meta-data; ii) the temporal global I/O pattern; and iii) the spatial global I/O pattern. We characterize the application off-line and once at I/O library level because it provides us two important benefits. First, to obtain a model of the application's I/O independent from the execution environment, i.e. the computer cluster. Second, to evaluate the behavior of the application with different I/O configurations, avoiding the overhead of the tracing tool.

We have implemented an extension of PAS2P library to characterize application at process level. PAS2P identifies and extracts phases of the application, and by similarity analysis, this selects the significant phases (by analyzing compute and communication) and their weights. The representative phases are used to create a Parallel Application Signature which allows us to predict the application performance in target machines. PAS2P instruments and executes applications in a parallel machine, and produces a trace log. The data collected is used to characterize computational and communication behavior. The extension of PAS2P library traces I/O operations of the MPI-2 standard. MPI-2 has three aspects to data access: positioning (explicit offset or implicit file pointer), synchronism (blocking, non-blocking and split collective), and coordination (non-collective or collective). Also there are two types of file pointers (individual and shared) [6].

From MPI-IO routines we extract: type of I/O operation, initial offset, displacement, request size, filename, and file

type . Then, the traces are analyzed and we extract the access patterns for the parallel application. We incorporate the I/O primitives to the PAS2P tracing tool to capture the relationship between the computations and the I/O operations. Thus, we created a library $libpas2p-io.so$ which is loaded when the application is executed with $LD\_PRELOAD$.

We identify the I/O phases with an access pattern and their weights (number of repetitions of the pattern). With the characterization, we try to find the application phases which are used as units for behavior analysis in the I/O system. Due to the fact that scientific applications show a repetitive behavior, m phases will exist in the application. We represent a local access pattern by the tuple: (*Operation*, *initialOffset*, *displacement*, *requestSize*, *repetitions*).

The I/O phases are a repetitive sequence of same pattern on a file for a number of processes of the parallel application, thus an I/O phase is represented by the tuple: (*IDProcess[i]*, *accessPattern[i]*, *weight*, *accessMode*, *accessType*, *FileName*) where $i \in \{0..Pph\}$, Pph is the number of processes of the I/O phase.

To explain the I/O phases' identification we present an example for the benchmark MADBench2 [7]. MADbench2 is a tool for testing the overall integrated performance of the I/O, communication and calculation subsystems of massively parallel architectures under the stress of a real scientific application. MADbench2 is based on the MADspec code, which calculates the maximum likelihood angular power spectrum of the Cosmic Microwave Background radiation from a noisy pixelated map of the sky and its pixel-pixel noise correlation matrix. MADbench2 can be run as single or multi-gang; in the former all the matrix operations are carried out distributed over all processors, whereas in the latter the matrices are built, summed and inverted over all the processors (S & D), but then redistributed over subsets of processors (gangs) for their subsequent manipulations (W & C).

MADbench2 can be run on IO mode, in which all calculations/communications are replaced with busy-work, and the D function is skipped entirely. The function S writes, W reads and writes, C reads. This is denoted as S_w, W_w, W_r, C_r. MADbench2 reports the mean, minimum and maximum time spent by each function during calculation/communication, busy-work, reading and writing in each function. Running MADbench2 requires a n^2 number of processors.

By tracing MADBench2 with our tool we have obtained its metadata:

- Individual file pointers, Non-collective I/O operations, Blocking I/O operations.
- Sequential access mode, Shared access type.
- A file shared by all processes

Figure 2 shows the first phase which is composed of eight writing operations, in the second phase all processes read their positions two first, the third phase is composed of six

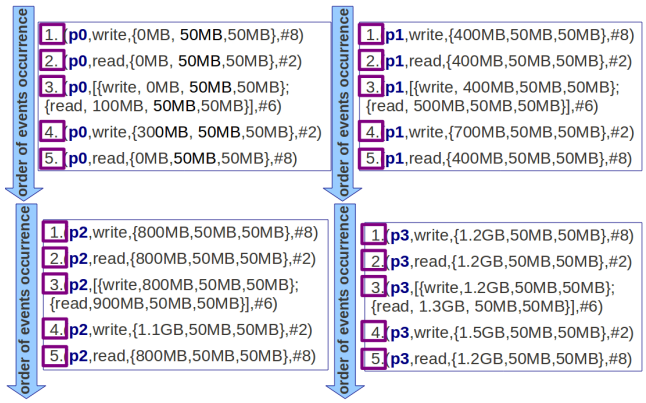

Fig. 2: Temporal and Spatial I/O pattern of MADBench2 for 4 processes (process, operation, {initialOffset, displacement, requestSize}, #repetitions)

writing/reading operations, in the fourth phase, processes write their last two positions, and in the fifth phase, processes read all their positions. This information is useful to determine the spatial pattern (the view of file and the access mode by process). However, to define the I/O phases we also need the temporal pattern (order occurrence of I/O operations on the file). Figure 2 shows the global temporal pattern of MADBench2. Note that each process shows a similar pattern (the events occur in the same order). If we analyze the phase 3 of process 0 it observes that a process repeats a writing operation six times (#6) on initial offset 0 and displacement 50 MB and request size 50MB, this is followed by a reading operation on initial offset 100MB and displacement 50MB with a request size 50MB. Figure 2 shows this pattern in the 4 processes, but with different initial offsets because each process works on disjoint sets of contiguous data.

We define five I/O phases for MADBench2 due to the similarity of its I/O patterns. Figure 2 shows the five I/O phases in purple boxes.

3.1.2 I/O System

In this step we identify the I/O system configuration. An I/O configuration depends on number and type of filesystem (local, distributed and parallel), number and type of network (dedicated use and shared with the computing), state and placement of buffer/cache, number of I/O devices, I/O devices organization (RAID level, JBOD), and number and placement of I/O node. For example, we define the following I/O configurations for an own cluster which is named Aohyper. This has the following technical characteristics: 8 nodes AMD Athlon(tm) 64 X2 Dual Core Processor 3800+, 2GB RAM memory, 150GB local disk. Local filesystem is Linux ext4 and two global filesystem: NFS and PVFS2. The NFS server has a RAID 1 (2 disks) with 230GB capacity and RAID 5 (5 disks) with stripe=256KB and 917GB capacity, both with write-cache enabled (write back). The nodes of

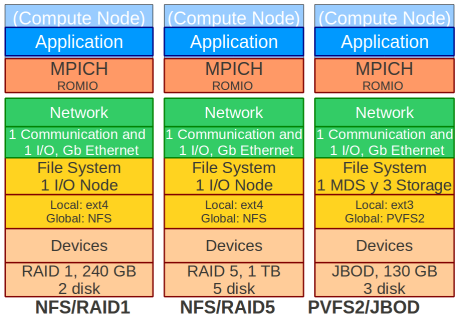

Fig. 3: I/O system configurations for Cluster Aohyper

PVFS2 are Intel(R) Pentium(R) 4 CPU 3.00GHz processors, 80 GB disk, and a Gigabit Ethernet network interconnection for data and communication.

The local filesystem is ext4 Linux for computing nodes and server NFS, and ext3 for nodes PVFS2. NFS server is an I/O node for shared accesses and there are eight I/O nodes for local accesses where users are responsible for data sharing. There are three storage nodes and a metadata Server for PVFS2 filesystem. PVFS2 is used by applications that require parallel accesses to files. The I/O nodes and computing node are interconnected with two Gigabit Ethernet networks, one for communication and the other for data. Figure 3 shows I/O configurations used in the cluster Aohyper.

3.2 Input/Output Analysis

There are three requirements that an I/O system must provide: storage capacity, availability and performance. Our work is focused on performance capacity. The performance is expressed by transfer rate (MB/sec) metrics, IOPs (Input/Output operations per second) and latency. This performance capacity is different at each I/O system level. The performance also depends on the connection of the I/O node, the management of I/O devices, placement of I/O node in network topology, buffer/cache state and placement, availability data and service. We obtain the performance capacity of I/O system at I/O library level for different access patterns through benchmark IOR [8]. Furthermore, we obtain the peak value at I/O devices level with benchmark IOzone [9].

We have executed the benchmarks in each I/O configurations with different I/O patterns and we have generated a data base by configuration with performance measures (bandwidth, latency, iops). The following data structure is used to store the I/O system performance (I/O devices, local and global filesystem, and I/O library): Operation Type (enumerate {write,read}), Request size (long integer (MBytes)), Access Type (enumerate {0 (Unique), 1 (Shared)}), Accesses Mode (enumerate {0 (Sequential), 1 (Strided), 2 (Random)}), Transfer Rate (double (MBytes/second)), Latency (double (microsecond)), Number of processes (integer).

To compare the I/O pattern of the application with benchmarks, we define the following data structure for I/O phases: ID of phase (integer), ID of files (integer), Operation Type (enumerate {write,read}), Request size (long integer (MBytes)), Access Type (enumerate {0 (Unique), 1 (Shared)}), Accesses Mode (enumerate {0 (Sequential), 1 (Strided), 2 (Random)}), Number of repetitions (integer), Number of processes (integer).

We analyze the I/O phases of the application and its weight to select the candidate configurations. We search the I/O patterns of phases on performance databases. Then, we calculate the I/O time for the I/O phases and we select the I/O configurations with the lowest I/O time. We applied the following algorithm to calculate the I/O time:

- Reading of patterns from each I/O phase
- Searching on the file of Performance the characterized transfer rate in the different I/O path levels based on I/O phases of application.
- The I/O time of the application is calculated with $\frac{DataTransferred(phase[i])}{transferRate}$ by each I/O phase, where i is the number of phase, *DataTransferred* is the data amount read or written in the phase i, *TransferRate* is the characterized value at I/O library level.

The algorithm to search the transfer rate for the I/O pattern is explained with the following steps:

- Opening the table of performance and setting the variable "found" to stop the searching when the values are found.
- If the operation type, access mode, and access type are equal to a value in the performance table, and the block size of the operation is:
  - less than minimum block size of the performance table then it selects the transfer rate corresponding to minimum block size.
  - greater than maximum block size of performance table then, it selects the transfer rate corresponding to the maximum block size.
  - equal to a block size of the performance table then it selects the transfer rate corresponding to such block size.
  - a value between the characterized values then it selects the closest upper value to the searched value.
- When the search finishes then the performance table is closed and the *TransferRate* is returned.

To explain this stage we evaluate the I/O phases to MADBench2 for 16 processes, 8KPIX, shared filetype, 32 MB request size. Figure 4 shows the I/O phases of MADBench2. Table 1 shows the I/O phases of MADBench in a general format. The I/O model of MadBench2 is represented with Fig. 4, Table 1 and its metadata.

We can observe that MADBench2 always writes and reads at the same I/O phases, when the number of processes increases the problem is divided among processes, therefore each process writes or reads a smaller block size. When

Table 1: I/O phases description of MADBench2 for 16 processes

Phase	#Oper.	InitOffset	Rep.
1	16 write	$IdProcess * 8 * 32MB$	8
2	16 read	$IdProcess * 8 * 32MB$	2
3	16 write 16 read	$IdProcess * 8 * 32MB$ $IdProcess * 8 * 32MB + +2 * 32MB$	6 6
4	16 write	$IdProcess * 8 * 32MB - -2 * 32MB$	2
5	16 read	$IdProcess * 8 * 32MB$	8

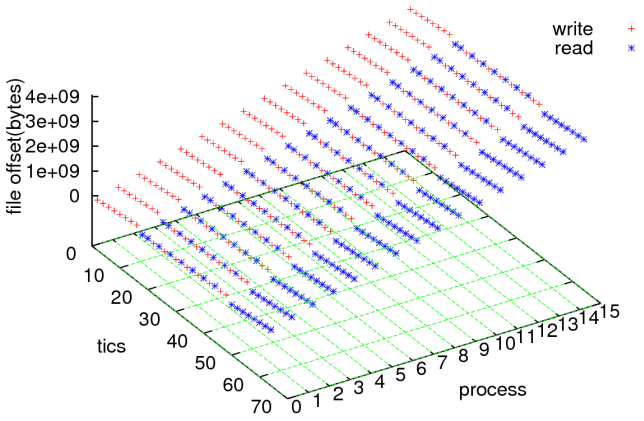

Fig. 4: I/O phases of MADBench2 where "tics" indicates the order of events occurrence

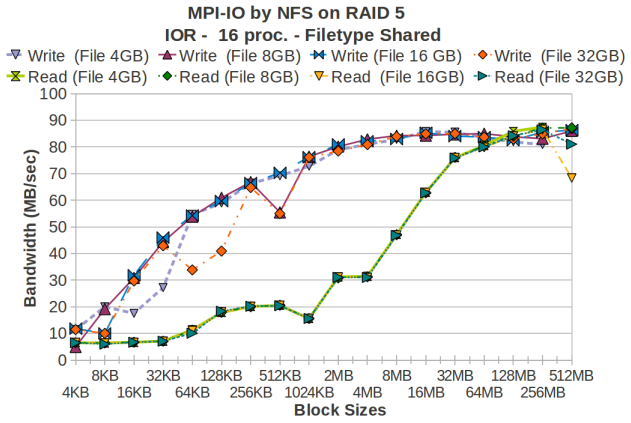
problem size increases (increases KPIX) then block size also increases.

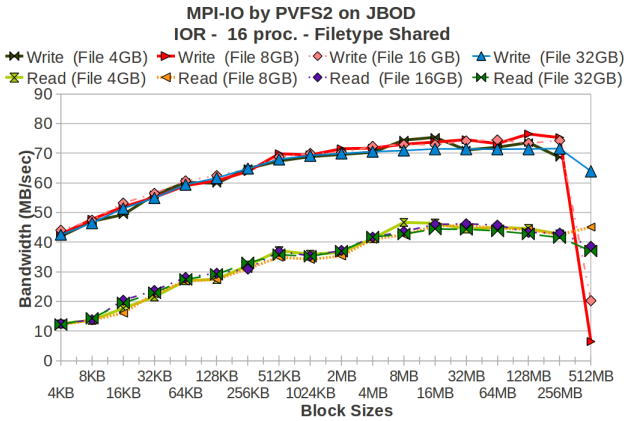
Following our example, we show in Figure 5 the characterization at I/O library level for I/O configurations of cluster Aohyper. We have selected NFS on RAID5 and PVFS2 on JBOD configurations to evaluate their utilization by MADBench2.

The results for reading operations shown in Figure 5(a) present lower performance values in NFS on RAID5 when working with block sizes below 8MB. In contrast, the transfer rate of writing operations increases proportionally to the increase in the block size. As could be seen in Figure 5(a), both writing and reading operations behave similarly for block sizes over 64MB. It is possible to infer from Figure 5(b) that in PVFS2, the transfer rate of reading operations is lower than the rate of writing operations. These results show that: the block size is the I/O factor with the highest impact in performance; while the evaluated file sizes have no high impacts in performance. Additionally, results of Figure 5(b) show a drop in performance for block size of 512MB for 16 processes, caused by timeouts in the file system due to network congestion.

The results of the characterization of both file systems, NFS (Figure 5(a)) and PVFS2 (Figure 5(b)), show two important things: i) PVFS2 on JBOD presents bigger transfer rates when working with smaller block sizes ($< 64KB$); and ii) NFS on RAID5 achieves greater transfer rates for bigger block sizes ($> 64MB$).



(a) I/O library on NFS



(b) I/O library on PVFS2

Fig. 5: I/O library on global filesystem Characterization

3.3 Evaluation

We evaluate the utilization of I/O system by the relation between the bandwidth characterized (BW-CH) and measured (BW-MD) where BW-CH depends on access patterns of each I/O phase. We define the utilization of I/O system as: $SystemUsage = \frac{BW-MD}{BW-CH}$. When a phase has two or more I/O operations then the BW-CH is calculated how the average of the BW-CH of each I/O operation that composes the I/O phase.

We can observe in the stage of I/O analysis that an application with a block size of 32MB, sequential access mode, and shared file will obtain higher transfer rates in NFS on RAID5 than in PVFS2 on JBOD (Figure 5). With this information we can select an candidate I/O configuration where possibly the application will have more performance. However, it is worth noting that we are not analyzing the absolute I/O time, because NFS on RAID5 and PVFS2 on JBOD are not directly comparable in terms of the storage capacity and the speed of devices. We compare performance results of these two I/O configurations from the characterization introduced in subsection 3.2 to observe how much from of the I/O capacity is used in each I/O configuration.

Table 2: I/O system utilization, BW-CH and BW-MD in MB/second for MADBench2 with 16 processes, file size 4 GB and a shared file on NFS

Phase	#Oper.	Data transferred	BW-CH on NFS	BW-MD on NFS	System Usage
1	128 W	4096 MB	85	93	1.09
2	32 R	1024 MB	76	68	0.90
3	192 W-R	6144 MB	80	63	0.79
4	32 W	1024 MB	85	89	1.04
5	128 R	4096 MB	76	66	0.84

Table 3: I/O system utilization, BW-CH and BW-MD in MB/second for MADBench2 with 16 processes, file size 4 GB and a shared file on PVFS2

Phase	#Oper.	Data transf.	BW-CH on PVFS2	BW-MD on PVFS2	System Usage
1	128 W	4096 MB	71	60	0.84
2	32 R	1024 MB	44	39	0.87
3	192 W-R	6144 MB	58	34	0.59
4	32 W	1024 MB	71	54	0.75
5	128 R	4096 MB	44	37	0.84

Table 2 shows the utilization of NFS on RAID5 and Table 3 shows the utilization of PVFS2 on JBOD. We also show the amount of data transferred in each I/O phase, the number and type of I/O operation (W=write, R=read, W-R=write-read), BW-CH and BW-MD in MB/second.

We can observe in Table 2 that the I/O system for the NFS on RAID5 is used at about 100% in phases with writing operations (phases 1 and 4) and 85% in phases with the reading operations (phases 2 and 5). This influences in the I/O time of phases 1 (49 sec.) and 4 (11 sec.) which are lower than in phases 5 (61 sec.) and 2 (16 sec.) in spite of to transfer the same amount of data.

Table 3 shows that the I/O system for PVFS2 on JBOD is used at about 80% in phases with writing operations and 85% in phases with the reading operations. I/O time in phases 2 (17 seconds) and 5 (43 seconds) is lower than in phases 4 (18 seconds) and 1 (61 seconds).

We can conclude from the evaluation that PVFS2 on JBOD is more efficient in the system usage in reading operations and NFS is more efficient in the system usage in writing operations. Finally, we can say that NFS on RAID5 provides lower I/O time than PVFS2 on JBOD to MADBench2.

4. Experimentation

To validate the methodology, the I/O phases identification is applied to Block Tridiagonal(BT) application of NAS Parallel Benchmark suite (NPB)[10]. The BTIO benchmark performs large collective MPI-IO writes and reads of a nested strided datatype, and it is an important test of the performance a system can provide for non-contiguous workloads. After every five time steps the entire solution field, consisting of five double-precision words per mesh point, must be written to one or more files. After all time steps

Table 4: I/O phases description of NAS BT-IO subtype FULL for 16 processes

Phase	Oper.	InitOffset	Rep.
1-40	16 W in each phase	$RS * IDProcess+$ $+(RS*(N-1)+$ $+(RS*15)*(N-1))$	1
41	16 R	$RS * IDProcess+$ $+(RS*(Rep-1)+$ $+(RS*15)*(Rep-1))$	40

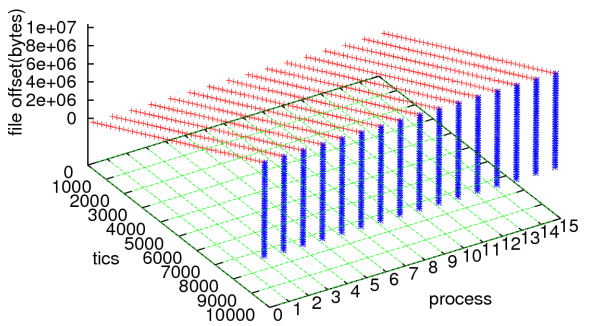


Fig. 6: I/O phases of NAS BT-IO

are finished, all data belonging to a single time step must be stored in the same file, and must be sorted by vector component, x-coordinate, y-coordinate, and z-coordinate, respectively. We have obtained the following meta-data of NAS BT-IO in the FULL subtype with our tool:

- Explicit offset, Blocking I/O operations, Collective operations.
- Strided access mode, Shared access type.
- MPI-IO routine MPI_Set_view with etype of 40.
- Request size 10MB.

Figure 6 shows I/O phases for 16 processes, Class C and FULL subtype. Table 4 shows description of I/O phases for NAS BT-IO where N is the number of phase $(1-40)$ and RS is request size, $IDProcess$ is the rank of MPI processes $(0-15)$.

We have executed NAS BT-IO in the Aohyper cluster: NFS on RAID5 and PVFS2 on JBOD, and we have evaluated their utilization.

4.1 Evaluation

Table 5 and Table 6 show the utilization of the I/O system on NFS and PVFS2. We also show the amount of data transferred in each I/O phase, the number and type of I/O operation (W=write, R=read, W-R=write-read), BW-CH and BW-MD in MB/second.

Table 5: Bandwidth Characterized (BW-CH) and Measured (BW-MD) in MB/sec for NAS BT-IO with 16 processes, file size 6.4GB and a shared file on NFS

Phase	#Oper.	Data transferred	BW-CH on NFS	BW-MD on NFS	System Usage
1 to 40	640 W	6.4GB	85	65	0.76
41	640 R	6.4GB	63	47	0.74

Table 6: Bandwidth Characterized (BW-CH) and Measured (BW-MD) in MB/sec for NAS BT-IO with 16 processes, file size 6.4GB and a shared file on PVFS2

Phase	#Oper.	Data transferred	BW-CH on PVFS2	BW-MD on PVFS2	System Usage
1 to 40	640 W	6.4GB	71	58	0.81
41	640 R	6.4GB	44	45	1.02

We observe that the I/O patterns of NAS BT-IO will obtain similar performance in both configurations, as infered from the I/O analysis stage presented in subsection 3.2.

NAS BT-IO reported that NFS on RAID5 has lower I/O time than PVFS2 on JBOD with a difference of 14 sec. (NFS on RAID5=244 seconds and PVFS2 on JBOD=259 seconds). PVFS2 on JBOD uses 80% of I/O capacity for writing operations, and 100% to reading operations; while NFS on RAID5 uses 76% of its I/O capacity for writing operations, and 74% in reading operations.

In principle, the two I/O configurations are suitable to I/O phases of NAS BT-IO FULL in its class C. When the problem is increased, NFS on RAID5 presents some interesting characteristics because of its I/O devices (higher storage capacity and data availability). However, PVFS2 on JBOD can be more suitable in situations where there are multiple processes accessing to a shared file (dynamic distribution of data through its scheme of the metadata and I/O servers), despite having less capacity and speed than NFS on RAID5. Besides, it is an option with low cost because we have configured PVFS2 with single disks and we have obtained acceptable performance.

5. Conclusion

A methodology to evaluate the I/O system utilization of parallel computers for the parallel scientific applications has been proposed and applied. It allows us to determine how much of the system's capacity is being used. The methodology can be used for selecting the more convenient configuration from the available configurations in an I/O system. We have presented an I/O model of the application depending on its I/O phases. The I/O model of application is defined by three characteristics: metadata, spatial global pattern and temporal global pattern. We instrument the application to obtain the access pattern and we analyze the pattern to find the I/O phases. This instumentation is done at MPI-IO level which does not requiere the source code. We have evaluated the I/O system utilization of different I/O configurations by considering the I/O model of application and the I/O system.

This methodology was applied in two different configurations for the NAS BT-IO benchmark and MadBench2. The characteristics of both I/O configurations were evaluated, as well as their performance usage by the application. We have extracted I/O models of applications and we evaluated the difference of performance on I/O configurations taking into account the I/O phase behavior of application in I/O devices.

As future work, we will extend the I/O phases identification to different applications which show different I/O behaviors. We are analyzing real scientific applications to obtain their I/O models. We will use the I/O model to support the evaluation, design and selection of different configurations of the I/O system.

Abstract

The MASS (Multi-Agent Spacial Simulation) library facilitates parallelization of applications that are viewed as interaction among up to millions of agents behaving over a shared virtual space and that are thus fitted to simulation of ecological, social, and physical mechanisms. The library invokes user-defined functions of all agents and array elements as well as exchanges data among them in parallel. The key to success of this library implementation is to accelerate function invocation with preprocessor-generated code and to facilitate an application debugging environment. This paper presents the design strategy, implementation, and usability of the MASS library preprocessor and debugger.

1 Introduction

Multi-agent individual-based models view computation as interaction among agents and individuals, each autonomously behaving in a shared simulation environment. They have been used for years to simulate ecological, social, and physical mechanisms that are generally difficult only with mathematical formulae. To parallelize these models, we are developing the MASS (Multi-Agent Spatial Simulation) library that updates the status of all objects at once with the *callAll* method and exchanges data among all objects at once with *exchangeAll* method. These methods are attributed as (1) one-sided parallel communication from the main function to all array elements and (2) one-sided parallel communication from each element. Therefore, MASS benefits not only multi-agent models but also data-intensive computation with its parallelization.

We implemented MASS in Java from the viewpoint of its widely used and convenient graphics features. However, due to Java's nature as well as the multi-agents' behavioral complexity, MASS encounters the following four challenges: (1) parallelization is killed by the slow Java reflection that is used to identify a user function called from *callAll/exchangeAll*; (2) *exchangeAll* incurs substantial communication overhead if applied to computationally fine-grained elements; (3) a programmer needs to check inter-element communication flow at an application level; and (4) agent migration is difficult to keep track of at a user level.

To address these problems, we have developed a language preprocessor and GUI-based debugger for the MASS library. The preprocessor inserts additional code in a given application for calling a user function from *callAll/exchangeAll* without using Java reflection and for transferring multi-element data in bulk. The debugger runs between a user application and the underlying MASS library to capture all the library calls so that it graphically shows each object's status, monitors inter-object communication, keeps track of agent migration, and stops/resumes the user program at a break point.

This paper describes the preprocessor-assisted MASS performance improvement and library extension, presents the features and internal design of the MASS debugger, and demonstrates the uniqueness and usability of these software tools in comparison with related work.

2 MASS Library

2.1 Execution Model

Places and *Agents* are keys to the MASS library. *Places* is a multi-dimensional array of elements that are dynamically allocated over a cluster of multi-core computing nodes. Each element called a *place*, is pointed to by a set of network-independent array indices, and is capable of exchanging information with any other *place* objects. *Agents* are a set of execution instances that can reside on a *place*, migrate to any other *place* with array indices, and interact with other *agent* objects as well as multiple *place*s.

As shown in Figure 1, parallelization with the MASS library uses a set of multithreaded communicating processes

*Corresponding author. Email: mfukuda@u.washington.edu, Phone: 1-425-352-3459, Fax: 1-425-352-5216

that are forked over a cluster and are connected to each other through ssh-tunneled TCP links. The library spawns the same number of threads as the number of CPU cores per node. Those threads take charge of method call and information exchange among *place*s and *agent*s in parallel.

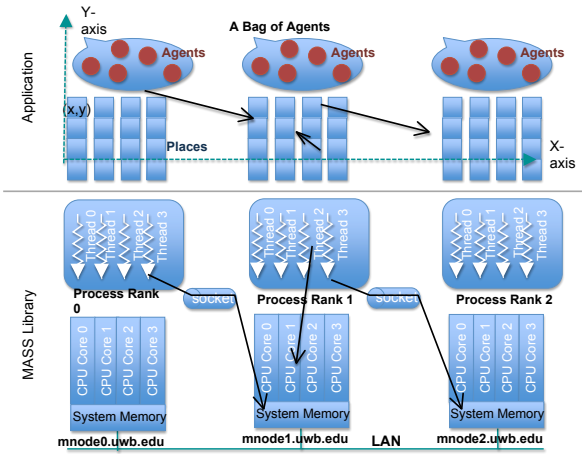

Figure 1. Parallel execution with MASS library

2.2 Library Specification

A user designs behaviors of a *place* and an *agent* by extending the *Place* and *Agent* base classes respectively, populates them through the *Places* and *Agents* classes, and performs their computation through the following methods.

Places Class

- ***public Places(int handle, [String primitive,] String className, Object argument, int... size)*** instantiates a shared array with *size* from *className* or a *primitive* data type as passing an *argument* to the *className* constructor. This array receives a user-given *handle*.
- ***public Object[] callAll(String functionName, Object[] arguments)*** calls the method specified with *functionName* of all array elements as passing *arguments[i]* to element[i], and receives a return value from it into *Object[i]*. Calls are performed in parallel among multi-processes/threads. In case of a multi-dimensional array, *i* is considered as the index when the array is flattened to a single dimension.
- ***public Object[] callSome(String functionName, Object[] argument, int... index)*** calls a given method of one or more selected array elements. If *index[i]* is not negative, it indexes a particular element, a row, or a column. If *index[i]* is negative, say $-x$, it indexes every x^th element. Calls are performed in parallel.
- ***public void exchangeAll(int handle, String functionName, Vector<int[]> destinations)*** calls from all elements a given method of all destination elements, each indexed with a different *Vector* element. Each vector element, say *destination[]* is an array of integers where *destination[i]* includes a relative index (or a distance) on the coordinate i from the current caller to the callee element. The caller passes its *outMessage[]* data member to the callee as a set of arguments, and receives return values in its *inMessage[]*.
- ***public void exchangeSome(int handle, String functionName, Vector<int[]> destinations, int... index)*** calls each of the elements indexed with *index[]*. The rest of the specification is the same as *exchangeAll()*.

Agents Class

- ***public Agents(int handle, String className, Object argument, Places places, int population)*** instantiates a set of agents from *className*, passes the *argument* to their constructor, associates them with a given *Places* matrix, and distributes them over these places, based on *map()* that is defined within the *Agent* class.
- ***public void manageAll()*** updates each agent's status, based on its latest calls of *migrate()*, *spawn()*, *kill()*, *sleep()*, *wakeup()*, and *wakeupAll()*. These methods are defined in the *Agent* base class and may be invoked from other functions through *callAll()* and *exchangeAll()*.

2.3 Design Issues

From the user viewpoint, *Places* and *Agents* are theoretically considered as an array or a collection of *Place* and *Agent* objects respectively. However, their underlying implementation is not so simple in order to not only serve as a general simulation framework but also to work over a distributed-memory cluster. We need to address the two design challenges below:

Language Issues: Unless a user implements base methods of the *Place* or *Agent* class, *Places* and *Agents* do not know any methods of a user-defined class. This in turn means that the *callAll/Some* and *exchangeAll/Some* methods cannot invoke a user function simply through object casting. Instead we need to use Java reflection to interrogate a user-defined class. The problem is that the reflection works one order slower than a direct function call in general. This slow performance kills parallelization where MASS calls the same function of all objects at once. To pursue both naming flexibility and high-speed invocation of user functions, we design a Java preprocessor that inserts additional code to match the names of user functions defined in MASS methods and the actual function bodies to invoke, so that the library calls user functions without the reflection.

Debugging Issues: Since *Places* and *Agents* may be allocated over a distributed-memory cluster, the status and execution of their elements is not always visible and traceable where the main program is running. For debugging purposes, users are responsible to collect remote element status by manually inserting combinations of *callAll/Some* and *exchangeAll/Some* methods as well as adding additional graphics code into their application programs. In particular, it is tedious work for application designers to keep track of migrating *Agent* objects over different computing nodes. We address these debugging issues by designing a wrapper that covers the original MASS library and facilitates GUI-based debugging features.

The next two sections explain these solutions.

3 Preprocessor Design

3.1 Library Extension

We extend MASS to avoid Java reflection and to accelerate message exchange among *Place* objects as follows:

Eliminating Java Reflection: Given a function name in the MASS methods, we need to quickly identify its function body to invoke. A trivial but naive idea is to store user function names in a symbol table at compile time and thereafter to compare each symbol table entry with a function name specified in a MASS method each time it is invoked at run time. The problem is repetitive string comparisons that may weigh more than actual computation at each *place* or *agent*. Instead we use integer comparisons where user function names found in MASS methods receive a different integer, (i.e., a function id) at compile time and a MASS method invokes the user function corresponding to a given function id. Figure 2 shows preprocessor-generated example code that jumps from two MASS methods to a different user function: two user function names such as "exchangeArray" and "putArray" in *exchangeAll()* and *callAll()* (lines 1-2) receive a function ID respectively (lines 6-7); the original *exchangeAll()* and *callAll()* calls the preprocessor-generated *callMethod()* (line 12); and the control branches off to the corresponding user function, based on the function id (lines 14-15).

Exchanging Each Place's Boundary Information: The MASS library originally assumes that a *Place* object is used as an individual element of a distributed array. However, the cost for *exchangeAll/Some* is substantial to fine-grained computation at each *Place* object, because data exchange generally takes place with multiple neighbors. Therefore, a user wants to include a collection of array elements in each *Place* object that then exchanges its boundary elements (or shadow elements) in fewer packets with neighbors as shown in Figure 3. This reduces the frequency of communication over an entire array while increasing the

```
1   // the original MASS methods
2   myPlaces.exchangeAll(h, exchangeArray, neighbors);
3   myPlaces.callAll(putArray, args);
4
5   // preprocessor-generated code to jump user functions
6   public static final int exchangeArrayP_ = 0;
7   public static final int putArrayP_      = 1;
8
9   myPlaces.exchangeAll(h, exchangeArrayP_, neighbors);
10  myPlaces.callAll(putArrayP_, arggs);
11
12  public Object callMethod(int funcId, Object args) {
13     switch(funcId) {
14        case exhangeArrayP_: return exchageArray(args);
15        case putArrayP_:     return putArray(args);
16     }
17     return null;
18  }
```

Figure 2. Two MASS methods and their preprocessor-generated code

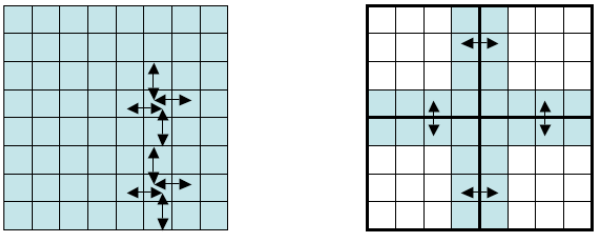

Figure 3. Communication among neighboring Place objects

computation amount per *Place*. A new MASS library function named *exchangeBulk* exchanges such boundary information among neighboring *Place*s. As shown in Figure 4, we achieve it by translating *exchangeBulk* into a combination of *exchangeAll* and *callAll* (lines 6-7): the former calls a given function of all neighboring *Place* objects to retrieve their boundary information, and the latter put the information into the local *Place*'s boundary space. The MASS preprocessor assumes that a user defines *exchangeArray* and *putArray*, where *Array* is a user-defined *Place* object, each actually achieving data retrieval and saving operations. If not, the preprocessor generates simple stub functions (lines 9-15). Thereafter, it converts this pair of *exchangeAll* and *callAll* into those calling the user functions with their function IDs as described in Figure 2.

3.2 Design Strategies

We design and implement the MASS preprocessor, based on the following two strategies. First, we use an existing Java compiler-compiler tools: JavaCC and JJTree

```
1   // A new MASS method to exchange boundary data
2   myPlaces.exchangeBulk(h, Array, neighbors);
3
4   // preprocessor-generated exchange/callAll from
5   // exchangeBulk
6   myPlaces.exchangeAll(h, "exchangeArray", neighbors);
7   myPlaces.callAll(h, "putArray", neighbors);
8
9   public Object exchangeArray(Object src) {
10     return (Object)Array.getBoundary((int[])src);
11  }
12  public Object putArray(Object arg) {
13     Array.putBoundary(inMessages);
14     return null;
15  }
```

Figure 4. exchangeBulk and its preprocessor generated code

for parsing and optimizing MASS user programs. Second, we carry out two passes of MASS program translation: pass 1 converts *exchangeBulk* into a combination of *exchangeAll/callAll*, and pass 2 generates additional code to call a user function from a MASS library method with its function ID. The following details an implementation of our MASS preprocessor.

3.3 Implementation

The preprocessor performs its optimizations by running the input code through a Java parser. The parser emits tokens in response to the input code. Actions are taken on specific tokens to check conditions, set flags, and modify output. A grammar defines a roughly correct version of Java. It has been modified to create Abstract Syntax trees. From the grammar, a parser is generated (as UnparseVisitor.java) which by default will output any input which matches the Java language as defined by the grammar. As shown in Figure 5, the parse methods can be overwritten with MASSOptimizer, ExchangeBulkOptimizer, or ReflectionOptimizer to perform MASS optimizations. For example, when parsing a *MethodDeclaration* token, a flag will be set to indicate that a new method is being parsed and that a new scope must be placed on the stack. Subsequently, if a *ResultType* token is parsed while the *MethodDeclaration* flag remains set, the return type of the parsed method can be recorded. These optimizers in Figure 5 set flags in their *visit()* methods and implement the logic to respond to those conditions in their *find(Token)* methods.

The preprocessor has been tested on some MASS programs including two-dimensional wave simulation (Wave2D) and three-dimensional computational fluid dynamics (CFD). The verification and performance evaluation has been conducted by comparing manually-translated versus preprocessor-generated code. Figure 6 demonstrated the competitive performance of preprocessor-generated code in

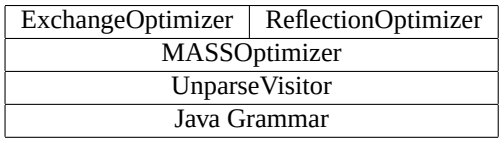

Figure 5. MASS preprocessor implementation

4 Debugger Design

A simple debugging program was implemented to assist MASS developers. Currently, the debugger uses the multi-threaded Java version of MASS. It allows users to view a logical arrangement of their computational spaces' values through a 2D or 3D graphical view.

4.1 Debugging Features

The basic objective of the debugger is to display the contents of computational nodes in a human-understandable format, as shown in Figure 7. Its features are designed to support this goal:

- Displays results in a flat view or hawk's eye view.
- Opens windows to display additional dimensionality.
- Allows debugging in code or in GUI.
- Sets break points and defines iteration points.
- Advances to next break point or by iteration.
- Shows communication between logical nodes.
- Saves and restores computational values.

The developer can set break points in program iteration. This differs from traditional debugging code break points, and is more akin to setting break points based on variable values. However, the developer can specify when in the driving code that an iteration occurs, allowing a more fine-grained approach than might be initially apparent.

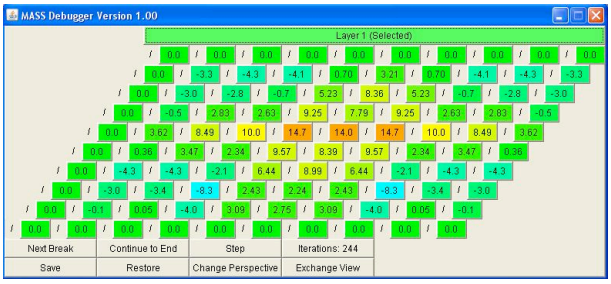

Figure 7. Debugger GUI's hawk's eye view of computational node values.

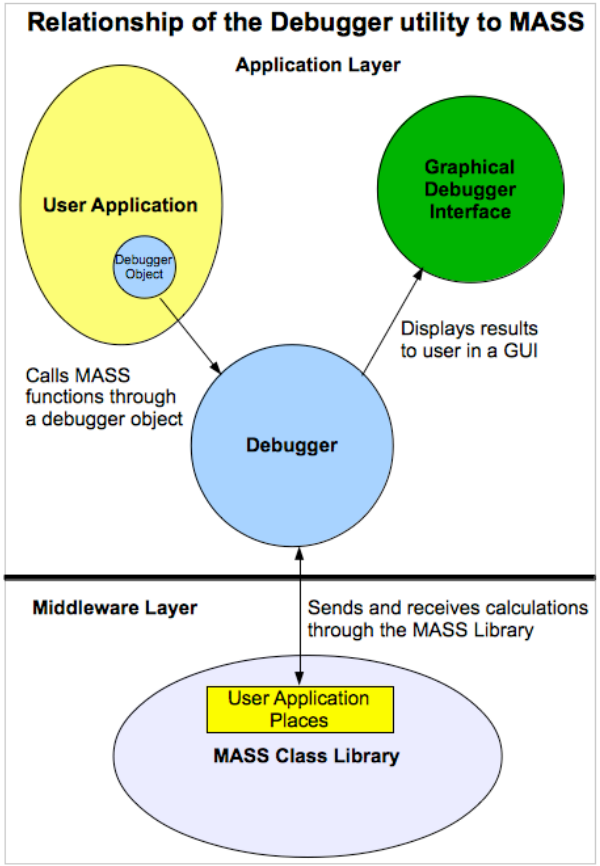

Figure 8. Interaction between the debugger, a user application, and MASS.

4.2 Design Strategies

Design of the debugger followed a twofold strategy. The debugger wraps functions of the MASS class library as shown in Figure 8, and development is driven by the need for features to show information in terms of the MASS application developer's perspective. The development of the debugger relied on an iterative approach that focused on design, planning, and prioritization of features. A basic goal is to implement features as simply as possible. Early in the process it became apparent that there were two challenges: accessing MASS and creating the graphical interface. Comparing the two, using MASS was simpler than creating the graphics, but had yet to be thoroughly explored. The debugger is the first application to demonstrate that multiple classes can utilize MASS concurrently.

4.3 Implementation

The debugger program exists separately from the MASS library. Therefore, it is not affected by changes in the MASS implementation that don't affect MASS function signatures. In effect, it serves as an intermediary layer that wraps MASS functions. In addition to the debugger class, there are classes for graphical control objects: the display windows and buttons. When data is returned from the MASS classes, in addition to returning the data to the user, the debugger also instantiates graphical objects using Java's awt classes, and displays the results. The organization of the results are based on the user-defined sizes of the arrays that are passed to MASS when it is initialized. In this context, the implementation of the debugging features only has to use simple private counters and Booleans to keep track of iterations and breakpoints. When a breakpoint is hit, further function calls to MASS are suspended. Since all MASS results are returned in single arrays, there is no latency in updating individual node results from the debugger or user perspective. Depiction of exchange results are more difficult, because MASS does not provide return values for them. The user provides a vector of relative node coordinates where data is exchanged. The debugger applies the vector to each computational node to determine the coordinates where the data exchange occurred, and shows the last computation (from a MASS *CallAll* function) as the data that is sent. Checkpoints take the return values from a computation and store them in a file. The file is read back into an array of objects when the checkpoint is restored, and passed to MASS. It is important to note that this method of restoring a checkpoint is only valid if the user's places do not rely on local resources, such as a local system clock, for their calculations. The debugger offers three general types of public methods, as shown in the sample code of a simple driver application in Figure 9:

- MASS-equivalent functions with identical signatures
- MASS-equivalent functions with extended signatures for the debugger
- Debugger-only functions, such as setting break points.

The MASS functions with extended signatures combine MASS-equivalent functions with debugger functions, trading fewer function calls for ones with more parameters. Control buttons also implement debugger functions for features such as advancing one iteration or continuing to the next break point while the user's program is running.

```
1  // Initialization of MASS through debugger
2  debugger.degubInit(totalSize, totalDimensions,
3        ''DebuggerDriver'', threads, 0, 999);
4
5  // Pure debugger functions
6  debugger.setTotalIterations(iterations);
7  debugger.setBreakPoint(20);
8  debugger.setStopOnBreakPoint(true);
9
10 // Use of MASS through debugger
11 while(!debugger.isFinished()) {
12    // MASS-equivalent function called through
13    // debugger (shows results in GUI by default)
14    debugger.debugCallAll(0, (Object[])null);
15
16    // ...with iteration set separately
17    debugger.iterate();
18
19    // MASS function with debugger parameters
20    // (ticks iterator shows results in GUI)
21    debugger.debugIterateCallAll(0, (Object[])null,
22       true);
23 }
24
25 // end debugger operations and clean up graphics
26 debugger.finish();
```

5 Related Work

5.1 Preprocessors

Our MASS library and preprocessor design involves library-assisted parallel execution, preprocessor-assisted code generation, and code manipulation. Those techniques are found in the following four language systems.

Parallel Java Library promotes hybrid SMP cluster programming in Java by combining multithreaded programming constructs and MPI-based message-passing functions [4]. MASS and Parallel Java libraries both take a similar approach in hiding all underlying parallelization work with their Java library classes and methods. However, the major difference is that MASS does not distinguish shared and distributed memory but gives a consistent view of multi-agents running on a shared array regardless of underlying memory architectures.

Extensible PreProcessor (EPP) defines plug-ins for generating tiny data-parallel Java code [3], where the special modifier *"parallel"* given to a Java class generates additional multithreading code in its *run()* method that handles all data with virtual processors in parallel. Although MASS and EPP use a preprocessor approach for parallelization, EPP focuses on multithreading, whereas the MASS preprocessor extends its scope to hybrid SMP cluster computing.

MPIPP is another preprocessor tool that converts a user-defined data structure into MPI-derived data types [6]. It is similar that our *exchangeBulk()* function converts a certain range of boundary array elements to *Place.outMessage* as well as *Place.inMessages* back to the original elements. However, our MASS preprocessor is different in generating *get()* and *put()* methods to automate entire boundary-to-boundary element transfers.

Javassist facilitates a compiler-assisted Java bytecode manipulation that defines new classes, freezes existing classes, and customizes class members [1]. Therefore, Javassist can works as another option to optimize the *exchangeBulk()* function and to match user function names in the MASS library and their actual function bodies, by directly manipulating a user program. However, it would be the same amount of work required if our preprocessor were redesigned to introspect and manipulate all MASS keywords with Javassist.

5.2 Debuggers

The MASS debugger is a framework-oriented, library-based, visualization-focused, and data-parallel application debugger. In these categories, we found similarities to and differences from the following four products.

Hadoop and the MASS debugger are both framework-oriented debugging utilities. Hadoop uses a Java class based on the JUnit3 test case and performs testing using a virtual map cluster [8]. The MASS debugger debugs through the actual execution of the MASS program, as MASS controls where its computational spaces run. Hadoop Test Case output is console output, shown through the user's IDE. MASS debugger output uses its own graphical interface.

MPI Debugging Interface is used to provide the conceptual message passing state of the program [2]. The debugger implementation studies the communicator queues; the MASS equivalent of these are the parameters of its major functions. Both applications conclude that accessing the library class must be led by the debugger. Specific interfaces to display data are not implemented by the MPI debugger in contrast to the MASS debugger's GUI.

TotalView is a feature-heavy, commercial debugging interface designed for distributed software [7]. TotalView, like MASS, makes use of a GUI for data visualization but lacks concurrent display of values. The TotalView software is more sophisticated than MASS but also more complicated, and is not free. MASS, in contrast, is geared specifically to MASS users and is currently free. Using TotalView with MASS would strip away all the abstraction that the

MASS library is providing.

Global Arrays are a means to solve data-parallel jobs, and intersects with MASS's application areas [5]. It gives the user very fine-grained control over the data objects it uses, but at the cost of a great deal of programming complexity in implementation. In contrast, MASS aims explicitly to simplify and abstract away complexity. Global Arrays do not in themselves provide explicit debugging tools; while the MASS debugger is an extension of MASS that does not currently exist in Global Arrays.

In summary, we believe that our design strategy for the MASS preprocessor and debugger fits user requirements for multi-agent spatial simulation.

6 Future Work

6.1 Preprocessor

At present our preprocessor has the following limitations and issues: (1) MASS applications to be processed should not contain a method named "*callMethod*" or use a trailing underscore ("_") as part of a method name; (2) all methods to be called from *callAll/Some* or *exchangeAll/Some* must accept the same set of parameters in the same order; (3) user-owned non-MASS methods should not have names identical to MASS methods; and (4) MASS variables may not be recognized if they are cast or assigned to other classes at runtime. We believe that these limitations are acceptable.

As our future work items, we are developing C, C++, and CUDA-C versions of the MASS library. Since C and C++ allow programmers to use dynamic linking and function pointers, we do not see any necessity of developing a MASS preprocessor for them. However, CUDA-C has its own extensions to C. Although these extensions are quite unique to GPUs, we are planning to develop a preprocessor that assists C programmers in running MASS applications on GPUs. Our ultimate goal is to facilitate a Java or C++ version of the MASS library for GPU computation through a cascading code translation to CUDA-C.

6.2 Debugger

Currently, the MASS debugger focuses on the step-by-step display of computational node data and communication. The limitations include: (1) agents and their migration are not displayed; (2) the interface is still only a proof-of-concept design; (3) break points are not based on computational node values; and (4) analysis and step-through of the developer code itself is not implemented.

Implementation of agent status and migration view is the immediate next step in terms of future development. The interface must be improved for the overall user experience. Allowing break points based on computational node values will give the user more flexibility. However, the goal of the MASS debugger is to provide an easy way to view MASS computations, not to become a commercial debugger with a full feature set. Consequently, certain debugger features: the ability to step through code and to set break points in the code itself, are not prioritized for future development.

7 Conclusions

The MASS library eases parallelization of multi-agent individual-based models as well as data-intensive applications. In this paper, we analyzed the current issues in code development and execution with the library, addressed them with our preprocessor approach and debugger design. The MASS library and tools will be made available upon an email request sent to *dslab@uw.edu*.

Stream Processing Approach on the Fuce System for parallelizing Nested Loops with Data Dependency

Satoshi Amamiya, Makoto Amamiya
Department of Informatics, Faculty of Information Science and Electrical Engineering,
Kyushu University

Abstract— *It is widely known that nested loops with data dependency can be parallelized by transforming the original loops by techniques such as loop skewing, loop interchange (so called software pipelining and/or wavefront method). However, these loop transformation techniques need to solve the equation of simultaneous inequalities and modify loop index variables by "human". These procedures require complicated formalities to programmers. We have developed a much simpler method to parallelize nested loops with data dependency, which is an straightforward application of asynchronous handshaking stream programming on the continuation-based multithreading.*

In this paper, we discuss our new approach in detail and show the enough performance enhancements can be exploited by our approach by evaluating the parallelized version of nested loop programs, on the Fuce runtime system on a commodity machine.

Keywords*: stream processing, multithreading, loop parallelization*

1. Introduction

The importance of high performance computing (HPC) have been widely recognized in the world and a lot of the researches on HPC have been conducted in past decades. High performance scientific computations are mostly large array operations. The speedup of array operations relies on basically the parallelization of multi-level nested loops for array. A variety of techniques for the loop parallelization was developed. In particular, for nested loops with data dependency, parallelization methods such as loop skewing, loop interchange (so called software pipelining and/or wavefront method) are noted. However, these loop transformation techniques need to solve the equation of simultaneous inequalities and modify loop index variables by "human". These procedures require complicated formalities to programmers.

We need a simpler approach to the parallelization and the programming techniques. We researched and developed the parallel architecture called Fuce[1] and its programming language CML (Continuation-based Multithreading Language) based on the idea of *continuation* and *non-interruptible thread*. The CML is designed for writing low-level event-/demand-driven concurrent processes, stream processing, mutual exclusions, memory management and so on in a unified form.

In this paper, we introduce the stream processing based on the asynchronous handshake multithreading. And then we discuss the simpler parallelization technique for nested loops with data dependency as an application of our stream processing approach. Also we describe the implementation of the Fuce runtime system for commodity machines and show evaluation results of the stream processing programs executed on the Fuce runtime system.

2. Conventional Method for Parallelization

The wavefront method[2] is known as a typical method for parallelizing multi level nested loops with data dependency. We briefly explain the wavefront method using the following sample program[3]:

```
for (i = 2; i <= 6; i++)
  for (j = 2; j <=6; j++)
    a[i][j] = (a[i-1][j] + a[i][j-1]
          +a[i+1][j] + a[i][j+1]) / 4
```

To eliminate data dependencies inside the loop, first we have to do loop-skewing and then interchange the outer and the inner loops. The transformed program looks like:

```
for (j = 4; i <= 12; j++)
  for (i = max(2,j-6);
        i <= min(6,j-2); j++)
    a[i][j-1] = (a[i-1][j-i]
      + a[i][j-1-i] + a[i+1][j-i]
      + a[i][j+1-i]) / 4
```

After a modification of this program with support of a parallel programming library, we execute the program in data parallel manner on parallel machines.

However, we have to solve a simultaneous inequality on variable i and j by hand to find the range of index variable i and j. We think this is not always a simple method. In addition, the users or programmers of such a wavefront program would not obtain high performance computation if they are not so familiar with a parallel programming library.

The idea of wavefront method itself seems to be simple and beautiful. But a implementation of a data parallel program based on this idea will become complicated. If we devise a different approach from the data parallelization, We will benefit from the basic idea of wavefront method without complicated procedures.

3. Stream Processing and the CML language

We introduce a special language called CML (Continuation-based Multithreading Language) to understand a basic behavior of stream processing. The large portion of the CML is derived from the ANSI C language. Some new grammatical constructs are designed and extended for stream processing. In this section, we give an outline of new constructs only for stream processing. The detail of the CML is described in the papers[4], [5].

3.1 The Language CML

On the stream processing, temporal data storage space is usually set up between the sender and the receiver of data. Normally it is a bounded FIFO buffer. Here, for this purpose, we define a simple buffer storage called *channel* which can store basically only one data.

Channel Struct

```
struct chan {int flag, value,
             from, to;}
```

The stream is closed if `flag==0`. A variable `value` holds a single stream data. The type of value is not only integer type, but also float or double is acceptable. We just re-define a new chan type as usage. A variable `from` holds sender process id and a variable `to` holds the receiver process id.

Process Definition

```
process P(chan *ch, ...) <2> {...}
```

`*ch` is a pointer to a channel struct. `<2>` is the number of fan-in of process P. If this notation is abbreviated. the number of fan-in is 1. `{...}`is a body of process P.

Here, the number of fan-in of a process means the number of data which the process requests to send from other processes. Therefore, Once the process is scheduled and the value of fan-in of the process is initialized, the value of fan-in is simply decreasing in each data arrival. When the value of fan-in becomes zero, the process becomes ready to run [1].

Instance Creation

```
int p = new P();
```

A data area and instance of process P are reserved.

Track-laying of Stream

Set the variable `from` in channel struct to the data sender process id and set the variable `to` to the receiver process id.

Process Invocation

When invoking a process, pass the channel name as actual parameter. And use *mode indicator* <+> for a sender process, <−> for a receiver process.
For example:

```
p(ch1<+>, ch2<->);
q(ch1<->, ch2<+>);
```

Here, the process p sends a data to the process q via channel ch1 and the process q sends a data to the process p via channel ch2.

3.2 Basic Behavior of Stream

Consider a pair of processes $\langle w, r \rangle$ connected by a channel ch and that w generates a series of values for x, and sends them to r. This stream processing can be written in CML as in Figure 1. The action of w and r is controlled by cont instructions. Here we call init-, trigger-, or ack-cont for each cont instruction according to its usage. Init-cont is issued to invoke a newly created process instance. Trigger-cont is issued to invoke or prompt to invoke the other processes. Ack-cont is issued to the other process by the process which becomes ready to receive the next data.

When W is invoked by an init-cont or an ack-cont issued by R, W puts a value of x to ch, then issues a trigger-cont to R so that R can get the value. When R is triggered by W, R gets the value of x from ch, then issues an ack-cont to W so that W can put the next value. Note that the number of fan-in for $W(R)$ is two since it requires a recur-cont plus a trigger-(ack-)cont.

It never happens that both W and R run at the same time, and that ch is accessed by both. Moreover, W and R run alternately, and it never happens that W puts values to ch in succession, and that R tries to get the next value from ch before another data is put.

This behaviour is easily understood by using a Petri net-like graph depicted in Figure 2. A token represented by a black disk corresponds to an issue of cont instruction. The token in the right arrow entering w is an init-token, the tokens in the left arrows of w and r are recur-conts.

3.3 Dynamic Growth of Stream

In the examples in section 3.2 the number of processes is small and fixed. They may be unworkable in the real world. In general, the number of processes will increase dynamically. The length of stream will grow accordingly.

Consider a process named *Create* which manages a process creation. Create process is written in CML for example as following:

```
process create(chan *ch) <2> {
    darea chan ch1;
    new RW(ch<*>, ch1<+>);
    new create(ch1<->);
}
```

Here, a storage for a variable declared as `darea` is dynamically allocated at run time. After Create process creates

[1]Processes in the CML are fundamentally equivalent to threads in the Fuce execution model.

```
process main() {
  w = new W(); r = new R();
  ch->from = w; ch->to = r;
  w(ch<+>); // w's recur-cont
  r(ch<->); // r's recur-cont
}
process W(chan *ch) <2> {
  /* computing x's value */
  ch->value = x;
  cont ch->to; //trigger-cont to r
  recur;
}
process R(chan *ch) <2> {
  x = ch->value;
  cont ch->from; // ack-cont to w
  /* using x's value */
  recur;
}
```

Figure 1: A CML code for a basic stream processing.

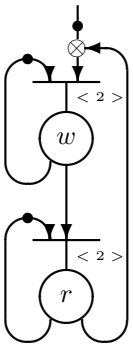

Figure 2: Petri net for a simple stream processing among two processes.

and invokes a process *RW*, it *re-creates* itself [2]. The second parameter of RW process is `ch1<+>` and the parameter of the new Create process is `ch1<->`. Therefore RW process and Create process form a stream processing among two processes as seen in Figure 1. The notation `<*>` added to the first parameter of RW process means that the channel is used for both of sending and receiving.

We define process RW in which the behavior of process W is added to process R in Figure 1. The CML code is as follows:

```
process RW(chan *in, chan *out)<3>{
  int x;
  in ?? x;   // read from channel
  out !! x;  // write to channel
  recur;
}
```

Here, '`in ?? x`' and '`out !! x`' are respectively the syntax sugar of
'`x = in->value; cont in->from;`',
'`out->value = x; cont out->to;`',
The operators `??`, `!!` are derived from CSP[6]. The number of fan-in of process RW is three because process RW is the sender as well as the receiver.

Next, in the definition of process *main* we replace the creation and invocation part of process R with them of process Create as follows:

```
process main() {
  int w = new W(ch<+>);
  new create(ch<->);
  cont w;
}
```

By this modification, process W and Create form a stream processing among two processes. And as mentioned above, process RW and Create also form a stream. When process Create is invoked, it creates process RW then pass a received data to process RW immediately. So data generated by process W are sent indirectly to process RW. Meanwhile process RW sends the data to process Create as soon as it receives. As the result as long as process W generates data, process RW is kept on being created and the size of the stream keeps on growing. Both ends of the stream is process W and Create. Between them there are myriad of process RW (refer to Figure 3).

4. Parallelization of Nested Loop

4.1 Parallelize Two-Level Nested Loop

We introduce local (instance) variable `i` to process W, `j` to process RW and Create which are defined in the section 3.3. When process W is invoked it increments the variable `i` and send the value of `i` (indirectly) to process RW via channel `ch`. Process Create increments variable `j` and creates process RW and Create with the value of `j`. Process RW keeps the value of `j` which is given at its creation.

Variables added to a parameter list of a process definition are treated as instance variables. For example, process Create is defined as follows:

```
process create(chan *ch, int j) <2>{
  darea chan ch1;
  j++;
  new RW(ch<*>, ch1<+>, j);
  new create(ch1<->, j);
}
```

Figure 3 shows the behavior of three kinds of the processes W, Create, RW which are completely moving in sync. In this figure the longitudinal direction shows passage of time, the lateral direction shows growth of the stream. Note that all these processes on the stream are moving in parallel.

[2]Note that Create process is not re-activated in tail-recursive manner by recur, it disappears after it creates another Create instance.

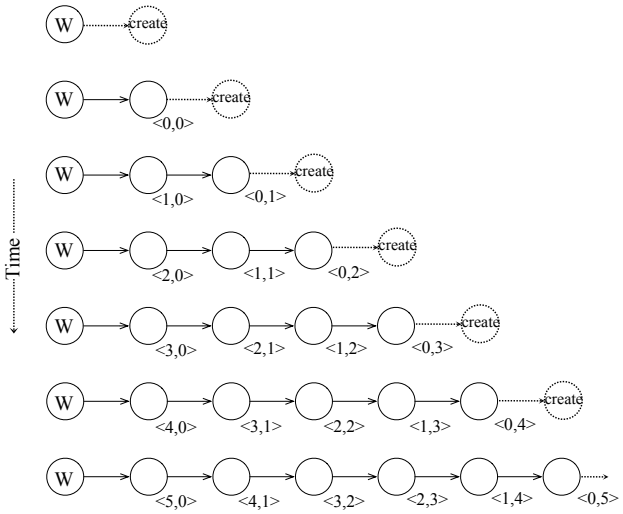

Figure 3: Ideal Stream Processing.

As mentioned above, process RW is kept on being created between process W and Create with time. The caption such like `<1,2>` in the figure is a pair of a data which is received from a immediate left process and the value of the instance variable `j` of the process RW. A data process RW receiving is initially sent by the process W, that is, the value of variable `i`.

We label the process immediate right of process W as RW_0. The initial value of `j` of process RW_0 is set to 0. A data received from process W (that is, the value of `i`) is incremented with time. The value of `j` of process RW_1 (RW_0's neighbor) is set to 1. A data RW_1 received from RW_0 is the data which the process W sent two clocks before. Therefore the value of the data RW_1 received is just as small by 1 as that of RW_o. In like wise manner, at the clock t, the pair of values process RW_n holds is `<t-n, n>`.

Now we consider the pair of values as a element of two dimensional array and observe every pair of values process RW holds at every clock. Array elements referred at same clock on the stream is completely same as the elements referred by the wavefront method[2].

That is, by using a stream processing driven by only three kinds of processes W, RW and Create, it is possible to parallelize a two-level nested loop for two dimensional array. The following loop program in C is mostly equivalent to the above stream processing:

```
for (i = 0; i < M; i++)
  for (j = 0; j < N; j++) {
    ... A[i][j]...; // array access
  }
```

4.2 Parallelize Nested Loop with Data Dependency

Consider the following nested loop:

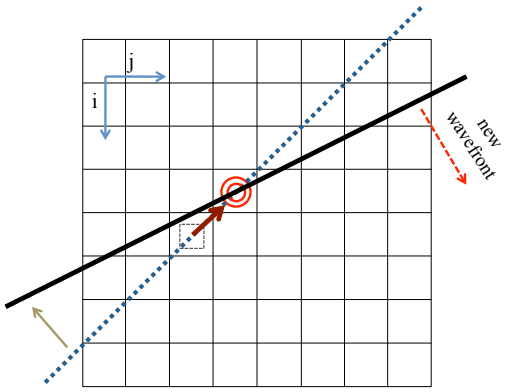

Figure 4: Wavefront on two dimensional array.

```
for (i = 0; i < M; i++)
  for (j = 0; j < N; j++)
    A[i][j] += A[i+1][j-1];
```

In this case there is a data dependency among a loop. To eliminate these kind of data dependency we have to change the direction of the wavefront movement. Figure 4 shows a movement of wavefront on a two dimensional array. The dotted line is the original wavefront. A data dependency(red arrow) exists just on the original wavefront. If the direction of the wavefront can be changed as the solid line, a data dependency disappears. To obtain the safe direction of the wavefront, we slow the speed of i-direction down by half of the speed of j-direction. When we reduce the supply of data (the value of `i`) passed on the stream by half per clock, the speed of i-direction is reduced by a half.

So, we introduce a dummy process D immediate left of process W and make process W trigger not only process RW_o but also process D. Process D triggers process W immediately when D is invoked. The number of fan-in of D is 2 and that of W is changed to 3. These modification make the speed of data supply reduced by a half because process W can run every two clocks. Figure 5 depicts the safe stream processing. Running or stopped processes is shown as white circle or gray circle respectively. A straight or curved arrow indicates a trigger-cont or a ack-cont respectively. A recur-cont is abbreviated in this figure.

While a half of processes is stopped at the same time as shown in the figure, the maximum parallelism of the stream is limited to a half number of all processes.

By the way, as we mentioned in section 3.2, in fact neighboring two processes cannot run at the same time. Therefore when we write a stream processing code naturally in CML, we get the safe stream processing like Figure 5. This is the default behavior of our stream processing approach. Such kind of data dependency disappears automatically. We don't need to care about.

Next, consider a data dependency in a loop as following:

```
A[i][j] += A[i+1][j-2];
```

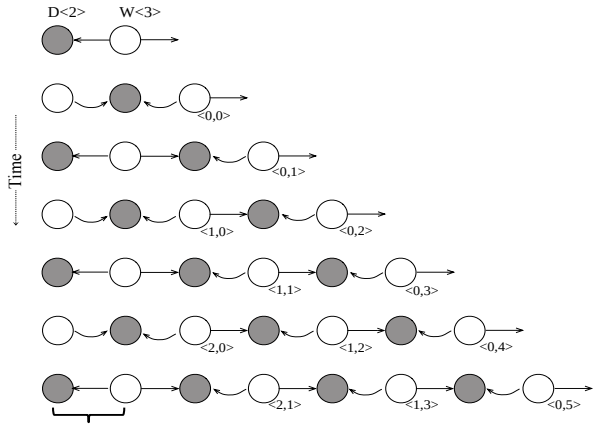

Figure 5: Stream Processing with No Data Dependency.

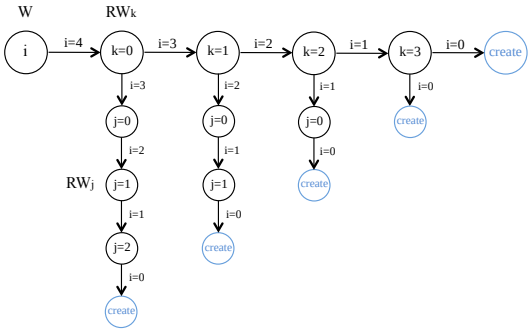

Figure 6: Stream Processing for a Three-level nested Loop.

The direction of the wavefront have to be changed also in this case. We introduce two dummy processes on left-side of process W. And each process issues ack-cont to not the neighbor process but after the next process. As a result, process W can only run every three clocks, the speed of data supply is reduced by one third. The direction of the wavefront changed to the way which satisfies $i : j = 1 : 3$.

4.3 Parallelize Three-level Nested Loop

With a small expansion of stream processing approach to a two-level nested loop, it is not so difficult to parallelize a three-level nested loop.

We modify the definition of process RW for a two-level nested loop so that process RW can act as same as process W and can make links to two different Create processes. Then two different streams will grow from a single process RW.

Figure 6 depicts a stream processing for a three-level nested Loop. A process on the crosswise stream named RW_k and that on the lengthwise stream named RW_j. The process RW_k sends the value of `i` which is passed from the process W to lengthwise and crosswise. The behavior of process RW_j is mostly as same as the process RW defined for a two-level nested loop. The wavefronts are generated as many as the number of the process RW_j and move continuously on a two dimensional array. The following three-level loop is mostly equivalent to the stream processing explained in this section:

```
for (i = 0; i < L; i++)
  for (k = 0; k < M; k++)
    for (j = 0; j < N; j++)
      ...A[i][k] = A[k][j]...;
```

By the way, if a new stream grows from RW_j, this stream processing corresponds to a four-level nested loop. In like wise, if every process on every stream has the ability to generate a new stream, a n-level nested loop can be parallelized by our stream processing approach.

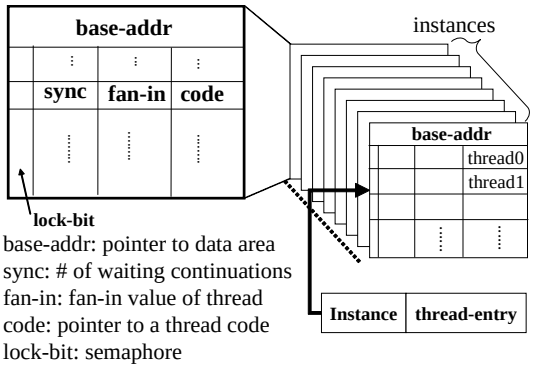

Figure 7: ACM.

5. Fuce Runtime System

We implemented the Fuce[1] processor as a software runtime on commodity OSes and parallel machines to judge the effectiveness of the idea of *non-interruptible threads* on Fuce.

5.1 ACM

The *Fuce* program is written as a set of functions. Each function is programmed using threads, and the corresponding function instances are executed in its runtime. Information of function instances is stored in a special storage called *Activation Control Memory* (ACM). Figure 7 depicts the structure of ACM. The information for controlling thread execution; sync-count, fan-in, code-entry and lock-bit, are stored in ACM.

5.2 TAC and TE

In this runtime, multiple thread execution engines are implemented. The key components of *Fuce* to support concurrent thread execution are the Thread Activation Controller (TAC), multiple Thread Execution units (TEs).

Each TE holds a ready thread queue independently. TE has the ability to *steal* a thread from the queue of another TE when its queue is empty. In order to realize this ability

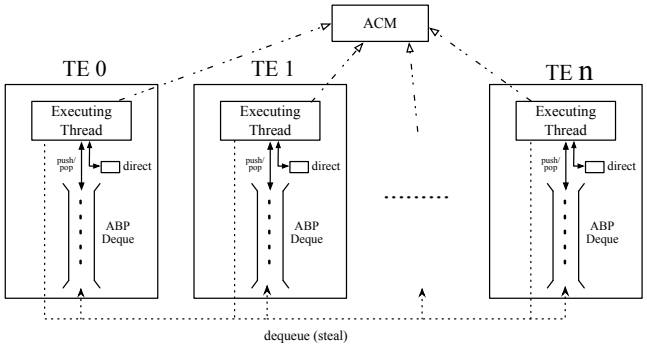

Figure 8: Multiple TEs and the ACM.

efficiently, we use ABP Deque[7] which is one of simple lock-free algorithm and can be used as a queue or a stack. With ABP Deque, a ready thread is pushed to the deque as a stack without any mutual exclusion. A thread is popped by the TE from its deque. If the deque is empty, the TE try to steal (dequeue) a thread from another TE's deque. Figure 8 shows multiple TEs accessing simultaneously to the ACM.

The main part of TE is implemented in C as following:

```
int thid;
Te_Env *env =
  (Te_Env *) GET_TE_ENV(thid);
while (!fuce_halt) {
  if (env->direct != NO_THREAD) {
    thid = env->direct;
    env->direct = NO_THREAD;
  } else {
    thid = pop(env->deque);
    if (thid == NO_THREAD)
      thid = steal_thread();
  }
  /*get thread info from ACM*/
  acm_page *page =
    &ACM[PAGE_NUM(thid)];
  thread_t *thinfo =
    &(page->entries[OFFSET(thid)]);
  void  *da  = page->darea;
  uint   id  = thinfo->id;
  Thread thr = thinfo->thread;
  thinfo->syncc = thinfo->fanin;
  /*invoke a thread as a func*/
  thr(id, da);
 }
```

Each TE can be executed concurrently on commodity OSes when the above routine is setup as a pthread.

5.3 Handling Cont Signals

a cont instruction as in Figure 1 is handled by the runtime function `cont()` with a thread id as a parameter. When the size and address of a stack for a TE (as a pthread) are properly initialized according to the pthread specification, we can determine which TE calls the function `cont()`. For example, if stack size is set to 1MB and some local variable is defined, we can obtain the stack address by the following operation:

```
#define GET_TE_ENV(ver)
    (((unsigned long) &ver)
     & (unsigned long) ~(0x100000 - 1L))
```

By using this macro the runtime function `cont()` can be simply defined as follows:

```
void cont(thid id) {
  Te_Env *env;
  int syncc;
  thread_t *target = get_thread(id);
  ATOMIC_DECREMENT(target->syncc);
  if (target->syncc < 0)
    ERROR(...);
  if (target->syncc == 0) {
    /*get current TE's env */
    env = (Te_Env *) GET_TE_ENV(id);
    if (env->direct == NO_THREAD)
      env->direct = id;
    else
      /* push thrd to ABP Deque*/
      push(env->deque, id);
  }
}
```

ACM is modified inside the function `cont()`. This modification must be done by a atomic operation because multiple threads executed in TEs would access the same location in the ACM at the same time.

6. Evaluation of Stream Processing

We evaluated the performances of stream processing CML codes on the Fuce runtime system. The program codes are transformed from two-level nested loop with data dependency. We used two benchmark programs, ISC'07 loop and the levenstein distance.

6.1 ISC'07 Loop

This sample program was created when we discovered and published[5] the basic idea of stream processing on Fuce for the first time. the program code is as follows:

```
for (i=1;i<N;i++)
  A[i][0] += A[i-1][0];
for (j=1;j<M;j++)
  for (i=0;i<N;i++) {
    if (i==0) A[i][j] += A[i+1][j-1];
    else if (i==N-1) A[i][j] += A[i-1][j];
    else  A[i][j] += A[i+1][j-1] + A[i-1][j];
   }
```

Pay attention to the second nested loop. a data dependency at the last else clause seems mostly as same type as that of example in section 4.2. We don't need to care about safety. The data dependency disappears naturally when it is transformed to a stream processing. The first loop can be fused into the inner loop of the second nested loop.

6.2 Levenstein Distance

The second benchmark program is the Levenstein distance algorithm, one of dynamic programming (DP) example.

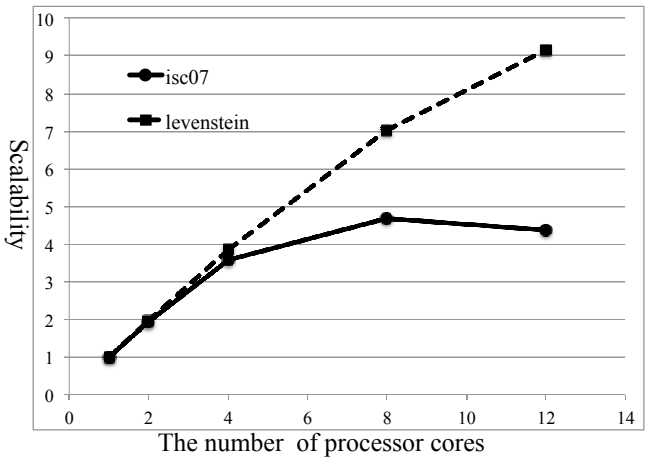

Figure 9: Scalability against the number of CPU cores.

Many other DP algorithms have similar structure to this program. the Levenstein code looks as follows:

```
int A[M+1][N+1];
for (i=0; i<M; i++) A[i][0] = i;
for (j=0; j<N; j++) A[0][j] = j;
for (i=1; i<=M; i++) {
  for (j=1; j<=N; j++) {
    int cost =
      (str[i-1] == str[j-1]) ? 0 : 1;
    A[i][j] = minimum(A[i-1][j] + 1,
            A[i][j-1] + 1,
            A[i-1][j-1] + cost); }}
```

The first two loops can be fused into the inner loop of the last nested loop. The data dependency of this program also disappears as well as that of ISC'07.

6.3 Performance Evaluation

The two transformed benchmark programs are executed on a Linux machine in which two Intel Xeon 3.3GHz processors is equipped. Each processor has six cores, in total twelve processor cores are utilized. Both transformed benchmark programs are configured so that input array size=16Kx16K, tile size=256 (256 array elements). Note that each process is defined with *tiling*[8] to operate 256 elements of array in a single process.

Figure 9 shows the scalability against the number of CPU cores for each program. On the basis of sequential execution times of the original programs, the speedups of the stream processing is shown on the graph. The performance of the levenstein is good enough. However that of ISC'07 reaches a ceiling around 8 CPU cores. We think that it is not so easy for the stream processing, especially for ISC'07 to utilize CPU caches sufficiently. Therefore the bandwidth of memory bus would be consumed away and it would interfere with communications between processes.

7. Conclusion

In this paper, we introduced the stream processing which is based on the asynchronous handshake multithreading technique and explained in detail a new approach to the wavefront method.

With our approach, it's possible to parallelize easily multi-level nested loops which hold strong data dependencies. Nested loops with data dependency appear frequently in dynamic programming algorithms. Many important time-consuming algorithms especially in biology fields are built up based on dynamic programming. We expect that the applications of our stream processing approach help to reduce time consumption of bioinformatic analyses greatly.

Error Classifications for Parallel Message Passing Programs: A Case Study

Jan B. Pedersen[1], **Michael Jones**[1]
[1]Department of Computer Science, University of Nevada Las Vegas, Las Vegas, NV, United States.

Abstract— *Parallel programming poses additional challenges over sequential programming. In particular, parallel programming raises complexities in design, implementation, and debugging. In this work, we analyze the mistakes that student programmers make on several parallel programming problems so that we can better understand their difficulties. We administer surveys for several parallel programming projects that use MPI in two graduate level courses. The survey records the problems that the programmer had with respect to error type, and location in the parallel programming domain, the time spent on each, and the tool usage. We classify the types of errors that they encounter and find that a large percentage of the errors are sequential; these errors turned out to be the fastest to correct. We also found that the most time consuming errors to correct are associated with the messages in the message passing system. The results of the study raise implications that we can address in the classroom and through improved programming and debugging tools.*

Keywords: Parallel Programming Errors, Debugging, Multilevel Debugging, Parallel Programming

1. Introduction

Debugging parallel and multi-threaded programs can be a challenging task when programmers need to reason about multiple processes running on different physical machines and exchanging messages, sometimes asynchronously. In this work, we collect and analyze data that provides insight into how students debug these problems so that future work can build upon this understanding. Specifically, we seek to better understand the *why, how, and what of errors* in several parallel programming assignments submitted by senior and graduate students in an upper division elective course.

Research by Eisenstadt [5] and Pancake [13] has shown that upwards of 90% of programmers debugging sequential programs primarily use print statements. Whether this number has remained this high with the introduction of development environments like Eclipse [1] and xCode [2] is not currently known, but it is probably reasonable to assume that programmers who do not utilize development environments still debug using print statements. Naturally, using debuggers like gdb [8] is wide spread, but simply attaching a number of sequential debuggers, one for each process in the parallel system, is not the way to go; it leads to information overload [14], and complicates the process even further.

A natural next step is to develop tools that support efficient debugging of parallel programs. In this paper we concentrate on parallel message programs which utilize the de-facto standard for message passing, namely MPI [4]. These programs are typically written in C.

A number of debugging tools have been proposed over the years, but none have been widely adopted (Most Unix/Linux installations come standard with gdb, but no parallel version of this tool exist, and no other tool is installed by default). A number of reasons have been given for the lack of adoption of debugging tools for parallel programming [14], these include information overload, incompatible granularity, and restrictive interfaces. We believe, that the lack of adoption of these tools resonates with Pancake's reason given in [12], namely that many tools are used only by their own developers, and without taking into account the types of errors that programmer make most frequently, we will not know where to focus the tool development. That is, if we understand what kind of errors the programmers make, then we can better pinpoint the type of tool support that will make a difference. A necessary first step, before tool development, is thus to take a closer look at the types of error found, where in the programming domain they occur, and how they are found and corrected.

In this paper we explore and categorize a number of programming errors made by student programmers in a graduate class at the University of Nevada, Las Vegas. Throughout the course the programmers reported all the errors they made (through a web classification interface), they classified the errors according to location within the parallel programming domain, as well as in a 3 dimensional *why/how/what* matrix inspired by Eisenstadt [5].

We present the findings of these error reports, as well as draw parallels to a previous study we did with a different class of programmers (using the same programs). The results of the previous study [16] (henceforth referred to as *the old study* or *the old survey*) inspired us to dig deeper and ask more questions in order to get a better understanding of the parallel debugging process.

Surprisingly, the results show that a majority of the errors are in the sequential code, followed by errors in the message passing and program decomposition.

In the remainder of this paper, section 2 discusses related

work on parallel programming and parallel fault classification, section 3 describes the framework we utilized for this research, section 4 describes the programs and the survey that the programmers completed, section 6 discusses our results and section 7 provides a summary of the results and directions for future work.

2. Related Work

This section is divided into two main parts; the first part looks at the parallel programming domain, and the second part explores the error classification domain.

2.1 The Parallel Programming Domain

In this section we briefly present the *parallel programming domain* with respect to parallel message passing programs. It should be noted that we do not take aspects concerned with performance into account. While performance is extremely important, correctness is even more crucial, and that is the focus of this investigation.

We start by looking at a four stage model for constructing parallel programs (referred to as PCAM) proposed in [6]. This model consists of four parts: *Partitioning*, which is the task of partitioning both the data and functionality of the algorithm being implemented. *Communication*, which is the task of determining and implementing interprocess communication, as well as the over all protocol for the algorithm. Two other parts, *Agglomeration*, which is an evaluation of performance and *Mapping*, which is the task of maximizing process utilization, exist, but since they are performance related, they are of no importance here.

Partitioning and Communication can be further decomposed. Partitioning can be either a decomposition of the data or the functionality of the program. *Data decomposition* is the task of determining how the data (typically originating from a sequential program) should be distributed across the multiple processes of the message passing program. This included resizing arrays, implementing additional supplemental data structures etc. *Functional decomposition* is the task of determining which part of the overall computation each process should perform. An example is the implementation of a pipe-line like computation; each process is in charge of one stage of the pipe-line.

Apart from the obvious need for each process to contain sequential code, which is injected with communication calls, the communication task can be decomposed into two further sub-categories. The first is *Data Exchange* (later on referred to as *Messages*), which in a message passing program means explicitly programming send and receive calls into the code. Typically these calls are point-to-point communication involving one sender and one receiver. Since most message passing programs utilize buffered asynchronous message passing, messages can be sent to an incorrect receiver, or to non-existent receivers, without causing any run-time errors; naturally this will cause the program to stop working at some point when messages are not properly received. Stray messages can be caused by incorrect use of the message passing API, or it could be caused by a problem with the overall communication scheme, that is, the protocol. The second sub-category is *Protocol Specification*, where we consider not just point-to-point communication, but the overall communication scheme.

The two sub-categories data exchange and protocol specification, along with the obvious sequential nature of the actual code running in each process, clearly make up an onion-like structure consisting of three layers: At the core is the *sequential level*, which is responsible for the actual calculations. The second layer is the *message level* (earlier referred to as Data Exchange), which is concerned with the point-to-point communication between two processes, and finally the outer layer is the *protocol level*, which we just described.

We now have a model consisting of two main categories: *Decomposition* (data and functional) and *implementation* (sequential, messages, and protocol), which means that we have five 'buckets' into which we can categorize errors.

This categorization can help us pin-point the overall place in the development process where the most errors are made, which in turn can help us better develop tools that target the specific category. It should be noted that developing tools for decomposition errors might be a challenging task. If the design of the program is incorrect, no amount of debugging will make it right; if the data is incorrectly distributed no amount of debugging will save such a program. Decomposition errors include design flaws that must be rectified at the time the algorithm is designed.

2.2 The Why, How and What of Errors

Eisenstadt describes in [5] a 3-dimensional space in which sequential errors are placed according to certain criteria. The 3 dimensions are:

- **Dimension 1**: Why is the error difficult to find?
- **Dimension 2**: How is the error found?
- **Dimension 3**: What is the root cause of the error?

Eisenstadt's original survey surveyed 51 programmers about errors they encountered in sequential programming, but we feel the 3 dimensions are equally applicable to the parallel programming domain. The numbers reported in the following paragraphs are the numbers reported by Eisenstadt.

Unfortunately we do not have enough space in this paper to thoroughly go through the subcategories for the 3 dimensions (there are 6, 5, and 10 respectively), but it is worth noting that almost 30% of dimension 1 (why was the error hard to find) is categorized as the *Cause/effect chasm* problem. (Section 3 lists the categories, but we refer to [5] for a more thorough explanation). What describes errors in this category is the fact that the symptom of the error is far removed in space and time from the root cause. This category is bound to be an issue in the parallel

programming domain where this separation of cause and effect is further exacerbated by message passing; now the cause and effect can be in different processes, or even in different source code files. The second most frequent answer was *Tools inapplicable or hampered*, which covers the so called 'Heisen bugs' [9]. It is notable that over 50% of the cases are caused by these two categories.

In dimension 2, concerned with how an error was found, the most frequent answer was *Gathering data* (53% of answers fell in this category). This category covers the use of print statements, debuggers, break points etc. The second most frequent answer was *Inspeculation*[1], which covers hand simulation and thinking about the code. 25.5% of answers fell in this category.

An interesting, but not surprising, result is that data gathering (e.g., print statements) and hand simulation account for almost 78% of the techniques reported in locating errors (in Eisenstadt's study). This result corroborates the result of Pancake [13]: up to 90% of all sequential debugging is done using print statements.

While the use of print statements is straightforward when working with sequential programs, their use in parallel programs is more complicated. Often, processes run on remote processors, which makes redirecting output to the console difficult. Even when output can be redirected to the console, all processes are writing to the same window, thus making the interpretation of the output a challenging task. This is an example of the information overload theory mentioned earlier. Furthermore, the order of the output (i.e., the debugging information from the concurrently executing processes) is not the same for every run, as the processes execute asynchronously and only synchronize through message passing. A possible solution is to have each process write its output to a disk file. However, this introduces the problem of non-flushed file buffers; if a process crashes, the buffer might not be flushed, thus missing output written by the program. Of course this can be solved by inserting calls to flush the I/O buffers, but if these are missing, the programmer ends up spending time on debugging the code he added for debugging purposes! In the worst case this can lead the programmer to believe that the process crashed somewhere between the last print statement that appears in the file, and the first one that does not. A lot of time can then be wasted looking for an error in a place where no error can be found.

The third dimension, the root cause of the error, contains 10 different categories; the most noteworthy is the most frequent one, *Memory*, which covers errors such as overwriting a reserved portion of the memory causing the system to crash, and array subscripts out of bounds, pointer errors etc. 25.5% of answers fell on this category. The second most frequent root cause was faulty hardware (the Vendor category) (with 17.7%) and in third and fourth place, with 13.7% and 11.8% respectively, came faulty design logic (Algorithmic design/implementation problems) and initialization, which covers wrong types, redefinition of the meaning of system keywords, or incorrectly initialization of a variable.

Nearly 50% of the errors are caused by the first two categories. This also perfectly agrees with previous studies where tools and runtime systems are described as a source of errors [13]. The classification used in dimension 3 is a mixture of deep plan analysis [10], [17] and phenomenological analysis [11]. Deep plan analysis states that many bugs can be accounted for by analyzing the high level abstract plans underlying specific programs, and by specifying both the possible fates that a plan component may undergo (i.e., missing or misplaced). An alternative phenomenological taxonomy can be found in [11] where the root causes are divided into nine categories.

If we accept the decomposition of the parallel programming domain as we stated it above, as well as the overall debugging technique of hypothesis development and verification (as described in [3]), we still need to gather information about the error types like Eisenstadt did for sequential errors. This is the study presented in the following sections.

3. The Framework

In out first attempt at classification of parallel message passing errors [16], we established the usability of the PCAM modelc̆iteFo95, the decomposition of the parallel programming domain as well as introduce the 3-D model of Eisenstadt. We also reported a number of results, some of which we will recap at the appropriate places in the result section of this paper. We stated in that paper that:

> "The main goal of this research is to clarify a number of subjects related to parallel programming and debugging of parallel programs. First of all, we wish to obtain some insight into the types of errors the programmers encounter, and secondly obtain data about the techniques they used to locate and correct them. We believe that this information serves as a good basis for how programming and debugging tools for parallel (message passing) programs should be developed. It is important to understand the programming domain (in this situation, the parallel programming domain with message passing) in order to make qualified decisions about how to correct the errors."

This naturally still stands as the overall goal, but in addition, we would like to "fine tune" the survey using the 3 dimensions of Eisenstadt. We used the same assignments in this second survey as we did in the old survey described in [16], which we believe will make the results comparable.

Naturally, the end goal should be proper tool development to support debugging and error finding/correction in

[1] See section 4 for an explanation of this made-up word.

parallel message passing programs; we believe that the kind of research described in this paper can help alleviate the biggest problem with current debugging tools, as described by Cherri Pancake in [12]: tools for parallel programming and debugging are often only used by their developers. She claims that this is caused by the fact that the tool developer and the tool user might have different foci on what they want/need from a tool.

4. The Error Reports

The programmers completed a web-based questionnaire to record the run-time errors they encountered throughout the semester. The web-based questionnaire contains seven questions:

1) Why was the error hard to find? (pick one of the following): 1.) Cause/effect chasm. 2.) Tools inapplicable/hampered. 3.) What You See is Probably Illusory, Guv. 4.) Faulty Assumption. 5.) Spaghetti code. 6.) Other.
2) How did you find the error? (pick one of the following): 1.) Gather data[2]. 2.) Inspeculation. 3.) Expert recognized cliche. 4.) Controlled experiment. 5.) Other.
3) What was the root cause of the error? (pick one of the following): 1.) Memory. 2.) Vendor. 3.) Design logic. 4.) Initialization. 5.) Variables. 6.) Lexical. 7.) Unsolved. 8.) Language. 9.) Behavior. 10.) Other
4) Did you mostly use print statements?
5) Did you use any debugging tools?
6) Place the error in one of the following categories: 1.) Sequential error (including API errors). 2.) Message error. 3.) Protocol error. 4.) Data decomposition error. 5.) Functional decomposition error. 6.) Other.
7) How long did it take to correct the error?

Questions 1, 2, and 3 correspond to Eisenstadt's 3 dimensions *why, how* and *what*. Each of the sub categories for the three first questions were equipped with a more detailed explanation. As an example, this is the explanation for Inspecuation: "This term covers inspecting the code, hand simulation, and speculation. Speculation involves leaving the code to think about the problem, then later returning to try to correct it." Questions 4 and 5 pertain to tool usage and the use of print statements as a primary debugging tool. Question 6 is concerned with the placement of the error in the decomposed parallel programming domain, and finally, question 7 deals with the time spent debugging.

4.1 The Programs

In this section we briefly describe seven programming assignments that they completed during the course of the semester. These programs are (listed in the order in which the assignments were given):

- **Mandelbrot** — Use one master and n slaves to compute a Mandelbrot set.
- **Differential Equation Solver** — Solve a differential equation using a discrete method.
- **Equation Solver** — Use one master and n slave processes to solve an upper triangular system of equations.
- **Partial Sum** — Implement a partial sum algorithm that runs in time $O(log\ n)$.
- **Pipeline Computation** — Use functional decomposition to implement a multistage pipeline with dispersers and collectors that allow for multiple instances of stages of the computation to achieve a good load balance.
- **Matrix Multiplication** — Implement the Pipe-and-Roll matrix multiplication algorithm [7].
- **A project** — This could be any parallel message passing program of the programmer's choice.

4.2 Programming Domain Decomposition

We classify the types of errors from the survey questions into six overall categories; this mirrors the approach taken in the first survey [16]. These six categories are based on the first two categories of the PCAM model (partitioning and communication) as well as the three levels of the parallel programming domain. For completeness, we have added an *other* category for errors that the programmers could not place in any of the other categories. The list of the six categories are as follows:

- **Data Decomposition** — The root of the bug had to do with the decomposition of the data set from the sequential to the parallel version of the program.
- **Functional Decomposition** — The root of the bug was the decomposition of the functionality when implementing the parallel version of the program.
- **Sequential Error** — This type of error is the type we know from sequential programs. This includes using = instead of == in tests etc.
- **Message Problem** — This type covers sending/receiving the wrong data, that is, it is concerned with the content of the messages, not the entire protocol of the system.
- **Protocol Problem** — This error type is concerned with stray/missing messages that violate the overall communication protocol of the parallel system.
- **Other** — Bugs that do not fit any of the above categories are reported as 'other'. This include wrong permissions on programs to be spawned, faulty parallel I/O etc.

5. Result of Error Reporting

In this section we consider the results obtained from the error reports. First we consider the replies to question 6 (see

[2]This category has six sub categories: step-and-study, wrap-and-profile, print-and-peruse, dump-and-diff, conditional break and inspect, specialist profile tool. Note, print-and-peruse is the classic 'debugging with print statements'.

subsection 4.2) (Where in the decomposed domain did the error fall), in the next section, we look at the answers to questions 1, 2 and 3 (corresponding to the 3 dimensions from Eisenstadt's matrix). Section 5.3 looks at the debugging time (question 7), and finally in section 5.4 we conclude with the results of questions 4 and 5 pertaining to debugging using print statements and tool usage.

5.1 Error Categorization According to Domain Decomposition

Table 1 summarizes the results of the online error reporting survey and figures 1 and 2 illustrate the results in two different ways: figure 1 shows the number of errors for a given category for each of the programs (e.g., for the partial sum algorithm, 11 errors fell in the sequential error category). Figure 2 illustrates what the percentage of errors within each program fell in which category (e.g., 68.75% of the errors reported for the partial sum algorithm fell in the sequential error category). The percent number in square brackets in table 1 are the corresponding percentages from the old survey [16].

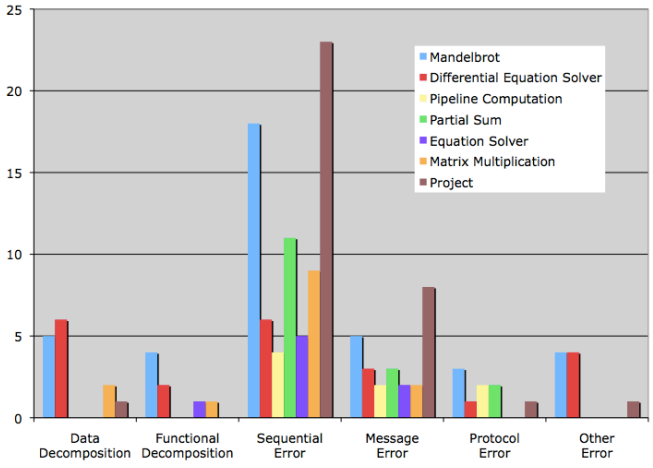

Fig. 1: Number of errors for each program categorized according to the parallel programming domain decomposition.

For the new survey, 19.63% of the errors were associated with the decomposition of the problem (for the old survey, this number was 25.16%), and 72.90% (versus 69.68% in the old survey) fell into one of the three parts of the parallel programming model. The *Other* was 7.48% (5.16% in the old survey). These results show, that the overall results from the old survey in [16] compare favorably to the result of the new survey. Now, let us look at the distribution of the errors within the parallel programming domain: In the old survey, the sequential errors made up 34.84% and in the new survey this number increased by approximately 15% to 49.53%. The message errors went from 10.32% to 15.89% and the protocol errors from 24.53% to 7.48%. (These numbers are the results excluding the project). We see that the sequential

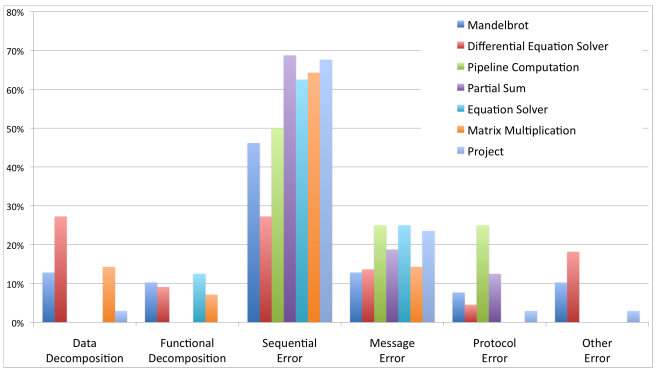

Fig. 2: Percent of errors for each program categorized according to the parallel programming domain decomposition.

errors have gone up a fair amount, and if we look at the results for the project (where no assignment or guidance was given), the sequential errors makes up a 67.63% of the errors here.

These overall results lead us to believe that support for debugging parallel programs should be focused on the sequential errors. It seems that the majority of errors (from the parallel programming domain decomposition) fall into the sequential error category; naturally support at this level must be tailored according to the already known issues such as information overload issues and granularity mismatch etc.

The old survey also reached the conclusion that sequential debugging was important, but one thing that we believe this survey revealed by including the project, is that when no guidance or development advice is given, that is, when the programmer must develop the algorithm and implement it himself from scratch, the number of sequential errors rises.

5.2 Eisenstadt's 3 Dimensional Error Matrix

The extension of the new survey was to include the categories from Eisenstadt's survey of sequential errors (Questions 1, 2, and 3). Table 2 shows the results of this categorization. The most frequently chosen category for why the error was hard to find was the *other* category (44%); unfortunately that does not tell us much. The second category is not surprisingly the *cause/effect chasm* with 23.4%; that was not unexpected as the introduction of message passing can spread the cause and the effect of an error over multiple files. These errors can greatly benefit from a tool that lets the users inspect the messages that flow from process to process. The third most reported category is the *What You See is Probably Illusory, Guv.* with 14.9%. This category covers the errors where the programmer misinterprets part of the code, that is, it does something other than he thought it would do. The fourth most reported is the *Faulty Assumption* with 13.5%. This category covers issues like assuming the stack grows down when it in fact grows up!

The most frequently chosen category for how the error was found was *gather data* with 48.2%. This category covers

Table 1: Result of the the online error reporting from (new) survey (Results from old survey in [16]).

	Data Decomposition	**Functional Decomposition**	**Sequential Error**	**Message Error**	**Protocol Error**	**Other**
Mandelbrot (n_1=39)	5 12.82[20.41]%	4 10.26[14.20]%	18 46.15[32.65]%	5 12.82[10.20]%	3 7.69[14.20]%	4 10.26[8.16]%

the use of print statements, debugging with break points etc. Second was *inspeculation* with 23.7%. Inspeculation is an amalgamation of inspection and simulation and covers for example hand simulation of the code. The *other* category made up 12.8%.

Design Logic was the most frequently chosen category for what caused the error (it was chosen 33.3% of the time), and it basically means incorrect algorithm implementation. *Behavior* came second with 30.7%, and this category covers for example users using the program in an incorrect way. *Variables* (covering incorrect use of operators and operands) with 25.4% and *Memory* with 17.5%. This category covers pointer errors, array out of bound errors etc. In the following subsection we briefly consider debugging time.

5.3 Debugging Time

Both in the old and in the new survey we asked the programmer to report the amount of time spent on debugging.

Table 3 shows the results of this question. Note, the standard deviation is only available for the new survey. In the old survey, the average time for finding and correcting a bug was 51 minutes, in the new survey the average time was 41 minutes.

One error report reported one error taking 840 minutes (this was in the Project category); this might be a mistake. Not taking this one error into account, table 4 shows the the average time it took to correct an error; it also shows the total amount of time spent in the different categories as well as a percent-wise break down of how much time was spent in the different categories in total.

Table 4 shows that the average time for finding and correcting a sequential error was approximately 24 minutes (in the old survey, his time was 37 minutes), but it also shows that a total of 1,846 minutes was spent on finding sequential errors and that made up almost 38% of the time (counting a total of 76 out of the 141 errors) spent debugging in total.

Although the sequential errors take the least amount of time to fix per error, a majority of time is spent on this particularly category; a total of almost 38% of debugging time is spent on finding and correcting sequential errors. It should also be noted that the message errors on average take more than twice as long to correct (61.4 minutes per error), and a total of 31.14% of the overall debugging time is spent on correcting these errors.

5.4 Tool Usage and Debugging-by-print-statements

Questions 4 and 5 cover the tool usage and debugging by the use of print statements. Table 5 tabulates the result of these two questions. As expected, the number of replies in the affirmative for tool usage is almost non-existing, and the percentage for print statements as the primary debugging tool is very high; at almost 86% it matches the numbers reported by Pancake for sequential programs. This is not unexpected, but it is disconcerting that a poor debugging technique from sequential debugging has been adopted in the parallel programming domain. The main reason for this is of course the lack of tools, something we hope to help alleviate.

6. Results

The results of the surveys show that a large number (76) of the errors are sequential in nature. Even though the sequential errors are amongst the quickest to correct, the overall time spent on finding and correcting the sequential errors (which count more than 3 times as many as the second most frequent category) is in the vicinity of 40%. In addition, the message errors are reasonably frequent and they take a lot longer to correct (more than twice as long as the sequential errors). It should be mentioned that approximately 16% of debugging time (and approximately 16% of the errors) is found at the decomposition level; but as stated earlier, these are hard to develop tool support for as they are errors that have to do with the algorithm rather than the implementation.

Interestingly, the category that rose to near the top in Eisenstadt's survey for what caused the error, namely the vendor category covering hardware and software errors scored 0% in our survey; this is perhaps not strange, as hardware and compiler software is extremely stable.

7. Conclusions and Future Work

This work presents the results of a survey concerning errors made by student programmers in a parallel programming course in which they implement a number of parallel message passing programs. We contrast the results obtained in this survey with a similar survey done in 2006, but also expand the survey to include a 3 dimensional matrix suggested by Eisenstadt into which the errors were categorized. The results show that the most frequent error types are sequential errors, whereas, those that take the longest to locate and correct are the message errors. Future tool development should focus on these errors because they are frequently made and take a long time to find and correct.

Within the sequential category we see that cause/effect chasm contributes to a large percentage of the errors, and interestingly enough, these errors are exacerbated further by the introduction of message passing, which again points to necessary tool support for message errors. The most frequently applied techniques for locating the error was gathering data and inspeculation (account for almost 72% of the answers), and the error was most frequently caused by *behavior*, *errors in design logic*, *variables* and *memory* issues.

The results motivate us to pursue the development of debugging tools for parallel programs. In particular, a multilevel debugging approach [15] may help programmers to more efficiently identify and correct the errors; Multilevel debugging is tailored to focus on the decomposition of the parallel programming domain as explained in section 2.

File Composition Technique to Improve the Performance of Accessing a Number of Small Files

Abstract— *One of the scalability issues in parallel applications, in which each process creates each file and writes data to the file, is the scalability of file management due to the increasing number of files. To mitigate this issue, a new file aggregation mechanism, called the file composition technique, is proposed. Unlike existing aggregation mechanisms, the file composition technique aggregates multiple files created by parallel processes into a single shared file without changing the code of file I/O operations. In contrast with the metadata operations in existing aggregation mechanisms, the metadata operations are distributed to each process in order to carry out scalability. The proposed file composition technique is evaluated using a climate simulation code, called SCALE. The result shows that the elapsed time of file output is approximately 30% faster than that of original POSIX I/O functions.*

Keywords: File I/O, Parallel file system, File aggregation

1. Introduction

I/O access patterns of parallel applications are broadly classified into three patterns: N-1, N-N, and N-M. The N-1 pattern means that all processes access some shared files, and the N-N pattern means that each process accesses some individual files. For example, in a climate simulation program, all processes save their local data to a single file or save each individual file. In the former case, the file I/O access pattern is called N-1 and is called N-N in the later case. Contrasting with applications employing the N-1 or N-N pattern in other parallel applications, such as data mining and processing huge sensor data, all processes following the N-M I/O pattern handle many files whose sizes are not uniform.

I/O access patterns of many parallel applications are categorized as the N-N pattern. For example, it was reported that, in ten projects using the Blue Gene/P at the Argonne National Laboratory [1], four, seven, and two projects employ the N-1, N-N, and N-M patterns, respectively. In the N-N pattern, as the number of processes increases, the number of files grows and the I/O performance becomes the bottleneck of scalability. For example, Figure 1 shows the execution time of parallel processes creating one individual file each. The execution time linearly increases according to the increasing number of processes. This is the result of using a cluster with the Lustre file system described in Section 4.

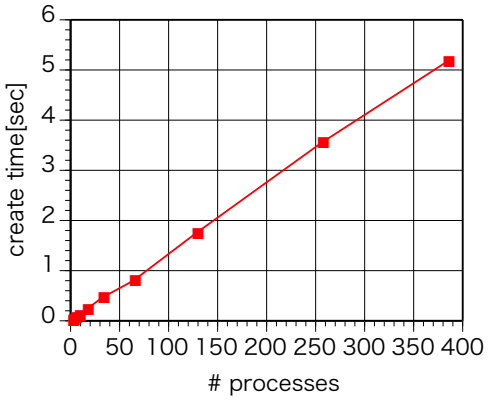

Figure 1: Time it takes parallel processes to create one file each

An approach to mitigating the above problem is introducing a file aggregation mechanism that gathers multiple data generated by an application and stores these data into one or a few files in order to reduce the number of files accessed by these processes. Several libraries carry out such a file aggregation mechanism, e.g., MPI-IO [2], PnetCDF [3], and SIONlib [4]. All of them assume that parallel applications are based on the single program multiple data 'SPMD' execution model, that is, all processes access files at the same time. Those libraries have two main issues, If an application is written using Posix file I/O APIs, it must be rewritten using their APIs. In the case that an application is not written in the SPMD manner, its modification cost is much higher. The other issue is the metadata management of libraries such as PnetCDF and SIONlib. Because the metadata of files is sequentially handled at the user level, metadata operations, such as creation and extension of files, limits scalability.

In this paper, a new file aggregation mechanism called the file composition technique is proposed. It makes application programmers select the I/O pattern such that each process may access multiple individual files. In the proposed technique, the middleware gathers files created in the application and stores them into a single shared file in a parallel file system. The Lustre file system [5] is currently utilized.

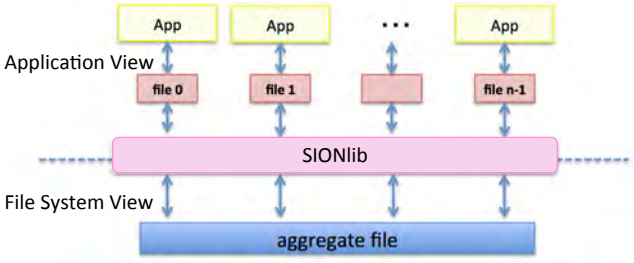

Figure 2: SIONlib

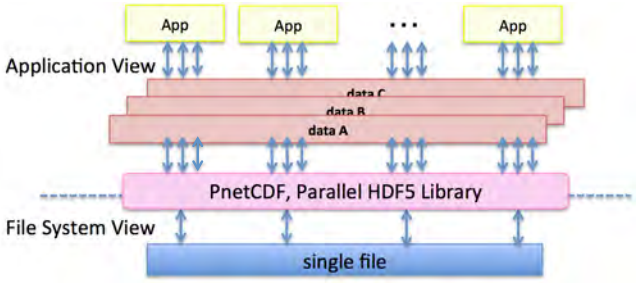

Figure 3: PnetCDF and Parallel HDF5

The remainder of the paper is structured as follows. In Section 2, existing file aggregation techniques are introduced. The concept of the file composition technique is proposed, followed by its design and implementation, in Section 3, and its basic performance is evaluated in Section 4. Section 5 presents a summary.

2. Related Work

Several techniques gather multiple data and store them into one file and that support mechanisms to access the gathered file by parallel processes.

2.1 SIONlib

Figure 2 shows the basic concept of SIONlib [4]. If the I/O pattern of a parallel application is such that each process creates multiple files, N, then the collective SIONlib function must be called N times, and this yields N aggregated files. As a result, the performance gain by the file aggregation can be degraded.

2.2 NetCDF and HDF5

NetCDF [6] and HDF5 [7] are the other I/O aggregation libraries providing self-describing data formats. NetCDF primarily supports a way to access files containing array-oriented data. HDF5 primarily supports a way to access hierarchical data. By using these libraries, the application programmer can describe and store various data into one file with the meta-information about the data and the data format. Parallel NetCDF [3] and Parallel HDF5 [7] are the parallel versions of NetCDF and HDF5, respectively. Both are extended by using MPI-IO and support storing data dispersed among parallel processes (Figure 3).

In both netCDF and HDF5, the data aggregation takes place so that the data structure is preserved. (P)netCDF and (parallel) HDF5 give users a good view of a complex data structure. However, when a user tries to change the file structure, then the aggregated file must be restructured. Thus, users sacrifice the flexibility of their data format.

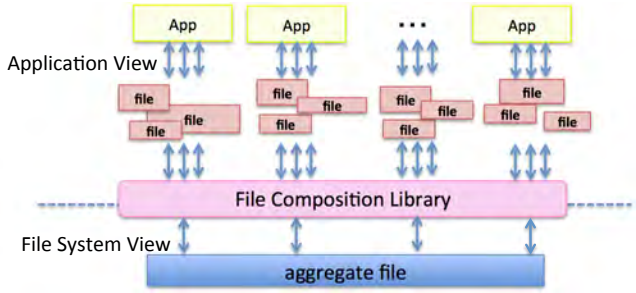

Figure 4: Concept of the file composition technique

3. File Composition Technique

In this section, we propose a new approach to store multiple data generated by a parallel application into a single shared file.

3.1 Proposal

We propose another approach to store multiple data generated by a parallel application into a single shared file by holding an application's I/O pattern. We call the new approach *file composition technique*. Figure 4 shows the basic concept of the file composition technique.

This file composition technique composes data, which looks like a file from the viewpoint of the application, into an aggregated larger file. Unlike SIONlib, (P)netCDF, and (parallel) HDF5, no restrictions are on how the "files" format the application view, and how they are organized and/or structured. Thus, the file composition technique can provide more flexibility than can the existing techniques.

In this paper, we call a file from the application view a "logical file," and a composed file "a physical file." In the application layer, application processes can access various data as if they are individual files. But in the file system layer, all logical files are stored on a single physical file. The file composition library aggregates I/O requests of application processes and translates them into I/O operations for a single shared physical file.

3.2 Design

In this subsection, a design of the implementation of the file composition library is described. We explain how to manage a logical file, how to map logical files to physical files, and how to access the physical file. Figure 5 shows a design overview of the file composition library.

Logical files are managed by our library at the computing node where each logical file has been created, not by a single server such as a metadata server. Even if parallel processes access each individual logical file at the same time, requests are not concentrated at a particular node. Thus, it is expected that the I/O performance does not decrease. Each library process treats logical files as separately divided into a metadata object and data objects. A metadata object holds the information about every logical file, filename, size, position in the physical file, and so on. A data object is an entity of each logical file.

The metadata object and the data objects are split into blocks of a constant size and are distributed into a logical file. By making the block size the same as the stripe size of the file system, each library process can access each individual stripe block without collisions with other processes.

The stripe size of a parallel file system is the maximum message size with which clients and the storage server can communicate. If each library accesses a physical file with the stripe size, then it is expected to have a higher I/O performance. So, each library process has a buffer for data objects with the length equal to the stripe size. If an application process writes many small logical files, then the buffer holds the data of these logical files and writes to a physical file when the buffer becomes full.

4. Evaluation

We implemented the file composition library and evaluated its performance on the Lustre file system. Figure 6 shows the evaluation environment where all of the following experiments took place. The cluster consists of 32 computing nodes and a parallel file system, Lustre. Each computing node has two Intel X5670 CPUs and 96 GiB memory and is connected with the other nodes and the file server nodes by Infiniband 4xQDR. Lustre consists of one Meta Data Server (MDS) and 12 Object Storage Servers (OSSs). Each OSS has 128 Object Storage Targets (OSTs) and the total capacity of the file system is 10 PB. Each OSS has 192 GiB memory. Two switches for the computing nodes and the file system servers are connected with four links. Throughout this evaluation section, the buffer size of the file composition technique is set to 16 MiB.

4.1 Micro Benchmark

We measured the basic performance of our file composition library and the performance of POSIX I/O for comparison. We show the performance of the create, write, and read operations. In each benchmark, the number of processes is increased from one process to 32 processes. Each process runs on one computing node.

On the Lustre file system, files are split into multiple object blocks and each object block is distributed to multiple servers. The size of each object block is called the *stripe size*, and the number of OSTs used to distribute the object blocks is called the *stripe count*. These parameters are factors of the I/O performance. In the case of POSIX I/O, the stripe count is set to 4 and 64, while in the case of using the file composition library, the stripe count is set to 64 and 160. The stripe size is set to 16 MiB constant in all cases.

File Create

Figure 7 shows the time of file creation. Each process repeats the procedure of calling the create and then the close functions for a file 128 times, yielding 128 files. The creations of each file are synchronized and the time is measured from the time to the first create call until the termination of the slowest call of close on the 128th file.

In the case of 32 processes, POSIX with the 4 stripe count took 0.69 seconds and POSIX with the 64 stripe count took 37 seconds. The file composition with the 64 stripe count and with the 160 stripe count took 0.08 seconds.

In all cases, the elapsed time increases as the number of processes increases. But the increasing rate of the file composition case is smaller than that of POSIX. This phenomenon can be considered as that the I/O requests are concentrated on the Meta Data Server in the POSIX I/O. In contrast, the file composition technique can decrease the degree of concentration.

In the POSIX case, when the stripe count gets larger, the creation time gets slower. This is because each create operation involves the operation on the Object Storage Target. In the file composition case, the creation time is constant over the number of processes, independent from the stripe count.

Write

Figure 8 shows the throughput of open-write-close. In this case, each process calls open, write, and close. Each process accesses 128 individual files. The open calls are synchronized and the time is measured from the time to the first create call until the termination of the slowest call of close on the 128th file.

The upper graph of Figure 8 shows the result of the case of setting the file size to 1 MiB, and the lower one shows the result of the case of setting the file size to 16 MiB.

In the case that the file size is set to 1 MiB, the file composition performance is almost twice better than that of POSIX. The assumed reason for this performance improvement is that the file creation time is reduced and that the

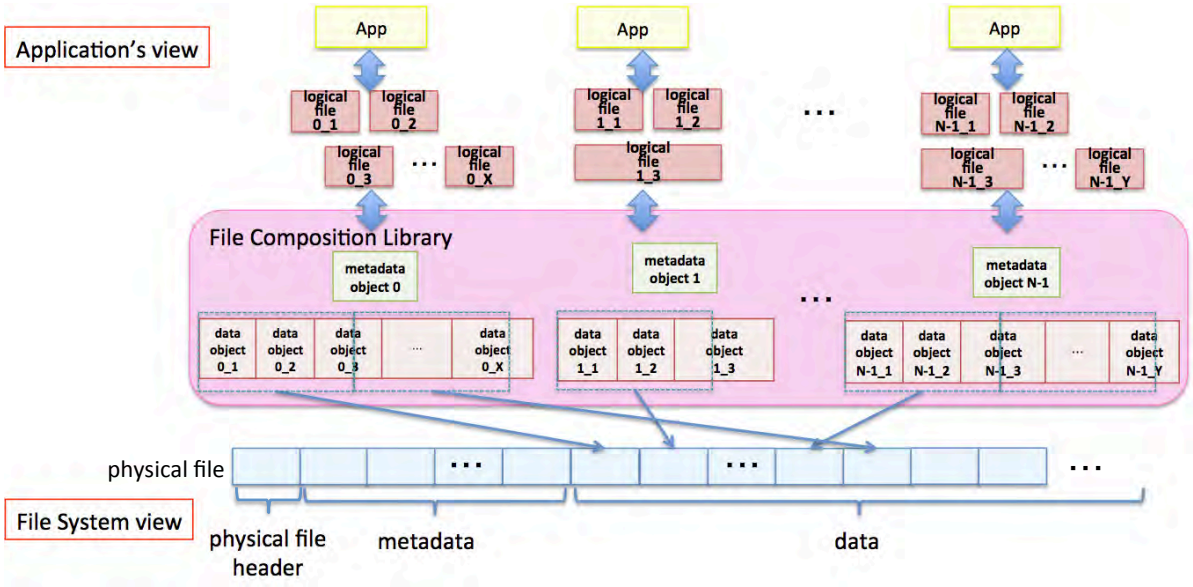

Figure 5: Design overview of the file composition library

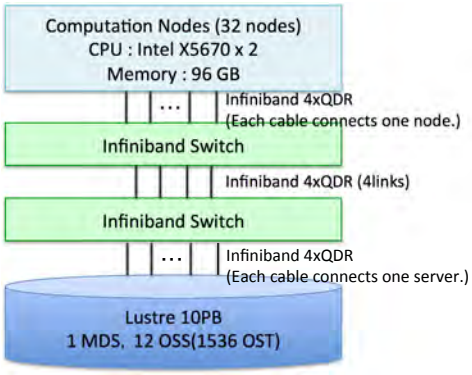

Figure 6: Evaluation environment

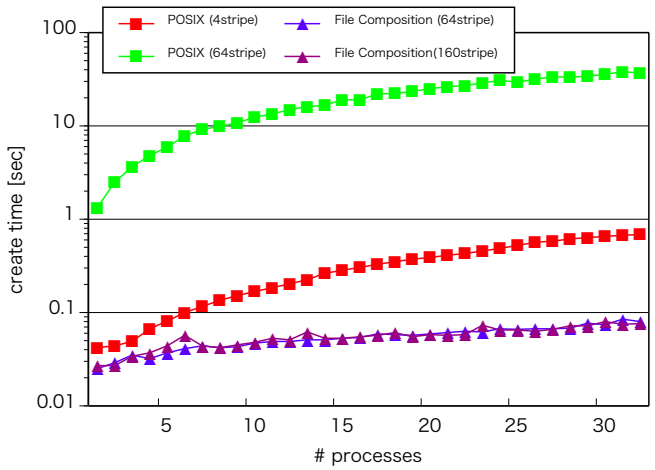

Figure 7: Time of create-close

buffering in the composition technique decreases the number of write calls.

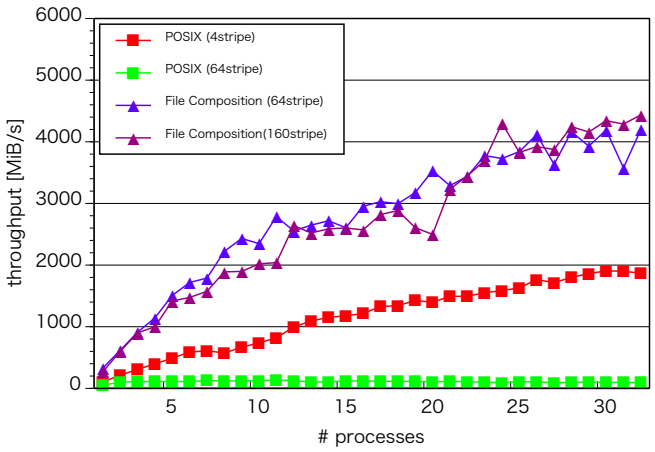
In the case that the file size is set to 16 MiB, the performance of the file composition is approximately twice faster than that of POSIX. This is because the file creation cost is reduced with the file composition technique. However, in the file composition case, when the stripe count is small and the number of processes is large, its performance gain is not high. This is because the number of Object Storage Targets that all processes can access is limited to the stripe counts with the file composition technique.

Read

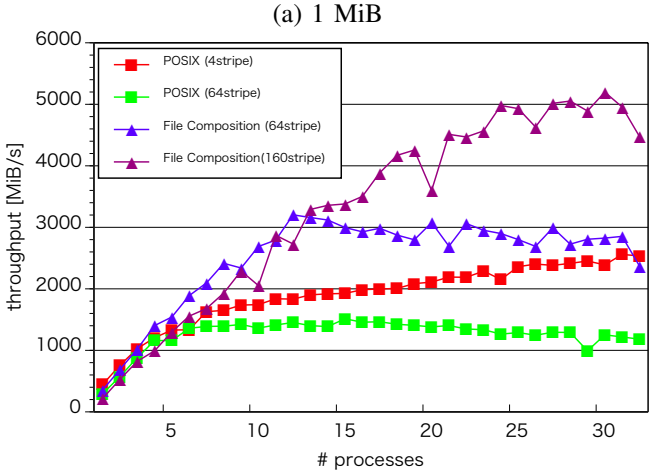
Figure 9 shows the throughput of open-read-close. Each process opens a file and reads data from the file and closes the file. Each process accesses 128 individual files that were created in the previous write benchmark runs. To eliminate the effect of page cache in the Linux kernel, the cache of all computation nodes and all file system servers is cleared before running this benchmark.

The upper graph of Figure 9 shows the result of the case that each file size is set to 1 MiB, and the lower graph shows the result of the case that each file size is set to 16 MiB.

In the case that the file size is set to 1 MiB, the performance of the file composition is approximately three times faster than that of POSIX. In the case that the file size is set to 16 MiB, the performance of the file composition is

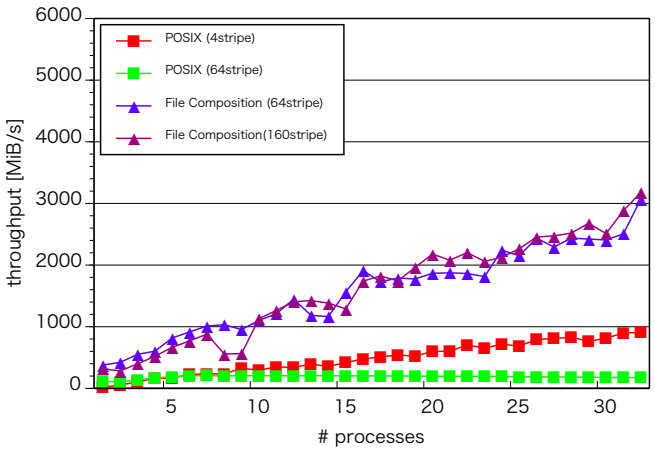


(a) 1 MiB

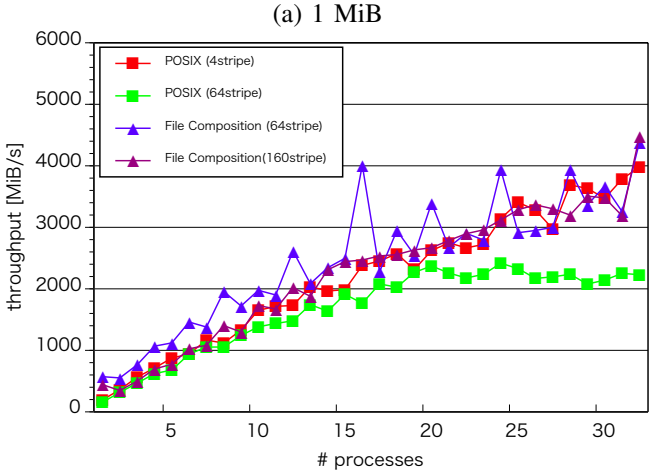


(b) 16 MiB

Figure 8: Throughput of open-write-close



(a) 1 MiB



(b) 16 MiB

Figure 9: Throughput of open-read-close

almost the same as that in the POSIX case. The assumed reason for this performance improvement in the case of 1 MiB is that the process can read the same stripe block as in the case of the file composition. In contrast, in the case that the file size is set to 16 MiB, which is the same size as the buffer of the file composition technique, the file composition technique has no buffering effect.

4.2 Evaluation with a real application

Finally, our file composition technique is applied to a real application that is a climate simulation program, called SCALE, being developed by RIKEN AICS Computational Climate Science Research Team.

When the program is running in parallel, each process periodically calls a file-output function that creates a new file and writes data into the file. When the file-output function is called, first, a new file is created and a file header is written. The file header has meta information about the data to be written in the file. Then, 16 arrays in the program are written and the file is closed.

We rewrote the file-output function by replacing the POSIX I/O functions with the function that our file composition library provides. The file composition library aggregates all files that the SCALE program creates and stores them into a single shared file throughout the whole program execution.

We executed the SCALE program in parallel and measured the elapsed time of the file-output function called by each application process. The program was executed with 32 processes and the size of one array was 10.1 MiB. The SCALE program was set up so that it repeated the file output 10 times. In the POSIX case, the stripe count was set to 0, because that was the fastest parameter variable setting. In the case of the file composition library, the stripe count was set to 160, which is the maximum value we can set.

Table 1 shows the result of the total elapsed time of the output function. The performance of the file composition library was approximately 30% faster than that of POSIX. The assumed reason for this performance improvement is

Table 1: Time of SCALE's file output.

	the fastest process	the slowest process	average of all processes
POSIX	12. 75	15.33	14.43
File Composition	8.79	12.17	10.37

[sec]

that the file composition technique could successfully reduce the number of accesses to a metadata server when each process creates files.

5. Summary

In this paper, we proposed the file composition technique that achieves good I/O scalability of parallel applications without changing the code using the POSIX file I/O interfaces. The library employing this technique aggregates I/O requests of parallel processes and translates them into I/O operations in a single shared file in a parallel file system, which is currently the Lustre file system. Two techniques are integrated to achieve good scalability of I/O operations. The metadata information is separately managed by each process to avoid the contention of metadata operations. The middleware of each process accesses its own stripe block exclusively in the parallel file system to avoid the contention of read/write operations.

The result of the basic performance showed that the proposed library is eight times faster than the regular POSIX I/O library in the case that 32 parallel processes create 128 files each. The results two times better throughput of parallel open-write-close operations and three times better throughput of parallel open-read-close operations. We also applied the file composition technique to the file-output function of a climate simulation program called SCALE. The elapsed time of the file-output function with the file composition library was approximately 30% faster than that of the POSIX I/O. These experiments demonstrated that I/O performance can be improved by using the file composition technique without changing the POSIX file I/O interfaces.

Is D the Answer to the One vs. Two Language High Performance Computing Dilemma?

Abstract – *During the course of our careers we have written a variety of high performance computing programs (parallel Genetic Algorithms [12, 13], genetic sequence analysis [4], automated reasoning applications such as theorem provers [5], and an asynchronous, dynamic, load-balancing library [1, 3, 7, 10]). In our projects we often found ourselves using a bilingual programming model to gain the advantages of both high performance execution and advanced language features like garbage collected data structures. D gives us access to both facilities in a single language. While D [8] is not a new language in the Computer Science scheme of things, it has only recently advanced to the point where we could begin to consider it as a solution to our dilemma. In this paper we discuss how we use D for rapid development of high performance code, and how we link it to legacy code such as MPICH2 [11] and ADLB.*

Keywords: D Programming, Bilingual Computing, High Performance Computing

1 Introduction

As computer scientists we recognize the value in learning multiple languages. Each language brings a unique set of features to the table that has the potential for providing elegant solutions to various problems. However, in a perfect world, we would only need to be an expert in one language, and that language would have all the features needed to easily create well-designed code. Since the world is not perfect, we have typically in the past focused on one language per project. In practice, the high performance world typically relies on Fortran or C, and in our case it was C. But the lure of scripting languages such as Python would occasionally draw us in. When our project needed the ease of built-in advanced data structures such as associative arrays along with automatic garbage collection of those structures, we used a high level scripting language such as Python. When high performance was absolutely critical or if we were doing low-level programming such as memory management, then we typically used some language that was a C-derivative.

Over time, we began to incorporate both scripting and compiled languages into one project in such a way that distinct pieces of the project might be in different languages, but the interaction between pieces written in different languages was minimal. For example, initially the *mpd* component of *MPICH2* [11] was written in Python while the rest of the modules were written in C [9]. The *mpd* component is a stand-alone process management system that has a trivial interface for connecting to other systems.

Because we always want both performance and ease of development, we have ended up doing bilingual computing. In the bilingual model of computing the interactions between the components written in different languages involve the concept of shared high-level data structures. The reason for two languages was sometimes to overcome a missing feature in C (the high-level data structure) [5]. And sometimes we used two languages to overcome a limiting feature in Python (the global interpreter lock) [6].

However, bilingual computing can be problematic. Besides the obvious requirement of being expert in two languages, bilingual computing introduces the problem of what parts of the project to do in each language and how to interface the various pieces with each other. These are not always trivial problems to overcome. So we are left with the dilemma of do we choose only one language for a project and lose important features of the other language, or do we choose two languages and deal with the problems of interfacing the two languages? And if we choose two languages, someone has to maintain both. As we mentioned previously, MPICH2 was written in C, but its process management component was written in Python. The MPICH2 team, however, felt compelled to rewrite the *mpd* component in C not for performance reasons but largely for ease of maintenance.

The solution to our dilemma is that we need a single programming language that has all the features to elegantly solve our problems. The D programming language [8] was initially developed with the idea of improving C++, and has recently stabilized into what we believe to be the answer to our dilemma. In this paper we begin by discussing salient attributes of D. We then

describe our interfaces to legacy code – specifically MPICH2 [11] and ADLB [1, 3, 7, 10].

2 Why D?

The obvious question to ask is, "Why D?" It doesn't even appear on the TIOBE Programming Community Index [14] of the top 20 most used programming languages. It is interesting to note, however, that the top five programming languages on the list are C derivatives, and four of the remaining languages in the list are scripting languages.

As mentioned before, D was initially developed with the idea of improving C++. Specifically, the developers asked this question:

> Can the power and capability of C++ be extracted, redesigned, and recast into a language that is simple, orthogonal, and practical? Can it all be put into a package that is easy for compiler writers to correctly implement, and which enables compilers to efficiently generate aggressively optimized code? [8]

Because of this, it has many of the features of C/C++ that we consider to be important for high performance computing:

- It is so compatible with C that it will link with existing C programs.
- It has all the features of C from pointers to inline assembly language.
- It has all the features of C++ including a simplified method of handling templates.
- Programming can look like C or C++.
- Performance is equivalent to C.
- The developers claim that on average it compiles 100 times faster than C++ and four times faster than GO. [2]

So we have the performance and features of the C derivative languages. But we also want the high-level data structures, automatic garbage collection, and rapid development time of scripting languages. D actually has many of these features as well. For instance:

- Rapid development can be done with the rdmd wrapper to dmd (the original D compiler) that allows for compiling, linking, and executing without appearing to compile and link.
- D has advanced data structures such as lists and associative arrays.
- D has automatic garbage collection.
- It has Perl-compatible regular expression handling.

In addition to having the aforementioned features of the C derivative languages and the scripting languages, D has some features that can be very helpful for high performance computing projects. Features such as:

- built-in language support for it's own thread model (it should be noted that memory is not shared by default, but it can easily be annotated as shared),
- built-in language support for unit test – both with compiler options and within actual code,
- facilities for contract programming

3 Interfacing D to Legacy HPC Code

Because D is link-friendly with C, i.e., it just links with C functions, one would be inclined to believe that it would also be compile-friendly with C. What we mean by that is you might think that it would allow you to include C header files. But that is not the case. Instead D imports its own modules. For example, you might expect to be able to include the mpi.h header file. Instead, the mpi.h header file has to be converted to a D

Figure 1. A portion of mpi.h.

module. To facilitate this process, there is a *htod* program. *htod* is quite useful in that it accomplishes most of the task, and most of ***what needs to be done by hand*** is annotated in the converted file with comments. Admittedly there is some

hand-crafting necessary to make the project work. The transformation process is shown in Figures 1 – 3 where we list a portion of the mpi.h header file, what that same portion looks like coming out of *htod*, and what the final hand-crafted portion looks like.

const MPI_BYTE =
cast(MPI_Datatype)0x4c00010d;
```

Figure 3. A portion of mpi.h that has been run through *htod* and then hand-crafted to work correctly

While the conversion process was a bit tedious, it was not difficult, and we were successful in using a small

subset of MPICH2 in D programs. We turned our results over to the current MPICH2 support team, and discussions are being held to determine if MPICH2 is going to support D as it already does C, C++, and Fortran.

Having this experience behind us, it was relatively trivial to perform the same operation on ADLB and begin using ADLB in D programs. Encouraged by these results, this semester we have provided D as an option in our graduate level parallel processing class which uses both MPI and ADLB.

As a purely intellectual exercise to convince ourselves that D would be a good replacement for C and/or Python, we did the necessary work to convert portions of mpd, ADLB, and the theorem prover into D. In cases where our major concern was nothing but performance, we found that writing D code was essentially equivalent to writing C code. If we wanted to, we could use pointers and write memory managers. On the other hand, if we wanted to let D handle memory management we could. In fact, D was able to handle practically all that we wanted it to handle. There were only two places where D was somewhat less than perfect for our needs. The first tiny flaw is that D's definition of associative arrays is not as elegant as Python's. If you want to map a single data type to another single data type, D is fine. But if you want to use multiple data types as the key, you have to use a *Variant* – so technically D is up to the task but it is not as elegant as Python. The second tiny flaw is that as far as we can tell, there is no serialization library right now in D. There is one proposed that has not been accepted. But to fully re-implement some of the mpd code, we would need serialization. As part of our exercise, we implemented a small serialization library suitable for our own needs, but it would be nice to have serialization as part of the distribution libraries.

4 Conclusions and Future Work

During the course of several decades of writing high performance code our goals have evolved. Initially the aim was simply to improve performance – which meant programming in C (or some C derivative). Over time our goals evolved to allow more features of scripting languages for small parts of a large project – features such as advanced data structures and automatic garbage collection. Eventually our goals would require the sharing of data structures between high-level scripting code and low-level performance code in a single project. The desire for both caused us to develop a bilingual programming model, thus requiring us to deal with the problems associated with sharing data structures between languages. This was not an ideal situation.

We believe the dilemma of whether to code a project in a single language or two languages can be solved by coding in D. D provides the power and capability of the C derivative languages. It also provides the flexibility of the scripting languages. And D has some added attributes that aren't available in the others. It is trivial to link D code to C code, and it is fairly easy to interface D to legacy code using the *htod* software. The interface to legacy code does require some manual labor to get the project to work, but it is minimal.

We have begun using D in our graduate Parallel Processing class as well as in our research. The elegance of the D threading model and its ease of use with MPI and ADLB have led to plans to use D next year in a Software Design and Development course which might not otherwise be able to use high performance computing facilities.

While we can use D on our own cluster, on machines like the BlueGene/Q, this might not currently be possible. Typically you can only be guaranteed C/C++ and Fortran. Since D is under consideration by the MPICH2 team, this may lead to availability of D on the bigger clusters/machines.

Just as people constantly argue about what language is better. They also have frequent discussions about whether or not languages are scalable. For example, they might say, "Perl's fine for quick and dirty hacks, but it's not scalable." Or they might say, "Python is elegant and scalable." We doubt that anyone would argue that C/C++ is not scalable. On the other hand, the large projects done in C/C++ may not be as elegant or as maintainable as those done in Python. All arguments aside, if you want performance, rapid development, elegance, scalability, safe language features, ease of maintenance, and advanced software engineering functionality, then it is really hard to find it all in one place other than D. At this point we see no reason to use anything other than D for new projects. From our point of view it scales elegantly, and gives us all the features we need.

Abstract

The present work investigates using non-blocking and minimum-blocking Java library classes as a basis for improving performance of parallel bidirectional search on a multiple-instruction multiple-data (MIMD) processor. The approach represents individual states as minimum-size, immutable objects. It uses a work queue to distribute states-for-expansion among worker threads, and it uses two sets for keeping track of states previously explored in each direction. The queue class is thread-safe and non-blocking, and the set class is thread-safe and non-blocking for read operations, with parallel locking of subsets for write operations. It is essentially a dataflow approach as opposed to a state machine approach. Rather than step worker threads through state transitions using blocking synchronization, it flows states to be expanded to worker threads in the order required by bidirectional search. This approach has clear, measurable advantages over approaches that use blocking synchronization.

Keywords

bidirectional search, concurrent programming, Java, multiprocessing, parallel programming

1. Introduction and related work

This report is an outcome of curriculum development for a senior and graduate-level course in multiprocessor programming.[1] The course uses the Java™ programming language because of its extensive library of thread-safe container classes and atomic data types, and its explicit memory model that supports aggressive optimization of dynamically compiled code [1]. We have found that for some algorithm benchmarks Java outperforms statically optimized C/C++ using the native compiler. This report focuses on applying Java library classes to the problems of parallel bidirectional search.

Bidirectional search is a classic approach to solving search space problems when both the initial and final states of the search are known in advance [2]. It searches for paths that connect these two states, typically searching for minimum-length paths. In problems with exponential growth of the search space size as a function of search path length, bidirectional search reduces the number of states inspected over unidirectional approaches by integrating the results of two shorter paths that grow simultaneously from the initial and final states.

Bidirectional search is an interesting algorithm for adaptation to parallel programming because it aims at improving run-time performance over simpler search algorithms such as depth-first or breadth-first search, and because it lends itself to parallel implementation. Figure 1 is a schematic view of bidirectional search as exploration of a maze in search of the shortest path, given knowledge of both the entrance and exit locations. Regardless of the concrete problem being solved, bidirectional search always requires knowledge of the starting and ending states of the search. It often utilizes problem-specific heuristics to prune the search space of dead ends, but it is not required to do so.

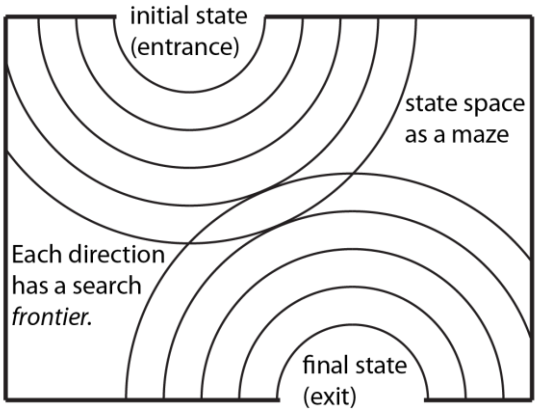

Figure 1: Bidirectional Search as a Maze

The fundamental point of bidirectional search is to limit the exponential growth in number of states explored in a single direction by exploring two shorter paths, one from each direction, and then detecting states in which those opposing paths meet. The outermost set of states currently being explored in either direction constitutes that direction's *frontier*. A single-threaded search based on breadth-first search uses a first-in first-out (FIFO) queue of states to expand as a work queue. The algorithm first enqueues the initial state and final state in the work queue, after which it iteratively removes a state, computes its single-step expansions, checks for cycles and converging DAG paths within the states of its

[1] This work was made possible by equipment grants from Sun Microsystems and the NVIDIA Corporation, and by stipend grants from the Intel Corporation and the PA State System of Higher Education. Please see the Acknowledgements section for details.

originating direction, and checks for collisions with states coming from the opposite direction. Cycle / converging paths and collision checking require storing explored states in a set (keyed on location in the space + search direction) or two sets (keyed on location only). Detection of opposing-path collisions uncovers shortest-path solutions to the problems. In the absence of cycles / converging paths and solutions, the algorithm enqueues one or more single-step expansions and repeats these steps until it locates a solution.

The worst case time, space complexity for unidirectional breadth-first search is $\mathbf{O(b^{d+1})}$, where base **b** is the number of alterative branches (*branching factor*) in the search path that can be taken at any step, and exponent **d** is the *depth* (or equivalently *length*) of the path. When b==3, for example, an un-pruned frontier contains 3 possible states after 1 step, 9 possible states after 2 steps, and so on, generalizing to $\mathbf{b^d}$ states at the frontier, although some may be eliminated through detection of cycles, converging DAG paths, or via application-specific heuristics. The total states explored leading up to the frontier + the frontier itself grows at the rate $\mathbf{O(b^{d+1})}$.

Bidirectional breadth-first search, in contrast, grows at the much lower rate $\mathbf{O(b^{d/2})}$. Each of the two search directions in bidirectional search grows to only half the length of the corresponding unidirectional search, thereby cutting down on the massive exponential growth in explored states that comes with the relative doubling of length in unidirectional search.

Recent work reported on integrating parallel processing with bidirectional search focuses on applying parallel implementation of heuristic strategies to prune the search space [3-5]. Using application-oriented heuristics to radically reduce the number of states explored is the primary means for accelerating the basic bidirectional algorithm. Observing the incremental state expansion of a search domain often uncovers useful heuristics.

2. Minimum Blocking Approach

Our initial solution to parallel bidirectional search used the following algorithm, which implements a two-phase state machine. Each immutable state object contains its internal state fields and an immutable reference to its predecessor in its search path.

```
enqueue initial state into work queue
enqueue final state into work queue
set forwardStatesSet to the set of {initial state}
set backwardStatesSet to the set of {final state}
set setOfSolutions to empty set {}
set direction to Forward
set isdone flag to False
while not isdone
    dequeue a state-to-expand from front of work queue
    if directionOf(state-to-expand) not equal direction
        post a pending-change-of-direction to all threads.
        block until all threads ready to reverse direction.
        set direction to its reverse.
    for each single-step expansion of state-to-expand
        if expansion is in StatesSet from opposing side
            if 1st solution or cost equals solution's cost
                add expansion's path to setOfSolutions
            else (cost is greater)
                set isdone flag to True
        else if expansion is in StatesSet from this side
            // a cycle or converging DAG path detected
            do not use this expansion
        else
            add expansion to StatesSet from this side
            enqueue expansion in work queue
```

Listing 1: Parallel, blocking state machine

Enqueues into the work queue and dequeues from the work queue do not block in this algorithm. The viability of non-blocking retrieval depends on the fact that exponential growth of the search space ensures that most dequeue operations will receive a state-to-expand from the work queue. It is only at the beginning of the search that some threads do not initially find states-to-expand via the non-blocking dequeue operation within a given phase (forward or backward). Those threads resort to a polling loop, trying the queue repeatedly until they receive data or until another thread posts a *pending-change-of-direction* flag. Idle polling consumes processors only until the work queue begins to grow at an exponential rate. Our implementation uses the ConcurrentLinkedQueue from the java.util.concurrent library package as the work queue. The documentation for that class states that, "This implementation employs an efficient "wait-free" algorithm." [6, 7]

The *forwardStatesSet* and *backwardStatesSet* of Listing 1 are objects of class ConcurrentHashMap of java.util.concurrent. There is no comparable Set class per se, but the keys of a Map can serve as elements of a Set. The documentation for this class states, "However, even though all operations are thread-safe, retrieval operations do *not* entail locking." Write locks are distributed across a number of *stripes*, where a stripe is a subset of the buckets in the hash table [8]. When two writers do not collide on the same stripe, they do not impede each other. Application programmers can adjust the number of stripes, trading increased parallelism against the memory cost of maintaining additional lock stripes.

A change of direction in the algorithm of Listing 1 entails waiting until all threads have completed expansion of the current direction, forward or backward. Referring to Figure 1, all threads expand the frontier of only one direction at a time during one phase of this state machine approach. Our thinking was to keep the set of states coming from the opposing side stable for collision testing during the expansion of states in the current side. We implemented blocking using the CyclicBarrier class from java.util.concurrent [6]. This library class blocks all calling worker threads until the last worker thread has entered the barrier. The final thread to enter reverses the direction of the search state variables, and then all threads enter the next phase of the search. CyclicBarrier provides very coarse-grain synchronization. The intent in

using CyclicBarrier was to minimize fine-grain synchronization while supporting stability in testing for state membership in the opposing *StateSet*.

After working with our implementation of Listing 1 we realized that we could eliminate locking altogether. Listing 2 gives the revised algorithm.

```
enqueue initial state into work queue
enqueue final state into work queue
set forwardStatesSet to the set of {initial state}
set backwardStatesSet to the set of {final state}
set setOfSolutions to empty set {}
set isdone flag to False
while not isdone
    dequeue a state-to-expand from front of work queue
    for each single-step expansion of state-to-expand
        if expansion is in StatesSet from opposing side
            if 1st solution or cost equals solutions' cost
                add expansion's path to setOfSolutions
            else (cost is greater)
                set isdone flag to True
        else if expansion is in StatesSet from this side
            // a cycle or converging DAG path detected
            do not use this expansion
        else
            add expansion to StatesSet from this side
            enqueue expansion in work queue
```

Listing 2: Parallel, minimum-blocking dataflow machine

The dataflow algorithm of Listing 2 dispenses with the CyclicBarrier waiting of Listing 1. The dequeue operation remains a non-blocking poll with looping until the work queue begins to fill, tests for *StatesSet* membership are non-blocking, and insertion of new states into *StatesSet* occurs using concurrent lock stripes. With a high lookup-to-insertion ratio for *StatesSet* members (all insertions are preceded by lookups to detect cycles and solutions), locking is minimal and configurable via the *StatesSet's* stripes constructor parameter.

Dispensing with coarse-grain synchronization of the two-phase state machine is possible because states flow through the *work queue* in approximately the correct order. Forward states-to-expand alternate with reverse states-to-expand, partitioned by frontier-being-expanded for the most part.

This temporal sequencing of wave fronts is stochastic, not deterministic. A thread that finds most (but not all) of its state expansions to be dead ends (cycles or converging DAG paths) for a series of dequeue operations places frontier states onto the work queue quickly; some worker threads could be two phases ahead of other threads, expanding a path of length L+1 for a given direction while some threads are expanding paths of length L for that same direction. There is no particular problem in occasionally "getting ahead," as implied by the overlapping frontiers of Figure 1. A thread that has gotten ahead on one turn may find an opposing path one level deeper into the opposing side's search space, but the discovered path is still a solution path. The algorithm retains only the set of minimum-length solution paths. Normally, by the time a thread has reached level N+1 in the search from its dequeued state-to-expand's origin, all other threads have dequeued all level N states from the work queue, and they will complete expansion of those N-level states before checking the *isdone* flag set by the first solution's discovery. Some of those N level expansions may be redundant with the N+1 level solution from the thread that "got ahead." The algorithm discards such redundant solutions.

There is still a potential problem, although we have not seen it in practice. The algorithm of Listing 2 makes it possible for some advanced state-to-expand to be multiple frontier levels ahead of other states being expanded in the same direction. If the thread that is expanding a level N+2 (or higher) state sets the *isdone* flag while other level N states are being expanded in the same direction, then some solutions could be missed in an exhaustive search for all distinct minimum-length paths. The fix is to discard a state-to-expand after a solution has been found, if the state-to-expand has a path length greater than the integer ceiling of ½ of the known solution's length, setting the *isdone* flag at that point. The length of the first known solution helps to prune state expansions. At the point that the work queue becomes empty after the *isdone* flag is set to True, worker threads can terminate their work. Of course, a thread may detect this condition and terminate just before another thread enqueues a state-to-expand, but at that point processing is converging on the last of the solutions, and the thread that enqueued the state-to-expand is guaranteed to be available to dequeue that state-to-expand, if no other thread gets there first. States-to-expand in possible solution paths will not be left in the work queue by all terminating threads, and detection of the *isdone* flag in combination with an empty work queue indicates convergence on the last of the solution paths.

One final problem with the fact that some states-to-expand may get multiple levels ahead of most states being expanded in a direction is the fact that these states may not lie in a solution path. The advanced state has gotten outside of the intersecting cones of the frontiers of Figure 1. This problem is a small efficiency concern, not a bug. There may be some unnecessary searching outside the intersecting frontiers of Figure 1, but the performance impact is insignificant compared to the benefits of the minimum-blocking algorithm. Exploration of such states does not lead to false solutions or premature termination.

3. Shortest path performance

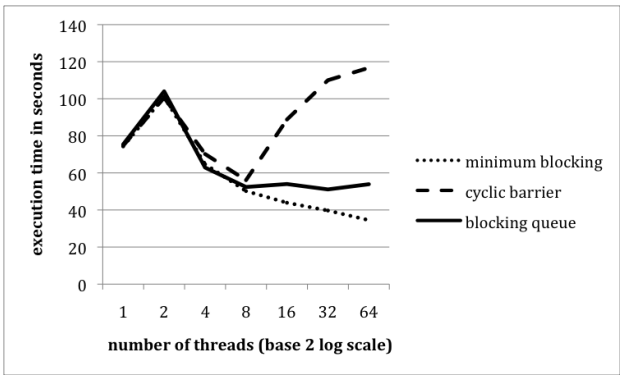
For the performance measurements of this section we ran two representative applications of bidirectional search. The first finds the solution of the so-called "Penny-Dime problem," where there is an arrangement of some number N of pennies P, followed by one blank space, followed the same number N of dimes D. The goal is to find the series of moves that will reverse a sequence such as

PPPPPP_DDDDDD to the sequence DDDDDD_PPPPPP. Legal moves consist of moving a coin one location into the space, or jumping a coin over a single neighbor (as in checkers) to the space. Heuristics such as avoiding retrograde moves can accelerate the search, but the overall form of the algorithm remains unchanged.

The other benchmark, which is the one reported here, is a simplification of a maze construction problem. The original algorithm searches for non-shortest paths that match some minimum-length threshold, in the interest of constructing interesting mazes.

For the benchmark reported here, we use an algorithm that simply searches for the shortest path from the maze entrance to its exit by crossing empty space with no obstacles other than outside walls. When the program starts, there is a pseudo-randomly selected entrance location, exit location, and outer walls, but the inside of the proposed maze is empty at that point. The algorithm simply finds the shortest path between two points, where the search from the entrance does not have knowledge of the location of the exit, and the search from the exit does not have knowledge of the location of the entrance. This is essentially blind search.

The machine used for this benchmark is a 64-threaded Sparc server obtained via a 2009 grant from Sun Microsystems [9]. It houses 8 cores x 8 threads-per-core = 64 hardware threads, 16 Gbytes of main memory, and a 1.2 Ghz clock speed. Each core is limited to a rather small 16 Kbytes of L1 instruction cache and 8 Kbytes of L1 data cache, with 4 Mbytes of L2 cache distributed across the cores. While not the best fit for large data sets with random access patterns due to the limited cache, it performs admirably when running Java programs with good memory locality or modest memory consumption. The individual states of the bidirectional search problems that we have benchmarked are small, although references to a large number of these small state objects can reside in the work queue and sets of the algorithm.

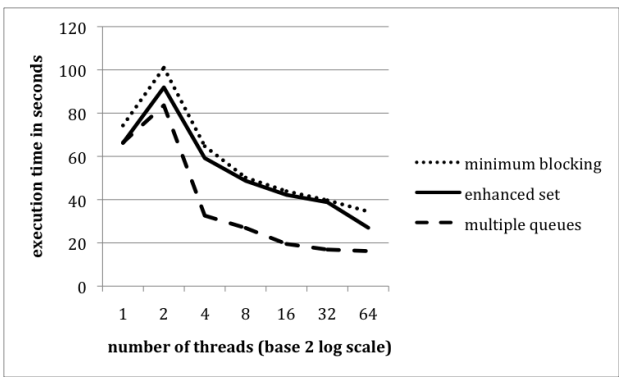


Graph 1: Multithreaded bidirectional maze construction

Graph 1 plots execution time in real seconds on the Y axis as a function of number of threads on the logarithmic X axis for construction of a minimal path of length 2947 in a 2500 x 2500 space using blind bidirectional search. The dashed *cyclic barrier* curve of Listing 1 reaches its peak performance at 8 threads (56.1 seconds compared to 74.7 seconds of its single-threaded case), after which execution time grows with the number of hardware threads employed. Normally adding threads beyond some optimal spot for an algorithm increases start-up and scheduling overhead, although in this case scheduling overhead is minimal because all 64 hardware threads are available for execution. The problem here is that when one or two threads lag behind the others in the exploration of a frontier, the remaining 30-to-31 or 62-to-63 threads block idly in the cyclic barrier until those one or two threads enter the barrier. With only 8 hardware threads employed, each thread has more states to expand for a given frontier, and the cost of exploration averages more evenly across the threads, so there are fewer opportunities for entering this degenerate state repeatedly. More threads wait repeatedly until time-consuming laggards complete their work in the 64-threaded case. In the 8-threaded case the per-thread workload averages out, minimizing the stalling effect of the cyclic barrier.

The dotted *minimum blocking* curve of Listing 2 starts at 74.3 seconds, shows a loss of performance due to two-threaded contention at 101 seconds, after which execution time decreases consistently to 34.5 seconds for 64 threads.

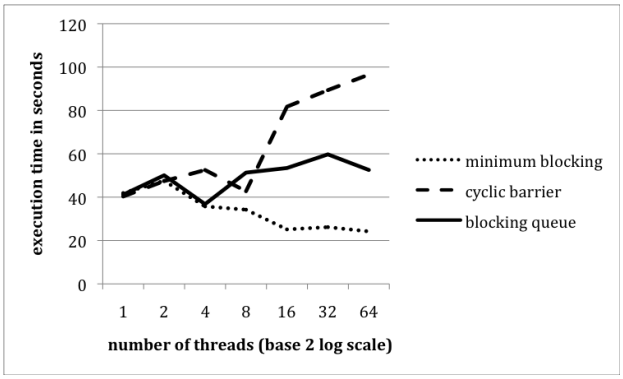
The final, *blocking queue* curve shows the result of replacing the ConcurrentLinkedQueue of *minimum blocking* case with the LinkedBlockingQueue class of the Java library, and using the blocking take() method instead of the non-blocking poll() method for dequeueing states-to-expand. Replacing queue polling with blocked waiting increases processing and scheduling overhead by the Java Virtual Machine and operating system. Polling, even when its finds no work in the queue, is better for this application because it avoids calls into the operating system. Given the exponential growth in number of states to be searched, most dequeue calls for LinkedBlockQueue do not block, yet the cost of calling dequeue methods that must acquire and release locks is clear from looking at Graph 1. After starting at 75.4 seconds for the single-threaded case and then rising to 104 seconds for the double-threaded case, the blocking queue approach drops to 52.4 seconds at 8 threads and then essentially levels off.



Graph 2: Improved nonblocking data structures

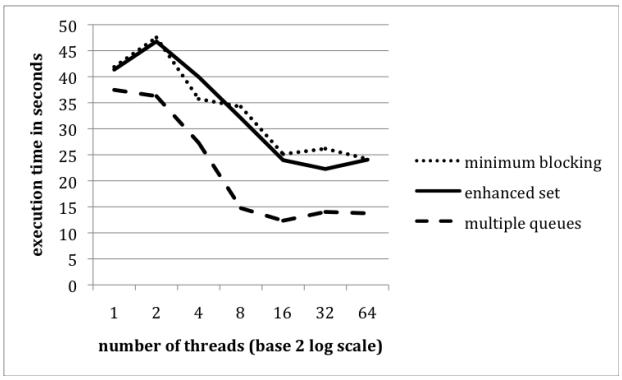
Because the overall halving of execution time in going from 1 thread to 64 threads for the *minimum blocking* approach is disappointing, we decided to attempt to tune the thread-safe data structures to get additional gains. Graph 2 shows the results. The dotted *minimum blocking* curve is the same as in Graph 1. The solid *enhanced set* curve shows the modest gains resulting from initializing the *StatesSet* implemented using ConcurrentHashMap to its known maximum size (4 million elements, determined empirically), reducing its load factor from the default .75 to .5, and increasing its number of lock stripes from the default 16 to 128. Initializing the set size reduces repeated growth overhead. Reducing the load factor reduces hash table collision overhead, and increasing the number of lock stripes reduces contention among concurrent writing threads.

More substantial gains come with the *multiple queues* test case that allocates one work queue per worker thread. Whenever a worker thread is about to enqueue a new state-to-expand, it increments an atomic integer and uses that value as an index to a thread-specific queue. The round-robin nature of enqueuing reduces the probability of thread contention for enqueuing, because a given queue will have its enqueue operation invoked only once for every T enqueue operations, where T is the number of worker threads. A given queue will have dequeue invoked only by its worker thread, eliminating dequeue contention entirely. This *multiple queues* approach bottoms out at an execution time of 16.2 seconds for the 64-threaded case, as compared with 27 seconds of the *enhanced set* approach and the 34.5 seconds of the basic *minimum blocking* approach at 64 threads. The multiple queue approach basically yields a second doubling of performance from its 66.4 second starting point when compared to the other approaches of Graph 2.



Graph 3: Graph 1 benchmarks on a 16-threaded Opteron

Graphs 3 and 4 repeat the benchmarks of Graphs 1 and 2 on a 16-threaded AMD Opteron server also obtained via a grant from Sun Microsystems. The server houses 8 cores x 2 threads-per-core = 16 hardware threads, 32 Gbytes of main memory, and a 2.7 Ghz clock speed. Each core has a substantial 128 Kbyte L1 cache and a 1 Mbyte L2 cache.



Graph 4: Graph 2 benchmarks on a 16-threaded Opteron

Differences in machine architectures such as instruction sets or cache sizes can make substantial differences in performance curves, but in this case the curves of Graphs 3 and 4 repeat the dynamics of Graphs 1 and 2.

4. Conclusions and future work

Bidirectional search is amenable to minimum blocking implementation using immutable state objects, non-blocking queuing of states-to-expand, non-blocking set membership tests in checking for cycles, converging DAG paths and solutions, and parallel lock stripes for updating sets. Java's ConcurrentLinkedQueue and ConcurrentHashMap library classes are excellent matches for the queue and set data structures required by this approach. Adjusting initial set size, load factor and lock striping can contribute modest performance enhancement. Replacing a single non-blocking work queue with multiple work queues that are written by all threads in round-robin order, and that are read respectively by only a single worker thread, leads to a second doubling of performance over the basic minimum blocking approach.

We anticipate porting this work to a NVIDIA Tesla graphical processing unit (GPU) in search of further performance gains. Initial study indicates that a heterogeneous MIMD CPU / GPU approach may be effective. A multithreaded CPU can construct multiple queues for GPU processing elements, one per element, during a CPU phase, along with building the required sets in GPU global, read-only memory. During a GPU phase, the processing elements drain their respective queues, discard cyclic and converging-path states, and send queue and set updates back to the CPU phase. The CPU can update set membership in global, read-only memory incrementally, redistribute the queues, and resume the GPU phase for the next round of state expansion. There are many details remaining to be ironed out in this basic plan.

5. Acknowledgements

This work was made possible by the generous grant of three multiprocessor servers from Sun Microsystems in 2009. A curriculum development grant from the PA State

System of Higher Education supported the initial round of designing benchmarks and course projects such as the one described here. A second curriculum development grant from Intel's *Parallelism in the Classroom* program is making ongoing extension of such materials possible. Finally, an equipment grant from NVIDIA makes the exploration of a Tesla GPU implementation of this work possible.

Concurrency Control and Recovery of Long Lived Transaction Processing in Virtualized Environment

Nazifa Noor, Motoyasu Nagata
Department of computer science, Osaka Kyoiku University, Osaka, Japan

Abstract *- This paper explores long lived transaction processing in the virtualized environment. The employment of the virtualization is motivated by the information sharing among database servers, which enhances concurrency of long lived transaction processing system. Our long lived transaction processing system is characterized by the combination of concurrency control and recovery. Our protocol exploits priority ceiling instead of traditional locking method, while employing and extending the concept of 'wait' inherent to altruistic locking approach. The recovery is efficient due to information sharing log, active list, commit list and abort list. Also, we have evaluated the performance of our approach and shown its effectiveness.*

Keywords: Long Lived Transaction Processing, Priority Ceiling, Two-phase-locking, Virtual Environment, Concurrency Control, Recovery techniques.

1 Introduction

As the database technologies are adapted to a wide range of applications, long lived transaction processing models are inevitably required to support various semantics associated with the applications for throughput enhancement. The ability to maintain concurrency control, and recover from erroneous execution or failure is essential requirement for long lived transaction processing system.

Long Lived Transactions (LLT), have long duration compared to the other transactions, therefore these transactions cause significant delays for Short transactions in the database systems, this compromises concurrency of the system.

In this paper, our goal is developing protocols to motivate concurrency of those database systems that contain long lived transactions. Our approach is exploiting priority ceiling to the long lived transactions in a virtual environment. Furthermore enhancement in the properties of altruistic locking is proposed. We claim that our proposed method brings more concurrency to transaction processing system. The concurrency control is the activity of coordinating concurrent accesses to database in multi-user database system. Concurrency in virtual environment permits users to access a database in a multi-programmed fashion with the illusion that access to databases of various location and servers is possible from one and nearest server. The concurrency control has been actively investigated several times for the past decade. One standard solution accepted to cope with the problem is *Two-Phase-Locking* method, which is applicable to any type of transaction processing system.

Considering the fact that long lived transactions (LLTs) conduct lengthy computation over database objects and their process interval is longer than others, applying two-phase-locking sounds too rigid.

By two-phase-locking method transactions encountering lock conflict are blocked for long period of time, which slow down the processing system. Basic Altruistic locking is a pioneering attempt to cope with concurrency control of LLTs; this concept sets the term of donating database objects (release before unlock). Database objects which are no longer needed by the transaction are released during the process interval of that transaction before it's terminated. Using altruistic locking, short lived transactions (SLT) can go into the state called *wake of LLTs* which means they can access the database objects donated by LLT.

2 Proposed Approach

Database servers from distinct and remote locations are virtually centralized in a way that gives user the illusion as they are located together in one and closest server. In virtual environments transaction manager TM, scheduler and database manager DM are centralize and share. This makes long lived transactions processing smoother than the distributed system with many TM, DM and servers.

2.1 Concurrency in virtual environments

. *Virtual enviromet is clearly structured by figure1*.

By the time that the LLT(long lived transaction) reaches the terminal of TM (Transaction Manager), its structure is

revealed to the TM, the requested data within a list is pitched to the transaction scheduler, Transaction scheduler checks for the availability of the data, while negotiating with Database manager if the data is available, the DM (Database manager) creates a temporary cache, this temporary cache contains all the requested data, at this time scheduler acknowledges TM the acceptance of the transaction, thus the transaction can accesses the required data within the temporary cache.

By the time that the transaction is terminated (commit or abort) the temporary cache is also terminated. And the updated data is flushed to the stable storage.

This way if a transaction comes in the wake of LLT, it will access the temporary cache created for the LLT.

Transaction Scheduler also has a pending queue which contains all the conflicting transactions.

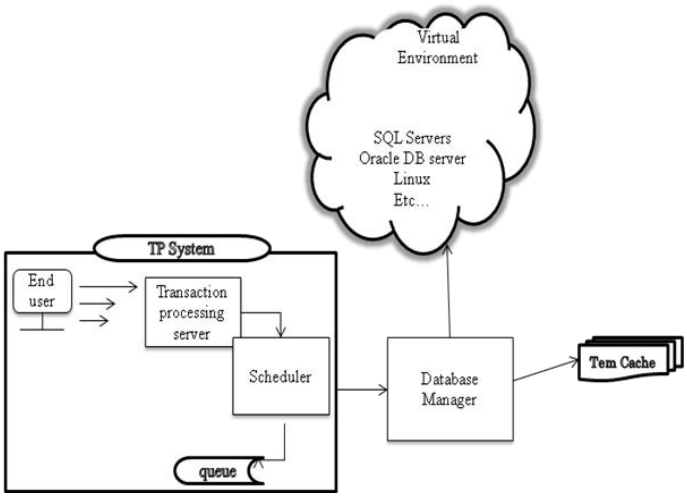

Figure 1, the transaction processing system in virtual environment

Advantages of VE

1. Since database servers share their databases, the maintenance of updates in the system is easier, therefore, consistency of database state is guaranteed.
2. Having centralized TM, DM, and scheduler is less complicated and time saving during transaction processing.
3. System recovery is easier with virtually shared environment since transaction dosn't need to roll-back/roll-forward in so many servers.

2.2 Enhancement of Altruistic Locking (EAL)

We want to further enhance the properties of altruistic locking:

2.2.1 Properties of Basic Altruistic locking (BAL)

1. Two transactions can't hold simultaneous locks on same database object, unless one of them has locked and released the object before the other locked it (second lock holder is in the wake of the releasing transaction).
2. If a transaction (SLT) is in the wake of other transaction(LLT) it should be completely in the wake of that transaction. It means that SLT can't access any data object outside of the wake for that transaction.

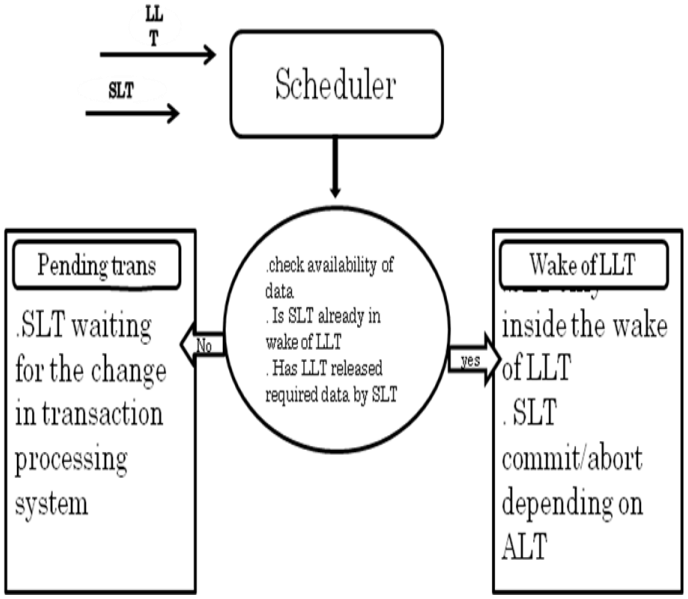

Figure 2, SLT can access data inside the wake of by LLT

2.2.2 EAL (Enhanced Altruistic Locking) properties

In order to represent our terms let's take a look at the following example.

Consider two virtually shared databases :
z[A,B,C,D,E] and ***y[F,G,H,I],***
LLT with two SLT.
Long Lived Transaction list, ***LLT locks [Read(A),Write(B),Reading(C),Read(E)]***
(The underlined C means LLT is now operating on C, and has successfully finished A and B, but has not yet reached E)
.
First Short Lived Transaction list, ***SLT1 try to lock [Read(E),Write(F),Read(A)]***

Second Short Lived Transaction list, ***SLT2 try to lock[Write(A),Write(B)].***

See also figure (3) bellow.

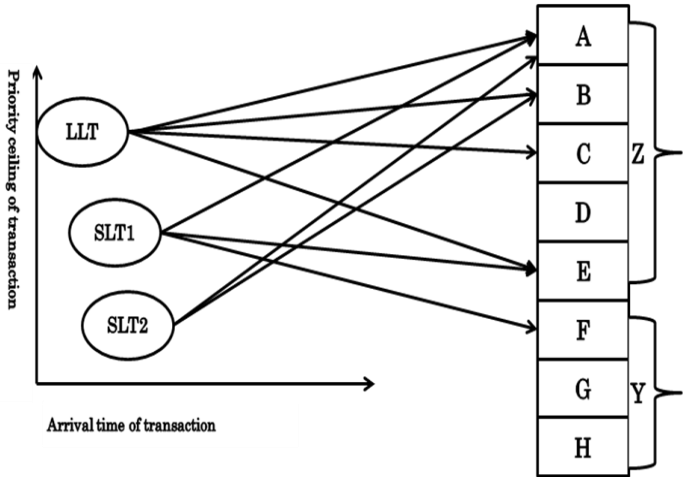

Figure3. Access of transactions, priority is based on arrival time

If we look at SLT1'srequest list, its approach is inside and outside process interval of LLT, according to altruistic locking rule SLT's lock requestcan't be granted.

However SLT2 can be granted, sinceSLT2'sapproach is only insidet hewake of LLT.

According to our conducted experiment to invoke enhanced altruistic locking (EAL), lets consider that the system grants lock request by SLT1.

The result is,

Because SLT1 is a commute transaction with LLT

$$SLT(reqData) \cap LLT(reqData) = Commute$$

It means the action committed by one of these transaction will not interrupt the other.

This proves that: *commute Short-Lived-Ttransaction scan enter inside the wake of long-lived transactions, but they don'tneed to be restricted during LLT' sprocess interval (wake).*

Based on the above assumption we canenhance the Basic Altruistic Locking (BAL) as following:

Enhanced Altruistic Locking's (EAL) properties for long lived transactions in virtual environments

1.Acquire a floppy lock before every read of database object bytransaction.

2.Acquire a solid lock before every write of database object by transaction.

The floppy-lock is a kind of lock by which, the second transaction can enter the wake of the first transaction without following the BAL rule (*restricted during LLT's proces sinterval*), for example, commute transactions.

The solid-lock is the one by which the second transaction has tobe completely under wake of the first transaction and its termination state(commit/abort) depends onfirsttransaction, for example, conflicttransactions.

EAL properties for short transactions in virtual environment

1. Acquire access to the release of floppy-locked data objects without entering the wake of LLT.
2. Acquire access of SLT to the release of solid-locked-data objects only by entering the wake of LLT.

2.3 Protocol

The priority between transactions can be implemented further as bellow:

Pursuing our method EAL combined with Priority ceiling between simultaneous transactions in virtual Environments, The overall protocol is listed bellow in a set of 3 steps:

Step1. The structure of all transactions becomes known to the TM, by the time the transaction arrives at the TM terminal.

Step 2. TM assigns priority based on the arrival time of T.

Step 3. Scheduler initiates and periodically updates the array-Table of current simultaneous transactions prior to their access to manage the priority of transactions. This array-Table contains notation as T[PC(i,j)=k], where T is the specific transaction, (i) shows priority of transaction, (j) is the innings of holding the lock on a single database object and (k) is the number of times T wants to access one specific object (as in table a LLT accesses data object (b) two times so k(b)=2.

Table A, shows the transaction priority and innings.

Transactions	A	B	C	E	F
LLT[PC(i,j)=k]	PC(1.1)=0	PC(1.2)=0	PC(1.3)=1 PCT(1.5)=0	PC(1.4)=0	
SLT1[PC(i,j)=k]	PC(2.1)=0			PC(2.2)=0	PC(2.3)=0
SLT2[PC(i,j)=k]	PC(3.1)=0	PC(3.2)=0			

Furthermore, the acceptance of transaction's attempt of accessing objectis based on the following priorityceiling terms:

1.No higher priority (T) exists for the same object.

2.Access times (k) of transaction over data is zero PCT (i,j)=0.

Commit in this case belongs to the easy calculation of T1(i,j) and T2 (i.j).

For example,PCT1(1,1)>PCT2(2,2) therefore T1which is LLTgets to commit first.

However, in case of PCT2 (2.2)=1 and PCT3 (3,1)=1 don't care since their timing and Required list is different.

The chart bellow shows theoverall structure of our methodology.

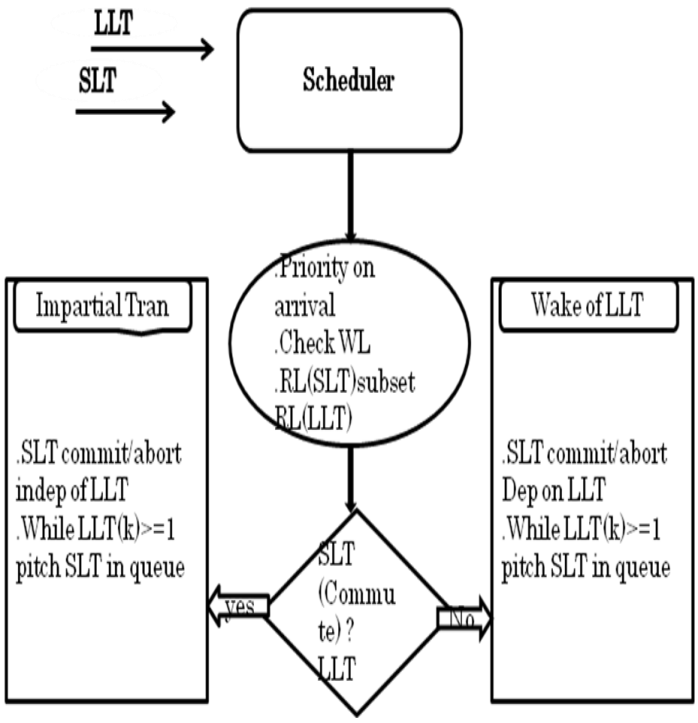

Figure 4, Based on transactions (commute and conflict) situation the structure of BAL is enhanced.

3 Recovery

Recovery rule is obtained by rollback procedure. Our proposed system contains periodical checkpoints, each checkpoint is in charge to backup the state of data (under manipulation by transaction) and over all states of the system from the last the checkpoint. The logging is essential part of this task. If any type of failure occurs in the system, recovery manager rolls back the system to the previous checkpoint in order to omit the aftermaths of failure and to recover the consistent state of the system.

Each checkpoint must maintain three important lists:

(1) active list which contains live operating transactions and live manipulated data object.

(2) commit list, list of the transactions that were committed by the time they reached the specific checkpoint.

(3) Abort list, is a list of transactions which were aborted by the time they reached particular checkpoint.

1. Commit

When the transaction processing is completed at the final server, contents of the cache slot are flushed to the corresponding database at each server.

2. Abort

The abort is caused by the following two cases.

Case1, the fault of the transaction itself occurs at the executing server, despite on the way or final servers.

Case2, the committed transaction read the object x which transaction T1 wrote, at this time transaction T1 is executed normally. However, later, transaction T1 becomes a situation where this transaction T1 must be aborted.

3. Restart

The restart must be carried out for two cases.

Case1, the restart must be executed by the normal periodical checkpoint.

Case2, the restart is also executed in emergency for fault occurrence.

Table 2, concurrencycontrol and recoveryin two different situation (Global Commit and Local Commit).

	Global Commit	Local Commit
Concurrency Control	Keep updated data at cache before commit.	Flush updated data to DB before commit.
	Transaction exists in active list.	Transaction exists in local commit list and local active list.
	Updated log is generated.	Updated log is generated.
	When commit is issued at the final server, commit log is broadcast.	When commit is issued at the final server, commit log is broadcast.
	Flush is done at every server simultaneously.	Flush is done at each server step by step.
Recovery	When abort is needed, abort log is broadcast to every server.	When abort is needed, abort log is broadcast to every server.
	Transaction is removed from active list and added to abort list.	Transaction is removed from local commit list and added to abort list.
	The updated data at cache is not flushed.	The before image of the updated data is flushed into DB (undo).

3.1 Index

Based on the proposed protocol using priority ceiling for the Long Lived Transaction processing, we simulated the concurrency control and obtained experimental results. The concurrency of transaction processing with respect to varying parameters was evaluated, in this case, number of objects located at different servers.

The concurrency of transaction processing is defined by the following equation:

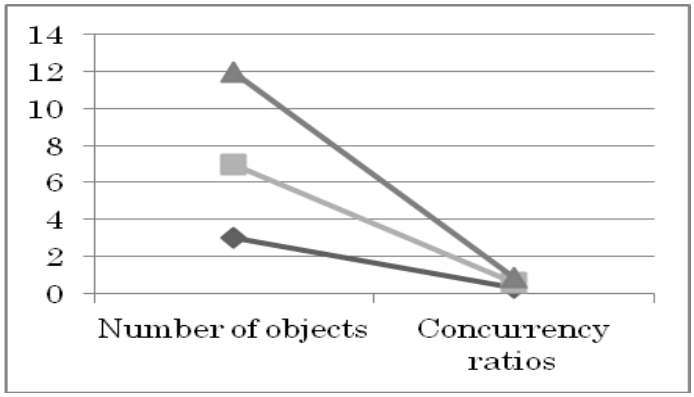
Concurrency of transaction = (number of object) x (issued number of transactions) — (observed access number to objects)

(N x I) – O

Where we assume that, every transaction accesses the same number of objects.

3.2 Experimental Results of Concurrency

The experimental result is illustrated in Figure 5 and 6 also shown in Table 3. As the result of performance evaluation, the concurrency ratio is 27.42 percent for three objects, the concurrency ratio is 28.94 percent for four objects, and the concurrency ratio is 29.02 percent for five objects. The simulation result showed that concurrency meaning the simultaneous accesses for different objects at different server's increases according to the increase of parameters. Meanwhile, for fixed five objects, the concurrency ratios are 28.96 %, 29.02 % and 28.94 %, when the issued numbers of transactions are 1000, 2000 and 3000, respectively. This experimental result indicates the concurrency of transaction processing almost same in spite of increase in the issued number of transactions'.



The figure 5, shows concurrency ratio as per the number of transaction

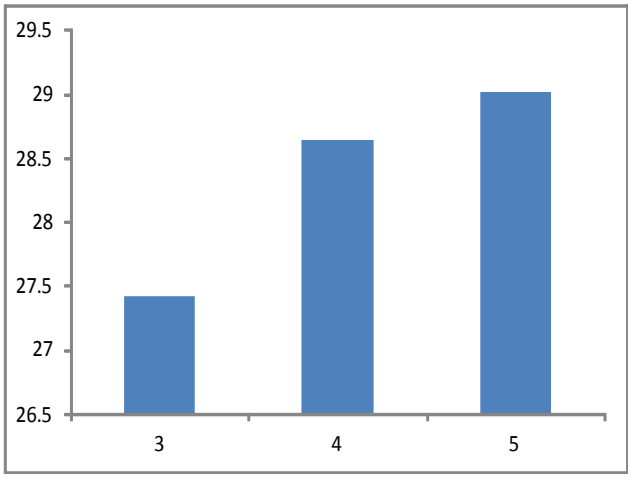


Figure 6, Comparison of concurrency ratios for different number of objects.

Table 3 Comparison of concurrency ratios for different number of objects

Number of objects	3	4	5
Concurrency ratios	0. 2742	0. 2864	0. 2902

4 Conclusions

The enhanced altruistic locking for Long Lived Transaction processing was proposed in virtual environment.
The motive was to promote concurrency in virtual environments with Long Lived Transactions.
The performance evaluation showed tendency of the concurrency ratio. The concurrency of Long Lived Transaction Processing in Virtual Environment was proposed. Priority Ceiling of transactions based on their arrival time was proposed as best option to bring more management in the system.
Aside from that, Recovery mechanisms were highlighted and over viewed.

5 Acknowladgment

Sincere gratitude is hereby extended to those who continued their help until this research was accomplished :
Mr. Kasuke Shuda, Mr. Noriho Okazaki, for conducting and sharing the programing expertise.

Special thanks to the laboratory members of transaction processing, my friends Ryuta Ono, Yuko Nishimura.

For the moral support, thanks to my family and friends who never give up on me.

Above all, utmost appreciation to the almighty God for the divine intervention in this academic endeavor.

Integrating HPC Resources, Services, and Cyberinfrastructure to Develop Science Applications Using Web Application Frameworks

M. P. Thomas[1,2], C. Cheng[2], S. More[2], and H. Shah[2]
[1]Department of Computer Science, San Diego State University, San Diego, CA, USA
[2]Computational Sciences Research Center, San Diego State University, San Diego, CA, USA

Abstract *– The Cyberinfrastructure Web Application Framework (CyberWeb) simplifies access to heterogeneous, computational environments required by high-performance computing applications. CyberWeb has three core components: a Pylons Web2.0 framework, including XML, JavaScript, AJAX, Google APIs, social networks, and security; a Database and Web interface for configuring installations, applications, users, remote services; a job distribution service framework for task execution and management. CyberWeb design philosophy includes: "plug-n-play" mode - applications dynamically discover modifications to the system and automatically reload new components; "non-invasive" philosophy - no software is required to be installed on remote resources, it interfaces existing software and services. CyberWeb supports basic job functions (accounts, authentication, execution, task history); operates in heterogeneous environments from remote large-scale systems (XSEDE/TeraGrid) to local systems; applications built on top of the core framework (ocean, thermochemistry, education). In this paper we present the CyberWeb architecture, highlighting the database and JODIS architectures, and demonstrate its usefulness with application examples.*

1. Introduction

Advances in technologies and languages used for parallel and distributed computing have often presented the science researcher with the challenge of migrating a model or application to ever increasingly complex systems. Often, many science applications require tremendously large compute, data and archival resources and high-speed networks in order to manage results, or the model is often legacy code that is stable, but no longer ports to the high-end systems that are available. Cyberinfrastructure (CI) integrates hardware and software for computing, data management and information retrieval, visualization and analysis using interoperable software/middleware and services that are based on Web and Internet technologies. The NSF's *Cyberinfrastructure Framework for 21st Century Science and Engineering (CF21)* sets an ambitious goal that next generation of cyberinfrastructure software must seamlessly couple high-end and low-end CI resources, networks and services, with users and applications using these commodity Internet and Web technologies [1]. The US DOE held a workshop in 2008 addressing the grand challenges and limitations that exist today in the field of high-resolution climate and Earth modeling systems [2]. The outcome of these efforts have helped to define the requirements for the next generation of HPC applications: new/updated models are needed that can take advantage of these cyberinfrastructure based environments; the NSF and DOE need to construct and support this cyberinfrastructure over the long run; and new tools and libraries are needed to facilitate the development of these applications.

There are many efforts to develop common tools that can be reused at all layers of the science gateway architecture, including services to resources (data, compute, visualization, network), middleware, and user interfaces and portals and science gateways. Science gateways (and computational environments) are terms used to characterize the systems and tools that facilitate the utilization of CI by science applications; gateways typically involve a user interface [3][4]. This research is part of this effort: the software developed is contributed to the suite of tools developed by the NSF funded Open Grid Computing Environments (OGCE) project [5], which focuses on the development of gateways and tools. In this paper we describe advances made the SDSU Cyberinfrastructure Web Application Framework (CyberWeb, [6]) which is designed to simplify the development of advanced computational environments (CEs) used by high-performance computing (HPC) applications and science gateways. CyberWeb improves on standard CI toolkit functions (job execution, account management, task history, GSI authentication, etc) by hosting all applications as Web services, portal Web pages, or Web 2.0 gadgets. CyberWeb is being used to develop applications that need to operate across large-scale grids such as the XSEDE/TeraGrid, local university clusters, and commercial or public systems.

In this paper, and overview of the CyberWeb architecture (Section 2), highlighting the database and JODIS architectures are presented. In Section 2.5, installation and deployment experiences are present, and Section 4 presents application examples.

2. CyberWeb Architecture

The Cyberinfrastructure Web Application Framework (CyberWeb) architecture is shown in Figure 1. It reflects the standard 3-tier architecture found in systems that connect clients (human, computer) to remote resources via middleware. Front-end clients can be applications, services, or human (browsers, desktop apps, command line interfaces). The backend tier (cyberinfrastructure) includes local services, web services, other applications, and remote

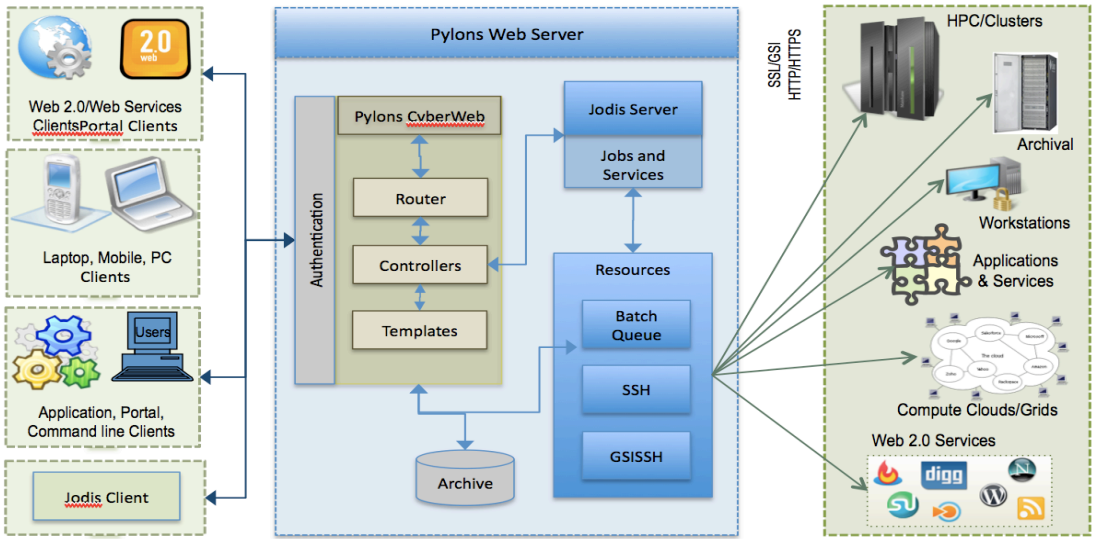

Figure 1. CyberWeb Architecture Showing client, middleware and backend resource cloud. Middleware layer includes the Pylons framework, the CyberWeb database and Jodis services [6].

grid, computing and data services. CyberWeb uses the Pylons Web Application Framework [7] for its core Web 2.0 services.

2.1 Pylons Web Application Framework

Pylons is a component based, lightweight Web 2.0 application framework that using only Web 2.0 technologies, including WSGI (Web Server Gateway Interface, relational databases, XML, JavaScript, AJAX, Google Gadgets, social networks, and security. Any number of components and libraries developed by other projects are part of the system and new ones are easily integrated. Pylons uses the model-view-controller (MVC) request-response architecture (Figure 1). The *Model* contains the data used by applications. Often the model refers to database tables. The *View* reads the data from the model and displays it to the user. The *Controller* manages the logic of the application, activates views to display data to the user, or parses information from the user and stores them to the models. CyberWeb application developers work with all three components. The MVC approach decouples the services layer from the logic of the code behind it, allowing the same application to be hosted as different service types (Web service, Web page, XML request, iGoogle gadget). Pylons supports dynamic routing via Routes (Python version of Rails), and is used for mapping URL's to Controllers/Actions and generating URL's. Routes makes it easy to create "pretty" and concise RESTful (REpresentational State Transfer) URIs (uniform resource indicators). Template packages are used to build dynamic Web pages from a variety of sources: HTML file, XML generators, scripts (perl, php), or templates.

2.1.1 Key Features

Pylons has several features that are beneficial to science application and gateway developers. A key philosophy of the Pylons project is external components can be plugged into the framework with only the minimal code-base necessary. This facilitates customization. Although the features of Pylons are as rich as the libraries and modules that are available to run with it, a few key features of importance to this research are listed here.

Routing and "Beautiful URLs:" The feature makes it easy to create "pretty" and concise RESTful (REpresentational State Transfer) URIs (uniform resource indicators). With RESTful URI's, the information being transferred is stateless, and independent of resource details.

SQLAlchemy database: Pylons supports many databases, including SQLAlchemy which is a Python SQL toolkit and Object Relational Mapper (ORM). ORMs map the database structure to objects.

Interfaces to multiple template packages: Templates are used to build Web pages in a dynamic manner. Pylons allows any type of HTML file, XML generators, or template modules to be used. xx This allows application developers flexibility in choosing how they want to build their application.

Dynamic update and interactive debugger: An important feature of Pylons is the "reload" feature: it supports dynamic class loading for all MVC layers; modifications to the code cause the compiler to update the binary and re-load it into the server while keeping the server live.

Web 2.0 and Open Social Interfaces: Pylons' RESTful Web services allows Pylons components be published as services, widgets and gadgets, and desktop applications. Pylons interfaces to other toolkits including: Google Application Engine and OpenSocial gadgets; PyWebKitGtk (an API for developers to program WebKit/Gtk).

In addition, AJAX/JavaScript support for libraries such as the Yahoo! UI Library (YUI). The YUI, CSS, AJAX, and Javascript are used by CyberWeb for nearly all demo web pages.

2.2 Model and Database Services

At the core of CyberWeb is its database system, where most of its configuration data is stored (users, hosts,

Table 1. List of CyberWeb model category and table names.

Table Category	Table Names	Description
Group	Users, Groups	CyberWeb user accounts (chosen by user), Groups (used for authentication & authorization; e.g. admin, developer, application)
Accounts	Account	Accounts on remote resources; owned by a CyberWeb user account.
Protocol	Protocol	HTTP/HTTPS, TCP/IP, SSH, GSISSH,
Services	Service Type, Name, Service	Used to define service types (authentication, queue, application, archival); names of specific services (SSH is type authentication); a Service (e.g. an SSH Service) has a type, name, and is installed onto a Resource.
Queue Systems	QueueType, Name, Info QueueService	Used to define queuing service types (batch, condor, grid); names of specific services (LSF, PBS, Torque, SGE); a QueueService (e.g. an SGE Service) has a type, name, infor, and is installed onto a Resource.
Resources	Resource	Defines compute, archival, and networks used (primarily) for remote job execution. A Resource has DN or IP address; and are used (typically) to host Services.
Job	Job	CyberWeb tracks internal Jobs and Tasks, maintaining job history. This is independent from job ids used on remote resources.
Message	MessageTypes, Message	Used for communication among CyberWeb users and applications, messages types include news, events, jobnotification; a Message has a type.

authentication, jobs, job history, etc.). In addition to using this database to store session and user information, a key design goal was to develop a database architecture must be easily modified, populated dynamically, and then be used to configure and build virtual organizations (VO's). Furthermore, the system must operate in a "plug-n-play" mode: once modifications are committed, the new information be readily available to the relevant components of the system. This includes adding compute and archival resources, defining and naming services, and configuring these services on a resource. Once set up, all internal services use this database to discover active resources, the operational status of services, and the ACL of a CWuser for that service or resource, and relevant user preferences.

2.2.1 Schema Design

The schema design was based on an evaluation of schema used by multiple projects (TeraGrid [8]; Open Grid Forum [9]; and W3C/IETF standards). The requirement that the schema be simple, and useful to non-database experts developing small applications, drove the design approach to simplify and reduce the number of tables and elements in them to a minimal set. The assumption is that an application developer can expand the initial database to meet project requirements. The perspective is from the point of view of a high-performance computing environment: a resource is typically a host computer (cluster, archival); services run on these resources (SSH, FTP); and users have access to them via authentication such as username/password or GSI certificates.

The database is initialized using a JSON input file, and can be populated dynamically. The database design has four key components: (1) SQLAlchemy: a Python SQL toolkit and Object Relational Mapper (ORM) that interfaces to multiple RDBs; (2) SQLite: a lightweight, easy to install database, the data is stored in memory within the server (note that CyberWeb has also used MySQL, which is desirable for larger databases); (3) The Model is coded into a python module, and loaded into the Pylons server at startup; and (4) Data is initialized using a flat text file written in JavaSript Object Notation (JSON) format, and easily edited to seed the database.

Because the model is defined in an ASCII file, the developer can easily add new or modify existing tables to the initialization database or make modification at run-time. Note that for the examples shown in Table 1, all examples can be modified or new ones added via the Database Admin Interface (CW-DAI), described below. However, caution should be used to ensure that core services are not adversely affected. A good practice is too define all core components and services in the initialization database.

If the codebase is loaded into a developer environment, the file can be viewed easily with JSON markup tags; if using an SVN, then an SVN viewer (eg. TRACS) allows for easy viewing of the model. This is a key advantage for developers who are not database experts. As part of the codebase, there is a demo portal which contains examples of how to query the model (database) for common tasks.

2.2.2 Database Admin Interface

The database can be managed via the SQLite (or MySQL) command line interface. CyberWeb also has a comprehensive Web based Database Admin Interface (DAI) that is used to dynamically add, delete, modify, configure and test resources, the services that will run on them, and a users/groups access control list (ACL). The DAI module is designed using the very Rich User Interface design. User Interface guides user to do operations like add, edit or delete on any entit, along with JQuery, Ajax, and javascript. Figure 2 captures a usecase of the workflow used to configure and activate accounts for CyberWeb users (CWusers) on a remote compute resource.

CyberWeb securely manages accounts (using HTTPS, and sensitive data is encrypted and stored outside Web space, and no passwords are stored), maps CWuser accounts to accounts on remote resources, and tracks preferred authentication schemes (e.g. PKI/SSH, GSI/SSH). All users have PKI serverside credentials; GSI credentials can be uploaded or obtained from a MyProxy server. For PKI authentication, CyberWeb configures a password-less SSH service for the Cyberweb user. To activate the resource for the CWuser, a secure test is performed using an SSH command. The CWuser must have an account on the remote resource.

2.3 Job Distribution Service (JODIS)

The job distribution Web service framework (JODIS) was allows CyberWeb applications to distribute jobs across several campus compute clusters each running a different resource manager and each controlled by a different system administrator. Its main duty is to distribute application workloads across heterogeneous computing systems by abstracting middleware and resource management systems. The JODIS Web Service application framework based on the master/worker design pattern using common commodity software allows us to bridge these systems unbeknownst to the developer and user. It has been tightly coupled with the SDSU Cyberinfrastructure Web Application Toolkit (cyberWeb) framework making it a full-scale web application [10].

2.3.1 JODIS APIs

Job Management: The job management API is the one component of JODIS that does not ease development by abstracting a layer in the application stack, instead, this API tracks and manages jobs run with this system. It aggregates every aspect of the job from what kind of job, how many tasks, when it was run and the run time. We believe all of these aspects are useful for the administrator of the portal and will ultimately be used to measure how well an application is running.

Job Queue: This API allows the developer to interface to any queuing system. The current system includes Condor, PBS and Sun Grid Engine (SGE). There are many more in use at SDSU and elsewhere. Each application has varying syntax and command-line parameters. The JODIS job queuing API abstracts these allowing the developer to make one call to a system's queuing application regardless of what that may be. This allows a developer to quickly move to a new system or handle system configuration changes.

File Transfer: The second API that JODIS provides is file transfer. The API mimics that of a secure copy command. This API allows a developer to move and copy files from one machine to the next regardless of the protocol you are using to connect. A big use case for this functionality is easy on-the-fly deployment of an application and transferring data as needed by your application. A second common use for this is allowing a user to access his/her data results and move it back to another machine possibly for visualization, archiving or sharing with colleagues. This file transfer view method discussed earlier in the paper extensively utilizes the JODIS file transfer API.

Raw System Calls: Jodis allows the developer to run raw commands on the remote resources as if he/she were at the command prompt. This gives the developer the ultimate flexibility when developing applications using CyberWeb and JODIS. A user can call the raw method and pass in the command to run. Unfortunately, this is done synchronously. The user must wait for the command to return before an HTTP response is sent back to the user.

2.3.2 JODIS Services

JODIS consists of multiple services offered through a Web 2.0 server environment. Providing each component as a service allows JODIS to scale horizontally. In the web application environment, these services work together to provide end-to-end job dispatching service simultaneously to multiple clients. The architecture for the JODIS system can be found in Fig. 1. The Web server environment (based on CyberWeb, see below) provides users with methods of communicating with JODIS using either a Python client API or Web Service to access the Job Service.

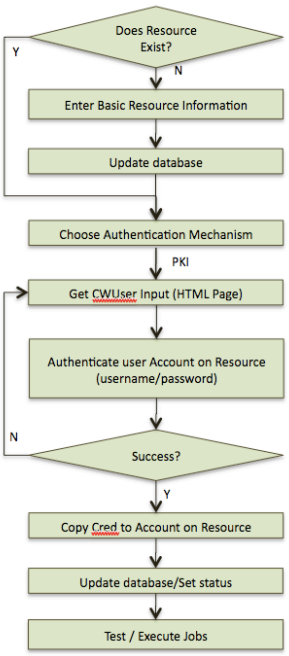

Figure 2. Admin flowchart for configuring user accounts on a resource.

The Web Service allows a wide variety of applications to interact with JODIS regardless of location, device or programming language. The Job Service provides a provides a majority of theuser-accessible function calls and manages a user's jobs regardless of the resource. The Resource Service works on the back end as a singleton to manage the various connections between the JODIS and the compute resources being used. The ability for JODIS to gather usage information and use this data for predicting job runtimes and for selecting where to run a job provides a useful approach to running MTC jobs.

Job Services: Clients primarily interact with the JODIS Job Service API. It is responsible for integrating all the services that make up Jodis. This service is used for job submission and monitoring. This service wraps the the resource management systems and abstracts the complexities involved with job submission such as job syntax, tracking and management of all jobs across the different resources. CyberWeb interfaces to batch queue systems (LSF, PBS, SGE) and schedulers (Condor, SGE). JODIS uses a job runtime "Guesstimation" to forecast job runtimes and a distribution policy to dynamically choose which compute resource to use for each job.

Resource Service: The resource service provides one essential functions to JODIS and that is controlling middleware. The resource service offers communication to the compute resources and client targets via Secure Shell (SSH) or GSI-Enabled SSH. This service leverages the CyberWeb database for fast and flexible storage of resource metadata, user account information and access control data. This service can also be used to stage files on the various compute resources and target machines.

Client Services: JODIS hosts a general client Web Service for authorized job submission. Clients interact with JODIS directly using the Python API, or more popularly,

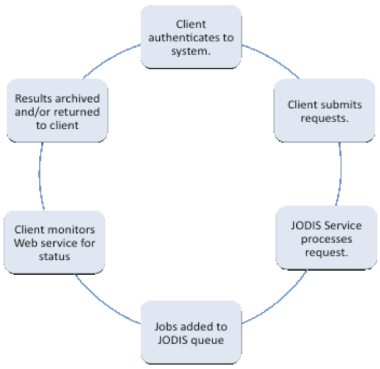

Figure 3. Diagram of a typical JODIS job cycle for job submission from a CHEQS client.

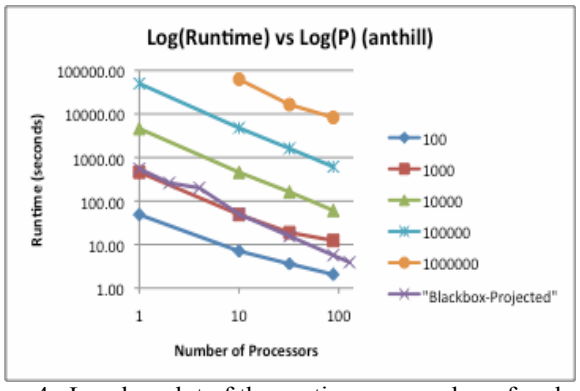

Figure 4. Log-log plot of the runtime vs. number of nodes as a function of the number of tasks on anthill.sdsu.edu [15].

through the RESTful Web Service interface. JODIS also hosts a WSDL that allows users to find the service as well as keep up-to-date on the latest API.. Developers can extend zzthe client service for specific applications with the use of the Job Builder Client interface. The client service can hook into the JODIS job service to provide functions such as pre-processing, post-processing and more. The client service is responsible for clustering the tasks, for each resource, which are then passed as a collection of jobs to the JODIS job service and distributed. An example of the Jodis job cycle can be found in Figure 3. An example of the client service is described below in Section 3.4.

2.4 Authentication

CyberWeb security works at two levels: requests and responses processed by the Pylons Web server; and transactions performed on behalf of a CWuser on a remote resource or service using PKI or GSI authentication. To authenticat users, CyerWeb uses the Pylons AuthKit module [7] which is a complete authentication and authorization framework for WSGI applications, and was written specifically to provide Pylons with a flexible framework for managing these tasks. This module queries the user table in the CyberWeb database. Once the user is authenticated, the user's ID and group information is stored with the user session data. Based on the ACL for an application, CyberWeb automatically requires the user to re-authenticate their session after a 5-minute period of idle time.

Decorators have been built using AuthKit to allow developers to permission applications based on the user or the group of a user. These decorators wrap access to the decorated method and redirect the user to the login page or a 404 – "permission denied" page depending on whether the user is not authenticated or lacks permission. The advantage to using these decorators is that the developer has fine-grain control over access and can control user interaction based on the application. For eample, a user might be able to create a workload to be run, but must have permission before the user can submit this workload.

For remote transactions, two methods are currently supported: Public Key Infrastructure (PKI) and Grid Security Infrastructure (GSI) developed by the Globus project [11]. PKI is used for *ssh* (secure shell) transactions. Users must set up passwordless access in order to use a resource (see Section 2.2.2). A credential associated with the server is created for all CWuser accounts. If the user has an account on a resource, then CyberWeb will put a copy of the credential into the appropriate file on the remote machine. For grid based transactions, CyberWeb uses the MyProxy API [11] to obtain a user proxy certificate, which is stored out of Web space, and *gsissh* to connect to remote resources for job execution.

2.5 Installation and Deployment

CyberWeb applications can be run from most modern-day operating systems: it has been tested on linux, Windows and Mac OS X. CyberWeb is written using the Pylons web framework. It requires minimally two Python libraries a) Pylons, the web framework core of CyberWeb, b) Paramiko, a Python wrapper for the SSH library. After installing the pre-requisites, download the CyberWeb source code: it can be run from any directory on your machine. An installation challenge is where the CyberWeb server is located. Network access to resources behind firewalls is a common issues. For example, in order to access the clusters at San Diego State University, servers must be on the campus network.

A key aspect of the OGCE project is its use of Maven [12] to install the entire framework and all software dependencies automatically for the client. In Python, this is done using the Easy Install package. Easy Install automatically downloads, builds, installs, and manages Python packages. It installs the tar or jar equivalent called the Python Egg. The Easy Install software comes with commands (configured by Pylons) that allow you to bundle your application into an egg for distribution. Earlier experiments with extending the Paste installation egg to include all software and versions needed for a complete CyberWeb package were successful and this will be done for future releases. The system administrator will be able to fire up CyberWeb out of the box. Settings for the CyberWeb installation can be found in the development.ini or production.ini depending on the environment. In many aspects, these two files will mirror each other. The main difference between the two should mainly be the debug variable. The production.ini file should have debug set to

false. This prevents the stack trace from being displayed when an uncaught error is encountered.

Straight out of the box, the development.ini file directs CyberWeb to create a folder in the top level directory of CyberWeb to store user data files. The top level directory is referred to by the variable *"%(here)s*". This CyberWeb data directory stores users' public/private keys at the top level and user directories and data in a directory below. The top level CyberWeb data directory is not accessible via CyberWeb or Paster, which is the same level of security that the linux operating system uses to store these keys.

New Pylons projects are built using Paste - a Web development and application installation tool similar to Ant or Make. It creates python middleware modules (router, config, and mapper template files), a simple python Webserver that can process WSGI requests, and the directory structure needed for a full site (to be populated by the developer). A single command installs the application template (all the codebase needed including the directory structure, basic files, and data to support a new portal): *%paster create –-template=pylons* pyGateSite. The portal server is started using the following command: *$paster serve –reload development.ini*, which lauches the welcome page. Alternatively, you can install all software into a "virtual environment" which is essentially an isolated working directory with all libraries contained within it. This allows developers to work independently of the host operating system, to keep stable versioning control, and locally manage development tasks. This facilitates distribution and deployment of a project. This will be useful for providing a reusable toolkit or deploying a Pylons application to a cloud computing resource.

3. Application Examples

CyberWeb has been used to develop Web services, Social gadgets, and portals in the biology, geospatial mapping, and ocean application areas. The examples below demonstrate client-server use of Web services, portals, and visualization Web pages.

3.1 CyberWeb Demo Portal

As part of our development of CyberWeb, a user portal has been developed that demonstrates how to build CI enabled applications and for testing services. Figure 5 is a composite image of the UCOAM portal (see Section 3.2), and many of the components are contained in the demo portal The portal system is intended to be used as a startup application for new projects. The portals capabilities include: secure login with group access control to selected pages; user and account management with the MyCyberWeb customization section; MyProxy credential management; job tracking and history; and data management using the Jodis file transfer widget; interactive Web pages for a Job execution and file management that are also part of a planned unit test system for checking resources and services. The portal also hosts the Database Admin pages. Through the myCyberWeb interface, a user can update preferences, send/receive messages, track jobs, and configure authentication on remote resources.

3.2 Unified Curvilinear Ocean and Atmospheric Model (UCOAM)

The UCOAM model differs significantly from the traditional approach, where the use of Cartesian coordinates forces the model to simulate terrain as a series of steps. UCOAM utilizes a full three-dimensional curvilinear transformation, which has been shown to have greater accuracy than similar models and to achieve results more efficiently [13] [14]. CyberWeb is being used to develop a computational environment for the UCOAM project with the following features: community access portal for expert and non-expert users (see Figure 5); running and managing jobs, and interacting with long running jobs; managing input and output files; quick visualization of results; publishing of computational Web services to be used by other systems such as larger climate models [**Error! Bookmark not defined.**] [10].

3.3 Data Viewer Tool

The Data Visualization tool is a custom application that is being developed for the UCOAM application. provides portal users with the ability to run a suite of post processing tasks including analysis of parallel performance, and model simulations. The Data Viewer utilizes several CyberWeb components (database, JODIS), and emerging technologies including python, pylons, AJAX, javascript, jQuery, gnuplot and gnuploy.py library. The tool allows users to select a job through the data browser and then to run the Job Analyzer. The Job Analyzer presents a job summary and a variety of plot options. These plotting options support different plots for viewing timing/performance, or contours of the velocity, temperature, or and pressure changes (see Figure 5). The plotting options are stored dynamically, and are extensible. Once the user selects any particular plot, an Ajax call is sent to the server, which uses Jodis to send commands to the archival host to create the image on remote using gnuplot scripts. This image file is then returned to the client browser in the form of data-bytes for display.

3.4 CyberCHEQS

This example highlights the use of JODIS and CyberWeb, we developed a simple job distribution Web service (Jodis), which runs a many-task computing (MTC) [15] jobs for the CyberCHEQS thermochemistry applications [16]. The tasks were run in a heterogeneous environment (Figure 4), using TeraGrid and SDSU machines simultaneously, on hundreds of nodes, moving data and results between remote resources. Using CyberWeb, the resolution of Flame3D was increased from 10^3 to more than 10^6 control volumes and significant reduction in run times (by a factor of over 40 for a large test case of 128 processors and 10^7 tasks)

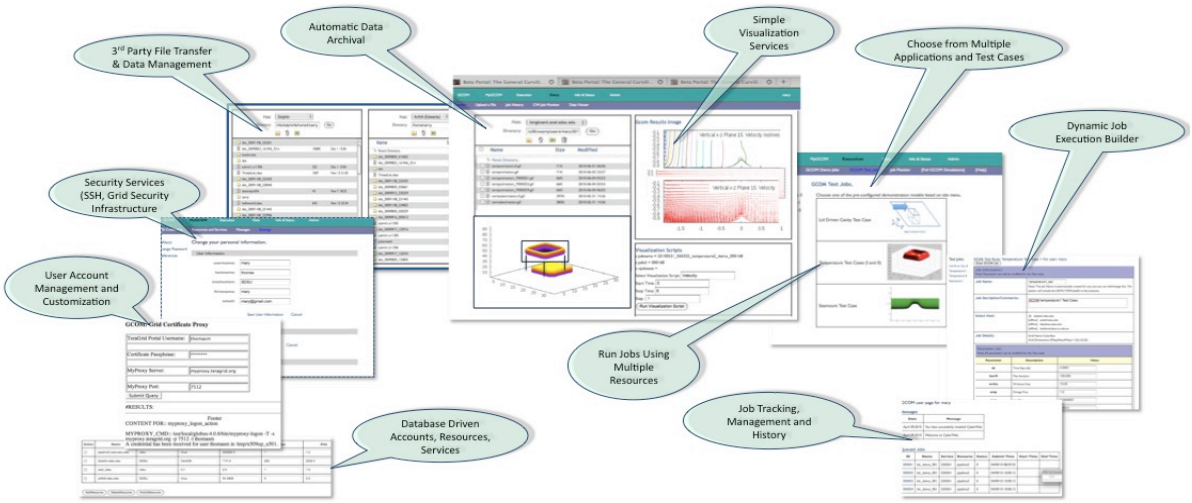

Figure 5. The UCOAM Simulation Portal. Composite image shows file management, user/account management, simulation job submission and history, and visualization [**Error! Bookmark not defined.**].

4. Conclusions and Future Work

CyberWeb applications have been developed that demonstrate its usefulness for client-server access to Web services, portals, and visualization Web pages. CyberWeb is able to operate in a "plug-n-play" mode: applications dynamically discover modifications to the database, check the service status, and when available, use that service or resource. It has a "non-invasive" philosophy: no software is required to be installed on remote resources; rather interfaces using existing software and services are created. CyberWeb has been used to develop applications in ocean modeling, thermochemistry, and education; it has been used to access large-scale (EXSEDE/TeraGrid) and local compute and archival systems.

Future plans include enhancing or developing: visualization tools; interactive job management; full third party file transfer; integration of cloud computing resources; interface to modifying the initialization JSON data for the database; addition of new authentication systems such as OAuth or Kerberos (both are used among in the scientific Cyberinfrastructure community); additional queuing systems. Plans are underway for the software to be bundled into a Python egg, and the software will be added to the NSF funded Open Grid Computing Environments (OGCE) project [5], which develops gateways and tools.

5. Acknowledgements

This work was supported in part by the National Science Foundation (Grants #0753283, #0721656), the Department of Energy (DOE # DE-GC02-02ER25516), and with resources available with an NSF funded XSEDE (TeraGrid) allocation (TG-CCR110014) and the San Diego State University Computational Sciences Research Center.

An Improved Cache Mechanism for a Cache-based Network Processor

Hayato Yamaki[1], **Hiroaki Nishi**[1]
[1]Graduate school of Science and Technology, Keio University, Yokohama, Japan

Abstract – *Internet traffic has increased due to the development of richer web content and services. In particular, IP telephony, Messengers, and Twitter are composed of a large number of small packets, and these services are expected to increase. Thus, routers need to handle large-bandwidth fine-grain communication. We proposed a network processor called P-Gear, which has a special cache mechanism that reduces the processing load by taking advantage of the localizations of network traffic. In this paper, we describe cache architecture for P-Gear and we propose an enhanced cache mechanism, Multi-Context-Aware Cache. Multi-Context-Aware Cache can improve the cache-hit ratio because it can control cache entry by analyzing the packet's header. We implemented P-Gear as software and we simulated this mechanism using real network traces. The simulation showed that Multi-Context-Aware Cache is effective in reducing the processing cost of processing arrays on a network processor.*

Keywords: Cache-based Network Processor, Layer-7 Analysis, Network Processor, Network Traffic Engineering

1 Introduction

Internet traffic has increased due to the popularization of personal computers, smartphones, and growth of richer web contents and services. Furthermore, services that are composed of a large number of small packets such as video traffic, IP telephony, and Messengers are expected grow in popularity. If these enormous fine-grain packets are concentrated in a router, its processing capacity might exceed its limit. Future backbone network router need to handle large-bandwidth fine-grain communication.

Conventional network processors utilize the characteristic independency of packets, where each packet can be processed independently by a Processing Unit (PU) or in parallel by increasing the number of Processing Units (PUs) or by implementing a multithreading mechanism to achieve high throughput packet processing [1][2]. However, the leakage of current or electrical power consumption makes it difficult to improve the number of PUs accumulated due to the scaling rule of semiconductors. Therefore, it is necessary for network processors to reduce PU processing costs.

In earlier research, a mechanism was proposed that the reduced costs of packet processing when retrieving routing tables [3][4][5]. This mechanism resolved the processing when retrieving routing table by using cache architecture. Thus, we proposed an architecture for a network processor, called P-Gear, which was an extension of this mechanism [6][7]. Eliminating the cache-miss ratio is significant for P-Gear and all cache-based network processors. P-Gear takes advantage of the temporal locality of network traffic to reduce processing costs like general network processors. It caches to process the packet, which improves the potential of cache-based network processor. However, the cache-hit ratio depends on the number of processing units required and the cache memory size. Reducing the cache-miss ratio is an important issue for P-Gear type network processors. In this paper, we propose and evaluate a mechanism that allows us to control cache entry by focusing on trends in network traffic to produce a lower cache-miss ratio using the same cache entry size.

2 Related Work

Various cache-based network processors have been proposed in earlier research. These processors exploit the temporal locality of network traffic, where many sequential packets arrive during a short period of time. In previous studies [3][4], a cache architecture for the high-speed processing of routing table lookup on layer 3 was proposed. This architecture utilized a quarter of the L1 cache to store the destination IP address and the results of routing table lookups. Part of the destination IP address was used as the virtual address of a cache. The ID of an output port was obtained when the cache was hits. Moreover, they considered that the cache entry size, block size, and associativity size were important and they proposed a method for compressing the entry size of the routing table [8]. In paper [5], another cache mechanism was proposed for routing table lookup, which was evaluated using real network traces. This study showed that it was effective to use the upper half of an IP address as a cache tag and the lower half of an IP address as an index in the cache.In another study [9], the cache architecture was partitioned according to a prefix length for routing table lookup. They demonstrated that IP traffic had temporal and spatial locality.

Thus, cache-based network processors are used for resolving the lookup of routing table entry. However, because of the emergence of rich services, recent network processors are required to execute a lot of complex processing in addition to routing table lookup, e.g., packet encapsulation, and these processes may be a bottleneck in packet processing. Thus, we proposed a cache-based network processor called P-Gear, which facilitates high-speed processing for various processes by caching the IP address, port, and protocol.

3 P-Gear

In this section, we provide an outline of P-Gear. P-Gear utilizes two features of packets. The first is that packets are processed by the same process in the same session. The second is that packets often arrive continuously in a short period. P-Gear caches before processing the packet and applies the cached process to later packets during the same session. The later packets in the same session can be processed without using PU. P-Gear defines a five-tuple (Source IP, Destination IP, Source Port, Destination Port, and Protocol) as one session. The architecture of P-Gear is shown in Figure 1.

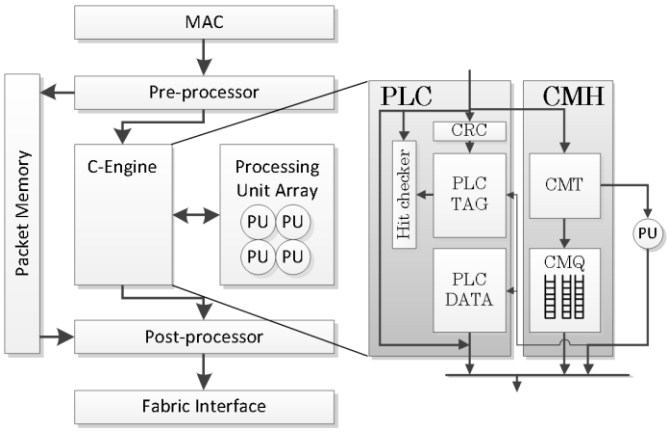

Fig. 1 Architecture of P-Gear

When PLC hits, P-Gear can process the packet without using PU by applying a cached process to packet processing. If there is a cache-miss, the packet is sent to the Cache Miss Handler (CMH), and P-Gear processes the packet normally using PU. After processing the packet, the session information of the packet and the results of the packet processing are stored in PLC. As a PLC address, the hashing value of the session information is used to analyze the spatial locality of packets. However, if a later packet arrives in PLC while an earlier packet is still being processed by a PU in the same session, the later packet does not match the cache entry in PLC, so the packet will be processed by another PU. To reduce this inefficient allocation of PU, we implemented a Cache Miss Table (CMT) and Cache Miss Queue (CMQ) in CMH. CMT stores a packet that has been processed by PU. When a later packet arrives in CMH, CMH checks whether CMT has the table entry for this packet. If the packet matches a table entry, the packet is sent to a queue called CMQ. After the earlier packet in the same session is processed by PU, the later packet in CMQ is processed based on the processing results for the earlier packet without being allocated to PU. Thus, the total cache-hit ratio is the summation of the hit ratio in PLC and CMH, while the cache-miss ratio for P-Gear is the ratio of packets allocated to PU.

In previous research, we concluded that four methods for associativity and a ca. 4K entries cache were an appropriate structure of PLC. It was also appropriate to use ca. 1K entries CMT and ca. 16K entries CMQ, respectively, according to the scaling limitation. We now propose a method for increasing the cache-hit ratio by adding a small hardware or implementing a tiny routine into the processing units of P-Gear.

4 Multi-Context-Aware Cache

P-Gear can utilize the temporal locality of packets effectively and it aims to achieve high throughput using a small number of PUs. In this section, we propose and describe Multi-Context-Aware Cache, which extends the cache mechanism of P-Gear to exploit the PLC cache more efficiently.

P-Gear captures the results of a process during one session into a PLC cache entry. When a cache hit occurs, P-Gear can process the packets of a stream using special wired logic. However, all the packets are cached to PLC with same priority. Because there are other trends of network traffic in addition to the temporal locality, we consider that it is effective for PLC to cache packets with different priorities instead of a uniform priority. For example, if a large number of packets with various headers are concentrated into P-Gear in a short period of time, degradation occurs in the cache-hit ratio because PLC stores useless entries. To prevent these useless entries, PLC is required to determine whether an incoming entry is reused based on implicit information in the IP layer and application layer. This context-based cache management is required to improve the efficiency of processing. Here, we propose a Multi-Context-Aware Cache, which facilitates controlled insertion and deletion of the cache entry by using several contexts simultaneously to achieve a higher cache-hit ratio without increasing the size of cache entries.

It is possible to use the specification of the services of an application layer as a context to determine whether the first packet from a service follows succeeding packets. For example, File Transfer Protocol (FTP) has a specification. It uses a control port and a data transfer port for communication. When a packet arrives at PLC and the source or destination port indicates that the packet is an FTP control packet, PLC can predict that it should not cache the control packet but that it should make a another cache entry for following data packets. This is called an FTP-Aware Cache. As another

example, the Session Initiation Protocol (SIP) of the Voice-of-IP Protocol also has the same behavior and this is known as an SIP-Aware Cache. These cache architectures were proposed and evaluated in our previous studies, and these architectures improved the cache-hit ratio by several percent when used in an IP backbone router [7]. In this paper, we propose a DNS-Aware cache: Rare-DstPort-Aware Cache and P2P-Aware Cache as a new cache architecture based on this strategy.

It is also possible to use request-and-reply transactions as a context, which is generally used in network services. The headers of reply packets can be predicted by interchanging the source and destination information of a request packet, which will be effective for making a cache entry that is generated according to this rule beforehand. We propose a Look-Ahead Cache based on this strategy.

Furthermore, it is also possible to use the characteristics as a context in a network attack. For example, when the packets of a port scan attack are concentrated in P-Gear, P-Gear generates cache entries for a large number of packets that have different destination IP addresses or ports in a short period. These entries will not be reused and they disturb the registration of PLC entries that will be used. Because the packets in a network attack are sent from a source to various destinations and they will not be sent to the same address again, it is effective for the cache not to make entries for packets that are generated by a source node and that are distributed to many different destinations. Similarly, attacks from a worm and DoS attacks often use specific source or destination ports, so it would be effective not to store packets with specific port numbers. We propose an Attack-Aware Cache based on these strategies.

In this paper, we propose and evaluate DNS-Aware Cache, Rare-DstPort-Aware Cache, P2P-Aware Cache, Look-Ahead Cache, and Attack-Aware Cache as subsets of Multi-Context-Aware Cache.

4.1 DNS-Aware Cache

Sessions on a Domain Name System (DNS) have no temporal locality because DNS communication is composed of one request packet and one reply packet, while the session is composed of only one packet. DNS transactions are cached by domain name server and they are rarely reused. Thus, we propose a DNS-Aware Cache, which is a mechanism that does not store the packets from DNS port #53.

We analyzed network traffic to find the ratio of DNS sessions traffic. The analysis showed that over 50% of all sessions were composed of only one packet. These types of sessions are known as one packet sessions. Table 1 and Table 2 show the frequent port numbers and the percentages of >1 packet sessions and one packet sessions. Packets from port #53 mainly appeared in one packet sessions when comparing

TABLE I
Rate of frequent ports in >1 packet sessions

Port number	Source		Destination	
	Quantity	Rate[%]	Quantity	Rate[%]
53	89,998	4.9	149,415	8.1
80	267,924	15	292,905	16
445	169,822	9.2	3,969	0.22
1433	430	0.023	211	0.011
6000	0	0	369	0.020
6881	17,398	0.94	16,725	0.91

TABLE II
Rate of frequent ports in one packet sessions

Port number	Source		Destination	
	Quantity	Rate[%]	Quantity	Rate[%]
53	1,649,237	36	1,700,323	37
80	8,642	0.19	54,057	1.2
445	10,022	0.22	170	0.0037
1433	198,260	4.3	2,200	0.048
6000	5,348	0.12	424,482	9.2
6881	39,249	0.85	37,581	0.81

Table 1 and Table 2. Furthermore, Table 2 shows that 73%of one packet sessions were DNS packets. Therefore, DNS-Aware Cache allows us to reject most of the one packet sessions and to utilize the cache entry more effectively.

4.2 Rare-DstPort-Aware Cache

Sessions with rarely used destination ports have no temporal locality, so there is no need to store them. We propose a Rare-DstPort-Aware Cache, which finds rarely used destination ports in a time window and does not store them in the next time window. The mechanism is shown below.

1. We set a window size and threshold, while a counter counts how many packets with the same destination port arrive in the window per destination port.

2. When the counter reaches the window size, Rare-DstPort-Aware Cache determines the destination ports that are not over threshold as rare destination ports.

3. In the next window, Rare-DstPort-Aware Cache does not store the packets with rare destination ports.

4.3 P2P-Aware Cache

A P2P protocol such as BitTorrent connects with extremely many nodes and the communication of the P2P protocol often finishes with only one packet. These situations will cause a disturbance in the cache. For this reason, we propose a cache mechanism that does not store packets with the specific ports used in the P2P protocol. This is known as a P2P-Aware Cache. It is known that BitTorrent uses 6881 to 6999 as a destination port and it mainly uses 6881. However, some P2P sessions are composed of >1 packets. Because of

this, the P2P-Aware Cache determines whether a BitTorrent session is finished by a packet by utilizing the packet length values of the packet headers, so it does not create a new cache entry if the packet lengths of the packets are less than certain values.

4.4 Look-Ahead Cache

When a packet arrives in a router, reply packets will often arrive soon after, while the difference between the arriving and replying packet header shows the source and destination IP and port that are exchanged. We propose a Look-Ahead Cache, which is a mechanism that creates a cache entry for reply packets based on the incoming packets by exchanging the source and destination information in advance. Figure 2 shows the architecture of the Look-Ahead Cache. In this figure, a packet arrives at the router, which comes from line card A and goes to line card B. At the ingress of Line card A, a cache entry of its egress is created at the same time during the ingress processing. This information is forwarded to the Line card B. Line card B creates a cache entry based on the header information of the outgoing packet or the forwarded information from Line Card A. The cache entry of egress of Line card B is also created at the same time. The ingress and egress network processor in line card A and B can process the concerning packet without allocating a PU.

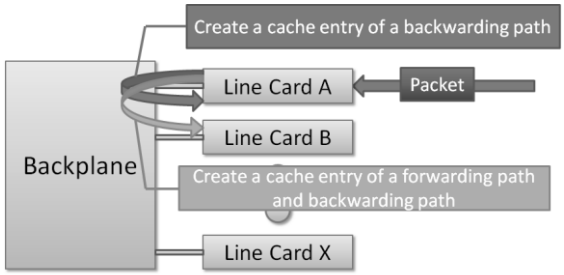

Fig. 2 Architecture of Look-Ahead Cache

4.5 Attack-Aware Cache

As described earlier, a port scan attack disturbs effective cache entries because P-Gear tries to store port scan packets with different destination ports. Therefore, it causes degradation of the cache-hit ratio. To reduce this degradation, we propose an Attack-Aware Cache that identifies network attack packets in network traffic and does not create a cache entry for these packets. In this paper, we propose two dynamic methods and one static method for determining network attacks.

Dynamic methods focus on the fact some types of attacks often send a large number of packets from a specific source node to a large number of destination nodes. To determine whether attackes are waged or not, it is effective to analyze the trend of traffic in increments of a certain amount of network transactions. If the number of connections exceeds a threshold in a window, a new entry is not created in the following window. We set the window size to 512 packets and the method applies results for each window to the next window to prevent entry creation. Dynamic method 1 processes network streams by two processing phases. In phase 1, a dominant source IP at the point of the number of receving packets is marked. Figure 3 shows the mechanism of this method. When a packet arrives, PLC calculates the hashed value of its source IP address using CRC. A 7-bit value is used as the hashed value. Next, A 5-bit counters count the number of packets arriving with the same hash value. If the counter causes an overflow, the IP addresses group that has the same hashed value is a candidate of dominant source in this window. In phase 2, the group is determined whether it conteins an attack source or not. Figure 4 shows the mechanism of this method. The method uses a memory that has three bits addresses. When a packet that has the dominant source arrives, 3-bit counters are incremented accrding to the destination address. As this counters, the 3-bit hash value of its destination IP address is used as an address in the memory. If the number of the counters which is not zero exceeds a threshold exist, this source IP group of the same hashed value is regarded as an attack source. PLC does not cache the packet from this IP group in the following window. Next, we describe dynamic method 2. Figure 5 shows the mechanism for this method. This method generates a hashed value for the source and destination IP address based on the arriving packet respectively using CRC. It calculates a 7-bit value as the

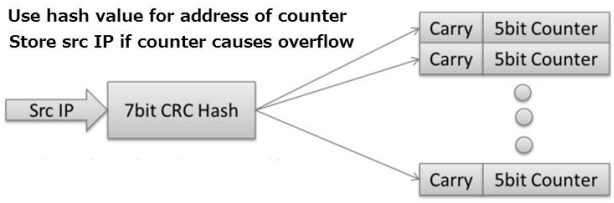

Fig. 3 Mechanism of dynamic method 1 in phase 1

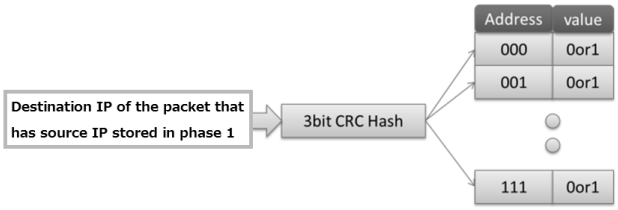

Fig. 4 Mechanism of dynamic method 1 in phase 2

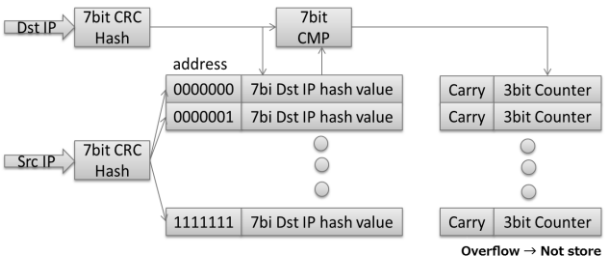

Fig. 5 Mechanism of dynamic method 2

hashed value and it stores the hash value of the destination IP address in memory. At this point, it uses the hash value of the source IP address as an address in its memory. When the same address is accessed again, it compares the hash values with the destination IP address. If the values are different, it increments a 3-bit counter. If the number of the counter exceeds a threshold, a new cache entry is not created until the counter is reset.

Static methods focus on the fact that some types of attacks use specific ports. For example, DoS attacks exploit the vulnerability of particular applications such as database services, so the attack packets used the specific ports for database services. Furthermore, the headers of these attack packets are often very variable. We analyzed the network traffic to find the ports used by attacks, and Table 1 and 2 show the results. We found that packets with destination port #1433 and source port #6000 were sent in bulk during one packet sessions. Packets with the destination port #1433 were sent to SQL as worm attacks, while packets with source port #6000 were sent as port scan attacks. By analyzing the network traffic, we found that packets with source port #1434 and source port #3306 could also be regarded as network attack packets. The static method identifies packets using these ports as attack packets and it does not create cache entries for them.

5 Evaluation

In this section, we show the simulation results, where we evaluate the five proposed cache mechanisms. We used P-Gear simulator and WIDE trace (150Mbps) as real network traffic for this evaluation. P-Gear simulator was written in C++ while PLC was implemented as a set associative cache using four methods. The size of cache entries was 1,024 because we considered a 394-bit PLC tag and 365-bit PLC data, so the capacity of the cache memory was estimated as 89 Kbytes. This size of the cache can be implemented as a high-speed on-chip L1 or L2 cache. The number of PUs was 32 and a delay when processing a packet was 2 μs in the simulations.

5.1 Results with the DNS-Aware Cache

We simulated the DNS-Aware Cache and compared it with a normal cache mechanism that caches all ports. Figure 6 shows the cache-miss ratio with the normal mechanism and the proposed mechanism over 12 hours (from 0:00AM to 12:00AM). The cache-miss ratio with DNS-Aware Cache was reduced by roughly 1-2 points, which led to a ca. 6% improvement in the packet processing costs of the PU. The DNS-Aware Cache eliminated most of the one packet sessions by preventing the creation of new entries for DNS packets, which was effective for reducing the cost of packet processing.

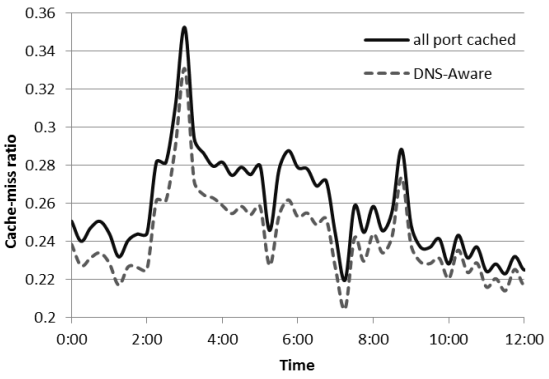

Fig. 6 Simulation results for the Cache-miss ratio with the DNS-Aware Cache

5.2 Results with the Rare-DstPort-Aware

Figure 7 shows the simulation results for the cache-miss ratio with each window size. We changed the window size (x-axis) and the threshold n for the Rare-DstPort-Aware Cache, as shown in the different graphs. With all thresholds, the cache-miss ratio was improved by increasing the window size. However, the cache-miss ratio with this mechanism was never less than the ratio when all destination ports were cached. This was because the destination port identified in the previous window appeared in the next window in some cases. When the window size was 5,000,000 packets, the number of unique destination ports was 8,426. However, one of these destination ports appeared in next window, which led to an increase in the cache-miss ratio. Furthermore, caching destination ports that never appeared in the window was sometimes ineffective because they may also appear in next window. We needed to consider a method that could identify rare destination ports more accurately.

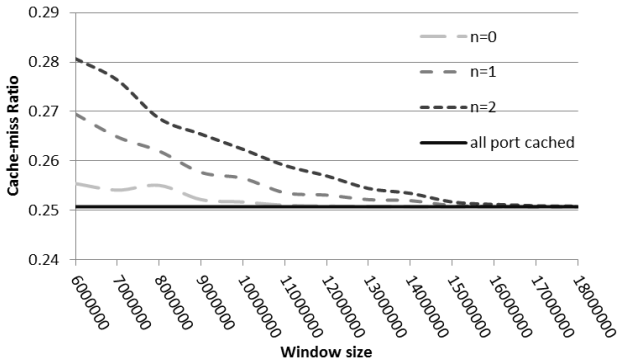

Fig. 7 Simulation results for the Cache-miss ratio with the Rare-DstPort-Aware Cache for each window size

5.3 Results with the P2P-Aware Cache

We simulated the P2P-Aware Cache using the same traffic and we compared the four mechanisms shown below.

A) Caching all ports (all ports cached)

B) Not caching port 6881 only, as mainly used by BitTorrent (P2P_6881)

C) Not caching port 6881 to port 6999, as used by BitTorrent (P2P_6881-6999)

D) Not caching port 6881 and less than 256-byte length packets (P2P_P-Length)

By analyzing packet length values of the packet headers, mechanism D determined whether the P2P sessions consisted of one packet or more. The threshold of the packet length was 256 bytes. If the packet length value was over the threshold, we identified the packet as a session with one packet.

We compared the cache-miss ratio with the P2P-Aware Cache and the cache-miss ratio using the all ports cached mechanism, and Figure 8 shows the results. All the P2P-Aware mechanisms improved the cache-miss ratio in many cases. However, P2P_6881 and P2P_6881-6999 sometimes increased the cache-miss ratio. This was because these mechanisms did not create entries for sessions composed of >1 packets, although packets for these sessions appeared in some cases. However, with P2P_P-Lngth, this increase in the cache-miss ratio was less than one-third, while the cache-miss ratio was improved by about 0.5%.

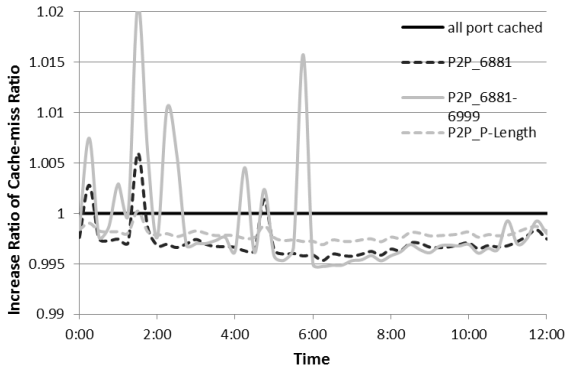

Fig. 8 Simulation results showing the increased cache-miss ratio with the P2P-Aware Cache

5.4 Results with the Look-Ahead Cache

We simulated the Look-Ahead Cache using the same traffic. This simulation assumed that request-and-reply transactions were processed on the same line card. Figure 9 shows the cache-miss ratio in the simulation. This shows that the mechanism reduced the cache-miss ratio by 2% compared with the normal mechanism while the cache-miss ratio using this mechanism was always lower than the normal mechanism. This demonstrates that the Look-Ahead Cache was effective and it improved the packet processing costs by about 9%.

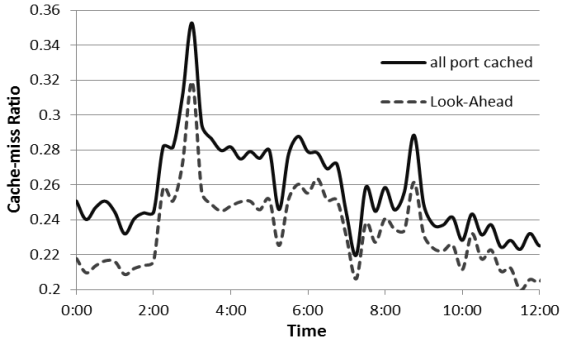

Fig. 9 Simulation results for the cache-miss ratio with the Look-Ahead Cache

5.5 Results with the Attack-Aware Cache

We simulated two dynamic mechanisms and one static mechanism with the Attack-Aware Cache. In the simulations of dynamic mechanisms, we changed the threshold from 4 to 32. Figure 10 and Figure 11 show the results of simulations for dynamic mechanisms each second. If the cache-miss ratio increased suddenly, both mechanisms reduced the cache-miss ratio by about 2 points. However, they increased the average of the cache-miss ratio because the source port determined by the dynamic mechanisms included sessions composed of >1 packets. As shown in figure 10 and Figure 11, dynamic mechanism 2 was more effective than dynamic mechanism 1.

In the simulations with the static mechanism, the mechanism did not cache packets that included destination port #1433, #1434, and #3306, and source port #6000. Figure 12 shows the shift in the cache-miss ratio during each second. As shown in Figure 12, when the cache-miss ratio increased suddenly, the static mechanism reduced the cache-miss ratio by 4%. The mechanism did not degrade the average cache-miss ratio in many cases. Therefore, this static mechanism was effective during network attacks and improved the packet processing costs by about 10% when the cache-miss ratio increased suddenly due to network attacks.

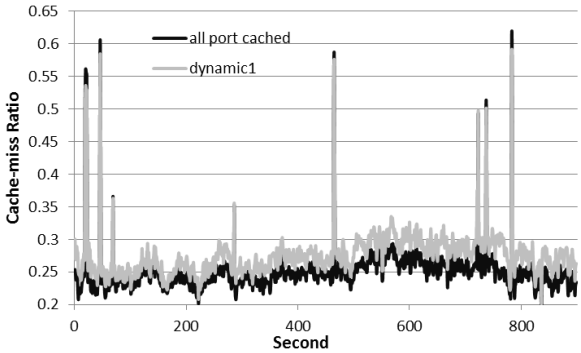

Fig. 10 Simulation results for the cache-miss ratio using the dynamic Attack-Aware mechanism 1

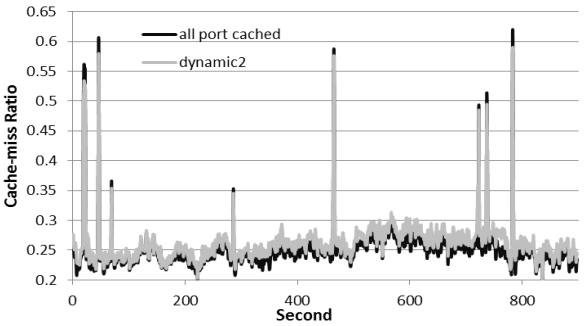

Fig. 11 Simulation results for the cache-miss ratio using the dynamic Attack-Aware mechanism 2

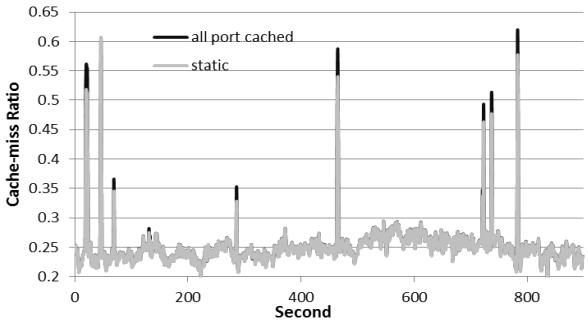

Fig. 12 Simulation results for the cache-miss ratio using the static Attack-Aware mechanism

6 Conclusions

We proposed P-Gear, which has a special cache architecture that efficiently utilizes the temporal locality of network traffic to achieve a higher throughput with a limited number of PUs. For P-Gear, the reduction of the cache-miss ratio is a significant requirement for reducing the processing costs of PUs. We proposed a cache mechanism known as Multi-Context-Aware Cache to improve the cache-miss ratio with P-Gear. Multi-Context-Aware Cache estimates trends in network traffic by continuously analyzing the packet headers and it optimally manages cache entry.

In this paper, we proposed and simulated five mechanisms that formed a subset of Multi-Context-Aware Cache. DNS-Aware Cache, Rare-DstPort-Aware Cache, and P2P-Aware Cache utilized port information to determine whether sessions had temporal locality. Look-Ahead Cache utilized the relationships of request-and-reply transactions. Attack-Aware Cache utilizes the trend in network attacks. In simulations, the DNS-Aware Cache eliminated about 70% of a session composed of one packets and it improved the cache-miss ratio by 6%. However, it was difficult to estimate rare destination ports using Rare-DstPort-Aware Cache. This method did not improve the cache-miss ratio, so there is still a need to estimate rarely used ports more accurately. P2P-Aware Cache eliminated the packets of BitTorrent, which often communicates using one packets and it improved the cache-hit ratio by 0.5%. However, we need to find a more precise method for determining whether sessions of packets are composed of only one packet. Furthermore, the Look-Ahead Cache estimated the reply packet headers and improved the cache-hit ratio by 9%. Finally, the Attack-Aware Cache identified network attack packets and improved the cache-hit ratio by almost 10% when the cache-miss ratio increased suddenly.

***Abstract*—How the topology of Internet is evolving? In this research we present a large scale longitudinal analysis of the changing topological pattern of Internet Autonomous Systems Network (ASN). Analysis of topological patterns for large scale network is not trivial. We introduce a novel technique called *generating function signatures* (GFS). It finds statistical signatures of various pattern graphs and observes the changes in snapshots of ASN collected over a period of five years. The study reveals several interesting trends about the evolutionary state of the ASN including its increasing trellis-like topological evolution.**

Keywords- topological analysis; generating function; internet.

I. INTRODUCTION

The Internet is a network of *autonomous systems* (AS). Each AS itself is a network –operated as one administrative domain owned by regional and national ISPs, large organizations, and customers. Autonomous systems are the basis of the distributed management of the Internet. Long haul Internet routing is performed on the basis of autonomous systems [1].

A number of researchers have studied various properties of on the ASN [2,3,4,5,6], such as size, degree distribution, clustering etc. However, very little previous studies exist on the evolution of its topological structure. This is because, the topological property study of the autonomous systems poses many challenges, making it difficult to examine and monitor them. First of all, the size of the ASN is very large. Fig- 1 shows the ASN in March 2004. The numbers of autonomous systems were over 7000 and the peer connections between them were 15000 about ten years ago. Since, then both numbers are increasing rapidly – at times reported to be exponentially [2,7] – on an annual basis. Secondly, there is no ideal pattern in such scale. The very concept of any concrete pattern degenerates in large scale systems making it hard, if not impossible, to apply any deterministic graph traversal technique. As evident in Fig-1 the network is complex- it has few recognizable topological features; the highly-connected nodes are in the center and the lower degree nodes branch out into points similar to a star topology. However, such visual recognition of structure has become impossible over time. The ASN also exhibits a steady level of dynamism. The network is in a constant state of evolution.

Despite the difficulties, nevertheless the analysis of the topological structure of the ASN can provide fundamental insight about the requirements and design on next generation internet. Oliveira et al [8] writes: "It [the Internet topology] provides an essential input to the understanding of limitations of existing routing protocols, the evaluations of new designs, as well as the projection of future needs; and it will help advance our understanding of the interplay between networking technology, the resulting topology, and the economic forces behind them". Lee and Kalb [9] from Sandia Lab details strategic advantages those can be derived from various network topologies ranging from familiar patterns like stars and rings to complex three- and four-dimensional structures like cubes and toroids in large scale communication networks. Kit is well known that knowledge about topological structure can help improving efficiency of systems [10, 11, 12].

In this paper we introduce a new technique based on *generating functions (GF)* that can overcome few of the difficulties. In this study we demonstrate a general process detailing the ways generating function signatures (GFS) can be used to trace the presence of various topological patterns in a large scale network by searching for the signature of specific topological patterns. These signatures are conceived to be a statistical characterization for each of these structures. With the aid of such GFS we are able to undertake one of the most comprehensive studies of the structural evolution for the ASN.

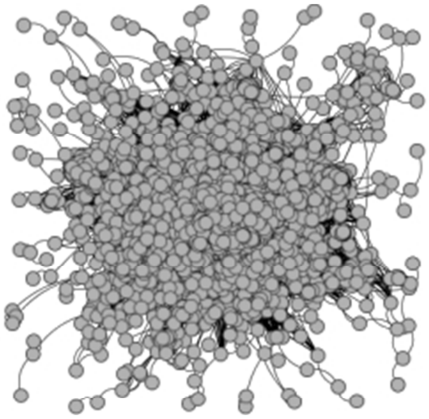

Fig-1 A map of the topology of the ASN in March 2004.

The data set used was obtained from Oliveira et al [13] for the analysis. This extensive trace of the ASN is built from data available from various AS observation sites such as BGP route tables and updates collected from numerous large networks, including RouteViews, RIPE-RIS, Abilene, CERNET route servers at Internet Exchange, BGP View, Packet Clearing

House, UCR, traceroute.org, Route Server Wiki, and Looking Glasses like NANOG and the Looking Glass Wiki. We present our findings on this paper.

The paper is organized in the following way. Section 2 covers recent research related to this work. Sections 3 and 4 then explain the process by which generating functions can be used for structural property analysis in a complex graph. We explain four specific topological patterns before discussing the method of searching for signatures of such patterns in a large complex network such as the ASN, including networks that mix multiple patterns. Finally, Section 5 presents the analysis and observations of the ASN as it evolved during the years 2004-2009.

II. Related Works

One of the earliest studies of ASN is attributed to Magoni and Pansiot [7] which analyzed six snapshots of ASN from November 1997 to May 2000 based solely on BGP data [7] and analyzed its size growth. Vazquez et al [2] used the autonomous system map from May 2001 and also took measures of the clustering coefficient and average betweenness of the nodes. Among other notable works are [3, 6] which found progressively more ASNs. Clegg et al [4] seems yto be the first to bring attention to topological analysis and proposed a 'Framework for Evolutionary Topology Analysis' (FETA) for the study of evolutionary topology. FETA provides a fast process comparing a model of a network to its real-world counterpart and taking measurements on its evolutionary qualities. This framework was used to study the ASN from January 2004 to August 2008. Their study revealed information such as degree 1 and degree 2 node count, maximum degree, and clustering based on the size of the network. Clegg et al reported declining degree 1 node counts and increasing degree 2 node counts as the number of connections rose. In addition, the clustering coefficient remained less than 0.06 regardless of network size. None of the studies however could proceed to analyze the topological pattern evolution of such a large ASN. This is because high computational cost of such analysis in complex networks with degenerated patterns.

In this endeavor we have also concluded an extensive longitudinal analysis of various complex network properties of the ASN (such as size, community structure, degree distribution etc) with unprecedented ev0olutionary view of the ASN. Interested researcher might want to read [14]. This paper particularly focuses on the evolution of topological pattern of ASN. As indicated before the proposed analysis is based on a novel use of generating functions (GF). Although GFs have not been used in such a way before, but GF techniques have been very useful in the analysis of idealized random graphs. Newman et al [15] introduced degree sequences in the form of generating functions and then derived various composite properties of graphs with specific distribution. Callaway et al [16] used generating functions in order to find analytical solutions to site percolation in random graphs and provide a process for testing the robustness of a network to the random failure of nodes and links by manipulating the generating functions of their random graphs. Generating function has also used to study directed ideal network graphs. Dorogovtsev and Mendes in [17] involved generating functions (called Z-transforms in their paper) for the degree distributions of networks in a directed graph that show preferential linking to solve Masters equations and demonstrated an efficient method for finding solutions to network evolution problems. Dorogovtsev and Mendes also developed a Master equation that represents the in-degree distribution of a network over multiple iterations as a Poisson generating function. It was based on the distribution of nodes, number of edges added to the network, and additional attractiveness of nodes to receive those new edges.

In this paper we use GFs as a signature of various topological pattern families and try to find topological resemblance in ASNs.

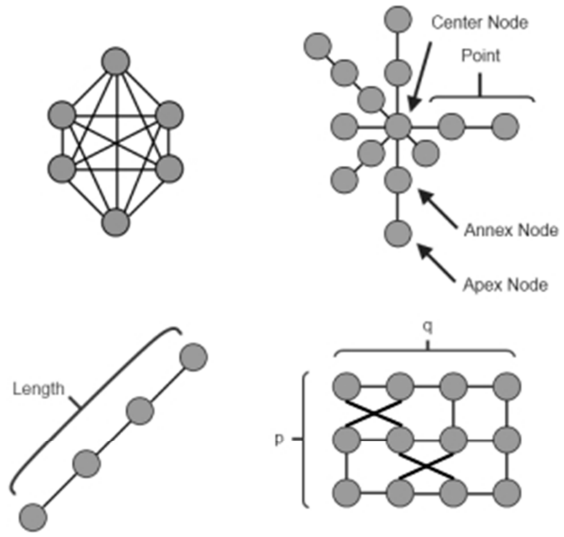

Fig-2 Examples of mesh, long star, chain and trellis (clockwise from top).

III. Special Pattern Graphs

The method of topological analysis proposed in this paper makes use of ordinary generating functions (OGF). A generating function is a polynomial function that represents some aspect of a network. They most commonly contain the degree distribution information for the nodes in a specific network. The ordinary form is used, similar to the form used by Newman et al in [15]:

$$G_0(x) = \sum_{k=0}^{\infty} \quad p_k x^k. \qquad (1)$$

Each k value represents the degree while the pk coefficients hold the probability that one node out of all nodes in the network has degree k. For example, the generating function G0(x) = 0.5x2 + 0.5x contains the information for a network that has an even distribution of degree 1 and degree 2 nodes.

Generating functions are used in this paper as a means of identification of various patterns in the network. The generating function of a network is compared to the generating function for special patterns to determine their likeness to each other.

A pattern graph is a regular topological structure. Fig-2 shows examples of four such patterns. Equation (2) is the GF of a *fully connected mesh* pattern when it has n nodes.

$$G_{mesh(n)}(x) = x^{n-1}. \quad (2)$$

A *star*, as it is commonly known, is a structure of *n* nodes similar to a tree with the central node being degree (*n*-1) and the other *n*-1 nodes being degree 1. For the purposes of this paper, we consider a generalized star with long legs referred to as *long star*. A long star has nodes of three types: the center, the apexes, and the annexes. The center node in the star has the highest degree *d* from which the points branch off. A long star pattern with n nodes and dimension *d* has generating function:

$$G_{s(n,d)}(x) = \frac{1}{n}x^d + \frac{n-d-1}{n}x^2 + \frac{d}{n}x. \quad (3)$$

A *chain* structure of *n* has generating function:

$$G_{c(n)}(x) = \frac{n-2}{n}x^2 + \frac{2}{n}x. \quad (4)$$

The *trellis mesh* (or simply just *trellis*) is a system of nodes arranged like a square matrix defined by a height and width *p* x *q*, requiring that $p \geq 2$ and $q \geq 2$. All nodes in this pattern have a degree of 2, 3, or 4 based on their position. One generating function for a trellis provides for many combinations of squares and crosses formed by the edges between each set of nodes. Fig-2 shows an illustration of a 3x4 trellis. A trellis structure with dimensions p x q has generating function

$$G_{g(p,q)}(x) = \frac{(p-2)(q-2)}{pq}x^4 + \frac{2(p+q-4)}{pq}x^3 + \frac{4}{pq}x^2. \quad (5)$$

IV. Comparison & Similarity Analysis

The analysis process begins by analyzing- (even visually if needed) the shape of the graph, utilizing it to discover its likeness to certain patterns. Network and pattern pairs should look similar to each other; they must share a similar signature, a common topological feature, with one another such as points of a star or a region of high clustering like a trellis. The terms in their generating functions also need to be comparable. Exponent in the pattern must also exist in the network.

Once the patterns have been decided upon for analysis, the *network generating function* (the function for the degree distribution of the network) and the *generating function signature* (the signatures such as (2)-(5) that characterize the generating functions for all patterns within an ensemble using parameters) need to be compared in order to find the right dimensions of the pattern graph.

Comparisons are always done using the *dominant coefficients*, the highest or most significant values from the generating function signature $G_0(x) = \sum f(n,m)$. Consider a generating function signature $G_0(x) = \frac{n-m-c}{n}x^k + \frac{m}{n}x^{k-1} + \frac{c}{n}x^{k-2}$ where *n* is the total node count, *m* is a distinct quality of the pattern that directly contributes to the node count, and *c* and *k* are constants. If the network is very large, the function becomes $\lim_{n\to\infty} G_0(x) \approx r_1x^k + r_2x^{k-1}$ where r_1 and r_2 are fractions of the remaining terms. While the degree (*k*-2) term disappears, the other coefficients remain large and are considered dominants.

With the dominant coefficients decided upon, the parameters for the generating function signature need to be calculated. The ratios of dominant coefficients are used in situations involving multiple dominant coefficients. The parameters from the dominant coefficients are then substituted into the generating function signature to obtain the specific *pattern generating function* (the function for the pattern graph closest to the network.) The error between the network generating function and pattern generating function is then minimized. The error value, E, can be calculated as:

$$E = \sum_{k\in f} | a_k - f_k\Delta |. \quad (6)$$

Here a_k is the coefficient for the degree *k* part of the network generating function, f_k is the coefficient for the degree *k* part of the pattern generating function, and Δ is the value that must be calculated to produce the smallest possible value for E. The L^1-norm is used here since a median of the limited terms is sufficient and for ease of calculation. The inversion of Δ produces a percentage that represents the resemblance between the network and its matching pattern.

A. Chain Similarity

The GF signature of chain (Eq-4) only contains x and x^2 terms and the x term has a dominant coefficient. The only dominant value here is the x^2 coefficient, and it must be set equal to the x^2 coefficient in the network generating function. Then the number of nodes *n* can be found by solving the equation:

$$\frac{n-2}{n} = a_2 \text{ or } n = \frac{2}{(1-a_2)}. \quad (7)$$

The value of a_2 is the x^2 coefficient in the network generating function. Replace *n* in the generating function signature with the value calculated from (7) to obtain the pattern generating function. Finally minimize the error between the two sets of coefficients for the x and x^2 terms and invert the Δ-value to find the chain similarity of the network.

B. Star Similarity

The GF signature of chain (Eq-3) has three terms; however, the x^d coefficient is $1/n$ so it is deemed non-dominant. The x^2 and x terms are dominant since it relies heavily on the node count. The coefficient of the x^2 term is the largest, and the coefficient for the x term is then the second largest. As stated earlier, the ratio of the most dominant and the second most dominant coefficients are taken when two dominant coefficients exist. The node count can then be decided by solving for *n* where a_2 and a_1 are coefficients of x^2 and x.

$$n = \frac{a_2 d}{a_1} + d + 1 \quad (8)$$

Any fractional part of the *n* value can be removed from the result of (8) to form the (*d*,*n*)-pair. These values are then used to create the pattern generating function by substituting them into the generating function signature.

C. Trellis Similarity

The x^3 and x^4 parts of (5) are the most dominant in the trellis structure as they are based on the dimensions of the trellis. The x^2 term, again being a constant value over the node count, does not carry anything significant. The ratio is then the x^4 to x^3 coefficients:

$$\frac{(p-2)(q-2)}{2(p+q-4)} = \frac{a_4}{a_3} \quad (9)$$

The a_4 and a_3 variables represent the x^4 and x^3 coefficients of the network generating function.

In order to obtain the p and q parameter values, some error testing is necessary. A value for q within the range $2 \geq q \geq$ diameter of the network must be found that produces the lowest error from the nearest integer. In other words, the (p,q)-pair that creates the best fit for (9) is needed. The following equation can be used for error testing:

$$p = \frac{2qr+2q-8r-4}{q-2-2r} \text{ for} r = \frac{a_4}{a_3}. \quad (10)$$

It is advised to remain within a threshold of ±0.1 when determining proper values for p. Since both p and q are equally significant in these functions and their values need to be integers, it is important to find the values that best fit the dimensions of the dominant trellis in the network. The error testing is the same as the other structures.

D. Similarity Analysis with Multiple Patterns

Analysis of network is non-trivial when there are multiple patterns present in the network. The simplest case of compounding is when the network is built from multiple occurrences of *congruent* pattern graphs (all with exact same generating function). It can be called *homogeneous forest of congruent patterns.* Complex networks may also be made of non-congruent patterns. These can be called *homogeneous forests*. The generating functions for two non-congruent patterns will differ in at least one of the coefficients or parameters. Further networks can be made of completely dissimilar patterns. These can be called *heterogeneous forest.* The pattern graphs in the forest may be disjoint from each other or linked together by relatively small number of additional edges in some manner. If the pattern features are significant, the small interconnection links may not disturb the analysis in the limit. The GF for complex networks can be stated as:

$$G_{h(n)\in F}(x) = \sum a(n).h(n). \quad (11)$$

This formula represents a network with a set of patterns, F, each basis with its own generating function $h(n)$. Here $a(n)$ is the proportion of nodes attributed to n^{th} pattern.

The GF of homogeneous forest of congruent patterns holds the same ratios of nodes of different degrees in the network like the pattern network. It causes no change in the pattern generating function in the limit. The analysis can proceed in the same way as that of the basic pattern signature analysis. Based on the node counts in basis pattern, the repetition factor can also be estimated.

The analyses of other type of forests are more complex and do not have guaranteed solvability. To analyze forests it is necessary to isolate each individual pattern. If a pattern GF has unique exponent (which is normally the case for heterogeneous forests)- then it normally can be isolated. When they share exponents then various constraints equalities can be formed by analyzing the ratio coefficients. The difficulty by which these equations can be solved lend to three different solvability categories for patterns: inseparable, separable, and separable with difficulty.

The approach to separating the network between patterns starts by determining the first pattern to isolate. It may involve visualize inspection. Separable structures should be isolated before patterns that are separable with difficulty. Once a pattern is chosen, and determined to be present significantly all subgraphs of that pattern from the network is removed. All remaining nodes for the shared terms contribute to the terms in the next pattern search.

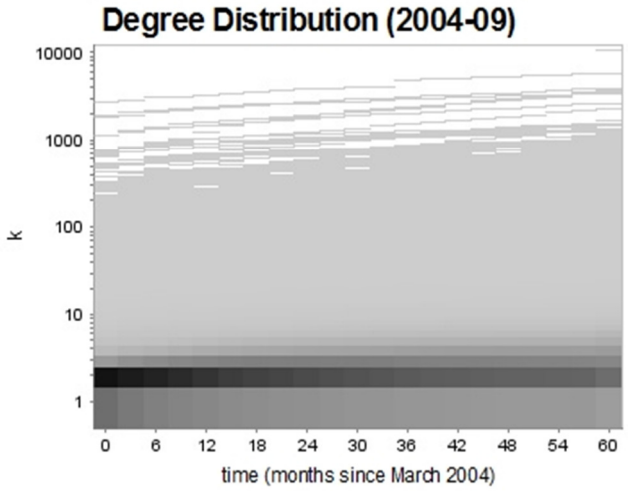

Fig-3. The *evolution of* degree distribution Darker grays and blacks are closer to $p_k = 0.5$ in (a) and $p_k = 0.01$ in (b). White blocks are $p_k = 0$.

Long stars are normally separable, especially when they have high dimension. Each apex of individual long star can be pulled from the network by taking its exponents and determining whether or not they form stars by determining their node counts using the ratio of annex nodes to apex nodes as in (9). On the other hand, the chain is a prime example of an inseparable pattern. It relies only on node count, and the only information held in the coefficients of a pattern generating function for a chain is the number of degree 1 nodes, a constant. With only a constant and an unknown variable, there is no way to solve equations dealing with chains. Trellis, when it is mixed with long-star, is normally separable. However, the non-congruent trellis patterns are only partially separable. Two trellis patterns normally yields under-constraint set of equations.

V. Analysis & Observations

A. Data Set

The extensiveness of the study derives from the massive data set of [13]. It creatively combines data from (a) BGP advertisements and updates observed at various AS observation sites such as large networks including Route Views, RIPE-RIS, Abilene, CERNET, (b) route server data at various Internet Exchanges such as BGP View, Packet Clearing House, UCR, traceroute.org, Route Server Wiki, and (c) data at Looking Glasses such as traceroute.org, NANOG, Looking Glass Wiki. This is the most extensive trace of the ASN available to-date. All data is obtained with publicly available software that allows for the viewing of routing information for the autonomous system of a single entity.

To improve accuracy, the data set did not combine any trace route data since AS paths cannot be accurately inferred from IP paths. The data, however, is still may not perfect. This method still can potentially miss links and nodes [18]. This is due to two reasons- unwillingness of service providers to allow their nodes to be discovered or drop of information in routing tables.

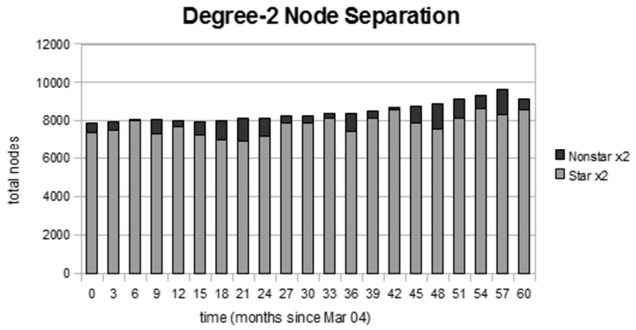

Fig- 4. The separation of the degree 2 nodes in the network between the star and non-star parts prior to analysis.

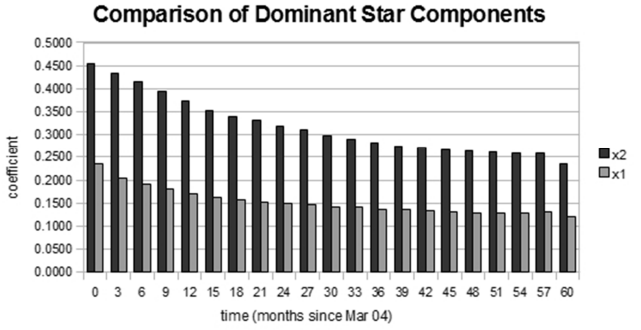
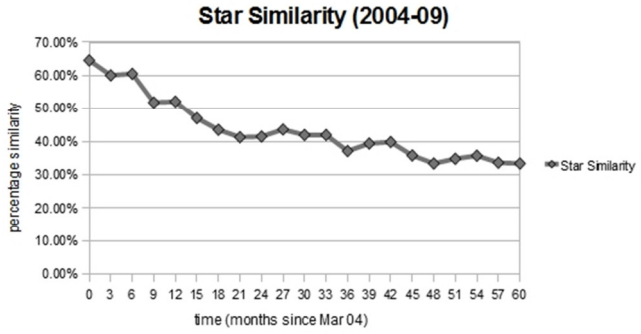


(a)



(b)

Fig- 5. (a) The distributions of the degree 1 and degree 2 nodes in the autonomous system network. (b) The calculated star similarity, resemblance of the ASN to its corresponding long star for each month of the study.

The data set taken from [13] contains the nodes and links from the first day of every third month for all viable years, ending with the month this project began. A topology map is built each day from these collections. The collected maps span over every March, June, September, and December from March 2004 (the first year the maps were created) to March 2009 (the date this project began.) Although more data is available, these 21 maps are used in the data set for this project.

Each iteration of the network is divided into two files. One carries the list of monitored nodes while the other contains a list of links. The records for these files start with the unique identification numbers of the ASes assigned by the IANA. The node files have one ID and the link files have two IDs, one for each AS connected to that link. The next two fields are the times the node or link was first and last monitored by the software, represented as Unix timestamps (seconds since the epoch.) The last piece of information represents the node or link's position in a customer-provider chain. A 0 is used for the start of a path, 1 for the middle, and 2 for the end.

The degree information and node counts stored for the graph of each month in the study were used to build the generating functions for each one. The functions were written in the form

$$G_0(x) = \sum_{k=1}^{\infty} \frac{t_k}{n} x^k \quad (12)$$

where k is the degree, t_k is the total number of nodes that were of degree k for that month, and n is the node count for the entire network. The generating functions were formulated this way to preserve each piece of data for future use.

B. Degree Distribution Trends Observed

The degree distributions showed some interesting results as illustrated in Fig-3. Each block represents the p_k value, distribution for nodes of degree k, for the corresponding degree and month in the study as indicated by the axes. The degree 1 and degree 2 node counts were the highest. They show up as distinct, dark colored bands that grow lighter over time. This trend shows that the ASN is slowly moving away from the stub configuration. The bands for the degrees between 3 and 10 follow the opposite pattern, starting light and gradually becoming darker as time moves on. These changes indicate that autonomous systems with one or two peers appear to be obtaining more links to providers or peers over time. Going across the chart from month to month, the contrast of the bands varies at all values of k. It can be seen that the darker colored blocks (the distributions of higher p_k) are moving higher over time, causing diagonal bands.

C. Dominant Pattern Analysis

The generating functions, metrics, and visual graphs were used to determine the pattern graphs to be tested. Among the many observations, the ASN shows signatures of the long star and the trellis mesh ensemble as the x, x^2, x^3, and x^4 terms of the generating functions were all fairly high. These two patterns share the x^2 term, however, so the degree 2 nodes would need to be divided between the two patterns.

Fig-4 shows the separation of the degree 2 nodes in the ASN for the long star ensemble. Since the long star is under the separable solvability category, the degree 2 nodes for the long stars were separated from the nodes that did not belong to them. The leftover nodes would be attributed to the trellis mesh ensemble. Due to the difficulty of separation for trellises, each iteration of the network was considered to contain only one trellis when determining their trellis similarity percentages. For

the separation of the star nodes, the system of equations is not used here since the x^d term is most significant in determining the star parameters and too many large degree numbers exist

Table-I Dominant Trellis Dimension over Time

Months since March 2004	Year	p	q
0 - 9	2004	4	5
21-Dec	2004	4	6
24 - 36	2005-06	4	7
39, 42	2006-07	4	8
45, 48	2007-08	4	9
51 - 60	2008-09	4	10

Note: Based on error testing as in Table II.

Table-II Dominant Trellis Error Testing

ratio	q=2	q=3	q=4	q=5	q=6	q=7	q=8	q=9	q=10
0.38	0	11.5	4.5	3.7	3.4	3.3	3.2	3.1	3

0.66	0	-10	9.8	5.9	5	4.5	4.3	4.1	4
0.7	0	-8.5	11.3	6.4	5.2	4.7	4.4	4.3	4.1

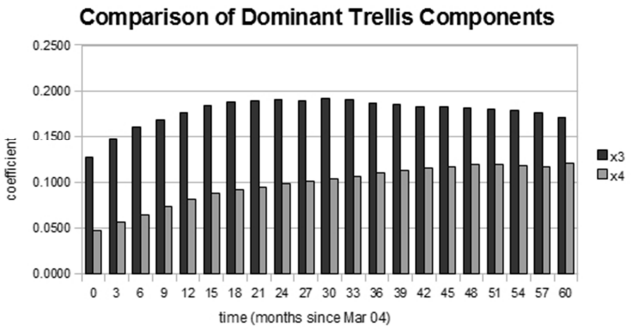
Note: Light gray values represent best fit. Dark gray values are too far out of the range.

for the number of degree 1 nodes. In this case, all degree values less than 5% of the node count were used as potential dimension numbers in order to limit *m*. The dimension values were substituted into (9) and then tested for error from the nearest integer. If the error was under 0.1 then the dimension and node count were kept as part of the pattern GF.

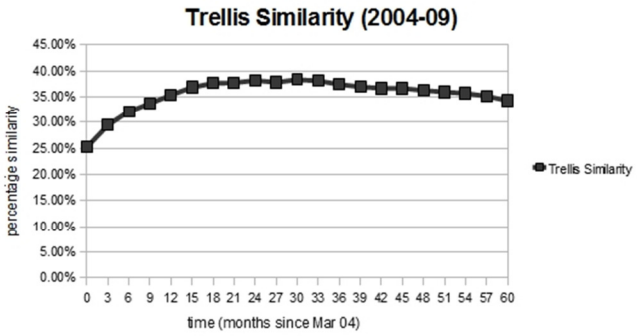
The view of the network as a heterogeneous forest of long stars and one trellis weighs heavily on the separation of degree 2 nodes in the network. Fig-4 shows that the majority of these nodes are part of the long star structures in the network. The trellis pattern has a small constant for the x^2 term in its generating function, so the low numbers help the error testing phase of trellis similarity calculation.

D. Star Ensemble Similarity Analysis

The visualization of the early network graphs (as in Fig- 1) showed significant presence of long star like ensembles at the edges of the network. In Fig- 5a we show the degree measures for significant components of the long star ensemble i.e. the numbers of nodes with degree 2 and degree 1 within the ASN. These were higher than all other numbers and several centers appeared to exist as many of the high degrees had p_k values of $1/n$. These two aspects made finding the star similarity of the ASN favorable.



(a)



(b)

Fig- 6. (a) The distributions of the degree 3 and degree 4 nodes in the ASN. (b) The calculated trellis similarity of the ASN to its closest trellis for each month of the study.

The dimensions and sizes of the long stars within the ASN loosely followed few trends. The stars did have a tendency to grow over time as they obtained more points; however, the higher the number of nodes the star accumulated, the more connected it became until it was too well-connected to be considered a star pattern.

The star ensemble analysis of the network exceeded 50% mark for the first year of the study; however, the number ended up dropping below that mark for the remainder of the study. The star similarity for March 2004 was nearly 65%. The next two months remained close to 60% before a sharp decrease occurs at the end of 2004. Month 15 was the first month in the study in which the star similarity value dropped below 50%. The star similarity percentage reaches its lowest point in March 2009 when it is slightly higher than 34%.

Fig-5a and 5b compare the dominant long star terms from the ASN against the calculated star similarity percentages for each iteration. Both charts show a steady decline in all values over the course of the study. Some differences are notable between the two statistics. The x and x^2 terms of the ASN remain on a decline from period to period; on the other hand, the star similarity percentages display a slight rise in value (less than 2.5%) during several iterations of the network.

E. Trellis Ensemble Similarity Analysis

The visualizations of the ASN showed a separation between the star-like points at the edge and the core of the network. The outer part of the core consists of low degree nodes that appear grid-like. The numbers for degree 3 and degree 4 nodes were fairly high and in proportion similar to the trellis generating function signature. In combination with the low count of degree 2 nodes outside the long stars, it helps support the presence of a pattern from the trellis ensemble within the ASN.

Table II shows the results for the dimensions for the dominant trellis in the network at each iteration, and Table III demonstrates the process used to find the dominant trellises. The p and q values represent height and width of the trellis mesh respectively. The first trellis observed was a 4x5 pattern. Roughly every twelve months, the trellis pattern became slightly larger as the width continually increased by 1. Rather than using a different dominant trellis with a different p value (a 5x6 trellis showed error less than 0.1) from the months before, the experiment was conducted with the 4x10 trellis for the final year of the study. The error in this adjustment did not alter the results much.

Fig-6a and 6b show the relationship between the dominant trellis terms from the ASN and the trellis similarity for each month in the study. The ASN appeared to go through two phases: the first phase in which it increased from 25% to 38% until the midpoint of the study (month 30) and the second phase in which it remained steady between 35% and 38%. The trellis similarity percentages are still below 40%. Side by side the two charts distinctly share a trend. The x^3 term of the ASN and the trellis similarity percentages follow almost exactly the same pattern over the course of the project.

VI. Conclusions

The work makes two main contributions in the area. This paper uses the novel technique of *generating function signature* GFS and extends their usefulness. The main advantages of GFS like techniques are twofold- that they can handle perturbation of target as well as pattern graphs which is very important for analysis of large scale complex networks. The method is also computationally efficient. It can be extended even to mega scale complex networks- if their degree distribution can be sampled with reasonable confidence.

However, GFS do have fundamental limits. Besides the difficulty in pattern separation, generating functions cannot pinpoint the location of a pattern within the topology or determine that the structure exists in one place. Pattern analysis through generating functions is only able to locate signatures of familiar patterns. The nodes belonging to any pattern could be scattered throughout the network without being visible.

This study also reveals another important trend possibly great engineering implications and not reported earlier- that the autonomous systems are becoming more trellis-like and continuously moving away from this single-home or star-like configuration. This transformation has been rapid from the very beginning of this study to the middle of 2006. Finally, there seems to be a fundamental transformation of the relative weights of edge and core ASN network where the ratio has shifted from roughly 70:30 to about 45:55 based on star and trellis similarity.

What are the implications of such trend? This pattern of evolution of ASN indeed call for a new regime of routing and transport protocols- than currently one- which can take advantage of increased parallel paths and regularized topology based communication. This indicates it might be time for a suit of next generation protocols (across layers) in the line of parallel communications in Internetworking.

Abstract— *It is essential to keep networking system available in emergency. Power consumption will therefore be one of the most important issues to realize both platform and communication environment. This paper describes about comprehensive evaluation of ultra-low-power data-driven networking system (ULP-DDNS). ULP-DDNS, which is a research project, is aiming at development of data-driven networking system which can achieve ultra-low-power consumption: 1/300 less than the present system. This paper firstly reports the effect of power saving schemes in ULP-DDNS. The authors have implemented ULP-DDNS node and platform simulator for evaluation of ULP-DDNS comprehensively. This paper then describes evaluation scheme of ULP-DDNS with ULP-DDNS node and simulators. Furthermore, this paper describes an implementation of ULP-DDCMP platform simulator and shows current status of experimental study. Finally, the authors propose data-driven load balancing scheme to maintain the networking system in working without over-loaded state.*

Keywords: ultra-low-power, data-driven principle, networking architecture, self-timed elastic pipeline, chip multiprocessor

1. Introduction

For rapid evacuation, it is important to keep communication environment available in emergency. It is necessary to realize such robust environment because some earthquakes and tornadoes occur in Japan in a few years. Infrastructureless communication environment can be then supposed in emergency. And power consumption is crucial issue to keep communication environment available for a long time as possible [1]-[3].

Currently, so-called pervasive networking environment as social infrastructure has been widely studied [4]. Furthermore, there are many studies about mobile ad hoc network[5] which is an infrastructureless network and is a group of wireless devices that organize themselves in a mesh topology to find routes and relay packets from the hardware platform through the network layer to application. Considering the case where next generation of pervasive networking is realized over ad hoc network suitable for emergency and some tentative accidents, some of authors study data-driven implementation of ad hoc communication environment [6].

The authors have started research project named "ultra-low-power data-driven networking system (ULP-DDNS)"[7]. ULP-DDNS project is aiming at development of data-driven networking system which can achieve ultra-low-power consumption: 1/300 less than the present system.

This paper firstly reports the effect of power saving schemes in ULP-DDNS. In ad hoc networking application layer, we have evaluated reducing the number of packets in broadcasting with load-aware flooding scheme. On platform, the authors have studied effective protocol handling such as data-driven implementation of UDP/IP, and optimized circular pipeline. Furthermore, this paper reports power saving scheme such as power gating and runtime voltage scaling on the platform. Toward comprehensive evaluation of ULP-DDNS, the authors have implemented ULP-DDNS node and platform simulator. This paper then describes evaluation scheme of ULP-DDNS. In ad hoc networking application layer, the authors have evaluated traffic in all of the ad hoc network with network simulator. We use logs of the network simulator as input of platform simulator for comprehensive evaluation. Furthermore, this paper describes an implementation of ULP-DDCMP platform simulator and shows current status of experimental study. Finally, the authors discuss about data-driven load balancing scheme to maintain the networking system in working without over-loaded state.

2. Power Saving Schemes in ULP-DDNS

This section reports power saving schemes in each layer of ULP-DDNS. Fig. 1 shows layer of ULP-DDNS. A node of ULP-DDNS is a platform which is used data-driven

chip multiprocessor(UDP-DDCMP) and self-timed elastic pipeline(ULP-STP). Runtime voltage scaling is implemented in the platform for ultra low power consumption. Ad hoc networking Application and UDP/IP handling is also implemented on the platform.

The method of reducing the number of UDP packet in ad hoc networking application layer and reducing power consumption on platform is described in following sections.

2.1 Power Saving Schemes of Ad hoc Networking Architecture

The authors have studied mobile ad hoc network as an applicable network architecture to disaster situation. In disaster situation, effective information discovery is firstly important. At a same time, effective secure communication is needed. They should be realized under the effective data transfer on ad hoc network. We have proposed these schemes in ultra low power consumption. Refer to [8] about these schemes. This paper reports about load-aware flooding[9] because this scheme is used in all communication on ad hoc network.

When an ad hoc network is to be used in a disaster situation, it is likely that emergency information will be broadcast by voice streaming from a small number of nodes. Conventionally, simple flooding (SF) has been used as a method of broadcasting streams to the entire network. However, if SF is applied to information flows in which packets are generated at a high rate, as is the case with voice streams, packet loss will occur frequently, causing degradation in the quality of service.

As a method of broadcast streaming, we have already proposed a Load-aware Dynamic Counter-based Flooding (LDCF), and showed that LDCF results in fewer unnecessary packets being sent and less degradation in quality of service (QoS) than SF or other methods. Furthermore we showed that the application of LDCF to broadcast voice streaming in an ad hoc network results in fewer instances of packet loss than SF. Nodes used in an ad hoc network are normally powered by a battery of finite capacity. Therefore a reduction of the number of exchanged packets is desirable, not only because of the reduction in traffic load itself, but also because it results in reduced power consumption. As a results, we have evaluated that LDCF generates less traffic and consumes less power per node than SF.

2.2 Data-Driven Implementation of UDP/IP for ULP-DDCMP

The authors have studied the effectiveness of an implementation of protocol offloader using networking-oriented

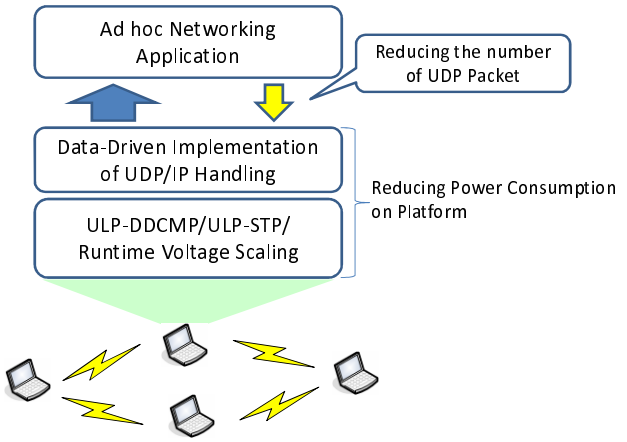

Fig. 1: Power Saving Schemes on Platform

data-driven processors CUE (Coordinating User's requirements and Engineering constraints) designed by CUE project [10], [11]. In ad hoc network, it is necessary to realize connection-less protocol such as UDP/IP for flexible routing and realtime communication. We proposed data-driven implementation of UDP/IP for ULP-DDCMP to minimize overheads in protocol handling.

Then we studied architecture of CUE-v2/CUE-v3 for ad hoc networking environment [12], [13]. And we evaluated effectiveness of protocol handling offloader using CUE processor system. It shows that data-driven protocol offloader can keep minimum turn-around time in comparison with conventional PC(Personal Computer) [14]. We realize header processing and data processing concurrently utilizing multiprocessing capability of data-driven processor without runtime overheads.

This paper shows evaluation of UDP/IP on ULP-DDCMP in power consumption in Section 3.2

2.3 Data-Driven Chip Multiprocessor

2.3.1 Self-Timed Power-Aware Elastic Pipeline:ULP-STP

The authors have studied data-driven chip multiprocessor based on self-timed elastic pipeline for ultra-low-power in realtime multiprocessing.

In data-driven chip multiprocessor, both the dynamic and static power dissipations are minimized by distributing the processing load over multiple processing cores which is slowed down by using runtime/dynamic voltage scaling (DVS) technique as long as the required processing speed is satisfied[15]. In addition, the voltage-supply to idle circuit blocks or cores is cut by using fine-grained power gating

(PG) technique[16]. It is therefore intended that the ultra-low-power DDCMP would be implemented by self-timed power-aware elastic pipeline named ultra-low-power self-timed pipeline (ULP-STP)[17]. Because of self-timed elastic data-transfer mechanism of the original STP, it can work well under variable voltage without adjusting clock frequency even if the altered voltage could transiently fluctuate at individual pipeline stage. Since the pipeline throughput can be adaptive to its processing load only by altering supply-voltage appropriately, a power-aware pipeline scheme can be realized naturally in terms of dynamic power saving. For instance, proportional-integral differential (PID) control method can be applied to such voltage control by monitoring consumption current of a target power domain within the chip. The STP is also suitable for gating power-supply to fine grain circuits since its stage-by-stage data-transfer control independently activates only pipeline stages with valid data. We therefore proposed a stage-by-stage power gating scheme adopted in the STP. This scheme provides natural signal gating, i.e., it stops the unnecessary signal propagation and transistor-switching at pipeline stage level without any global control mechanisms resulting in both power dissipation and processing speed degradation. Moreover, it makes it possible to scale the voltage even when the stages are activated because it can be realized without any global oscillator such as phase-locked loop (PLL) circuit, which forces pipeline flush ahead of the frequency and voltage change. In order to analyze the low-power characteristics of the ULP-STP and to estimate power-performance of various ULP-STP based systems, an experimental LSI chip has been fabricated by using 65 nm CMOS process. We have implemented ultra-low-power data-driven chip multi processor: ULP-DDCMP based on evaluation of the experimental LSI.

2.3.2 An Implementation of Ultra-Low-Power Data-Driven Chip Multiprocessor: ULP-DDCMP

In our previous study on the data-driven processor, it is already revealed that the networking protocol handling consists of several sequential processing parts such as a processing part to generate output data by reading an array sequentially. To prevent such sequential processing part from being the bottleneck of the networking protocol handling, some of the authors has already proposed a hybrid processor architecture in which a control-driven instruction execution is realized by out-of-order execution scheme suitable for the sequential processing in addition to the ordinary data-driven instruction execution[13]. Based on this previous study, it is revealed that the sequential processing parts should be efficiently executed in parallel with the execution of the other non-sequential processing parts. However, from a viewpoint of low-power processing, the previously proposed hybrid architecture is unsuited for the ULP-DDNS, because the control-driven execution requires additional controls to execute instructions in contrast to the pure data-driven processor. Therefore, the ULP-DDCMP is designed to exploit the data-driven principle and its instruction execution pipeline is discussed in this paper by focusing on the utilization frequency of the instruction execution pipeline stages activated by unary-operation instructions which are the main constituent of the sequential processing parts. In the ULP-DDCMP, a processor core is realized by a circular pipeline necessary for instruction execution, and each pipeline stage is activated or driven only when a packetized data is transferred, and thus signal gating at pipeline stage level is naturally realized without any additional circuit[18]. In fact, ULP-DDCMP has no dynamic power dissipation. On the other hand, it is important to reduce the amount of leakage current which is the dominant cause of the increase of static power dissipation, in order to exploit the benefits of the scaling of transistor to the improvement of the performance of the ULP-DDCMP. We focused on the utilization frequency of the instruction execution modules, and have proposed an instruction execution pipeline structure in which infrequently used modules are bypassed and/or powered off to shorten the instruction execution time and to reduce static power dissipation. The effectiveness of the proposed pipeline structure is estimated based on a prototype LSI implementation.

The authors have studied reasonable mechanism for avoid over-loaded state by using processor core configuration of ULP-DDCMP and observability of ULP-STP. Conventional schemes for avoid over-loaded state is relatively much power consumption in each service because restriction is excess for performance. We proposed mechanism which is combined DVS function and I/O control for observation of load with load-distribution by round-robin. It is effective to realize ultra-low-power networking environment which is suitable for demanded performance. In addition, we have developed ULP-DDNS node. Refer also [18] about this node in detail.

3. Comprehensive Evaluation of Power Saving Scheme by Platform Simulator

This section proposes comprehensive evaluation scheme with network simulator and platform simulator. Fig. 2 shows image of summation of power consumption. Network simulator have already used evaluation in ad hoc networking application. As comprehensive evaluation, we proposes using logs as a network simulation result to input of the

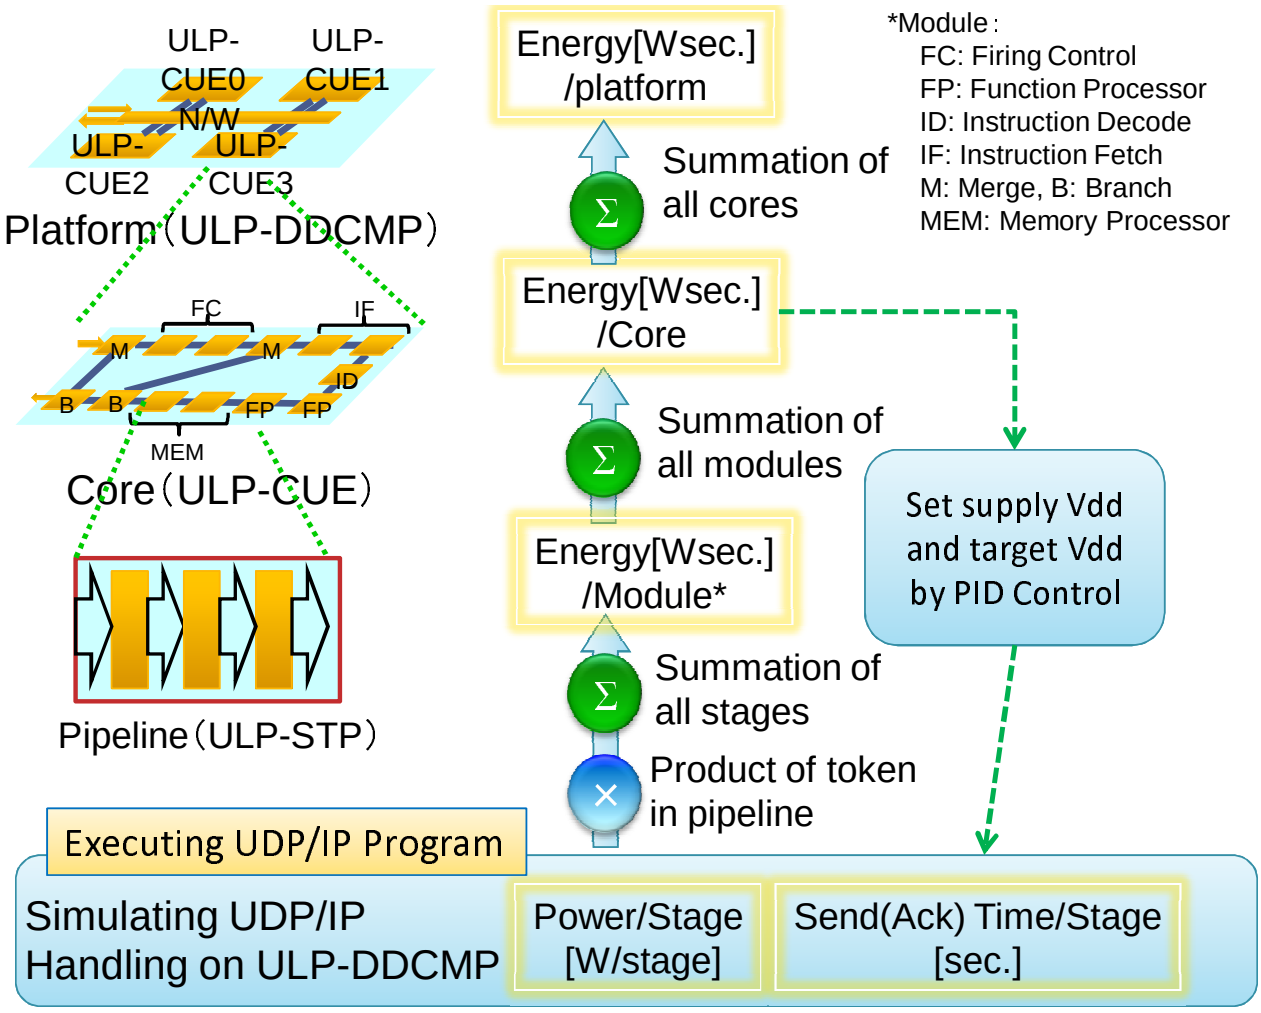

Fig. 2: Comprehensive Evaluation of ULP-DDNS

platform simulator. Platform simulator can evaluate power consumption and turn-around time of program on data-driven chip multiprocessor. Platform simulator is necessary to evaluate energy of platform in UDP/IP handling because analog electronic circuit simulator which is SPICE is too complicated to measure power and turn-around time in UDP/IP handling according to network simulation log. In execution program, logs which has input time and data length can be used as input for the platform. Summation power consumption in each platform is a total power consumption of ULP-DDNS.

Platform simulator has hierarchy among self-timed elastic pipeline (ULP-STP), cores (ULP-CUE), and platform (ULP-DDCMP) as shown in Fig. 2. Firstly, platform simulator evaluates power consumption and switching time of stages of ULP-STP. Power in each stage and send/ack time between stages are then derived from ULP-DDNS node, prototype of ULP-STP and gate simulation. In PID control, time in change supply voltage and target Vdd is simulated by platform simulator. Parameters such as some gain is tuned by data of gate simulation. Platform simulator sums up energy of stages of which a module consist. ULP-CUE consists of some module such as firing control (FC), function processor (FP), instruction decode (ID), etc. All modules of which ULP-CUE consists is connected as a circular pipeline. Platform simulator also sums up energy of all stages of a circular pipeline which is elements of an ULP-CUE. Furthermore, the simulator sums up energy of all cores on an ULP-DDCMP. It is power consumption of a platform.

3.1 Platform Simulator for ULP Platform

It is necessary to validate power consumption of ULP-DDNS in detail. So the authors proposed power simulator/validator as a platform simulator[19]. Then, we have

implemented the platform simulator. This paper shows how to use of the platform simulator.

Fig. 3 shows input to platform simulator and output from it. Platform simulator requires schedule of token stream as an input. This schedule is generated from network simulation logs. Platform simulator also demands UDP/IP program to evaluate power consumption in UDP/IP handling. Platform simulator has a topology of platform, a topology of core and parameters which indicate specification in each stage such as power and switching time in order to calculate power consumption of platform. Platform simulator then outputs energy and turn-around time in UDP/IP Handling.

Fig. 4 shows pipeline structure in the simulator and simulation results. Fig. 4(a) shows a circular pipeline structure of ULP-CUE. The platform simulator can freely design pipeline structure of core and router in a platform. Then, the simulator can set parameters power and time which is evaluated in a platform flexibly.

When input datagrams concretely create, it is necessary to collaborate with network simulator which evaluates networking architecture. The authors have studied how to communicate between our simulator and network simulator. We uses data log in network simulator can use information of data input in our simulator. On the other hand, specification of CMP in our platform simulator may apply to a node in network simulator.

Multi pipeline loop of ULP-CUE is applied to pipeline structure of core in this simulation because ULP-CUE has same pipeline. Fig. 4(b) shows graph as a simulation result. X axis of the graph is execution time of UDP/IP on a platform which is target of simulation. And y axis of the graph is power consumption in each time. We evaluate and tune a platform on ULP-DDNS, and show effectiveness in ultra-low-power of ULP-DDNS. Then, it is necessary to adjust parameters in PID control to runtime/dynamic voltage scaling mechanism. So the authors have been simulating UDP/IP on ULP-DDCMP architecture in several settings of PID control by using platform simulator.

3.2 Evaluation of ULP Platform

This section reports current status of the comprehensive evaluation. The authors have validated logs of network simulation. Fig. 5 shows percentage of sending packets in LDCF to SF. X axis of the graph is node ID which identify node on the network. Y axis of the graph is percentage of sending packet in LDCF to SF. Almost node is less than 10% of SF in sending packet. Fig. 6 shows the distribution of its percentage. X axis of graph is percentage of sending packet in LDCF to SF. And y axis of the graph is the number

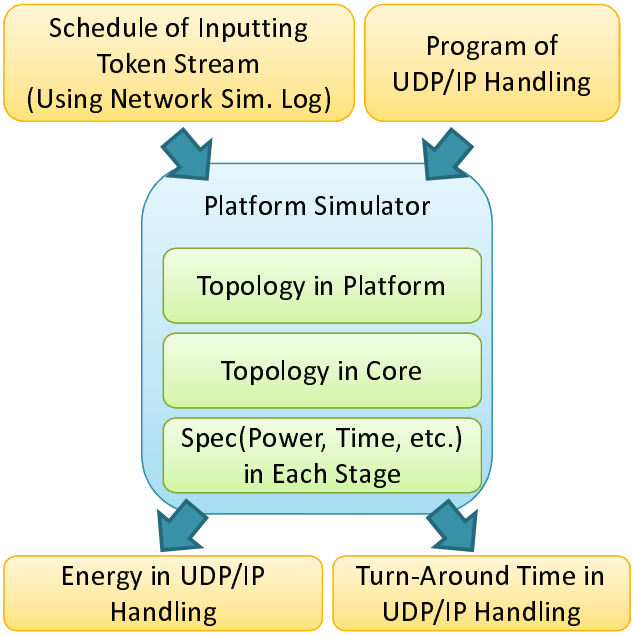

Fig. 3: Specification of Platform Simulator

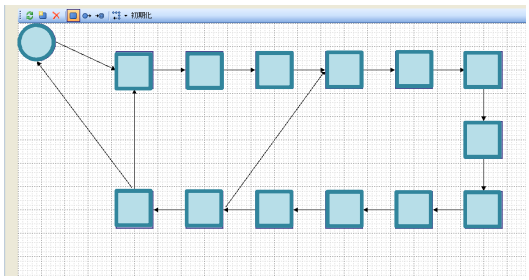
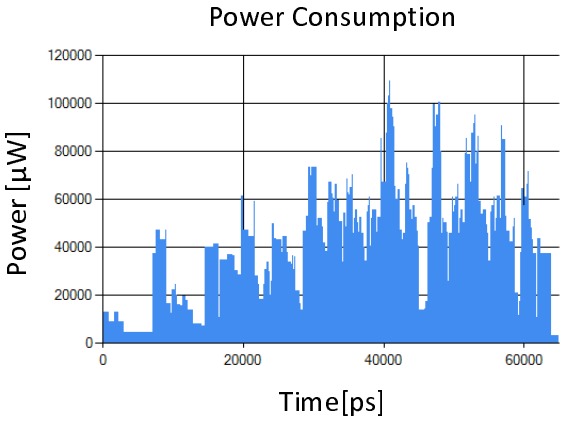
of nodes of which sending packet is in each percentage. For comprehensive evaluation, 10 nodes is enough to sampling node in logs of network simulator because of estimation in confidential interval.

Furthermore, the authors have evaluated power consumption of conventional processor to compare power consumption with ULP-DDCMP. ULP-DDNS node has Atom as a application processor which driven Linux OS. So, we have evaluated power consumption of Atom on ULP-DDNS node. On Atom, it is necessary to drive OS in order to handle UDP/IP. To evaluate power consumption in just UDP/IP handling, we firstly measured power consumption in stand by mode of Atom. Its power was 210.7 μWsec./packet. We then measured power consumption in UDP/IP handling on Atom. Its power was 232.6μWsec./packet. Thus, power in just UDP/IP handling is 21.9 μWsec./packet. Then we need to consider power consumption of L2 cache because L2 cache is not used in UDP/IP handling. We estimated power consumption of L2 cache and deduct it from measured power consumption. As a result, power consumption of L2 cache is 10.9 μWsec. because ratio of circuit area of L2 cache to a chip is less than 1/2. Therefore, we have evaluated that power in UDP/IP handling on Atom is 11.0 μWsec./packet.

On the other hand, power in UDP/IP handling on ULP-DDCMP is 3.2 μWsec./packet. Hence, power consumption of ULP-DDCMP is 1/3 of Atom in UDP/IP handling. So we evaluated that ULP-DDCMP is enough to have ultra-



(a) Configuration of Circular Pipeline



(b) Evaluation Result

Fig. 4: Power of UDP/IP on ULP-DDCMP

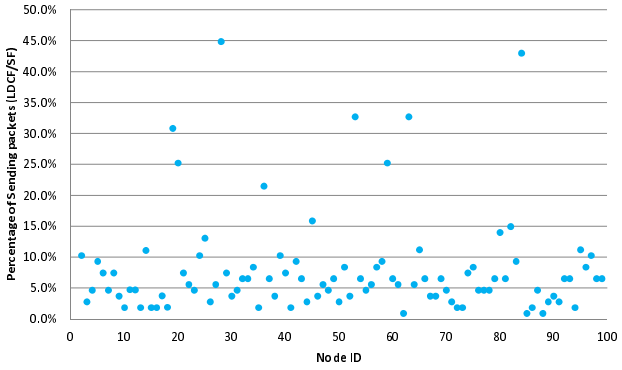


Fig. 5: Percentage of Sending Packets in LDCF to SF

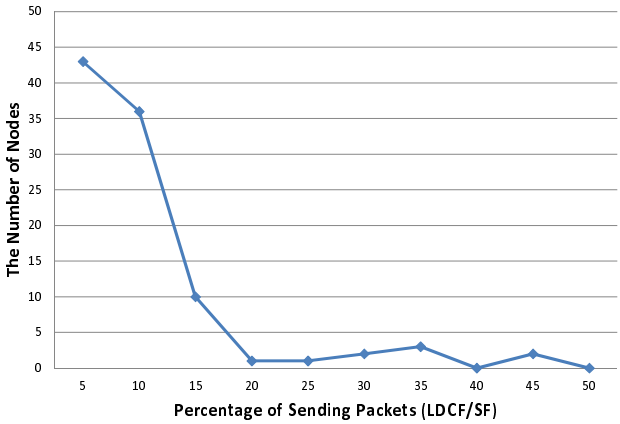

Fig. 6: Distribution in Percentage of Sending Packets in LDCF to SF

low-power effect.

As a future direction, we will firstly analyze UDP/IP handling on ULP-DDCMP when packets input according to time of network simulation log. This simulation result can be compare with power consumption on ULP-DDNS node which handle UDP/IP on ULP-DDCMP. At the same time, we will tune simulation model of power consumption more concretely. For example, it is necessary to tune power consumption model in DVS because current model in platform simulator is too simple to evaluate power consumption in DVS. Furthermore, tuning instruction set on ULP-DDCMP is important to save power. We then need to study offloading scheme, which is to optimize executing application on ULP-DDCMP. At least, it is necessary to implement ad hoc networking application on ULP-DDCMP because we verificate evaluation of platform simulator whether it match the evaluation of network simulator. And the authors have studied implementation of overload avoidance function on ULP-DDCMP. Refer to [20], [21] about these study.

4. Conclusion

This paper firstly reports power saving schemes of each layer in ULP-DDNS project. It is clear to achieve high effect in reducing power consumption with proposed schemes. The authors then proposed comprehensive evaluation method which uses output of network simulator as input of platform simulator. We showed that power consumption of ULP-DDNS can be evaluated by its cooperation. Furthermore, we analyzed logs of network simulator, and we showed

the distribution of percentage of sending packet in LDCF to SF. As a standpoint of estimation considering confidential interval, 10 nodes is enough as sample nodes for the evaluation. This paper describes implementation of platform simulator, and reports current status and future direction of the comprehensive evaluation.

As a further works, the authors will comprehensively evaluate power consumption of ULP-DDCMP as shown in previous section. And Tuning platform simulator will be needed to evaluate power consumption precisely. Furthermore, we have studied overload avoidance function in platform and networking system to realize robust networking system.

Acknowledgments

Although it is impossible to give credit individually to all those who organized and supported the CUE project and the ULP-DDNS project, the authors would like to express their sincere appreciation to all the colleagues in the project.

The CUE project and the ULP-DDNS project are partially supported by Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Agency, Strategic Information and Communications R&D Promotion Programme (SCOPE), Ministry of Internal Affairs and Communications, Japan, the Grants-in-Aid for Scientific Research of Japan Society for the Promotion of Science and Semiconductor Technology Academic Research Center (STARC). And, this work is supported by VLSI Design and Education Center(VDEC), the University of Tokyo in collaboration with Synopsys, Inc. and Cadence Design Systems, Inc.

Abstract – *This paper describes the up-to-date results got through Ultra Low-Power Data-Driven Networking System (ULPDDNS) project mainly about the network portion. The ULPDDNS has been aiming at achieving reduction of power consumption to 1/100 – 1/1000 compared with the existing systems. We have been tackling with the networks applicable to the emergency situation such as natural disaster. In the emergency case, the need of low power consumption systems and networks are really essential due to lack of power infrastructure. We believe the most applicable network to disaster situation is Mobile Ad hoc NETwork (MANET). This paper shows the evaluation results on the ULPDDNS networking layer activities on MANET by integrating three techniques to establish highly efficient and energy saving MANETs with reasonable performance: (1) GPS-aided target information discovery, (2) Load-aware broadcast-type contents delivery, and (3) Trust relationship list based key management.*

Keywords: Mobile Ad hoc Network, broadcasting, information discovery, trust management

1 Introduction

The ULPDDNS consists of mainly two parts: one is the platform (processor) and the other is the network. Our objective is to develop a data-driven networking system that can achieve reduction of power consumption to 1/100-1/1000 compared with the existing systems, especially in the situation just after a disaster happens.

We believe the most applicable network architecture to disaster situation is Mobile Ad hoc NETwork (MANET) [1][2]. A MANET is defined as a group of wireless devices that are capable of organizing themselves in a mesh topology in order to find routes and relay packets from each node to any other node within the network without a support of a pre-installed infrastructure. The deployment of these networks is expected to take place in critical environments such as during disaster or on battlefield, where pre-installed infrastructure is not available. We assume the network portion of ULPDDNS is to be MANET and have been studying MANET architecture that can achieve the high efficiency to reduce power consumption with keeping possibly high performance. In order to make both network efficiency and performance (QoS and security) better, we have to consider that emergency network has two network usage phases such as (1) network setting-up phase (just after a disaster happened) and (2) stable phase.

Regarding the intermediate reports of our activities has already been shown in [3]. There we had three main approaches, (1) GPS-aided target information discovery, (2) Load-aware broadcast-type contents delivery, and (3) Trust relationship list based key management. This paper will show the integrated effects of those three approaches as the final stage evaluation of our ULPDDNS project. It firstly shows three main approaches we have been proposing one by one. Then it shows the each result got so far for each approach. Then, assuming a traffic model that could be realistic in case of emergency, the paper shows the integrated evaluation results of our approaches.

2 MANET for disaster

Although we have already reported in [3] the relation of MANET to disaster situation and possible solutions, we would like to summarize them here.

2.1 Applicability of MANET to the disaster situation

As shown above, MANET has no infrastructure, no centralized controllability, dynamically changing network topology, and multi-hop information transmission. It is an infrastructure-less and a group of wireless and mobile devices that organize themselves, can be an alternative to the existing network infrastructure in case of emergency and/or events, and will play an important role for achieving low power consumption network. Our target is reduction of "number of packets (redundant packet transmission)" to 1/10 of the present in case of emergency (just after disaster happens). MANET is most applicable to the disaster situation and the situation needs ultra low power consumption to make battery have longer life time.

After the disaster, we have to consider network life time. We consider following two phases.

- Phase 1 (transient): This phase means that of just after the disaster happened. Several nodes in some area may organize a MANET but each node may not know IDs of other nodes such as IP addresses. So, usual routing (unicast or multicast data transfer) cannot be executed. In this phase, however, useful information must be sent all over the network urgently such as "where is a refuge, hospital?", "how is my house?", and so on. Both "Pull" (Information discovering) and "Push" (Information broadcasting) are needed without use of IP addresses.

- Phase 2 (stable): In this phase, each node has each routing table and the network becomes stable. Usual communication based on routing with possibly high QoS and security will be required. We have clarified main three study issues in association with two phases above after MANET setting up.

As for phase 1, "effective information discovery" without IP addresses is needed because people in the network, just after the disaster, would probably need such information as refuges, hospitals, and his own house. For this purpose, we have proposed "a GPS based discovery mechanism" [4][5]with reduced control packets. For phase 1, "Effective data transfer" is also needed because people who have some useful information would like to let as many people as possible know the information without IP addresses. For this purpose, we have proposed "Load-aware flooding". This flooding mechanism needs no IP address and can reduce redundant packets. Of course the flooding can be used in phase 2 also.

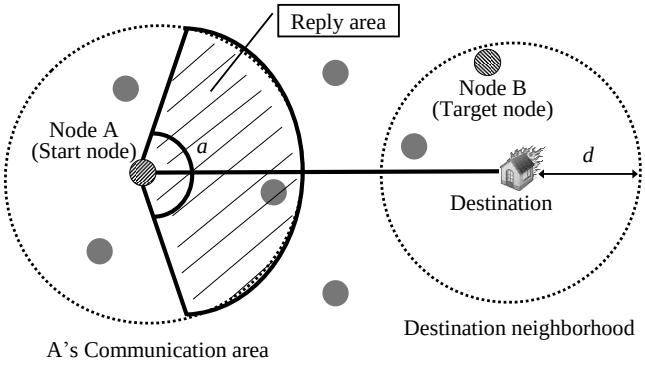
As for phase 2, networks become stable and usual communication by use of IP addresses will be executed. In some cases, "effective secure communication" with ciphering will be needed. For this purpose, we have proposed "Self-organized key management based on trust relationship list".

Below, we show how these mechanisms are effective.

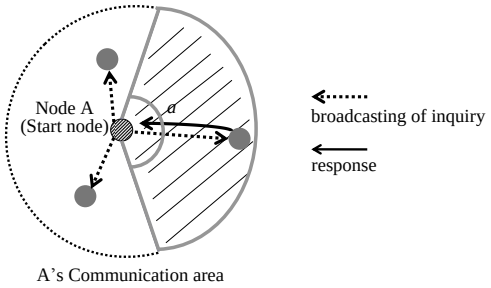
2.2 GPS-aided target information discovery

In case of an emergency phase 1 (just after the disaster happens), local information is probably needed. For instance, for people in the MANET, information about refuges, hospitals and their own houses is urgently needed. This fact requires some information or contents discovery mechanism. Those who need such information would like to inquire other people in the MANET about the information. However, in phase 1, there are some constraints, one of which is that each node address is not well known to other nodes and usual routing based communication (unicasting and multicasting) is unavailable to use. In this situation, only available way of inquiry is using "Simple Flooding (SF)." The SF mechanism is as follows: Simple Flooding is used to deliver messages to the whole network. A node that originates a packet broadcasts it. The packet reaches all the nodes that exist within the area covered by the radio wave transmitted by the origin node. A node that has received the packet re-broadcasts it. This process is repeated by subsequent nodes until the packet reaches all the nodes in the network. In the information discovery, a node sends an inquiry packet to the whole nodes using SF. But, multiplication and contention of inquiry packets will occur and result in waste of electric power. Hence, Effective information discovery with reducing wasteful inquiry packets is needed.

We have proposed a discovery method, which uses location coordinates of nodes using Global Positioning System (GPS), and successive queries and replies between adjacent nodes [4][5]. This method assumes that (i) a node inquiring information (start node) knows the location of destination of which the starting node needs information, for example by use of a map, (ii) some node in the neighbor area of the destination may have the information about the destination which itself is not a ad hoc node, and (iii) each node has GPS terminal. Fig.1 shows a rough sketch of our proposed procedure. To prevent the widespread diffusion of messages in the network which is the major problem with SF, the proposed method uses the location information so that reply packets are sent in response to queries only which have been sent in the pre-defined reply area (hatched area in Fig. 1) direction of the destination.



(a) Outline of the proposed method (Step 1)



(b) Outline of the proposed method (Step 2)

Fig.1 Outline of the GPS based discovery mechanism

By the computer simulation, it is clarified that this method reduces to 25% of simple flooding in best case both the number of packets transmitted/received and the power

consumed in the entire network (Fig. 2), and showed power needed to GPS operation is negligible.

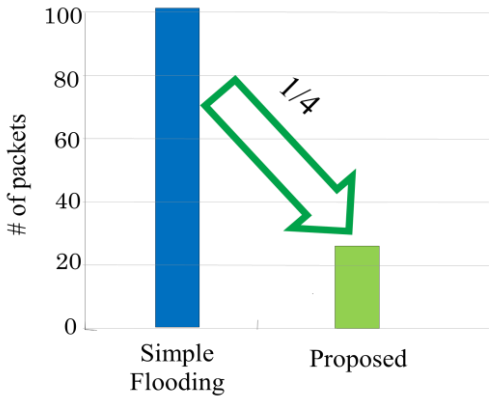


Fig.2 Effect of GPS based discovery

2.3 Load-aware broadcast-type contents delivery

In emergency situation (phase 1), a number of specific nodes may send urgent audio or video messages, such as evacuation instructions for disaster victims or instructions for rescue teams, to the entire network at a high bit rate without using any routing protocol. Flooding is the only delivery method to achieve this. However, as described in 3.2, conventional SF is not well suited for this purpose because it results in broadcasting too many unnecessary packets, which increases the chance of data collisions and buffer overflows, resulting in an increase in packet loss. Nodes in an ad hoc network are generally powered by batteries with a finite capacity and so reducing power consumption is an important issue. Since the transmission of redundant packets accelerates the consumption of battery power, an effective network protocol-based solution to reducing power consumption is to reduce the transmission of redundant packets.

Hence, we have proposed an effective data broadcasting, "Load-aware flooding" [6][7]. Our method uses the number of packets waiting for transmission in the MAC output queue of each node to obtain neighboring load information without periodical transmission of Hello messages. The reason why our method uses the number of packets in the queue is that at the time when the packets exist in a node's queue, the node is going to transmit frames exceeding its link capacity. If the node rebroadcasts a message in this situation, frame loss and collision due to buffer overflow are likely to happen. Therefore, the number of packets in the queue is useful information to recognize the load conditions without any status informing packet transmission.

By the computer simulation, it is clarified that this method reduces to 15% of simple flooding in best case for both the number of packets transmitted/received and the power consumed in the entire network (Fig.3). Our method also increases packets reachability from 71% to 99.9%, which means most of packets penetrate all over the network.

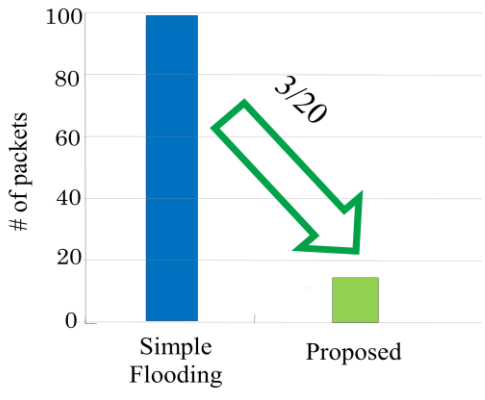

Fig.3 Effect of Load-aware Flooding

2.4 Effective secure communication

After contents discovery and routing table construction, the network enters stable phase 2. In phase 2, secure communication may be needed also in the MANET. The main problem of any public key based security system is to make each user's public key available to others in such a way that its authenticity is verifiable. In mobile ad hoc networks, this problem becomes even more difficult to solve because of the absence of centralized services, and possible network partitions. More precisely, two users willing to authenticate each other are likely to have access only to a subset of nodes of the network. The best known approach to the public key management problem is based on PKI (public Key Infrastructure) [8]. A public key certificate is a data structure in which a public key is bound to an identity by the digital signature of the issuer of the certificate. However, in a MANET without any infrastructure support, most traditional solutions are not directly applicable. The goal of our research is to understand the specific challenges for providing key management in MANETs and use this understanding to design an effective key management framework.

We, for the purpose, proposed a Trust Relationship based Self-Organize Key Management system [9][10] that allows users to create, store, distribute, and revoke their public keys without the help of any trusted authority or fixed server. Web-of-Trust fits naturally with MANETs, relying on each mobile node to issue certificates to other nodes at their own discretion [11]. This approach, however, suffers from frequent communication and much memory spaces because it must collect all the public key certificates beforehand. In order to resolve this defect, our approach, instead of collecting certificates themselves, generates and modifies "trust relationship lists" describing the trust relationship only without certificates among users.

By computer simulation, our proposal drastically reduces number of packets (1/100 to the existing method) (Fig.4).

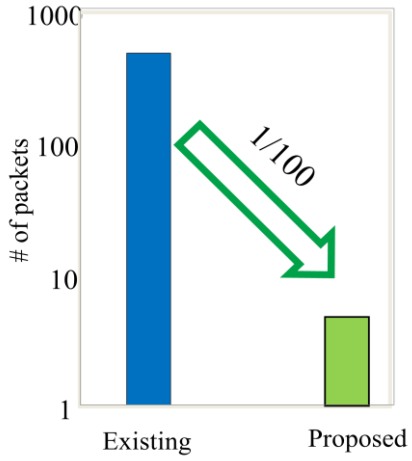

Fig.6 Effect of Trust Relationship based Self-Organize Key Management

3 Integrated evaluation

As shown in the previous chapter, our proposing methodologies are effective to reduce redundant packets that results in reduction of power consumption. In this chapter, we will evaluate what methodologies are used in a real situation and to what extent integrated three methodologies are effective.

3.1 What methodologies are used in real situation

In section 2.1, we have defined two different phases after the disaster happened, that is Phase 1: transient and Phase 2: stable. In those phases, what kind of communication is needed? And what kind of communication is executable? The purpose of network is of course communication. The MANET that might be established after the disaster is also aiming at communication.

3.1.1 Phase 1

Suppose emergency situation happens and neither communication nor power infrastructure becomes out-of-order. It is very difficult to realize one-to-one-communication. It is because as shown in 2.2, in Phase 1, IP addresses are not known to others. But in this phase you probably need communication to get information from and to tell your situation to other people. The former is "information discovery" related to 2.3 and the latter is information distribution (broadcasting) related to 2.3. Fortunately, these communications can be executed without any specific addresses but with "broadcast" address only.

3.1.2 Phase 2

After appropriate time, the MANET will be stable. What is stable means that each node has his own routing table and is able to make a point-to-point (p-p) communication. In this phase, normal p-p, ciphered p-p related to 2.4, and broadcasting communications will be needed. As for the discovery, p-p communication may cover the need.

3.2 Effect of methodologies when combined

Here we evaluate the integrated effect of our proposal in a real traffic condition according to the investigation in 3.1. Assumed parameters and values are as follows. Values are used and got in the simulation. Here, traffic ratio means ratio of how many users try the methodology to number of all the users during the observation time frame.

Table 1 Parameters

name of methodologies	items	parameters/values
common	number of network nodes	100
	average # of hops between nodes	3
discovery	traffic ratio	Rd
	#of packets sent (SF) for 1 trial	100
	# of packets sent (proposal) for 1 trial	25
	# of response packets	5
broadcast	traffic ratio	Rb
	# of packets (SF) for 1 trial	35,000
	# of packets (LDCF) for 1 trial	5,000
p-p	data traffic ratio	Rp
	traffic ratio of OLSR hello	0.1
	# of packets per communication	5
secure communication	data traffic ratio (ciphered)	Rc

3.2.1 Phase 1

As discussed in 3.1.1, in this phase, Discovery and Broadcasting are the main methodologies used.

(1) Discovery

100*Rd nodes initiate discovery. Simple Flooding discovery needs 100 packets for one discovery but our proposal needs 25. After discovery, discovered node responds to the initiator with 5 packets (same number as normal p-p data) and those make 3 hops. So, the average number of each methodology for discovery produces following numbers of packets.

SF: $100 \times R_d \times (100 + 5 \times 3)$ [packets] (1)

Our proposal: $100 \times R_d \times (25 + 5 \times 3)$ [packets] (2)

(2) Broadcasting

$100 \times R_b$ nodes broadcast information. Simple flooding case delivers 35,000 packet in average for one broadcast. Our proposal (LDCF) sends 5,000 packets.

SF: $100 \times R_b \times 35{,}000$ [packets] (3)

Our proposal: $100 \times R_b \times 5{,}000$ [packets] (4)

(3) Packet reduction effect in phase 1 by our proposal

By equations (1) through (4), the average number of transmitted packets for existing and our proposed methods will be;

Existing (SF): $11{,}500 \times R_d + 3{,}500{,}000 \times R_b$ [packets] (5)

Our proposal: $4{,}000 \times R_d + 500{,}000 \times R_b$ [packets] (6)

3.2.2 Phase2

As described in 3.1.2, in this phase 2, normal p-p (ciphered and unciphered), ciphered p-p, and broadcasting communications will be needed.

(1) normal p-p data (ciphered + unciphered)

$100 \times R_p$ nodes make p-p data communications each of which contains 5 packets in average and travels through 3 hops. Here we assume all the nodes use OLSR [12] as a routing protocol. Then average number of packets related to normal p-p data communication is:

$$100 \times R_p \times 5 \times 3 + 100 \times 0.1 \times 1 \text{ [packets]} \quad (7)$$

(2) Secure communication (ciphered)

$100 \times R_c$ nodes make secure communication. In the existing method, all the nodes must exchange their own certificates beforehand. Each exchange is made by broadcasting so that one certificate must be broadcasted 100 times. On the contrary, our method exchanges certificate only when normal p-p data communication happens. So, assuming number of packets to send a certificate is 2, average number of packets needed to ciphered communication becomes as follows.

Existing: $100 \times 100 \times 2 = 20000$ [packets] (8)

Our proposal: $100 \times R_c \times 3(\text{hop}) \times 2(\text{round trip}) \times 2$ [packets] (9)

(3) Broadcasting

This is same as equations (3) and (4).

(4) Packet reduction effect in phase 2 by our proposal

By equations (7), (8), (9), (3) and (4), the average number of transmitted packets for existing and our proposed methods will be;

Existing:

$$1{,}500 \times R_p + 20{,}000 + 3{,}500{,}000 \times R_b \text{ [packets]} \quad (10)$$

Proposal:

$$1{,}500 \times R_p + 1200 \times R_c + 500{,}000 \times R_b \text{ [packets]} \quad (11)$$

3.2.3 Evaluation

Here, we assume actual number for traffic ratio and evaluates the effect of our proposal specifically.

(1) Assumption (phase 1)

- Rd: 0.05 (about 5 users will make discovery)

- Rb: 0.05 (about 5 users will make broadcast)

Then, equation (5) becomes 175575 and (6) does 25200, so that reduction ratio is **14%**.

(2) Assumption (phase 2)

Rp: 0.5 (about 50 users will make p-p communication)

Rc: 0.01 (about 1 user will make discovery)

Rb: 0.01 (about 1 user will make discovery)

Then, (10) becomes 55750 and (11) becomes 5752, so that reduction ratio is **10**%.

These are just an example value but anyhow, in both phases 1 and 2, dominant traffic is broadcasting. In phase 2, however, the reduction effect of our proposal for secure communication is a kind of large, so that total reduction ratio is less than that in phase 1.

4 Conclusion

This paper summarizes achievement of ULPDDNS project for the network layer. It explained our proposed methodologies to reduce redundant packets for information discovery, broadcasting, and secure communication. It also shows effectiveness of each proposal. And it evaluates the integrated effects of those three proposal and shows our proposals drastically reduces redundant packets, that is , the reduction ratio becomes around 10% under some assumption.

From now, to finalize our project, we will make easy-to-understand explanation and deploy fruitful results to coming implementation oriented projects.

Abstract – *Ad hoc networks are being studied as being resilient in a disaster situation. This paper considers cases where a specific number of nodes in an ad hoc network broadcast video and audio streams to the entire network. For this purpose, we have already proposed Load and Battery Charge Oriented Flooding (LBF) which reduces degradation in delivery quality, and energy consumption, and prevents nodes from being interrupted due to the complete discharge of their batteries. This paper shows performance evaluation of our method through the network simulation and confirms that LBF can prolong a network life time without degradation of delivery quality.*

Keywords: Ad Hoc Network, Broadcast, Flooding, Battery, Low Power Consumption

1 Introduction

Large-scale disasters often disable existing communications infrastructures or render stable power supply to communications terminals or base stations difficult. It is therefore important to study networks that can operate with low power consumption. Ad hoc networks are being studied as being resilient in a disaster situation [1].

This paper considers cases where a specific number of nodes in an ad hoc network broadcast video and audio streams over the entire network. In a disaster, several numbers of specific nodes will send urgent audio or video messages, such as evacuation instructions for disaster victims or instructions for rescue teams, to the entire network at a high bit rate without using any routing protocol. Flooding is the only delivery method to achieve this. However, conventional Simple Flooding (SF) [2] is not well suited for this purpose because it results in broadcasting too many redundant packets, which increases the chance of data collisions and buffer overflows, resulting in an increase in packet loss. Therefore, it is necessary to study how to maintain sufficient packet reachability. There have been some proposals for revising Simple Flooding to reduce redundant re-broadcasts [3-5].

Nodes in an ad hoc network are generally powered by batteries with a finite capacity and so reducing power consumption is an important issue. When an ad hoc network delivers video and audio streaming data, which generates packets at a high rate, the battery charge of nodes will dissipate rapidly. As a result, many nodes will stop functioning and the network's delivery capacity will fall. It is imperative to reduce redundant transmissions of packets in order to reduce the power consumption of nodes. In addition, it is necessary to reduce the chances of nodes becoming inoperative due to the complete discharge of their batteries.

To sum up, if we are to broadcast streaming video and audio data in a disaster situation, it is necessary (1) to achieve high packet reachability and reduce the degradation of delivery quality, (2) to reduce the energy consumption of nodes to make effective use of their battery charge, and (3) to reduce the chances of nodes becoming inoperative due to the complete discharge of their batteries. To achieve broadcast streaming method satisfying above three requirements, we have already proposed Load and Battery Charge oriented Flooding (LBF) [6]. This paper shows the evaluation of basic performance of LBF through the network simulation and confirms that our method can improve energy efficiency maintaining packet reachability. In addition this paper shows the evaluation of a network running time and confirms that LBF can prolong network running time without degradation of delivery quality.

Section 2 explains existing methods and their problems. Section 3 describes the proposed method. Section 4 shows the effectiveness of the proposed method using network simulation in terms of energy efficiency and packet reachability. Section 5 shows the evaluation of the network running time. Section 6 gives the conclusions.

2 Existing methods and their problems

As mentioned in Section 1, Simple Flooding (SF) [2] is the most frequently used broadcast-type delivery. The basic operation of SF is as follows: A node that originates packets (initiator node) broadcasts them. These packets reach all the nodes that exist within the area covered by the radio wave transmitted by the initiator node. A node that has received one of these packets re-broadcasts it. This process is repeated by subsequent nodes until the packets reach all the nodes in the network. When it is applied to the streaming delivery of video and audio data, which generates packets at a

high rate, redundant re-broadcasts occur, increasing the chances of collisions and buffer overflows, and resulting in a considerable degradation in delivery quality.

2.1 Counter-based schemes

There have been several proposals to revise Simple Flooding in order to reduce redundant broadcasts [3-5]. A well-known revision of Simple Flooding that does not depend on a special device, such as a Global Positioning System (GPS), is a Counter-based Scheme [3-4].

In this scheme, a node determines whether to re-broadcast a packet on the basis of the number of times the same packet has been received. A packet is identified by the combination of the ID of the node that generated it and the packet sequence. The basic operation of this scheme is as follows. When a node receives a packet, it sets the counter for that packet to "1". If it receives the same packet again during an arbitrary pre-defined time (*decision_time*), "1" is added to the counter. When the counter value reaches the counter threshold (*c_threshold*), re-broadcasting of that packet is suspended. If the counter value has not reached the counter threshold (*c_threshold*) after an elapse of *decision_time*, the packet is re-broadcast.

It is to be noted that the performance of this scheme greatly depends on *c_threshold* [4]. In a network in which nodes are scattered sparsely, re-broadcasts are limited when *c_threshold* is small (e.g., 2), but packet reachability is reduced. In a network in which nodes are distributed densely, *c_threshold* does not affect packet reachability too much. It is desirable to set *c_threshold* to 3 or 4. It has been reported that if *c_threshold* is as large as 6, this scheme behaves much like Simple Flooding, and thus cannot reduce redundant re-broadcasts [7].

To solve the above problem, Adaptive Counter-based Scheme, which sets *c_ threshold* dynamically, has been proposed [8]. In this scheme, each node sends a Hello packet periodically. These packets enable a node to determine the number of its surrounding nodes. The node determines whether to re-broadcast a packet on the basis of this information. A problem with this scheme is that the periodic transmission of Hello packets consumes the battery charge of each node and the wireless resources of the network.

While these two schemes reduce redundant re-broadcasts, they do not take the remaining charge of node batteries into consideration. They make no attempt to reduce re-broadcasts by nodes with low remaining battery charge, thereby increasing the chance that such nodes become inoperative due to the complete discharge of their batteries.

2.2 Existing battery-aware flooding methods

There have been a few proposals that take the remaining charge of node batteries into consideration [7-8]. Koide et al. [7] proposed a flooding scheme that uses a routing protocol. It sets a delay time that is dependent on the remaining battery charge. If a node receives the same packet again within its delay time, it discards the packet. Kasamatsu et al. [10] proposed a scheme in which the delay time set for each node is dependent on the distance from neighboring node, which is obtained using GPS, and the remaining battery charge. A node that has received the same packet again within its delay time, discards the packet. This scheme operates in such a way that nodes with a low battery charge are less likely to be selected for the re-broadcasting of packets. The scheme presented in [7] assumes the use of a routing protocol for the propagation of messages, and does not assume applications that generate packets at a high rate, such as a streaming delivery of video and audio data. Nor has it been evaluated for such applications. The scheme presented in [8] assumes that each node has a GPS and thus can obtain its location and distance information. However, in a disaster, it cannot be ensured that the correct location information can be obtained using a GPS. Therefore, it is unclear whether these schemes can be applied to the situation described in Section 1.

3 Proposed method

3.1 Assumed network environment and requirements

This paper focuses on unidirectional live streaming delivery. The network nodes are mobile communications terminals that are not equipped with any special device, such as a GPS, and can communicate over an IEEE802.11-series wireless LAN. No QoS (Quality of Service) control is considered. Packets are sent on a best-effort basis using UDP/IP.

We consider the application of our method to the situation described in Section 1, and study how to meet the following three requirements for the streaming delivery of video and audio data, which generates packets at a high rate. (i) The redundant transmissions of packets should be reduced in order to reduce degradation in delivery quality due to collisions and power consumption by terminals. (ii) Re-broadcasts by nodes with a low remaining battery level should be avoided in order to reduce the chance of these nodes becoming inoperative due to complete discharge of their batteries. (iii) Packets for checking the network state, such as Hello packets, should not be used, in order to reduce the network load and power consumption by nodes.

3.2 Load and Battery Charge Oriented Flooding (LBF)

To meet the requirements listed in Section 3.1, We have already proposed a flooding method that is sensitive to the

remaining battery levels of nodes, the existence of packets on the MAC transmission queue, and uses a counter in determining whether a packet should be re-broadcast or not [6]. We call this scheme Load and Battery Charge Oriented Flooding (LBF). Requirement (i) is met as follows. Each node monitors the number of packets existing in its MAC transmission queue at certain intervals. Then, if there is at least one packet in the MAC transmission queue, the node judges it is in a high load condition, and abandons re-broadcast. In addition, as is used in existing counter-based schemes, LBF determines whether to re-broadcast packets on the basis of the number of times that the same packet has been received, thereby reducing the transmission of redundant packets. Requirements (ii) and (iii) are satisfied as follows. Existing counter-based schemes use a fixed value for *c_threshold*, and thus cannot operate in a way that is sensitive to the remaining battery level of each node. LBF sets *c_threshold* dynamically in such a way as to reduce re-broadcasts by nodes with a low battery level. This makes it unnecessary for each node to send monitoring packets to its surrounding nodes in order to learn about their remaining battery levels. Nodes can operate autonomously.

The specific operation of the proposed method is as follows: For each node, the user sets, in advance, the maximum value of the counter threshold (*max_c_threshold*), and defines the range of a value generated by Random(), a function that generates a random value. Each node monitors its remaining battery level at certain intervals (*get_interval*), and reflects the value obtained in a variable, *remain_battery*. Then, *c_threshold* is calculated using the following equation:

$$c\_threshold = \mathbf{ceil(}\ max\_c\_threshold * (remain\_battery / max\_battery)\mathbf{)} \quad (1)$$

where **ceil(**Real *x***)** returns the value of a real variable, *x*, rounded up to the nearest integer. The value set in *max_c_threshold* and the value set in *c_threshold*, which is determined according to the remaining battery level.

A node that receives a packet from a node that initiated the packet (initiator node) operates as follows:

1. The node that has received the packet sets the packet's counter (*counter*) to "1" if it had not received the same packet earlier.

2. The time (*decision_time*) for which the node waits before it determines whether to re-broadcast the received packet is determined as follows:

$$decision\_time = \text{Random}() * 2(max\_c\_threshold - c\_threshold) \quad (2)$$

3. The node waits during *decision_time*. If during this time it receives the same packet again, it adds "1" to *counter*.

Variables and parameters

○Variable: Integer *queue*
// The num. of packets at the MAC transmission queue.
○Variable: Real *remain_battery*
// The remaining battery level at the node.
○Variable: Real *max_battery*
// The maximum battery level at the node.
○Variable: Integer *c_threshold*
// The threshold value of the counter.
○Variable: Integer *max_c_threshold*
// The maximum value of *c_threshold*
○Variable: Integer *counter*
// The number of times that the same packet has been received.
○Parameter: Integer *get_interval*
// The time interval for getting the num. of packets at the MAC transmission queue and the remaining battery level.
○Procedure: getQueue()
// The function to get the num. of packets at the MAC transmission queue.
○Procedure: getBattery()
// The function to get the remaining battery level.

(a) The method of getting data on the remaining battery level
Executed at certain intervals (*get_interval*)

```
queue ← getQueue()
if (queue > 0)
 then   (b) is not executed (all re-broadcast is canceled)
 else   remain_battery ← getBattery()
        c_threshold
          ← ceil(max_c_threshold*(remain_battery /max_battery)).
end if
End.
```

(b) The receiving and rebroadcast procedure

```
Receiving a packet.
if (The same packet as one that the node has already received)
 then  END.
 else  counter ← 1.
       decision_time ← Random() * 2^(max_c_threshold - c_threshold) .
       while (decision_time)
                if (Receiving the same packet again)
                  then  counter++.
                end if
       end while
       if (counter >= c_threshold)
         then   Rebroadcast is cancelled.
         else   Rebroadcast the packet.
       end if
end if
End.
```

Fig.1 The operation of a node for LBF

4. If, at the expiry of *decision_time*, counter does not exceed *c_threshold*, the received packet is sent to the lower layer and re-broadcast.

4 Evaluation of basic performance

This section compares the basic performance of the proposed LBF with those of existing schemes, in the video streaming, using a network simulator, OPNET [9].

4.1 Simulation configurations

The simulation configuration is as follows: Two geographical network areas are considered for simulation. In Space A, the area is 1000 m x 600 m, representing a network in which nodes are densely distributed. In Space B, the area is 2000 m x 1200 m, representing a network in which nodes are sparsely distributed. There are 100 nodes in the network, of which two nodes originates the video streams. The MAC layer is IEEE802.11b. The data rate is 2Mbps. The transmission power is 0.005W. The MAC layer of the nodes is IEEE802.11b. The data rate is 2 Mbps. The transmitted power is 0.005W. The received power threshold above which packets can be received successfully is -85 dBm. Nodes are initially located at random. All nodes move at a speed of [0.00, 4.00] m/s according to the random waypoint model. This is intended to simulate the walking of humans. A node that has received a packet from the initiator node re-transmits it using one of three delivery methods: the existing Simple Flooding (SF), the existing Counter-based scheme using a fixed *c_threshold*, and the proposed method. The parameters used in each method are as shown in Table 1. Using different values of the fixed *c_threshold*, three cases are considered for the Counter-based scheme: C4, C3 and C2. Similarly, using different values of *max_c_threshold*, three cases are considered for the proposed method: LB4, LB3 and LB2. In LBF, the interval at which the remaining battery level is monitored (*get_interval*) is 1 seconds.
